The criminal classes were not slow to recognise this fact, and took every means to circumvent a successful portrait being taken of themselves, while the great aim of the authorities was to obtain a serviceable portrait by which the subject might be identified at sight beyond a doubt. That this proved a difficult matter will be apparent to any one who visits a "Rogue's Gallery," as the collection of criminal portraits is called in police parlance, and which may be seen in all large cities and towns. It will be seen at a glance that, as portraits, these pictures are not a success, almost all of them having been unwilling sitters who distorted their features, and, as a result, the photographs are almost valueless for the purposes for which they are intended.

With the advent of the dry plate, instantaneous, and Blitz photography of the present day a new era opened, of which the various police bureaus were not slow to avail themselves, where formerly in "wet plate days" the criminal was taken to the "skylight" of the photographer who had the contract with the department, and which was often squares away from headquarters, and the attempt at portraiture would end in failure, even after a physical struggle with his guardians.

The writer recollects one instance in which it took four stalwart officers to hold a prisoner while the "artist" got his picture. The "cabinet" not only showed the face horribly distorted, with eyes shut and tongue out, but also the hands of one officer holding his ears, the second officer holding him by the hair, while the hands of the third showed as if he was choking the prisoner. Under the new *regime* all such scenes fall away; the subject is now taken instantaneously when he least expects it, a perfect front and profile being obtained at the same instant, showing not alone the features at rest, but also the subject's natural position.

This applies especially to the capitals of Germany and France, while the old system is still more or less in vogue in this country and England. In the latter country much dissatisfaction, photographically speaking, has lately cropped out with the Scotland Yard authorities for their adherence to the old methods, and on more than one occasion the question was brought up in the House of Commons, so far, however, without bringing any response from the Home Secretary.

In France, the photographic methods, which are extraordinarily accurate, are supplemented with a series of measurements known as "Systeme Anthropométrique." The photographic department of police headquarters in Paris now consists of a series of rooms, one for making the exposure, into which opens a waiting-room, and several dark rooms. The main room is so arranged with mirrors that face and side views are taken at the same time on the same plate. In connection with this department are facilities for making silver or bromide prints and mounting; all work and detail are done within the department without any aid or knowledge of outside parties.

It is, however, in Berlin where the highest development of police photography has been reached. Formerly the work was done by the well-known firm of Zielsdorf and Adler. Now it is done by employees of the department in the new Präsidial building erected in the Alexanderplatz, where a series of rooms connected with the criminal department has been set aside for photographic purposes, and so constructed that portraits can be taken at any hour of the day or night, the illuminant being Blitz pulver, and it is done so quickly that the accused introduced into the chamber or passage-way on his way to a hearing is actually photographed before he even has a presentiment of what has taken place. This is accomplished as follows: When the subject comes to within two or two and a half metres of the concealed cameras, a gum bulb is pressed by the operator, who is also concealed. This mere pressure not only opens the shutter, but simultaneously ignites two Blitz flash lamps, which are placed at right angles in front, about six feet to the right and left of the subject. A simple pressure of the pneumatic tube, a flash, and before the subject can get over his surprise he is led out of the room, while the plate is developed and fixed in the adjacent dark room. It is said that the exposures obtained by this process have been almost always successful.—*American Journal of Photography.*

PHOTOGRAPHIC CLUB.—Subject for discussion Wednesday, July 30th, "Printing with the Salts of Chromium;" August 6th, "New Hand-Cameras." Saturday outing, July 26th, St. Albans. Train from St. Pancras, 2.37.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—The subject for consideration on Thursday, July 31st, will be "Home Portraiture;" the question to be opened by Mr. W. E. Debenham. Visitors invited.

PHOTOGRAPHY was represented in the theatre of the Liverpool Polytechnic Exhibition on Thursday last. Mr. Henry E. Burn delivered a lecture on the progress and promise of the art science, which was followed by a lantern exhibition of the work of the Walton Photographic Society, of which he is the president. Mr. W. Tyerman was the lanternist, and the chair was filled by Mr. F. Murphy, an amateur photographer.

PECULIARITIES OF EIKONOGEN.—The members of the Providence Camera Club have had a singular experience with eikonogen. Stock solutions stored in glass-stoppered bottles in the lockers of the dark room deteriorate badly within twenty-four hours, while the same solutions retain their good qualities for weeks in the private dark rooms of the members. This opens up an interesting question, and one that we would like to have satisfactorily answered. It may be that the large number of different chemicals kept in the club lockers may be responsible for the trouble, or there may be some peculiar atmospheric conditions present, or, as Mr. Davison suggests, the trouble may be caused by the fact that the dissolving key of the stereopticon is kept in the lockers. Any one who has had any experience with dissolving keys knows that there always hangs about them a strong odour of gas, the presence of which may have caused the mischief. Eikonogen has as many moods as the fair sex is credited with, only in the case of eikonogen they are not always charming.—*American Amateur Photographer.*

THE AMERICAN PHOTOGRAPHIC CONVENTION.

Before the appearance of another issue of *The Beacon* the seven thousand, more or less, photographers of this country will, like the ten virgins, be divided into the wise and the foolish; but, we very much fear, unlike their prototypes, not in anything like equal numbers. We need hardly say that the wise are those who will by that time have resolved to be present at the Washington Convention and the unveiling of the Daguerre Memorial; and the foolish those who have decided to remain at home.

We believe that on a careful consideration of the *pros* and *cons* connected with such a visit the againsts will be few and the fors many.

It is true that the affairs of the Association have not always, or even often, been conducted in such a way as to meet our approval, and that the actual, as compared with the possible, benefits have not infrequently been as Falstaff's bread to his sack; but that is more the fault of those who stayed away than of those who were present. They, or most of them, did the best they could, according to their light, and while that best was not always, according to our idea, in the right direction, we have always been willing to give them all due credit for good intentions. If but one-half of those for whom photography makes the pot boil could see attendance at the Convention to be, as it is, both a duty and a pleasure, the three thousand five hundred would be a noble gathering, and one from whose ranks enough good men and true could be found to give the Conventions a character that they have never had, and do more to raise the status of photography than any scheme hitherto devised.

We know that there are hundreds, perhaps thousands, throughout the country, especially amongst those who work almost single handed, who think they cannot leave the seat of custom, without, in some degree at least, losing their trade; but this is a sad mistake. Trade, or even the *appearance* of trade, attracts trade, and the same is true also of the professions. Ministers, doctors, and lawyers know and take advantage of this fact. The hard worked or working clergyman, who leaves his pastoral for ten days to attend the general assembly of his church in some of the larger cities, is not only not blamed, but thought more highly of, therefore, by his parishioners; the young doctor, laying the foundation of a profitable practice, knows that there is no more sure or rapid means of doing so than by seeming to have his time so fully occupied as to make it somewhat difficult to find him; and the lawyer and dentist who have been students of human nature as well as of dentistry and law, keep would-be patients and clients kicking their heels in their waiting rooms, as the surest way of conveying an idea of their importance.

The practice of photography is amenable to the same influence. The time has not yet come when the studio from which the best pictures issue is the most crowded, but rather that in which the largest quantity of work is turned out, and the dear, easily led, and often misled public are often more ready to patronise the gallery where engagements can only be made several days in advance than the one in which they can only make sure of being taken at any time. Then, as it is with the parishioners of a clergyman, so it is with the *clientèle* of a photographer. They may not yet be willing to pay for his advanced culture and artistic training, but they take a pride in, and boast of the fact that *their* photographer keeps abreast of the times, and annually goes to attend the great Convention, where he can learn how to practice all the latest improvements and newest processes. All this, and more, is true, and our hesitating readers may rest assured that even from a pecuniary point of view, attendance at the Convention pays.

But there are other and not less important points from which the question, to go, or not to go? should be looked at. "All work and no play makes Jack a dull boy," and the dullness is contagious, and influences all around him. But an objectless holiday is not the true remedy. He must have something to take his mind from the ordinary routine of every-day life, and nothing is so likely to attain the end desired than attendance at the annual Convention. "As iron sharpeneth iron, so does the countenance of a man that of his friend," and in like manner, the social intercourse with one's fellow labourers in the photographic art obtainable at such meetings, and the being brought into friendly relation with many of those whose names are as household words, cannot fail to exercise an influence for good.

Over and above all this is the actual practical benefit derived from a study of the exhibition of photographs, which ought to and generally does include the embodied ideas of the best men in the profession on both sides of the Atlantic as to what ought to be the aim and object of the photographer. That this embodiment has hitherto run too much to the technical, to the detriment of the truly artistic, is the result of accidental circumstances more than the fault of conventions as such, and as the best men gradually become, as they are becoming, more of the artist and less of the mere photographer, the educating influence of those exhibitions will acquire a higher and higher degree of value.

In conclusion, we may say that we do not think our expectation of seeing at the Convention an attendance of between three and four thousand—half the photographers of the country—at all too high. The Washington will not in all probability reach anything like that number, nor may any of those of the next few years, but we believe that photographers are gradually learning that the true way to raise their status and secure the respect they are fully entitled to, is to respect themselves, and to become worthy of respect by taking advantage of every opportunity for self-improvement, the diffusion of the *entente cordiale* between the members of the profession generally, and carefully studying the highest possibilities of the art as they are exhibited, and straining every nerve to equal, if not surpass them. These are the desiderata that conventions are intended to bring about, and the object will be attained just in proportion as the attendence at the conventions increase.—*The Beacon.*

Miss Catherine Weed Barnes, the writer of the article "Illustrating Poems by Photography," quoted in our last issue, is preparing to enter the competition for the illustration of the poem "Enoch Arden," to be exhibited at the Photographic Convention at Washington on the 12th of August.

Aluminium.—M. Minet has placed before the French Academy of Sciences a process of extraction of aluminium by the electrolysis of a fluoride of this metal in a molten state; he employs an electrolytic bath composed of chloride of sodium 60 grammes, double fluoride of aluminium and sodium 40 grammes. He gives various details of the method of procedure. He produces by this method 21·5 grammes of aluminium for an expenditure of 1-horse power per hour, and 30 grammes might be attained in actual practice.—*Invention.*

Notes.

Sometimes complaints are sent to us about photographers who detain the specimens they have demanded from assistants out of a situation, such detention being often a grievous injury to the member of the fraternity in adverse circumstances. The informants give us the names and addresses of the photographers who are alleged to have done such a shady trick, in order that we may publish the same, and thus take the moral and legal responsibility of bringing a public charge against a man's character, based on alleged facts outside our personal knowledge, unless by means of previous investigation which could rarely be given. A better remedy which has been suggested is, that the assistant should write the particulars to the superintendent of police in the town in which the photographer resides. We have another suggestion to make, and that is that the Photographers' Benevolent Association should investigate and deal with such cases. It would increase its popularity immensely, and it seems to be within its province to take action of this kind, to prevent the said assistants from being obliged later on to make a heavier and more prolonged demand upon its funds and attention.

The advice given by an American journal to a photographic amateur who asked the best method of reducing a photograph, and received for reply, "Grind it down on the step of the back door," has been partially paralleled in sober earnest in France. The last number of the *Bulletin* of the Photographic Society of the North of France sets forth how M. Poly gave a demonstration before the Society of his method of obtaining a matt surface on Obernetter paper proofs. The finished prints were rubbed with fine pumice powder, and the results, says the report of the Society, were "very artistic."

The same journal contains an interesting collotype illustration by Messrs. Berthand, Brothers, from a negative by M. J. Cornetet, representing the theatre of Augustus, at Arles; also other Roman ruins in its proximity. The action of time and weather, the depredations of man, and occasional tremblings of the earth, have done much to destroy this building since it was repaired by Constantine; the ruins are nevertheless remarkable and of great extent, and they are now carefully preserved. The women of sunny Arles, in the South of France, are said to be the most beautiful in Europe, and the Editing Committee of the North of France Society says that this reputation may be in part due to their graceful costume, which changes not with the fashions of the day, but is of high antiquity, and preserved unchanged to this day.

Now that the tourist season is approaching, it may not be inappropriate to draw attention to a difference in his favour which the landscape photographer will find when working in some parts of Switzerland and other portions of central Europe far from the Atlantic, namely, the small average amount of wind to disturb the foliage. About the Lucerne district, for instance, it is common for three or four days in succession to pass away without sufficient wind to disturb the delicate leaves of the silver birch. When a Swiss from this district first visits England, for the first week or two, until the impression wears off, he wonders what is the matter with the weather, for the wind seems to him to be eternally blowing with a persistence outside his previous experience.

Potassic chlorate has been responsible for not a few deaths from its accidental ignition or explosion. These have mostly occurred with oxygen gas making for the limelight, and, happily, the number of such accidents will be reduced to a minimum now that the ready-made gas has become such a common article of commerce. A few fearful accidents have, too, overtaken boys with chemical proclivities who, in their experimental zeal, have endeavoured to make "bangs" by the attrition or percussion of chlorate with some sulphur compound; but the most curious accident with this explosive agent which has yet been recorded took place recently at some chemical works at Flint, where a workman, striking a match upon his trousers, after the manner of workmen, found himself enveloped in fire, which burned the poor fellow so shockingly that no hopes are entertained of his recovery. It seems that his clothing had become so impregnated with the chlorate that it resembled a mass of touch-paper, only waiting for the initial spark to set it aflame. That spark the match supplied.

It is easy enough to be wise after the event, and to point out how the terrible fatality might have been obviated by taking precautions against the dust accumulating, or by preventing the use of matches in the building. But the right course to follow would be to give to every workman who has to deal with dangerous agents a knowledge of their properties and general behaviour under different conditions. Many months have not elapsed since, at a quarry, some men were killed while thawing dynamite over an open fire in a saucepan. The inquest revealed the startling fact that, although proper vessels are constructed for this work, no one in the place knew anything about them. The saucepan had always been used by the men, and familiarity had bred a contempt for danger which they dearly paid for.

The *Standard* of Monday last, referring to the identification of the body of the burglar who, a few days previously, shot himself to avoid capture, states that "It is a curious fact that the police have in their possession sheets of photographs of discharged prisoners, including one which was believed to be the deceased, described as Richard Batten, who was sentenced at the Central Criminal Court in 1877 to seven years' penal servitude." We do not quite see why this fact should have anything phenomenal about it, considering that for many years it has been the custom to

photograph all prisoners; but it is certainly curious that the police failed to identify the body by the picture which they possessed, and that it was left for his widow to do so by the clothing upon the body.

"A prominent photographer," who has been recently interviewed by a reporter of the *New York Sun*, has had a good deal to say against people who come to be photographed accompanied by interfering relatives who know—or think that they know—much more about posing and lighting than does the artist himself. He quotes one case in which a lady in bridal attire came to his studio: "She walked up to the chair, and as she turned to face me the silk train and thin veil fell in wonderful folds of graceful outline. I told her not to stir, but while I stepped back to get the effect, her friend darted out and straightened the whole thing out like a flag in a head wind." Many of our readers have good reason, we feel sure, for sympathising with this complainant. It is, however, difficult to suggest a remedy which would not be likely to cause offence. A little tact mingled with courtesy will, as a rule, be the best mixture to apply.

Pyrogallol is so little used in medicine that it has no place in the British Pharmacopœia. Its principal employment—beyond its well-known use in photography—is for hair dyeing, when it is also used in conjunction with silver nitrate. It has also been recommended as the principal constituent of a salve for certain cases of skin disease, but so far as we know has never been used in any shape or form for internal administration. It is known to be extremely poisonous, but how many grains may represent a fatal dose has not, happily, as yet been determined.

The decision given in the celebrated copyright photographic case, in which the Stereoscopic Company were the plaintiffs, received endorsement in a judgment delivered by Mr. Justice Wills the other day. It will be remembered that in the photographic case it was laid down that the operator who took the photograph, and not the proprietor of the business, was the author for purposes of registration. The case decided the other day turned upon the question of copyright in a drawing. The originator of the idea had the drawing made by an artist, and this drawing was afterwards pirated by the defendants, although the reproduction was not an exact copy. The judge held that the action for infringement of copyright could not be maintained, one of his reasons being that the plaintiff, though the originator of the idea, was not the author of the drawing. It is well that photographers should bear the law in mind, as they may lose their rights in a valuable photograph from ignorance of legal technicalities.

This decision in the case of photography involves a certain amount of absurdity, because it is clear that one man may pose the sitter, and make all the arrangements, and be responsible for the art qualities of the picture, while the other man does no more than take off the cap and develop the plate. Yet the mechanical operator is deemed the author! This is only one of the anomalies of the Copyright Act, which, according to a well-known barrister, is full of blunders. It is said that the clauses are so exclusive of this and that right, that now, unless a special agreement is drawn up and signed "before purchase," the copyright is lost to both purchaser and painter. Even if the purchaser gave the painter the copyright, after purchase "the gift fails for want of consideration," and the same if the gift is from the painter to his patron. In certain cases, the value of the copyright becomes so enormous that it would be interesting to know how the parties interpret the Act. Take Mr. W. E. Lockhart's much talked-of jubilee picture, for instance. In the first place, the painter's commission was £1,000, and when it came to the disposal of copyright, the best offer obtained was one of £200 from a leading firm of dealers for the right to reproduce the picture, and absolute control over it for one year. Mr. Lockhart thought the copyright was worth more, and he organised a syndicate to exhibit the picture, with the result that the painter received £2,000 for the copyright and use of it for exhibition during twelve months. It is said that the sale of photogravures will probably produce between two and three thousand pounds more. This transaction on the face of it appears to be a little involved, and one would like to know how the more involved conditions of the Copyright Act have been complied with.

M. Reutlinger, the well-known photographer of Paris, is the photographer *par excellence* of cats. A delightful photograph of a kitten in a large glass funnel stuck in a bottle, is reproduced in a recent issue of *La Nature*, and its charming unconsciousness and grace are commented upon in terms of well deserved praise by the editor, M. Tissandier. M. Tissandier strongly advises amateurs to practise taking the photographs of animals, and quotes approvingly M. Legouvé's witty description of the average portraits of the human being, as seen in the album, to show the superiority of animals as sitters from an artistic point of view. M. Legouvé, looking through an album one day, said: "These people are much more like their portraits than they think for, for it is not to be doubted they have worked in themselves their own likeness, and have thus been at once models and painters. More than one, I am sure, when sitting down on the photographic chair, has taken his favourite pose, and has arranged his features according to his own predilection, expressing not what he is, but what he believes himself to be. For instance, here is one who is slily smiling; evidently, he imagines himself to be witty. This, with the eyes uplifted to Heaven and his wild hair, belongs to the class of inspired poets! I should be surprised if this person, who looks you in the face with such keen eyes as though he would pierce you through and through, is not saying to himself: 'What an eagle eye I have, nothing escapes me!' "There is nothing like this in the photographs of animals," observes M. Tissandier, and everyone will agree with him.

THE GLOW OF PHOSPHORUS.*

BY PROFESSOR T. E. THORPE, F.R.S.

THE earlier volumes of the "Philosophical Transactions" contain several papers on the luminosity of phosphorus, and one by Dr. Frederick Slare is noteworthy as giving one of the earliest, if not actually the earliest, account of what is one of the most paradoxical phenomena connected with the luminosity of phosphorus, namely, its increase on rarefying the air. "It being now generally agreed that the fire and flame (of phosphorus) have their pabulum out of the air, I was willing to try this matter *in vacuo*. To effect this, I placed a considerable lump of this matter (phosphorus) under a glass, which I fixed to an engine for exhausting the air; then presently working the engine, I found it grow lighter (*i.e.*, more luminous), though a charcoal that was well kindled would be quite extinguished at the first exhaustion; and upon the third or fourth draught, which very well exhausted the glass, it much increased its light, and continued so to shine with its increased light for a long time; on re-admitting the air, it returns again to its former dulness." This observation was repeated, and its result confirmed by Hawksbee in this country, and by Homberg in France, and seems subsequently to have led Berzelius and after him Marchaud, to the conclusion thatt he luminosity of phosphorus was altogether independent of the air (*i.e.*, the oxygen), but was solely due to the volatility of the body. Many facts, however, combine to show that the air (oxygen) is necessary to the phenomenon. Lampadius found that phosphorus would not glow in the Torricellian vacuum, and Lavoisier, in 1777, showed that it would not inflame under the same conditions; and the subsequent experiments of Schrötter, Meissner, and Müller are decisive on the point that the glow is the concomitant of a chemical process dependent upon the presence of oxygen. It is, however, remarkable that phosphorus will not glow in oxygen at the ordinary atmospheric pressure and temperature, but that if the oxygen be rarefied the glow at once begins, but ceases again the moment the oxygen is compressed. Indeed, phosphorus will not glow in compressed air, and the flame of feebly-burning phosphorus may be extinguished by suddenly increasing the pressure of the gas. Phosphorus, however, can be made to glow in oxygen at the ordinary pressure, or in compressed air, if the gases are gently warmed. In the case of oxygen the glow begins at 25°, and becomes very bright at 36°. In compressed air the temperature at which the glow is initiated depends upon the tension. If the oxygen is absolutely deprived of moisture, the phosphorus refuses to glow under any conditions. This fact, strange as it may seem, is not without analogy: the presence of traces of moisture appears to be necessary for the initiation or continuance of chemical combination in a number of instances.

It was observed by Boyle that a minute quantity of the vapour of a number of essential oils extinguished the glow of phosphorus. The late Professor Graham confirmed and extended these observations; he showed that relatively small quantities of olefiant gas, and of the vapours of ether, naphtha, and oil of turpentine entirely prevented the glow, and subsequent observers have found that many essential oils, such as those of peppermint and lemon, and the vapours of camphor and asafœtida, even when present in very small quantity, stop the absorption of oxygen and the slow combustion of phosphorus in air.

* A portion of a lecture delivered at the Royal Institution.

It has been established that whenever phosphorus glows in air, or in rarefied oxygen, ozone and hydrogen peroxide are formed, but it is not definitely known whether the formation of these substances is the cause or the effect of the chemical process of which the glow is the visible sign. That there is some intimate connection between the luminosity of the phosphorus and the production of these bodies is highly probable. Schönbein, as far back as 1848, sought to demonstrate that the glow depends on the presence of ozone. It is certainly true that many of the substances—such as the essential oils—which prevent the glow of phosphorus also destroy ozone. At a low temperature phosphorus produces no ozone in contact with air, neither does it glow. It has been found, in fact, that with air ozone is produced in largest quantity at 25°, at which temperature phosphorus glows brightly. On the assumption that the oxidation of the phosphorus consists in the immediate formation of the highest oxide, the production of the ozone and the hydrogen peroxide has been represented by the following equations:—

$$P_2 + O_2 = P_2O_3 + O$$
$$O + O_2 = O_3$$
$$O + H_2O = H_2O_2.$$

Both these reactions may, of course, go on simultaneously, as ozone and hydrogen peroxide are not mutually incompatible; the synthesis of hydrogen peroxide by the direct oxidation of water seems to occur in a number of processes. But such symbolic expressions can at most be only very partial representations of what actually occurs. It is highly probable that the combination which give rise to the glow only occurs between the *vapour* of phosphorus and the oxygen. Phosphorus is sensibly volatile at ordinary temperatures, and by rarefying the atmosphere in which it is placed its volatilisation is increased, which serves to account for the increased glow when the pressure of the gas is diminished. When phosphorus is placed in an atmosphere of hydrogen, nitrogen, or carbonic acid, these gases, when brought into contact with oxygen, become luminous from the oxidation of the vapour of phosphorus diffused through them. The rapidity of volatilisation varies with the particular gas; it is greatest in the case of hydrogen, and least in that of carbonic acid. Indeed, a stream of hydrogen gas at ordinary temperatures carries away comparatively large quantities of phosphorus, which may be collected by appropriate solvents. No ozone and no glow are produced in oxygen gas at ordinary temperatures and pressures, but on warming the oxygen both the ozone and the glow are formed. On passing ozone into oxygen at temperatures at which phosphorus refuses to glow, the phosphorus at once becomes luminous, oxygen is absorbed, and the characteristic cloud of oxide is produced, and the effect continues so long as the supply of ozone is maintained. A drop of ether at once extinguishes the glow.

The ether is in all probability converted into vinyl alcohol with simultaneous formation of hydrogen peroxide by the reaction indicated by Poleck and Thümmel

$$\left.\begin{matrix} CH_3CH_2 \\ CH_3CH_2 \end{matrix}\right\rangle O + O_3 = \left.\begin{matrix} CH_2CHOH \\ CH_2CHOH \end{matrix}\right. + \left.\begin{matrix} OH \\ OH \end{matrix}\right\}$$

Formic, acetic, and oxalic acids are also formed by the action of ozonised oxygen on ether.

Phosphorus combines with oxygen in several proportions, and the study of the mode of formation and properties of these oxides is calculated to throw light upon the nature of the chemical process which attends the glow of phosphorus. Certain of these oxides have

recently been the subject of study in the chemical laboratories of the Normal School of Science. When phosphorus is slowly burned in air, there is produced a considerable quantity of a volatile substance, having a characteristic garlic-like smell which solidifies, when cooled, in beautiful arborescent masses of white crystals. It melts at about 23°, and boils at 173°. In a sealed tube kept in the dark it may be preserved unchanged, but on exposure to light, and especially to bright sunshine, it rapidly becomes deep red.* It slowly absorbs oxygen at the ordinary temperature and pressure, but from the mode in which the solid product of the reaction (P_2O_5) is deposited, it is evident that the union only takes place between the vapour of the oxide and the oxygen gas. Under diminished pressure the act of combination is attended with a glow which increases in brilliancy if ozone be present. On compressing the oxygen the glow ceases. No ozone is formed during the act of oxidation. The degree of rarefaction needed to initiate the glow depends upon the temperature of the oxide; the warmer the oxide the less is the diminution of pressure required. By gradually warming the oxide the luminosity steadily increases both in area and intensity, until at a certain temperature the mass ignites. The change from glow to actual flame is perfectly regular and gradual, and is unattended with any sudden increase in brilliancy. In this respect the process of oxidation is analogous to the slow and barely visible burning of fire-damp which is sometimes seen to occur in the Davy lamp, or to the slow combustion of ether and other vapours, which has been specially studied by Dr. Perkin. Other instances of what may be called *degraded combustion* are known to chemists. Thrown into warm oxygen the substance bursts into flame at once, and burns brilliantly; and it also takes fire in contact with chlorine. Alcohol also ignites it, and when it is warmed with water or a solution of potash it evolves spontaneously inflammable phosphoretted hydrogen. In contact with cold water it suffers only a very gradual change, and many days may elapse before even a comparatively small quantity is dissolved. This substance has long been known; it was discovered, in fact, by the French chemist, Sage, but its true nature has only now been determined: its chemical formula is found P_4O_8; hence its composition is similar to that of its chemical analogue, arsenious oxide.

The study of the properties of this remarkable substance enables us to gain a clearer insight into the nature of the chemical change attending the glow of phosphorus. When phosphorus is placed in oxygen, or in an atmosphere containing oxygen, under such conditions that it volatilises, the phosphorus oxidises, partly into phosphoric oxide, and partly into phosphorus oxide; ozone is formed, possibly in the mode already indicated, and this reacts upon the residual phosphorus vapour and the phosphorus oxide, with the production of the luminous effect to which the element owes its name. The glow itself is nothing but a slowly burning flame having an extremely low temperature, caused by the chemical union of oxygen with the vapours of phosphorus and phosphorus oxide. By suitable means this glow can be gradually augmented, until it passes by regular gradation into the active vigourous combustion which we ordinarily associate with flame. Many substances, in fact, may be used to phosphoresce in a similar way.

* This is the substance spoken of by Captain Abney in his recent lecture at the Royal Institution.—Ed.

STOPS OR DIAPHRAGMS.

BY ELLERSLIE WALLACE.

It is not quite easy to determine why the short and convenient word "stop" has been universally accepted by the photographic world as a substitute for the longer one of "diaphragm," unless we remember that photographers, as a rule, are very practical folk, and like things called by plain and short names.

It may be that the term "stop" was adopted from the fact of the light being really *stopped out* by the diaphragm; and as the Germans call it "blende," which means a blind or screen, there seems to be some probability that this is true.

Lenses sent out by manufacturers of reputation always have the stops supplied, and the position they occupy is generally fixed. This is true for such lenses as are not intended to be taken apart and their parts used alone; when this is the case the position of the stop must be changed.

Now, in spite of all this, it will be found well worth while to be familiar with a few general facts about the diaphragm or stop. First of all, we may say that stops are used to improve the defining powers of the lens, particularly on the margins and corners of the picture. This is accomplished by stopping out such rays of light as would come to a focus too near the lens, and by allowing only such oblique pencils of rays to pass as come to their focus on the plane of the ground glass. The pencils forming the more central portions of the picture pass through the opening in the stop, and come to their proper focus in very much the same manner as they would if there were no stop at all in the lens.

It is fair to say that the type or representative lens of the present day is the symmetrical doublet; or, in other words, a lens consisting of a front and a back combination which are nearly or quite twins in every respect. A more exact term in optical parlance would be to speak of the lens as what it really is, namely, a *system* of lenses.

Now, it is a matter of common observation that the position of the diaphragm or stop in these doublet lenses is always in the middle of the tube, at equal distances from the front and the back combinations. If one of the combinations be unscrewed and removed from its position, the other one can still be used for photographic exposures. The focal length of either combination, when thus used simply, is about twice that of the original lens or "system," and the field covered by the single combination will be proportionately increased in size. But if the diaphragm or stop be left in its original position, the work accomplished will not be nearly so good as it would be if the stop were moved to a new point to suit the new condition of affairs. Each of the combinations of the lens being of the meniscus form, the old rule should be here observed of turning the concave surface of the lens *toward* the subject, and of removing the stop to a distance of about one-fifth of the focal length in front of the said surface.

To take a familiar example: suppose an eleven-inch rapid rectilinear combination with the stop in the middle of the tube in the usual position, which is about an inch from either combination. Now, if it were desired to obtain the best results with either of the combinations alone, and thus to utilise the increased focal length of twenty-two inches, the proper plan would be to remove the front combination, leaving the back one *in situ*, and set the stop forward four inches from its anterior surface.

In practice this is seldom possible to do, unless a short extra tube be so adapted to the screw-thread in the front of the "system" that the desired increase of distance can be obtained. But we are sure that this hint will prove very serviceable to those who have failed in producing satisfactory results with either combinatiou of a "system."

An attempt to use the front lens of a system alone, with the stop left in its original position, thus bringing it in the rear, would be in every respect unsatisfactory.

A great deal of mechanical iugenuity has been expended upon the different forms of stops or diaphragms. The simplest and least expensive of them is the common flat, oblong piece of metal with the aperture in its centre. The sets of six of these which are usually furnished with the better classes of lenses should always have these openings quite concentric with each other. This can be verified at a glance by laying the stops together so that their sides correspond, when any want of exactitude in the openings will be seen at once.

All things considered, we should prefer this model of the stop or diaphragm to any other. The only objectiou to it is the danger of the loss of one or more of the set. In indoor work this risk will not make itself felt to the same degree as in landscape photography, where the loss of the stops would be a very serious matter indeed. A partial safeguard will be to rivet all the six together at the top, so that any one of the set may be inserted into the lens, leaving the others outside. Of course it may be objected that the loss of one will thus entail the loss of the whole; so it is, indeed, but we can safely say, after many years of work out of doors with this arrangement, that a very small amount of care will keep matters right.

The new Iris diaphragms supplied with some of the superior makes of lenses are new chiefly in the fact of an index and pointer being supplied, so that a desired size of opening can be promptly secured at will. The principle of the Iris diaphragm itself is by no means new. The fact of there being no loose pieces to get lost is the stroug recommendation of this form of stop; and when we have said this, we have pretty fairly summed up its merits. Supposing that the operator desired to make a change in the stop opening to one of another size, and that he also desired to effect the change without removing the focussing cloth from over his head and blinding his eyes with the stroug light, the ordinary central stop would be preferable to the Iris. The change from one stop to another is easily done by feeling, while with the Iris model it is necessary to see just what is being done.

The "rotating diaphragms," as they are called, are also very convenient; more so, we think, than the expensive Iris; but their use is limited to the slower working lenses, which are never used with very large or full openings.

We may here take occasion to remark that practical photographiug rarely, if ever, demands as many as six different stop-apertures. Taking landscape photography, for instauce, we may safe say that three sizes of stops would be all-sufficient. One small enough to give good definition over the entire plate, and require a rather long exposure; a large one, nearly the full opening of the lens, for instantaneous effects; and one of medium size for subjects of odd character, would be enough for practical purposes, and directly conduce to good and uniform results in timing.

Nothing has ever been gained by altering the stop opening from a circle to a square, oblong, triangular, or other form. A circular hole, neatly countersunk in the metal, so that a mere edge is presented to the rays of light as they enter, is all that is necessary. Stops standing at an angle, and "sky-scrapers," as they used to be called, have had their day, and are now forgotten.—*American Journal of Photography.*

PHOTOGRAPHY IN GERMANY.

BY HERMANN E. GUNTHER.

New Intensifying Method—Combined Hydroquinone and Eikonogen Developer—Collodion Dry Plates of High Sensitiveness—Table of Comparative Intensities of Various Illuminants.

A New Intensifying Method.—A method of intensifyiug a weak negative by which the actual silver image is not the least altered is described by Mr. R. E. Liesegang as follows: The varnished negative is coated with collodion or varnish in which a red or green aniline colour has been dissolved. Aniline colours, as it is known, are most sensitive to the action of light. After coating, the negative is exposed for some time to sunlight so that it acts through the glass plate, and through the negative film on the colour coating. At the parts where the latter has been exposed it bleaches, while it remains unaltered at the parts which have been less or not at all exposed, rendering the dark parts of the negative denser in exact relation. As, however, aniline colours cannot afterwards be made insensitive to light, the effect will disappear after the negative has been used for some time; but it is then only necessary to repeat the process of varnishing and exposing. Certain iron salts with development, as they are used in cyanotype, may be substituted for the aniliue colours, and then the intensification will be permanent.

Combined Hydroquinone and Eikonogen Developer.—It has been found that in mixing the hydroquinone with the eikonogen developer a combination is produced which is superior to the single developers; it acts as powerfully as eikonogen without fogging the shadows, and yields the characteristic intensity of hydroquinone. I have found this experience confirmed in my own practice. The combined developer I use is the following:—

Sodium sulphite	100 grammes
Eikonogen	15 ,,
Hydroquinone	5 ,,

are dissolved hot in

Water	1000 c.c.

After cooling down,

Carbonate of potassium	50 grammes

are added to the solution. In well stoppered bottles the developer keeps well for months. It may be mentioned here that Mr. Eugen Himly has of late made experiments with glycerine added to the eikonogen developer, and that he has found confirmation of the fact which was first pointed out in this journal by Mr. F. Goldby, that the keepiug qualities of the concentrated eikonogen developer are much improved by the addition of glycerine. Capt. Himly recommends the following composition:—

Water	1000 c.c.
Glycerine	100 ,,
Potassium metabisulphite	2 grammes
Sodium bisulphite	75 ,,
Eikonogen	12 ,,
Carbonate of potassium	60 ,,

I have tried to complete this by the addition of—

Hydroquinone	4 grammes

which gives an excellent combined developer, of the keeping qualities of which I can only say that a solution prepared six weeks ago is still entirely unaltered. The addition of yellow prussiate of potash to the above concentrated developer gives good results, according to the statement of Capt. Himly. It acts not only as a preservative, but it is said to give also more contrast in the high lights, and clearer shadows, and also to prevent fog. The formula remains the same as above, with the addition of

Yellow prussiate of potash ... 40 grammes

The developing solution may be used either concentrated, or diluted with one to two of its volume of water. For travelling purposes the bulk of the stock solution may be diminished by taking the quantity of the water as given in the above formula, and doubling the quantities of all the other components. The development may be accelerated by the addition of a few drops of caustic potash or caustic soda solution (1:10). Finally, a very good developer may be given here which was recommended at the last meeting of the Photographic Society of Frankfort-on-Maine, by its chairman, Mr. T. H. Voigt:—

No. 1.—*Stock Solution.*

Water	800 c.c.
Sodium sulphite	160 grammes
Hydroquinone	20 ,,
Potassium carbonate	230 ,,

No. 2.

In a dropping tube are poured—

Alcohol	60 c.c.
Glycerine	10 ,,
Pyro (dry)	10 grammes

For use, 50 c.c. of water, 10 c.c. of solution No. 1, and 5 to 10 drops of solution No. 2 are mixed. The stock solution keeps well.

Collodion Dry Plates of High Sensitiveness.—After seven years' work and several thousands of experiments, Mr. Gaedicke has at last succeeded in preparing permanent and highly sensitive collodion dry plates, which combine with the sensitiveness and the keeping qualities of a gelatine dry plate all the well-known advantages of a wet collodion plate. Mr. J. Gaedicke is an investigator of high reputation, and we are indebted to him for many a useful improvement and invention, so that we may have full confidence in his new successful work, which he announced at the last meeting of the German Society of Amateur Photographers of Berlin. The following are some of the qualities which the inventor claims for his collodion dry plates: As to the permanence, his experience extends to six months, during which period the plates have kept unaltered, and in his opinion there is no reason to doubt a further permanency. The plates may be developed six weeks (and probably even a much longer time) after they have been exposed. The sensitiveness of these plates is that of a gelatine plate of average sensitiveness. They are prepared exclusively colour-sensitive. The film is very thin, and rich in silver, and in the dry state it is very easily injured, so that it requires careful manipulation. After fixing, however, in the wet state it is so tough that it can be safely rubbed over with the finger. The treatment of the plates is the following: After exposure, the plate is placed in a dish containing clean water, and the film is allowed to soak for a minute. Then the water is poured away and the developer poured on the plate. An old, repeatedly used hydroquinone developer, to which about one-tenth of its volume of freshly prepared hydroquinone developer has been added, serves well. The image appears within six to twenty seconds, according to the exposure, and after one to two minutes the development will be completed. The plate is now thoroughly rinsed, and placed in an ordinary hypo solution for one-half to one minute. It is then rinsed again, washed for about five minutes in several changes of water, and can then be dried and varnished. The following are the advantages which the inventor claims for his plates in comparison to gelatine plates: In consequence of the thin film the image is sharper; the deposit is of a finer grain; the time of exposure offers a greater latitude, so that it is difficult to over-expose; the processes of development, fixing, washing, and drying are much shortened; the time required for printing is only about one-half; the negatives keep better; the preparation and the development are independent of the season and of the climate, since the film is insoluble in water. Mr. Gaedicke promised to give further particulars, and he said that he would prefer to have the plates prepared abroad, since in his experience inventions of this kind are more acknowledged abroad than in Germany.

Table of Comparative Intensities of Various Illuminants.—Mr. Alexander Lainer publishes in the *Correspondenz* an interesting and important treatise on tables of comparative exposures, in which he compares the tables of artificial illuminants contained in the book, "Le Temps de Pose," by M. de la Baume Pluvinel, with that published by Prof. Eder in his Year-Book. For this purpose he converted the latter into comparative exposures, taking the sunlight with 60,000 candles as unit.

Table of Comparative Exposures of Various Illuminants.

Sunlight	1
Electrical light of a dynamo: Arc light	10—46
Electrical light of a dynamo: Ordinary arc light	150—300
Electrical light of a dynamo: Incandescent light (Edison or Swan)	3000—6000
Light of 40 Grove cells	166
,, 48 Bunsen ,, ...	158
Limelight (oxygen and house gas, ordinary pressure)	666—2608
Limelight under 3½ atmosph. pressure ...	75·1
Magnesium wire, 0·3 mm.	811
,, ,, stronger	300—600
Oil lamp	5454—6000
Gas lamp (fish-tail burner)	6000—10·000
,, (Argand burner)	3530—3750
Petroleum lamp (flat burner)	1200
,, ,, (round burner, 15 mm. diam.)	9231
,, ,, (,, ,, 25 ,, ,,)	4286
Siemens' regenerative round burner ...	600—666
Standard wax candle, or paraffin candle ...	60·000
Tallow candle...	66 666—85·714

Mr. Lainer thinks that this table agrees much more with the actual circumstances than that compiled by M. Pluvinel.

A MOVEMENT is on foot, originating at a meeting of the Meteorological Society of Berlin, to take *simultaneous* photographs of flashes of lightning from widely different points of view, during this summer, with a view to obtaining a more accurate knowledge than now exists as to the length and direction of each flash.

A NEW and rather surprising use, says *Anthony's Bulletin*, has been discovered and patented by Mr. C. H. Koyl, of Euston, Pa., for celluloid. By silvering the back of a sheet of this material, Mr. Koyl has succeeded in producing a looking-glass which is not only of excellent quality, but is much less destructible, and has also the advantage of being bent or formed into almost any shape.

THE PHOTOGRAPHIC IMAGE.*

BY PROFESSOR RAPHAEL MELDOLA, F.R.S., M.R.I.

THE photographic film of the present time is a gelatino-haloid (generally bromide) emulsion. If a solution of silver nitrate is added to a solution of potassium bromide and the mixture well shaken, the silver bromide coagulates, and rapidly subsides to the bottom of the liquid as a dense, curdy precipitate. [Shown.] If instead of water we use a viscid medium, such as gelatine solution, the bromide does not settle down, but forms an emulsion, which becomes quite homogeneous on agitation. [Shown.] This operation, omitting all details of ripening, washing, &c., as well known to practical photographers, is the basis of all the recent photographic methods of obtaining negatives in the camera. The use of this invaluable vehicle, gelatine, was practically introduced by R. L. Maddox in 1871, previous experiments in the same direction having been made by Gaudin (1853-61). Such a gelatino-bromide emulsion can be spread uniformly over any substratum—glass, paper, gelatine, or celluloid—and when dry gives a highly sensitive film.

The fundamental problem which fifty years' experience with silver haloid films has left in the hands of chemists is that of the nature of the chemical change which occurs when a ray of light falls on such a silver salt. Long before the days of photography—far back in the sixteenth century—Fabricius, the alchemist, noticed that native horn silver became coloured when brought from the mine and exposed. The fact presented itself to Robert Boyle in the seventeenth century, and to Beccarius, of Turin, in the eighteenth century. The change of colour undergone by the chloride was first shown to be associated with chemical decomposition in 1777, by Scheele, who proved that chlorine was given off when this salt darkened under water. I can show you this in a form which admits of its being seen by all. [Potassium iodide and starch paper were placed in a glass cell with silver chloride, and the arrangement exposed to the electric light till the paper had become blue.] The gas which is given off under these circumstances is either the free halogen, or an oxide or acid of the halogen, according to the quantity of moisture present and the intensity of the light. I have found that the bromide affects the iodide and starch paper in the same way, but silver iodide does not give off any gas which colours the test paper. All the silver haloids become coloured on exposure to light, the change being most marked in the chloride, less in the bromide, and least of all in the iodide. The latter must be associated with some halogen absorbent to render the change visible. [Strips of paper coated with the pure haloids, the lower halves brushed over with silver nitrate solution, were exposed.] The different degrees of colouration in the three cases must not be considered as a measure of the relative sensitiveness; it simply means that the products of photo-chemical change in the three haloids are inherently possessed of different depths of colour.

From the fact that halogen in some form is given off, it follows that we are concerned with photo-chemical decomposition, and not with a physical change only. All the evidence is in favour of this view. Halogen absorbents, such as silver nitrate on the lower halves of the papers in the last experiment, organic matter, such as the gelatine in an emulsion, and reducing agents generally, all accelerate the change of colour. Oxidising and halogenising agents, such as mercuric chloride, potassium dichromate, &c., all retard the colour change. [Silver chloride paper, painted with stripes of solutions of sodium sulphite, mercuric chloride, and potassium dichromate, was exposed.] It is impossible to account for the action of these chemical agents except on the view of chemical decomposition. The ray of light falling upon a silver haloid must be regarded as doing chemical work; the vibratory energy is partly spent in doing the work of chemical separation, and the light passes through a film of such haloid partly robbed of its power of doing similar work upon a second film. It is difficult to demonstrate this satisfactorily in the lecture-room, on account of the opacity of the silver haloids, but the work of Sir John Herschel, J. W. Draper, and others, has put it beyond doubt that there is a relationship of this kind between absorption and decomposition. It is well known, also, that the more refrangible rays are the most active in promoting the decomposition in the case of the silver haloids. This was first proved for the chloride by Scheele, and is now known to be true for the other haloids. It would be presumption on my part, in the presence of Captain Abney, to enlarge upon the effects of the different spectral colours on these haloids, as this is a subject upon which he can speak with the authority of an investigator. It only remains to add that the old idea of a special "actinic" force at the more refrangible end of the spectrum has long been abandoned. It is only because the silver haloids absorb these particular rays that the blue end of the spectrum is most active in promoting their decomposition. Many other instances of photo-chemical decomposition are known in which the less refrangible rays are the most active, and it is possible to modify the silver haloids themselves so as to make them sensitive for the red end of the spectrum.

The chemical nature of the coloured products of photo-chemical decomposition is still enshrouded in mystery. Beyond the fact that they contain less halogen than the normal salt, we are not much in advance of the knowledge bequeathed to us by Scheele in the last century. The problem has been attacked by chemists again and again, but its solution presents extraordinary difficulties. These products are never formed—even under the most favourable conditions of division, and with prolonged periods of exposure—in quantities beyond what the chemists would call "a mere trace." Their existence appears to be determined by the great excess of unaltered haloid with which they are combined. Were I to give free rein to the imagination, I might set up the hypothesis that the element silver is really a compound body invariably containing a minute percentage of some other element, which resembles the compound which we now call silver in all its chemical reactions, but alone is sensitive to light. I offer this suggestion for the consideration of the speculative chemist.* For the coloured product as a whole, *i.e.*, the product of photo-decomposition with its combined unchanged haloid, Carey Lea has proposed the convenient term "photo-salt." It will avoid circumlocution if we

* Continued from page 558.

* I have gone so far as to test this idea experimentally in a preliminary way, the result being, as might have been anticipated, negative. Silver chloride, well darkened by long exposure, was extracted with a hot saturated solution of potassium chloride, and the dissolved portion, after precipitation by water, compared with the ordinary chloride by exposure to light. Not the slightest difference was observable either in the rate of colouration or in the colours of the products. Perhaps it may be thought worth while to repeat the experiment, using a method analogous to the "method of fractionation" of Crookes.

adopt this name. The photo-salts have been thought, at various times, to contain metallic silver, allotropic silver, a sub-haloid, such as argentous chloride, &c., or an oxy-haloid. The free metal theory is disposed of by the fact that silver chloride darkens under nitric acid of sufficient strength to dissolve the metal freely. The acid certainly retards the formation of the photo-salt, but does not prevent it altogether. When once formed, the photo-chloride is but slowly attacked by boiling dilute nitric acid, and from the dry photo-salt mercury extracts no silver. The assumption of the existence of an allotropic form of silver insoluble in nitric acid cannot be seriously maintained. The sub-haloid theory of the product may be true, but it has not yet been established with that precision which the chemist has a right to demand. We must have analyses giving not only the percentage of halogen, but also the percentage of silver, in order that it may be ascertained whether the photo-salt contains anything besides metal and halogen. The same may be said of the oxyhaloid theory: it may be true, but it has not been demonstrated.

The oxyhaloid theory was first suggested by Robert Hunt* for the chloride: it was taken up by Sahler, and has recently been revived by Dr. W. R. Hodgkinson. It has been thought that this theory is disposed of by the fact that the chloride darkens under liquids, such as hydrocarbons, which are free from oxygen. I have been repeating some of these experiments with various liquids, using every possible precaution to exclude oxygen and moisture; dry silver chloride heated to incipient fusion has been sealed up in tubes in dry benzene, petroleum, and carbon tetrachloride, and exposed since March. [Tubes shown.] In all cases the chloride has darkened. The salt darkens, moreover, in a Crookesian vacuum.† By these experiments the oxychloride theory may be scotched, but it is not yet killed; the question now presents itself, whether the composition of the photo-salt may not vary according to the medium in which it is generated. Analogy sanctions the supposition that when the haloid darkens under water or other oxygen-containing liquid, or even in contact with moist or dry air, that an oxychloride may be formed, and enter into the composition of the photo-salt. The analogy is supplied by the corresponding salt of copper, viz., cuprous chloride, which darkens rapidly on exposure. [Design printed on flat cell filled with cuprous chloride by exposure to electric light.] Wöhler conjectured that the darkened product was an oxychloride, and this view receives a certain amount of indirect support from these tubes [shown], in which dry cuprous chloride has been sealed up in benzene and carbon tetrachloride since March; and although exposed in a southern window during the whole of that time, the salt is as white as when first prepared. Some cuprous chloride sealed up in water, and exposed for the same time, is now almost black. [Shown.]

When silver is precipitated by reduction in a finely divided state in the presence of the haloid, and the product treated with acids, the excess of silver is removed and coloured products are left which are somewhat analogous to the photo-salts proper. These coloured haloids are also termed by Carey Lea photo-salts, because they present many analogies with the coloured products of photo-chemical change. Whether they are identical in composition it is not yet possible to decide, as we have no complete analyses. The first observations in this direction were published more than thirty years ago in a report by a British Association Committee*, in which the red and chocolate coloured chlorides are distinctly described. Carey Lea has since contributed largely to our knowledge of these coloured haloids, and has at least made it appear highly probable that they are related to the products formed by the action of light. [Red photo-chloride and purple photo-bromide and iodide shown.]

(To be continued.)

* "Researches on Light." 2nd ed. 1854, p. 80.

† Some dry silver chloride which Mr. Crookes has been good enough to seal up for me in a high vacuum, darkens on exposure quite as rapidly as the dry salt in air. It soon regains its original colour when kept in the dark. It behaves, in fact, just as the chloride is known to behave when sealed up in chlorine, although its colour is, of course, much more intense after exposure than is the case with the chloride in chlorine. The tube in which the chloride had been sealed up in benzene, gave off a considerable quantity of hydrogen chloride on breaking the point in June.

* These results were arrived at in three ways. In one case hydrogen was passed through silver citrate suspended in hot water, and the product extracted with citric acid. "The result of treating the residue with chlorhydric acid, and then dissolving the silver by dilute nitric acid, was a rose-tinted chloride of silver." In another experiment the dry citrate was heated in a stream of hydrogen at 212° F., and the product, which was partly soluble in water, gave a brown residue, which furnished "a very pale red body on being transformed by chlorhydric and nitric acids." In another experiment silver arsenite was formed, this being treated with caustic soda, and the black precipitate then treated successfully with chlorhydric and nitric acids: "Silver is dissolved, and there is left a substance . . . . [of] a rich chocolate or maroon, &c." This, on analysis, was found to contain 24 per cent. of chlorine, the normal chloride requiring 24·74, and the sub-chloride 14·08 per cent. The committee which conducted these experiments consisted of Messrs. Maskelyne, Hadow, Hardwich, and Llewelyn. B.A. Rep. 1859, p. 103.

Specifications Published.

12,309. *August 2nd*, 1889.—"Treatment of Paper or other Fabrics to Render them suitable for Photographic Purposes." JAMES WILLIAMS, Willesden Paper Works, Willesden Junction, Middlesex, Chemist.

Paper is at the present time treated by dipping in an ammoniacal solution of oxide of copper (cuprammonium hydro-oxide) in the manufacture of the well-known Willesden waterproof paper. Such paper has, however, comparatively rough surfaces unless glazed with roller pressure.

Paper and textile fabrics have also been glazed by applying a coating of cellulose dissolved in cuprammonium hydro-oxide, but, owing to the manner in which this was done, the resulting surface was not suitable for photographic purposes.

I have discovered that instead of dissolving cellulose in cuprammonium, it is essential to success to first prepare a bath of strong cuprammonium hydro-oxide solution, which must be of the utmost possible purity, and I find it convenient to use from 1·5 to 2·5 per cent. by weight of metallic copper, according to the degree of brilliancy required. Upon this bath I float the surface of the paper or other fabric to be treated, taking care that only one side comes in contact with the solution, by which means I convert the surface of the paper or other fabric into a structureless film of cellulose, such film at this stage existing in combination with the oxide of copper, ammonia, and water employed. I then conduct the sheet of paper or other fabric, with as little exposure as possible to the air consistent with the setting of the film, to one or more hot rollers, taking care to lead it over the first, so that the untouched surface is in contact with it, by which means I expel the ammonia and water from the deposited film.

The material thus treated has a green tint, due to the copper hydrate contained in the deposited film. In order to remove this and render it suitable for photographic purposes, I pass it through consecutive baths of weak acid, such as sulphuric acid, which dissolves out the copper without affecting the glazed surface. I then wash and dry the paper or other fabric.

By this invention a permanent glaze, capable of withstanding the action of water, steam, weak acids, alkalies, and ordinary solvents, and with a surface closely resembling the albumenised paper used in photography, is obtained.

In place of cuprammonium hydro-oxide, other suitable solvents may be used.

What I claim is:—

1. The process of forming a practically pure, structureless film of cellulose upon the surface of paper or other fabric, by exposing it to the action of a solvent, and then removing or neutralising such solvent.

2. The process of forming a practically pure, structureless film of cellulose upon paper or other fabric, by floating the paper or other fabric upon the surface of a solvent, and then extracting or neutralising such solvent.

3. The process of forming a practically pure, structureless film of cellulose upon the surface of paper or other fabric, by exposing it to the action of cuprammonium hydro-oxide, and afterwards to acid.

4. The process of forming a practically pure, structureless film of cellulose upon the surface of paper or other fabric, by floating the paper or other fabric upon the surface of cuprammonium hydro-oxide, and afterwards exposing it to the action of acid.

5. The treatment of paper or other fabrics to render them suitable for photographic purposes.

14,508. *Sept. 14th*, 1889.—"Applying Luminous Preparation to Paper." JAMES ALBERT CAUSTON, of the firm of Sir Joseph Causton and Sons, 9, Eastcheap, London, Printer, and James Challis, of 9, Eastcheap, London, Commercial Traveller.

Our improved process consists in printing any design or pattern in an adhesive composition, such as gold size or mucilage, upon paper or other substance from type, blocks, or lithographic stones by an ordinary printing press or otherwise; and, while the design is still wet or tacky, dusting or flocking upon it a layer of the chemical compound known as luminous powder, which has the property of absorbing rays of light and afterwards emitting them in the dark; being the acting ingredient in the well-known luminous paint, and composed of sulphur and lime.

To obtain a greater body of the luminous powder, we sometimes mix a portion of it with the mucilage used in printing the design, and afterwards dust on the powder. The non-luminous portions of the design are printed in the usual manner.

We are aware that luminous designs have been produced by painting, and also by washing or coating the entire surface with luminous paint, and stopping out the required non-luminous portion by printing or otherwise. These methods, however, involve a very large consumption of the luminous compound, while the effect obtained both on the luminous and the stopped-out portions is extremely coarse; whereas, by our improved process, we can produce designs of very great delicacy and beauty with the least possible expenditure of material.

18,139. *November 13th*, 1889.—"Apparatus for Facilitating the Microscopical Examination of Photographs." HENRY DUNCAN, 16, Tokenhouse Yard, London, Stockbroker.

My invention relates to apparatus for facilitating the microscopical examination of photographic pictures, maps, and documents, and other small or microscopic objects.

My said invention is chiefly designed to afford the means whereby photographic miniatures of maps or the like, which, while occupying a comparatively small space, correspond to a very large area, can be easily examined.

My said invention is particularly serviceable to bicyclists and tourists, and for military and other purposes where ordinary maps would be objectionable by reason of their bulk, or by reason of the difficulty of using them, particularly in stormy or wet weather.

An important feature of my said invention is the provision of suitable means whereby the microscope may be readily adjusted relatively to the map or other object, so that any desired section of the said map or other object can be brought into the field of the said microscope. By this means, with a comparatively small lens, it is possible to examine objects which, as a whole, occupy an area very much larger than the field of such lens. For example, any desired part of a small scale map showing an area of, say, three or four hundred square miles may be examined by adjusting the microscope as required.

In making a portable apparatus according to my said invention, I arrange the lens or lenses in a suitable tube or holder capable of sliding in a disc or other piece fitted to rotate in or upon the frame of the map, picture, or the like; or I provide other suitable means for adjusting the lens or lenses in any direction relatively to the said map, picture, or the like for the purpose above specified.

The tube carrying the lens or lenses is sometimes arranged to slide into and out of the main portion of the apparatus.

The map or the like is preferably photographed on a greatly reduced scale on a disc of glass which will fit into a suitable case or holder provided with a removable cover, and is protected with another disc of glass secured to the first disc in any convenient manner. I sometimes so construct these discs as to prevent rotation of the same in their case or holder; for example, I form notches in them to engage with a stud or projection in the holder. I can, if desired, provide the apparatus with any desired number of interchangeable maps, pictures, or the like mounted in this manner.

A stud or projection is sometimes provided on the said frame to facilitate the use of the apparatus by indicating which is the top or north of the map. This stud or projection, moreover, engages with a notch in the cover of the holder for the map or the like, and prevents rotation of the said cover relatively to the said holder.

In some cases I make the map or other object adjustable while keeping the lens fixed, so that different parts of the said map or the like can be brought into the field of the said lens, or both the lens and the object may be made adjustable relatively to each other.

6,093. *April 22nd*, 1890.—"A Photographic Camera." John Merritt, 842, President Street, and William Edward Spencer, 293, Dekalb Avenue, Brooklyn, State of New York, Physicians.

This patent is inexplicable without the aid of mechanical drawings, and has fifteen claims.

Correspondence.

EXPOSURE AND DEVELOPMENT.

Sir,—In your report of the last meeting of the Hackney Photographic Society your printer has substituted "on glass" for "in glens;" the sentence should read "Preferred dull weather when photographing *in glens*."

As some little misunderstanding might arise about the development of an isochromatic plate by candle-light, permit me to point out that I used the developing dish designed by myself, which has a transparent ruby glass bottom, with a well at one end to hold developer when the dish is held upright. By this means it is unnecessary to remove the plate from the developing dish to examine it for density, or to pour off the developer. This prevents bubbles in the developer and staining of fingers, as it is not necessary to touch the plate at all until development is complete and the solutions washed off. The ruby glass bottom prevents the light from reaching the back of plate when examining for density, my experience proving that plates are mostly fogged in this way. As to the glass side of the film it remains sensitive, whereas the surface of film is partly protected by the developer and the reduced image.

Birt Acres.

BRIXTON AND CLAPHAM CAMERA CLUB.

Sir,—Can you spare a corner in this week's issue to announce that in future we meet at Gresham Hall, Gresham Road, Brixton, S.W., opening there on Thursday, 31st inst., and that we shall be glad to see any photographers residing in the neighbourhood on that occasion, or at any of our meetings? Thanking you in anticipation, F. W. Levett, *Hon. Sec.*

126, *Lowden Road, Herne Hill, S.E., 21st July.*

Proceedings of Societies.

Photographic Society of Great Britain.

The monthly technical meeting of this Society was held on July 22, Mr. T. Sebastian Davis in the Chair.

A set of photographs from paintings of eminent masters amongst musical composers was received from an establishment at Munich.

An illustration of photographic enterprise was narrated by Mr. L. Warnerke. A photographer in the Isle of Wight was in the habit of posting himself at a stopping place of the Ventnor coach, and photographing the vehicle and passengers at about eleven o'clock in the morning, and by five in the afternoon, on the return journey, the passengers were met with a supply of mounted prints made from the negative taken only a few hours earlier.

An enquiry being made as to the character of Watkins' exposure meter, Mr. Chapman Jones said that a description of it would be found in the *Journal of Chemical Industry*.

The Chairman asked what would be considered a fair time to expect commercial sensitised paper to keep in good condition?

Mr. W. E. Debenham said that there were two causes which operated to spoil sensitised paper. One cause was the influence of an impure atmosphere, such as that of large cities. It must not be expected that silver paper could be prepared to resist this influence. The other cause was the inherent constitution of the sensitised paper itself. It was this that the manufacturer could influence. Paper must therefore be judged by its ability to keep in good condition if well preserved from the atmosphere. There were also two kinds of deterioration, discolouration, and a change which prevented the paper from taking a rich and satisfactory tone. He had noticed that with paper kept loose this change had come on before there was any serious discolouration.

Mr. Chapman Jones had found paper keep better, as far as freedom from discolouration is concerned when loose in a box than when rolled up.

Mr. Warnerke had some sensitised paper which was more than two years old. It had been kept wrapped in tinfoil, and was as good as at first, with the exception of the outside sheet, which was spoiled.

Mr. A. Cowan had found paper keep perfectly good when placed between folds of blotting-paper that had been prepared with a solution of common washing soda and dried.

Mr. Warnerke had used in this way paper treated with potassium nitrite.

Mr. J. R. Gotz considered that the influence of impure atmosphere was very strong in spoiling sensitised paper. He had known paper to keep perfectly good for two years at a country place in Shropshire, whilst in Sheffield as many months sufficed to spoil it.

The Chairman said that it would be an advantage if albumenisers would prepare paper in other and larger sizes than the one now exclusively adopted. There would be no difficulty in getting the paper from the mills.

Mr. Gotz then exhibited McKellan's new magazine hand-camera, and showed its working, which appeared to be simple and satisfactory.

London and Provincial Photographic Association.

At the meeting on the 17th inst. Mr. F. A. Bridge occupied the chair.

Mr. S. T. Chang was elected a member.

Mr. J. R. Gotz exhibited some half-plate negatives taken on Obernetter films; the substratum of these films is hardened gelatine. Mr. Gotz said the treatment of these films was similar to others. After washing, they were transferred to a bath containing a little spirits of wine and about 7 per cent. of glycerine, in which they were allowed to remain about half an hour, and then dried between sheets of blotting-paper. He also passed round some prints on Obernetter paper with a matt surface.

Mr. A. Haddon said that at a former meeting Mr. Hastings had shown some prints on Reynolds' iridium paper. He had subjected a piece of this paper to various tests, but was unable to trace any iridium.

The report of the delegates appointed by the Association to attend the Convention at Chester was given by Mr. A. Haddon.

The subject for discussion on the 31st inst. will be "Outdoor Portraiture."

Newcastle-on-Tyne and Northern Counties Photographic Association.

July 15th.—Mr James Brown in the chair. About forty members were present.

Mr. H. M. Smith, of the Eastman Company, attended to exhibit and explain the kodak and new rollable transparent film. In introducing his subject, Mr. Smith said he would naturally be expected to refer to the attacks which had been made upon the kodak, and, in fact, he was there partly for that very purpose. He emphatically protested against anonymous and erroneous statements which had appeared in one of the photographic papers, and he especially invited the writer who signed himself "Newcastle" to come forward, if present, and argue the matter out; an invitation which, however, was not responded to. It was the intention of the Company, whenever the identity of a correspondent could be established, to go boldly to him and afford every facility for the settlement of disputed points. Had any of these anonymous gentlemen given the most cursory examination to the kodak, they would have found that the lens is not a single non-achromatic; and as to price, that was entirely a matter between buyer and seller. He wished to state, in as public a manner as possible, that in the No. 1 kodak the lens was not a single but a periscopic—a doublet lens. It was not achromatised, but was

placed so as to work at its chemical focus, and he could appeal to results to show its quality. With the sole exception of the No. 1, all the other forms of kodak sent out by his Company were fitted with rapid rectilinear lenses made by one of the principal firms of lens makers in America, and they would bear comparison with any in the market. The focus of the quarter-plate was five and a quarter inches, and the 5 × 4 six and a half inches, and all were capable of adjustment to various distances. Results of exposures taken in the kodak during the Convention were passed round, some hand exposures and others with a tripod, as well as enlargements from the same negatives. It was intended to demonstrate the development of the films, but time did not admit.

After remarks from Messrs. Dunn, Park, Pike, Hemy, the Chairman, and others, a vote of thanks was accorded to Mr. Smith for his address.

BRISTOL AND WEST OF ENGLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE excursion on the 18th to Tintern was attended by a few members, including Mr. E. Brightman. The weather was fine, and some good work was done.

On the Saturday following (the 21 inst.) a large number of members went for a day's photography and pleasure to Keynsham and Saltford, in response to the invitation of the president, Mr. H. A. H. Daniel. The party left the train at Keynsham, where they visited the interesting Parish Church, and were thence driven by Mr. Daniel to Keynsham Manor House, where they were hospitably regaled before proceeding farther. Return was made to Keynsham Manor in the late afternoon. Mr. Boyden took an excellent group before the party dispersed.

Raglan was settled on for the July excursion, which was arranged to take place on Saturday, the 26th, the journey being made on the previous evening.

A resolution of regret was passed by the members present at the announcement of the death, after a rather sudden illness, of Mr. E. S. Walsh, a member of the Society.

A CARBON PROCESS.—Mr. O. Volkner publishes the following dust carbon printing process, which appears to be easy to carry out, requires no reversed negatives, and yields permanent prints. We also think it can be used in making phototypic printing blocks. Make a solution of gelatine in water (1:60) and draw sheets of good strong paper through it, and hang it up to dry. Wet it again and squeeze it down on a piece of glass. Now brush over it a solution of ten parts gelatine, ten parts gum arabic, twenty parts white sugar, eighty parts distilled water. While still quite moist, put it in a dusting box (such as used for photogravure) which contains a mixture of 100 parts to white dry sugar and five parts of French lampblack. After a lapse of eight to ten minutes withdraw it, and you will find it covered with innumerable particles of dust. Paper thus prepared will keep, and has to be sensitised in a bath of fifty parts bichromate of potassium, fifty parts bichromate of ammonia, six thousand parts water and aqua ammonia, until it assumes a light yellow colour, and at last, to avoid the too quick dissolution of the gum arabic, immerse in twenty parts chromic acid in 1,500 alcohol. Print by Vogel's photometer 16° to 18°. To develop, use warm water first, and afterwards cold, leaving the print for several hours in water, to which may be added a little aqua ammonia, in case the printing was carried too far. The prints show a singular and very pleasing grain, and need no transferring.—*Dr. Eder's Jahrbuch.*

RECEIVED.—The catalogue of Mr. R. Abraham, whose business will in future be carried on under the name of Adams and Co. This catalogue begins with thirty-six pages of good literary matter on practical photographic subjects by Mr. Andrew Pringle and other good writers.——We have also received with thanks and suspended in the office, as requested, our coloured book-cover supplement, recently issued, neatly framed by Mr. W. F. Slater, of Southampton Street, Camberwell, as a specimen of his skill in the framing of photographs.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and to the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

COL. WATERHOUSE.—*Guaiacol Developer, &c.* We thank you for the letter dated 24th ult., and for the promise of further particulars, also for the memorandum sent. The change which you describe is not confined to India, but occurs in more temperate climates, and sometimes even in England.

H. S.—*Card Mounts.* Two cabinets received showing defects, the cause of which cannot be ascertained by mere inspection. We will look further into the matter and report to you later on.

FOCUS.—*Right of Reproduction.* Amongst amateurs who are friends, it is not likely that there can be any objection to the proposed course, which is intended as a personal compliment; but as a measure of courtesy you ought to apprise your absent colleague of the step you are taking, even though he, being at the antipodes, may not get to hear of it until after your copies are distributed. All depends upon the character of the individual, and the degree of intimacy subsisting between you. We have done so under similar circumstances without giving offence.

D. M.—*Eikonogen Development; German Formula.* The use of eikonogen introduces no new practice as regards the method of fixing the plates developed therewith. Bromide is supposed to have an influence by virtue of its exerting a slight solvent action upon the haloid salts of silver contained in the sensitive film; the same claim is made on behalf of the trace of hypo sometimes employed as an accelerator.

E. O. C. (Boston).—*Photo-Mechanical Processes.* In last week's NEWS you will have seen further references to Kiewning's and to Maschek's processes.

INQUIRER.—*Hygrometers.* The instrument figured and described at page 547 may not be altogether novel, but is probably much more delicate than the cat-gut hygrometer in frequent use. The wet and dry bulb thermometers may be depended upon to give correct indications; these are worked with Mr. Glaisher's tables.

L. P. (Yarmouth).—*Ferrous Oxalate.* Your letter is answered by reference to the concluding summary, which has now been published. See bottom of page 552.

TYRO.—*Brown Spots in Silver Prints.* The circular marks appear to be due to bubbles formed whilst the prints are in the fixing bath. The cure should be occasional lifting and more agitation in the hypo, with greater care in removing the excess of silver by preliminary washing.

S. D.—*Cockled Ebonite Shutter.* Try the effect of tying up the slide between two zinc plates, immerse in boiling water, and allow gradually to cool. It ought then to be permanently flattened.

J. M. S.—*Weather Forecasts.* From long observation and comparisons we should be inclined to put the "successes" rather lower than *two out of three*, and several of the later prophecies have been exceedingly unfortunate. Photographers are quite as much interested as the farmers in getting true indications, but we must wait for the progress of science, and hope for better results. America is fortunate in having a great continent and wide ocean to help their meteorological forecasts, which are nearly always right; whilst our insular position precludes the attainment of this degree of certainty, and with us, so far, they are about as often wrong as right.

W. C. N.—"*London Purple.*" We have never known Magenta residues to be called by this name, but from them may be prepared Ruby Powder, which, in some respects, answers to your description.

RECEIVED.—Photargus, B. B. and Co., and E.B.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1665.—*August* 1, 1890.

CONTENTS.

THE WEIGHTS AND MEASURES USED BY PHOTOGRAPHERS IN AMERICA.

As it seems probable that the system of weights and measures used by British photographers will soon be the same as those employed in the rest of civilised Europe, it remains to be considered whether a variation from the general uniformity will be found in the United States of America. In relation to the weights and measures of the United States, Professor T. C. Mendenhall, the superintendent of the United States Coast and Geodetic Survey, recently delivered a long address to the Pharmacopœial Convention held at Washington; that address contained a mass of useful information on the subject now under notice.

Professor Mendenhall set forth that in the United States the old English system of weights and measures, resting upon no scientific basis, is in general use, and that, whilst within the last fifty years the English had somewhat improved their ancient system, the example had not been followed in his country. He said that the United States was one of the first nations to receive copies of the metre. During the French Revolution, the Committee on Safety, of which Robespierre was chairman, transmitted to the United States a copper metre and a copper kilogramme by order of the Committee, and this metre and kilogramme were placed in the national archives. In the archives of the United States Coast Survey Office is what is known as the Committee metre—an iron bar of great historic interest, as only three or four are now in existence. This is one of the fifteen iron bars which were prepared from a study of the metre, and was obtained very long ago. Professor Mendenhall added that in 1868 a law was passed by the Congress of the United States legalising the use of the metric system in that country, and establishing certain approximate relations between the metric and the customary systems. He said that he wanted to emphasise one fact which is not generally recognised in relation to this subject, and that is, that to-day the metre and the kilogramme are the only units that have been established by Congress for the whole country.

In the course of his address, he also set forth that in 1869 the French Government invited other governments to send delegates to Paris in order to attend the International Bureau of Weights and Measures, that they might agree on the construction of a new international metre. The old metre of the archives was still preserved, but it no longer possessed the great authority it formerly had, since its form was not recognised as coming up to the modern ideas of metrology. The French Government, therefore, concluded that it was time to construct a new metre which should be first in authority the world over.

The United States sent delegates, and in 1875 the International Bureau of Weights and Measures was organised by an International Convention. It was held in France; about twenty-five nations were represented, and the result of that was the introduction of a new prototype standard. Copies of this prototype standard were subsequently distributed to all the nations of the world who had participated in the Convention, and two of these copies went to the United States, two metres and two kilogrammes. One of these metres and one of these kilogrammes were carried over from Paris by Mr. Graham, of the Geodetic Survey, and were deposited in the archives of the Bureau of Weights and Measures. They bore the seal of the United States Minister at Paris, and of Prof. Davidson and Dr. Gould. On the 2nd day of January, 1890, these standards were taken to the Executive Mansion, to the Cabinet room, and were opened. The seals were broken by the President of the United States, witnessed by the Secretary of State and the Secretary of the Treasury, also by twenty or thirty distinguished scientific men. Models were constructed of these standards, and Professor Mendenhall exhibited one of them to the Convention, made of 90 per cent. platinum and 10 per cent. iridium, coated with aluminium. It is in the form of a bar, but it has a peculiar cross section of the form of the letter H, so that any stress that the bar may receive will be compensated for; a short distance from each end are fine lines, and they represent the length of the

metre. He also exhibited a model of the standard kilogramme composed of the same platinum-iridium alloy.

From this it seems that great attention is being paid just now in the United States to the metric system, and it may be inferred that the matter is likely to be considered without delay by photographers there, who are already displaying much interest in the steps recently taken in England in relation to the standardising of the mounts of lenses.

DARK ROOM COMFORTS.

It is a common belief that any place will do for a dark room for photographic purposes, and many men are content—sometimes, unfortunately, by compulsion—to utilize a cupboard under the stairs, or some other corner of the household where, to use a common but expressive term, "there is not room to swing a cat," for the purposes of development. We never yet met with a photographer who possessed any intense desire "to swing a cat," but all of us are desirous of sufficient room in our workshops to swing our own arms without the danger of smashing bottles or dishes in the process. The "cupboard" form of dark room is bad for other reasons, the chief being the want of ventilation, so that half-an-hour's work therein causes a feeling of exhaustion which is not always traced to the real cause. One pair of lungs soon vitiates the available oxygen in a small room, and if the process is helped by a lamp, which consumes a great deal more, the place soon becomes likened to the black hole of Calcutta.

We lately saw at the house of an ardent amateur photographer a very ingenious method by which his bath-room was transformed in two minutes into an effective dark room. The idea seemed to us to be so original in conception that we made a note of the arrangements, by leave of the owner, for the benefit of others. The bath was of the usual household type, with cold water laid on by an ordinary tap, and was placed immediately under a window through which the afternoon sun poured liberally into the room. The window had a vallance above it, and curtains on either side, and without close examination did not reveal any other fittings; but this window was really far more worthy of patenting than many photographic contrivances which are daily brought under our notice.

In the first place, it was fitted with a blind made of ruby medium, which was fastened to a roller like any other window blind. When pulled down the light in the room instantly changed to crimson, but there were, of course, gaps on each side through which treacherous, undiluted daylight still streamed in sufficient quantities to affect the least sensitive of photographic compounds. No light came in from beneath the blind, for it was made of such a length that its lower edge and lath came over the window ledge, and could be fastened there by a button in the wall.

But fixed to the outer edges of the window frame on each side, and hidden until required by the curtains, were two wings of black material (silesia) each about ten inches broad. These flaps were pulled over the edges of the blind, and two or three elastic tapes fastened to the edge of one of them found resting places on corresponding buttons sewn on the edge of the other one. In this way the window was quite obscured, while plenty of red light came into the room from the broad band of ruby medium that was left exposed right down its centre. With this clever makeshift the bath-room was changed into a red room with ease, and plates could be developed in comfort upon a wooden grid that was temporarily laid across under the tap. It is true that the interior of the bath bore traces of experiments with various developers, and the paint gave evidence of chemical discolouration, but this we should not have remarked had it not been pointed out to us by the fair lady of the house.

Where a bath room can be adapted in this way one great desideratum gained is a plentiful supply of water. The importance of this is not always recognised by photographers, and thereby many a good negative has been sacrificed. A properly fitted dark room should not only have a copious supply of this "staff" of modern photography—it was not of so much consequence in the days of collodion—but it should also have a large sized sink in which plates may be left with the water running upon them after the alum bath, as a final precaution against the enemy hypo.

The right choice of a dark room lamp is another matter upon which comfort much depends. When electricity is "laid on" to our houses that difficulty will be solved, for there is nothing better than a glow-lamp in a red lantern, or—as they will doubtless be supplied for photographic uses—with ruby glass bulbs of their own. In the meantime gas is, without doubt, the best thing to use where it is available. The lantern box in which it is contained should be large, and may conveniently be fitted with panes of different material, according to the work in hand. But perhaps the chief recommendation of gas is that it can readily be turned up or down, according to the amount of light which it is deemed safe to use with different varieties of plates.

There are many other points which greatly add to dark room comfort, too many, indeed, to discuss in detail, but one or two which are commonly neglected may be mentioned. Every bottle should be legibly labelled, and in the case of compounds, such as developers, the actual formula should be written at length on the label. The ability to fill a bottle afresh, without the necessity of hunting through several Year-Books to find the original formula, is a comfort indeed. A bottle of water, acidulated with hydrochloric acid, and a sponge, should be kept close to the sink in order to wash out dishes and measures after use; and we may mention in passing that the same sponge passed over a sheet of glass, followed by a good rinse under the tap, will give a chemically clean surface more quickly, perhaps, than any other agent. These are little things, but attention to such details leads to big things.

STEELING PHOTOGRAVURE PLATES.

In an illustrated pamphlet on "Photogravure," by W. T. Wilkinson, issued this week by Iliffe and Son, will be found thirty-two pages of reading matter, giving photographers information how to etch their own photogravure plates, and to print off impressions therefrom. The artistic effects producible by photogravure are now fully recognised, and it is not impossible that this process may play an important part in the professional photography of the future.

The pamphlet is clearly written, and likely to be useful. In it Mr. Wilkinson gives the following instructions for the steeling of the etched plates when large numbers of prints are required therefrom:—

"When the plate has been proved, the next operation will be to steel-face it, for which purpose it is thoroughly cleaned with whiting moistened with turpentine and naphtha, polishing with a soft cloth; a small portion of the plate behind is scraped clean, and a piece of copper wire soldered to it. The steeling solution is placed in a wooden cell, the positive and negative poles from the battery (Leclanche) ending in copper rods the whole length of the cell. The solution is composed of—

Warm water	... 20 ounces
Ammonium chloride	... 3 ,,
Sulphate of iron and ammonia ...	... 4 ,,

When dissolved, filter, and let it stand in the cell twenty-four hours before use. When required for use, the copper-plate is hung upon the rod connecting with the negative pole of battery, the positive pole being occupied by the anode (a plate of pure steel), which must be the same size or larger than the copper-plate. The two plates being in position, the current is turned on by pushing in the rod of battery, and in from three to five minutes the operation is complete, the copper-plate being covered by a very thin film of steel. The plate, when steel-faced, is thoroughly washed and dried, and then cleaned with whiting and turps and naphtha, the copper wire behind carefully unsoldered, and the back scraped flat. If the battery is not to be used again for some time the anode should be removed and wiped dry, the cell being carefully covered up."

A SUPPLEMENT TO THE "PHOTOGRAPHIC NEWS."

We desire to remind the readers of this Journal that on Friday, August 15th, a fine photo-etching, representing the house at Eversley of the late Charles Kingsley, will be issued as a Supplement to the Photographic News.

Clearing Collodion.—Collodion, which is often slow in settling and clearing after preparation, may, according to the *Photo. Archiv*, be entirely cleared by shaking it up with clear quartz sand. This carries the flocks and impurities to the bottom with it, and leaves the liquid above entirely clear.

Toning Gelatino-Chloride Paper.—The simplest toning bath for gelatino-chloride paper we have seen is that proposed by W. K. Burton, of Tokio, Japan; it is as follows:—

Hyposulphite of soda	... 3 ounces
Distilled water	... 20 ,,
Chloride of gold	... 6 grains

with the addition of three grains of nitrate of lead to preserve the whites. The above bath tones slowly, and does not give the richness produced by the sulpho-cyanide of ammonia formula, but will recommend itself to many on account of its simplicity.—*Wilson's Photographic Magazine.*

LIMITATIONS IN THE TREATMENT OF SUBJECTS BY FOCUS.*

BY W. K. BURTON.

It must be some year or two now since I wrote to your columns, pointing out what I considered to be a fallacy in a statement made by Mr. T. R. Dallmeyer in connection with the effect of reflection from the surfaces of lenses. Mr. Dallmeyer, at that time, replied to my communication that he intended to go into the matter thoroughly by the aid of drawings, and I have been ever since eagerly looking out for any farther word from him on the subject. I see an announcement in a photographic periodical that has just reached me that he is, at last, going to take the matter up. I therefore do not enter into this question at present farther than to say that if he, Mr. Dallmeyer, has not gone into the matter before he has seen this, he may hereby know that there is at least one person anxiously waiting to hear of his results.

I now come to say a word or two in reply to some remarks made by Mr. Dallmeyer in his recent paper read before the Camera Club Conference, entitled "Limitations in the Treatment of Subjects by Focus," in which he criticises some sayings of mine.

I cannot help thinking that Mr. Dallmeyer either wilfully misrepresents me, or has not understood the paper of mine that he refers to, "On One or Two Tenets of the Naturalists," and, as I cannot believe the former, I must believe the latter assumption, and assume that my paper was not clear. I therefore make a little farther explanation.

In the paper of mine referred to I stated that I believed the common statement, that the eye defines less perfectly than a good lens, to be a mistake. I should certainly have added that this is as far as refers to axial definition only. My authority is Lord Rayleigh who, unless I remember very imperfectly, some years ago demonstrated that the normal human eye gives central definition in one plane *as good as any lens is physically capable of giving*, but I have, unfortunately, not the means by me here to quote chapter and verse.

Mr. Dallmeyer contradicts my statement, and gives Helmholz as his authority; but he persistently ignores the whole point of my argument, to wit, that granted that the eye gives ever so much worse definition than a lens, there still should be in the image given by a photographic lens, so far as any scientific reasoning goes, one plane rendered as sharp as the lens is capable of rendering it; because, whatever falling off of definition due to imperfection in the eye there may be in looking at an object, there will be exactly the same falling off in looking at an image of the object made with a lens that gives *absolute* sharpness in one plane.

But I am repeating what I have already said several times, and doubtless weary your readers. If Mr. Dallmeyer really wishes to know what my views on the subject really are—and they are very different from his representation of them at the Camera Club Conference—I refer him to page 55 of the Year-Book for 1890, as I think that I there succeeded in expressing myself more clearly than I did in the paper I wrote for the Camera Club.

I now come to what is the real reason for my writing at the present time. It is a question in relation to diffusion of focus.

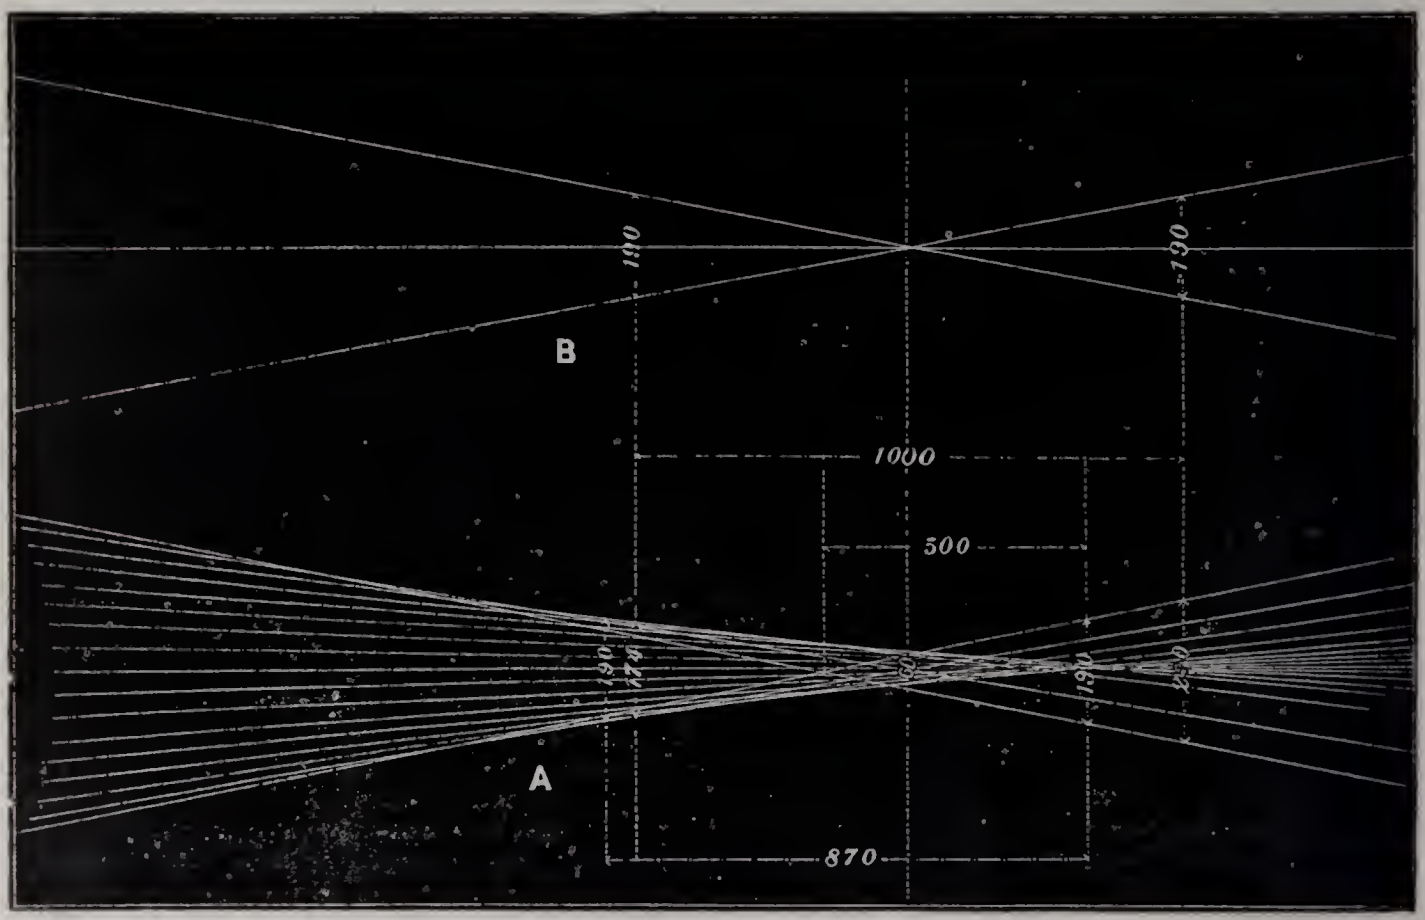
* The full title of this article, as sent to us by Mr. Burton, is "Dallmeyer on Limitations in the Treatment of Subjects by Focus, and on one or two other Subjects."—Ed.

I consider a double apology due for touching on this subject again, one to your readers for once more bringing up a matter that has, as most will, I fear, consider, been discussed *ad nauseum* already, and another to Mr. Dallmeyer for venturing to differ from so great an authority as himself on a purely optical subject. It is with the utmost diffidence that I do so because, for one thing, optics are a very slippery subject, and one is liable to stumble, even after all care; for another, I must confess that I sometimes have difficulty in quite following Mr. Dallmeyer's meaning. This I have not the smallest doubt is my own fault; but if I have misunderstood Mr. Dallmeyer in the particular point that I am now taking up, I am sure that I will be held excused, for I think there must be many others who have misunderstood him as well as me.

To come to the point, Mr. Dallmeyer has several times stated that, in the case of a lens with diffusion of focus introduced in the form of positive spherical aberration, the effect, if a middle distance object is focussed, is that the falling off of definition, although greater for a near object than in the case of a thoroughly corrected lens, is less for the distance, and that, the important object being to reduce the contrast between the definition of the object focussed for and the distance, diffusion of focus is a useful thing.

Now I state that the facts are *the direct opposite of this*. Positive spherical aberration favours the *nearer* objects at the expense of the distance. I think that I can prove this, and that, consequently, all Mr. Dallmeyer's arguments in a recent controversy with Mr. W. E. Debenham, and also those at the recent Camera Club Conference, fall to the ground.

I must ask for leave to have reproduced an illustration that has done service many times, namely, that of Mr. Thomas Grubb, used by him in combating the claims of the late Mr. Dallmeyer in the matter of diffusion of focus.



I would ask a close inspection of this cut. The upper diagram represents the condensation of the rays of light from a point after passing through a lens without spherical aberration; the lower, the condensation of similar rays after passing through a lens having diffusion in the form of positive spherical aberration.

In the former case the rays come to a focus at a point; in the latter case they do not, but come to a series of foci at different distances from the lens, forming, however, a "quasi-focus," which is generally assumed to be at that distance from the lens where the bundle of rays is of the smallest diameter.

It will be seen that, in the case of the upper diagram, the diameters of the cones of light, or "bundles of rays," are given at equal distances in front of and behind the point of focus, the diameters being equal, and, in each case, 190 units.

In the case of the other diagram, where there is diffusion represented, the diameters are again given at equal distances behind and in front of the quasi-focus, and that at that same distance as in the case of the lens without spherical aberration. In this case it will be found that the bundles of rays are *not* of equal diameter, but that, whereas that farther from the lens is represented by 280, which is much more than 190, the other is represented by 174, which is somewhat less than 190, so that in this case there is a positive gain in the size of the circle of confusion representing a point.

So far the argument is sound, but after this it seems to me that it woefully ceases to be so. Mr. Dallmeyer goes

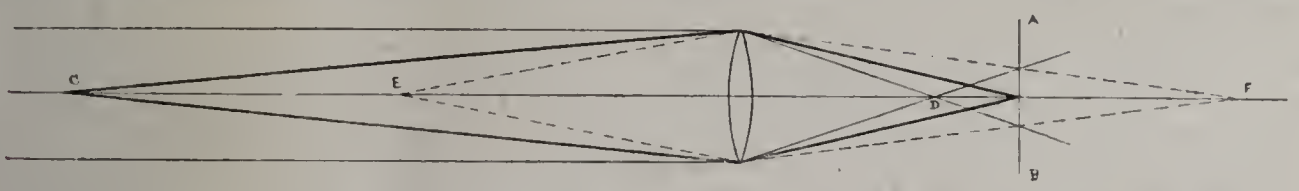
on to speak of the bundle of rays nearer the lens than the quasi-focus as representing planes "beyond the point focussed upon." He refers to this several times, about the most distinct statement appearing in a letter to the Photographic News of April 27th, 1888. I quote from the letter:—"My claims for the advantages on the side of the lens in question cannot fairly be refuted by Mr. Debenham or any other photographer; and they are founded on the ground that it is chiefly and almost entirely the better definition of planes beyond the point focussed upon that we are aiming at, neglecting as far as possible the question of foreground, where the disadvantageous conditions would appear."

Mr. Dallmeyer assumes that the bundle of rays nearer the lens than the plane of focus represents the distance, those farther from the plane of focus the foreground. Now *the exact reverse is the truth.* If a middle distance object be focussed for, the distance is represented by a part of the bundle of rays *farther* from the lens than the point or points where they crossed; an object in the foreground is represented by a portion of the bundle *nearer* than the point or points where they would cross, were they to pass through the plate or focussing glass.

It is true that, in focussing, we move the lens nearer to the ground glass for a distant than for a near object, but this has nothing to do with the position at which the bundles of rays are cut by the plane of the ground glass when this is not in a fixed position. I think this will be made clear by a diagram that I have made.

In this sketch A B is intended to represent the plane of the focussing glass. C is supposed to be the point focussed for, and the light, represented by two thick lines, is shown as meeting at a point in the plane of the ground glass.

The thin, full lines (parallel till they reach the lens) are supposed to represent light from a distant object. It will be seen that the light rays cross *nearer* the lens than the plane of the ground glass, namely, at D. The dotted lines are supposed to represent light from a foreground



object at E. It will be seen that they cross *farther* from the lens than the ground glass, namely, at F. I have not attempted to show actual spherical aberration in this illustration, as the result would be too confusing, but a moment's reference to the diagram of Grubb given above along with my own will show that *were* there spherical aberration, the distant point would be represented by a much larger disc of confusion than the foreground point.

I think it will be conceded that the whole of the recent ingenious demonstration given by Mr. Dallmeyer at the Camera Club goes to show that the result of introducing diffusion in the form of positive spherical aberration is to improve the definition of the foreground a very little at the cost of the distance, which is thereby thrown into much worse definition than with a completely corrected lens. This may be partly compensated for in practice by the fact that we do not focus when there is positive spherical aberration for that part of the bundle of rays that is of least diameter, but for a plane somewhat nearer the lens than this, as I have already described in the Photographic News.

After all this, I do not by any means wish to argue that diffusion of focus is of no use. I have, on the contrary, always held that it is of great practical use, but only in reducing the *contrast* of definition. If Mr. Dallmeyer had confined himself to claiming this he would have been on safe ground, but he has tried to prove too much. Another thing in this. Although the effect of positive spherical aberration certainly is to improve the definition of the foreground at the cost of the distance, I notice, in examining the illustration that accompanies Mr. Dallmeyer's paper read before the Camera Club, that there is no appreciable difference between the two until much more spherical aberration is introduced than would be tolerated in practice.

Farther than this, I do not at all know that I agree with the dictum of Mr. Dallmeyer in which he lays it down that it is always most desirable to reduce the amount of lack of definition of the *distance* without reference to the foreground. I think there are many cases in which the exact reverse is the case.

A Curious Legal Case.—The Supreme Court at St. Paul, Minnesota, handed down a decision on July 1st., in the case of Ida Moore, of Minneapolis, against Photographer Rugg. Rugg sold a copy of Mrs. Moore's picture, which was put on exhibition in improper places, much to the discredit of the lady, and she brought suit for damages. The Supreme Court holds that it is a case in which there is ground for the recovery of damages; that the photographer has no right to dispose of pictures which are the sole property of the sitter. The decision is an important one. Similar cases have arisen once or twice previously in other parts of the country.—*American Journal of Photography.*

Toning Bath for Gelatino-Chloride Paper.—Herr Steiglitz recommends the following toning bath for this paper:—

Chloride of gold	0·25 gramme
Nitrate of uranium	0·25 ,,
Bicarbonate of soda	5· grammes
Distilled water	300 c.c.

This bath should be used immediately, as it does not keep. The prints should be printed deeply, and washed at least in six changes of water before printing. Fix with:—

Hyposulphite of soda	1 part
Water	5 parts
Ammonia	a few drops

The prints are toned in a few minutes.

To obtain a reversed negative, Mr. Kronenberg makes use of the Eastman negative transfer paper. He places in the frame a perfectly clean plate, having the thickness of one millimetre; he applies the negative paper, then a second plate, so as to obtain perfect planitude. After exposure and development, the paper is placed for two minutes in a bath of 500 cubic centimetres of distilled water and one cubic centimetre of acetic acid, then in the hyposulphite; wash for ten minutes, then transfer the print to a glass plate coated with gum-arabic dissolved in benzine. To obtain adherence use the squeegee, then place the whole in tepid water, and at the end of three minutes remove the paper. If necessary strengthen in the ordinary manner.—*Deutsche Photographen Zeitung.*

THE RECENT CITY PHOTOGRAPHIC EXHIBITION.

THE following is the report of the Executive Committee of the Photographic Section of the London Chamber of Commerce in relation to the recent Photographic Exhibition at the Drapers' Hall, London.

The executive committee appointed by the Section to organise the Exhibition promptly commenced its duties by issuing a circular to the trade, and, efficiently assisted by the secretary of the Chamber, carried it through with a fair measure of success in the manner you have witnessed.

There were seventy exhibitors, eleven hailing from the provinces, and fifty-nine representing the metropolis. A large and interesting display of apparatus was made, and a representative collection of photographs and processes of printing gathered together at Drapers' Hall, every available foot of space in the noble suite of rooms lent to us being occupied. The soirée was numerously and influentially attended, and in its arrangements a success. The visitors to the Exhibition were mostly city men and their friends, the numbers averaging about 1,200 a day for the ten days it was open. Many of the visitors took quite a practical interest in the apparatus, and showed a lively appreciation of the photographs displayed. Some amount of business issued directly from the Exhibition your committee knows, and, considered commercially, one may safely say that the trades represented enjoyed a peculiarly efficacious advertisement at a moderate cost.

The statement of receipts and expenditure now submitted bears witness to a small balance in hand. The treasurer of your committee availed himself of the convenience of passing receipts and expenses direct through the Chamber, which received £340 6s. 6d., and paid away £332 18s. 7d., handing to him a balance of £7 7s. 11d. This balance became increased to £8 8s. 5d., from which £5 16s. 0d. was refunded to exhibitors who had paid for more space than the committee were able to allot, leaving a nett surplus of £2 12s. 5d., the disposal of which you will determine. Of the total receipts, the sum of £18 17s. 6d. was contributed by the Chamber, which levied a small tax on its members outside the Photographic Section in the shape of a charge on tickets for the soirée. On the whole conduct of the Exhibition your committee has had the benefit of the knowledge, experience, and influence of the Chamber.

(Signed) W. S. BIRD, *Chairman Executive Com.*

FRANK BISHOP.

YELLOW STAINS.—Every photographer is, no doubt, to his own sorrow, familiar with a yellow stain in the negative, caused by taking the plate from the fixing bath before it is thoroughly fixed. Mr. Belitski, the well-known photo-chemist, made some experiments recently to remove this stain, and succeeded very well. A slight stain can often be removed by placing the negative in the following solution: 50 parts alum, 1,000 parts water, 10 parts bichromate of potassium, 20 parts muriatic acid. After several minutes the negative turns yellow all through. It is washed now very thoroughly, exposed to sunlight for several minutes, and developed or blackened with the ordinary iron developer. When the stain is very intense this remedy will not prove to be of any avail, and only by leaving it for twenty-four hours in the Lainer acid fixing bath (so often described in all journals recently) he succeeded in removing the stain, and saving valuable negatives.—*Deutsche Photographen Zeitung.*

PHOTOGRAPHY IN FRANCE.

BY LEON VIDAL.

PHOTOGRAPHIC NOMENCLATURE—NEGLECT OF THE TOMB AND WORK OF DAGUERRE AT CORMEIL-EN-PARISIS—NEW PROPERTY OF GELATINE—ACETATE OF AMYL LAMP—SENSITO-COLORIMETRY FOR ORTHOCHROMATIC PHOTOGRAPHY—LANTERN SLIDES PROJECTED IN STEREOSCOPIC RELIEF—LANTERN CARRIER BY M. DONNADIEU—FREEDOM OF PHOTOGRAPHY IN THE STREETS OF PARIS—LITERATURE.

Photographic Nomenclature.—In connection with the presentation of the latest work of the French Photographic Society, regrets have been expressed that the terms adopted by the International Congress of 1889 have not been employed. We look upon these regrets as premature. The work of the Paris Congress is destined to be revised by another Congress, which will take place probably in Brussels in 1891. It is very probable that many of the decisions of the preparatory Congress of Paris will be reversed, and it is desirable to await a fuller authorisation before hastening to adopt expressions on which a better understanding may be arrived at. For our own part, we opposed in the Congress the use of the expression *phototype* as the designation of the photographic negative, and we hope that the necessity for the employment of another word will be recognised, since the word *phototypie* has to serve as designating the application of photography to typography. The Congress of Paris, although held during the Universal Exhibition, did not include such a number of adherents that its work can be considered as definitive; therefore why should it be desired at once to impose the putting in practice of solutions essentially provisional?

Neglect of the Tomb and Work of Daguerre.—In spite of the glory which is attached to the name of Daguerre, his tomb at Cormeil-en-Parisis appears to be absolutely neglected. The curé of this commune has informed the Photographic Society of the fact. He adds that the painting executed by Daguerre in the choir of the church requires considerable restoration. The cost of both reparations would amount to between three thousand and four thousand francs. It would seem not to require a great effort for the Society and other photographic groups to cause these restorations to be promptly undertaken. It is a duty that should be attended to at once, and we hope that the curé of Cormeil will not in vain have addressed himself to our photographic association, which is rich, and equal of itself to the accomplishment of this task.

New Property of Gelatine.—Messrs. Louis and Auguste Lumière, of Lyons, announce the property of chloride of barium of dissolving gelatine. Mr. Bardy says in this connection that chlorides of magnesium and of zinc possess the same property.

Acetate of Amyl Lamp.—General Sebért has presented an acetate of amyl lamp made according to the specifications laid down by the Congress. A screen carrier has been added in such manner as to cut the flame at the desired height. The model is very well made, but the price would be too high for it to come into practical use. Instruments of this character cannot be in the hands of every one, unless the cost is such as to render them accessible to all. Until that time a simple candle has much greater chance of being generally adopted than lamps, however perfect, the cost of which is from fifty to sixty

frames. Apparatus of other kinds, still based upon the decisions of the Congress, are in course of construction. We see no objection to this. It will permit that they may be put to the test of trial before the meeting of the new Congress, in which there may be questions of introducing improvements if certain defects are recognised. Only it is well to look upon all this for the present as provisional, since it may be reversed at the Brussels Congress.

Sensito-Colorimetry for Orthochromatic Photography.—Mr. Stebbing desired us to confide to him the execution of the sensito-colorimeter which we presented at a preceding meeting of the Society. He has copied the model and presented several examples of it. It consists, as is known, of a polychromatic screen bearing the principal colours of the spectrum. These colours are deep and light blue, deep and light green, deep and light yellow, and finally, deep and light red. Behind the transverse bands formed by the colours, there are four bands cutting across them formed of yellow screens of different depths suitable for orthochromatic photography. The instrument permits us to ascertain the behaviour of orthochromatic plates to rays of various colours, with the aid of yellow screens of various degrees of intensity, as well as without the addition of such screens. The accompanying diagram will explain the arrangement better than any description. The indications B_1 b_1 signify deep blue with the yellow screen No. 1, and light blue with the same screen. In the same way, R_3 and r_3 signify deep red with screen No. 3, and light red also with the No. 3 screen. The letters *B*, *V*, &c., without numbers represent deep blue, deep green, &c., without a yellow screen, and so on. We believe that this method of uniform control will allow comparable observations on orthochromatic sensitiveness to be made by all.

Lantern Slides Projected with Stereoscopic Relief.—M. Molteni held a meeting showing the application of a method of obtaining stereoscopic relief in pictures projected by the lantern. Two lanterns are placed side by side, furnished the one with a red and the other with a green glass (complementary colours). On the screen there are thus found two images, one red and one green, and they are superposed as exactly as possible. The spectators are also supplied with eye-glasses, the glass for one eye being red, and for the other green. The image seen on the screen is monochromatised, and the relief is very apparent if the superposition is exact. The experiment was truly of great interest.

Lantern Carrier.—M. Donnadieu, Professor of the Faculty of Science at Lyons, has designed a new lantern carrier, of which the following is a description, for the purpose of overcoming the difficulties that occur in centreing and properly placing an image on the screen when one has to work in a dim light.

The front portion of the plate carrier is made of a piece of wood with an aperture of eight centimetres square, bordered by a double rebate, the inner one chamfered, so as not to throw any shade upon the opening itself. It is closed by a shutter turning on pivots or hinges worked at will by a button. Behind the wood which forms the bottom of the carrier is placed a strong glass. The frame is pierced on each of its four sides by a slit, in which is a sliding piece in the form of a T. A pinching-screw placed above each slide fixes it in any required position, and the slide, being narrower than the slit, may be placed obliquely, and, being scarcely a millimetre thick, does not project beyond the thickness of any plate that may be used. In the frame is fitted a movable guide, which is cut out in the centre to receive the plate. This opening must, therefore, be of the size of the plate, or may take carriers themselves fitting the plate. A spring pressure board with opening, covered on the side next the negative with cloth, serves to keep the plate flat against the stout glass of the carrier. A ground glass, marked with perpendicular and diagonal lines, is placed in one of the rebates. The negative is then adjusted in a full light to the desired position against the lines, and the ground glass being removed, the carrier may be taken into the dark room and placed in the lantern by feeling only.

Photography in the Streets of Paris.—We are now at liberty to photograph in the streets of Paris without any preliminary authorisation from the Prefecture of Police. At the present time photography expands more and more every day. The measure which has just been taken was an inevitable one, and it is well that the Prefecture has at last yielded to the many representations that have been addressed to it on this subject by the general syndicate of photography.

Photographic Literature.—M. Mathet, chemist, has just published a work on photographic chemistry, which is at the same time a sort of general treatise on photography. The new work by Col. Waterhouse, on the photographic reproduction of designs, entitled "Practical Notes on the Preparation of Drawings for Photographic Reproduction," is of very important character. It is a classic for schools of design and photography. We cannot too highly recommend it to the reader.

Coating Celluloid Films.—A point of interest to users of celluloid films is brought to light in one of our exchanges, to the effect that the various makers of these films coat the celluloid on different sides, some makers preferring the matt surface as a support for the sensitive emulsion, and others coating on the polished side. Of course it behoves the user to familiarise himself with the method followed in the films he uses, as otherwise it will be an easy matter to place it in the holder "wrong side out," which would be most unfortunate, though from just such a blunder as this our exchange procured some negatives through the films which had the quality of being unusually free from halation.—*Anthony's Bulletin.*

PHOTOGRAPHY IN COPENHAGEN.

Two numbers have reached us, by the courtesy of the editor, of the *Beretninger fra Dansk Fotografisk Forening*, or news from the Danish Photographic Association, a journal which is published by the Association, and is now in its twelfth year of existence.

The number for April contains among its leading articles a notice of the transactions of the Association at a meeting held on the 31st March, contributed by the able editor, J. Petersen; also an article by Immanuel Mohr on albumen paper and its sensitising, and an article on a festival held on the 10th and 11th of April by the Association in aid of its photographic work.

The number for May contains a notice of a meeting on the 28th April, at which the President gave as the subject for discussion "What is the reason some pictures become yellow with age, and others do not?" The speaker advised the members to collect old pictures which might bear upon the subject of the question. It would, he said, be interesting to form a small exhibition of such pictures on albumen paper, salted paper, and so forth.

The Vice-President gave it as his opinion that the cause of this yellowing lay chiefly in the paper employed; the older papers were better, he opined, than those at present used.

Hr. Hartmann, in some observations about the darkening of white colours used in retouching, said that it was advisable to be careful to use good opaque colours, which were not liable to change. Hr. Cand. Pharm. Schleisner thereupon said that a good test for the stability of the white colour was to pour upon it a few drops of sulphide of ammonium; if the colour under this experiment did not change to black, it would well resist the influence of the atmosphere. "Permanent" white was permanent, but not so good for covering. Lead colours were good for covering, but not permanent.

The President then proposed a summer meeting, and Hr. P. Fristup, speaking for himself and Hr. Schon, said they would be glad to do all that lay in their power, but advised a preliminary meeting at the earliest opportunity in some spot where there was a garden in which one might promenade, and also a bowling green, with other forms of amusement. The larger summer meeting might, he thought, be best arranged in such a minor assembly. The Vice-President promised that the proposition should be laid before the general committee.

The next article in the May number by L. Belitski is concerned with an exact comparison of different photographic objectives. Immanuel Mohr continues his article on albumen paper and its sensitising. An interesting treatise on carbon printing is contributed by O. Volkmer, vice-director of the royal press.

Under the head of literature is announced the appearance of a hand-book of photography, with numerous illustrations, edited by Albin Roosval. This work was commenced by the late lamented Swede, Adolf Dahlström, and is continued by the editor of the *Swedish Photographic Journal*. One great feature in this work is that only so much of the technique of the photographic art is communicated as is necessary for the practical artist, and it avoids long, scientific explanations. The book might, in the opinion of the *Beretninger*, take a leading place among its congeners in Scandinavia. Though written in Swedish, no Norseman or Dane would experience much difficulty in its perusal. What little difficulty there may be could be easily helped by the addition at the end of a small Swedish, Danish, and Norwegian glossary, including such Swedish words as might seem stumbling-blocks to readers from Norway or Denmark. The cost of such an addition would be trifling, and the value of the work thereby greatly increased.

The number concludes with a notice of the death of Hr. E. Rye, who died on the 15th April, in his seventieth year. He was one of the veterans of the photographic profession. Like many others of the pioneers of the photographic art in Denmark, Hr. Rye lived a very busy life. When quite a boy he began his career as assistant to an apothecary, but very soon left that occupation, which suited him not a jot. After being a tutor for a few years he took to the wine business, and later on bought a hotel in Grenaa; but the business of playing the host at Grenaa was not of the kind to satisfy this energetic young man.

At that time photography was a newly-discovered art in Denmark. Rye saw, with the eye of the prophet, the great future in store for it, and, thinking that his pharmaceutical experience and knowledge might serve him in good stead, sold his hotel, and devoted himself to photography. His prentice hand was tried in Aachen, in the establishment of the well-known Wothly. Upon his return home, he busied himself for a whole winter with photographing the most noteworthy objects in Thorvaldsen's Museum, and gave instruction at odd intervals in the art of photographing on glass. Then he thought of building himself a studio, but met with obstacles set in his way by the fire brigade, and, since he feared there were then already too many photographers in Copenhagen, he gave up his idea, and travelled to Finland. After a year's furlough, he returned home and set up a studio in Vegle, and then another in Aarhus, and lastly, took Petersen's studio in Odense. Together with Schröder he practised phototypy. An attempt to make this new invention a success in America met with very poor encouragement.

After other devices equally vain to make his fortune in the far west, Rye at last determined, in 1872, to settle in Copenhagen. And now, indeed, it seemed as if fortune was disposed to favour him. His studio in Ostergade became very soon a celebrated resort, and for some years everything went very well. Then, in the height of his prosperity, came sickness, at first like a little cloud no bigger than a man's hand, but afterwards by degrees extending over him more and more, till at last he fell into the state of a confirmed invalid, and his business into consequent decay. Broken in body and in heart, he left his studio, left his photographic labours, left, finally, his life. His earnings, for some reason or other, were not sufficient to ensure him comfort in his old age.

He was a member of the Danish Photographic Association, and for several years one of the most assiduous and constant attendants at its meetings. "It was only when sickness marked him for her own," says the *Beretninger*, "that we missed him from our midst." The Association sent a wreath to be laid upon his coffin, and many members mourning followed him to his grave.

THE NEWCASTLE-ON-TYNE PHOTOGRAPHIC ASSOCIATION.—Mr. E. G. Lee, honorary secretary to this Association, writes that it has arranged the following outdoor meetings:—Thursday, 14th August, "Gilsland and Naworth." Leader—M. Auty, Front Street, Tynemouth. Thursday, 18th September, (district not yet fixed). Leader—J. P. Gibson, Fore Street, Hexham.

PRINTING OPERATIONS.

BY ELLERSLIE WALLACE.

The drying of a photographic print after the final washings have been completed is a simple enough matter, yet it is possible for the most exasperating failures to occur at this stage of the process; the disappointment experienced being all the more keen because the work is, in a certain sense, finished.

Those unacquainted with photographic neatness might easily imagine that all that was necessary was to take the print out of the water, and lay it aside in any convenient place to dry. They would soon find out, however, that if the substance with which the wet print came into contact were capable of communicating any impurity, the print would be sure to show it in the form of stains. For instance, suppose that the prints were hung over wooden poles, or laid on wooden shelves, while still wet, there would hardly be a possibility of escape from stains. This would be true in the case either of silver prints of any kind, bromides, or blue prints.

Silver prints on plain paper and blue prints are more manageable in drying than the other forms, which are made on papers prepared with a contractile substance like gelatine or albumen. Supposing that the wooden poles or shelves before spoken of were covered with clean white linen or blotting paper, all those forms of prints having a plain surface might safely be dried there, but an albumen paper print would not do so well. If laid out flat on the shelf it would contract unequally, and be so crinkled and shrunken that there would be serious difficulty in trimming. Drying over the pole would be preferable, but the albumenised surface would be put on the stretch unequally, so that in the case of a highly glazed surface there would be fissures and cracks very detrimental to the finished result.

The best method of drying prints of all descriptions, and a very convenient and inexpensive one also, is the following: Provide a number of spring clothes-pins, a few yards of ordinary brass wire, and a couple of good-sized screw-eyes. Having selected a suitable place in the work-room where the prints will not be disturbed, screw in one of the screw-eyes to the wood of the window or door jamb at the height of the shoulder; pass one end of the brass wire into the eye and secure it, then string the clothes-pins on to the wire, and secure its other end by means of the other screw-eye at a convenient point across the room. Having brought the prints from the washing tank in an ordinary deep pan, select those of similar sizes, bring them together neatly, back to back, while in the water, then take them out and suspend the pair from one or more of the clothes-pins, according to the size of the prints. If they are very large, it may require three of the clothes-pins to fully support them, and avoid risk of the wet mass tearing by its own weight: while on the other hand, small sizes, such as 5 by 4 inches, may be held by a single pin. When the paper is very glossy, and the weather dry, the larger sizes may require to be pinched together at the bottom corners by an additional couple of clothes-pins, which will prevent the prints from separating until thoroughly dry.

Prints dried in the manner described will be quite flat, and free from stains of any kind. We need hardly add that the clothes-pins should be new and clean, and kept for this purpose only. If the prints are hung up to dry in the evening, they will be ready for trimming in the morning, when the end of the wire may be released, and the whole turned aside out of the way until the next occasion for use. If the wash-water is muddy, as is often the case, the deep pan in which the prints are transferred to the drying room may be filled with clean filtered water, so that the collected mud in the paper may be soaked out before drying.

The warm weather we are now passing through reminds us of a few matters which have greatly eased our own labours in the printing room, and, simple as they are, we will mention them.

It sometimes happens that there is trouble in securing pure whites in prints on albumen paper, an universal yellow stain covering everything. The best remedy for this is the use of alum in the printing bath, as originally suggested by the late Mr. Anthony, of New York. Care also must be taken that the paper is quite dry before being fumed. Operators are too apt to forget that, as the thermometer rises, so does the amount of watery vapour in the air increase, and that sheets of paper will often dry more quickly on a bright day in winter than on many hot days in summer. The way the paper feels to the hand is the best guide, and some little attention is required to be able to tell accurately.

The question whether the strength of the silver bath should be reduced or not during warm weather is open to some discussion. If the paper be of first-class quality, and the bath contain alum, as before alluded to, it would be possible to continue making good prints having pure whites with the bath at full strength, by which we mean fifty to seventy grains to the ounce. There is no question of the fact that the sensitiveness of the prepared paper increases when floated on a strong bath, and that the compound which is then formed between the albumen and the silver is more prone to decomposition. It will occasionally happen, if the prints come out yellow, metallic-looking, and covered with minute black specks, that weakening the silver bath down to the strength of forty-five or even forty grains will cure the trouble. A strength of forty grains, however, we should consider a low one, and only to be resorted to for unusually hot weather or for particular kinds of paper, such as very thin and delicate Rives.

The paper should not be left in the fuming-box for too long a time in hot weather. If things are properly arranged for the purpose, ten to twelve minutes ought to suffice for thorough fuming. It is important, of course, that good strong ammonia be employed, and care should be taken that the glass stopper be well secured in the bottle. In a hot printing room the stoppers of ammonia bottles are frequently blown out by the vapour and fall on the floor, leaving the contents of the bottle to lose strength rapidly.—*American Journal of Photography.*

It is hardly to be wondered at that Japan seems destined to take such a prominent place in photography, when we think that she has always worshipped the Sun-Goddess, and that its representative, the burnished mirror of bronze, is still such an important household article, and plays such a prominent part as it does in the social economy of the country.

The Late Paris Exhibition.—The New York *Lithographic Art Journal* says that the engraving of the diploma for those who were awarded prizes at the last year's Paris Exhibition is now finished, and has by this time gone to press. Before the diploma will be issued at least four months more will have elapsed, and whoever gets it then may obtain the silver or gold medal awarded him—by ordering somebody to make it for him.

Notes.

Mr. Adams has exhibited to us his "Ideal" detective camera, which has exteriorly no projecting parts, and measures $8\frac{5}{8} \times 4\frac{3}{4} \times 8$ inches. It is fitted with a Newman's shutter of modified form, and Newman's pneumatic shutter has, by the test of general experience, proved to be a good one for the regulation of the duration of short exposures amounting to but small fractions of a second. The shutter works in the diaphragm slot, and requires no setting; there is also an arrangement for what are called "time" exposures. The plates are packed in sheaths, and each plate, after exposure, is drawn downwards by means of a clutch governed by a rod which is handled from outside the box; springs then push the next plate in the batch into position for exposure, and so on in succession.

Last week we drew attention to the advantage to the tourist photographer of the relatively small amount of wind in some parts of Switzerland, but now wish to speak of various meteorological phenomena which do not promote photographic work. Among the Swiss mountains there are such things as wind avalanches; in a mild form they amount but to strong gusts, which come upon the wayfarer at unexpected moments, when at a little distance all is calm. These sudden "windfalls" are frequent and dangerous enough to have stopped the use of small sailing boats on some of the Swiss lakes; in the past such boats have sometimes been upset by the unexpected squalls, and lives have been lost. On rare occasions wind avalanches have been directly dangerous to pedestrians. In the *Alpine Journal* of June, 1864, is a paper by Mr. Gosset, describing a fatal accident on the Haut-de-Cry in February of that year, to which paper Mr. F. M. Millard, of Maidstone, draws attention in last week's *Nature*. A body of air rendered colder and heavier than the surrounding air by the snow and ice, suddenly descended upon a mountaineering party of six, with disastrous results. Mr. Gosset says:—

"Bennen advanced; he had made but a few steps when we heard a deep, cutting sound. The snow-field split in two about fourteen or fifteen feet above us. The cleft was at first quite narrow—not more than an inch broad. An awful silence ensued . . . . broken by Bennen's voice: 'Wir sind alle verloren.' . . . They were his last words. I drove my alpenstock into the snow, and brought the weight of my body to bear on it. . . . I turned my head to see whether Bennen had done the same thing. To my astonishment, I saw him turn round, face the valley, and stretch out both arms. The ground on which we stood began to move slowly, and I felt the utter uselessness of any alpenstock. I soon sank up to my shoulders, and began descending backwards. . . . . The speed of the avalanche increased rapidly, and before long I was covered up with snow. I was suffocating when I suddenly came to the surface again. I was on a wave of the avalanche, and saw it before me as I was carried down. . . . The head alone was preceded by a thick cloud of snow-dust; the rest of the avalanche was clear. Around me I heard the horrid hissing of the snow, and far before me the thundering of the foremost part of the avalanche. . . . . At last I noticed that I was moving slower; then I saw the pieces of snow in front of me stop at some yards' distance; then the snow straight before me stopped. . . . . I felt that I also had stopped, ... but the snow behind me was still in motion; its pressure on my body was so strong that I thought I should be crushed to death. . . . . The avalanche may have taken a minute to descend; I can give no correct estimation on this point."

On one occasion, from the side of a valley we were photographing the distant range of the St. Gothard and intervening scenery, upon a hot, sunshiny day when there was no trace of wind except upon the hill-side a few hundred yards in advance of the camera; a narrow band of wind was there pouring down, keeping the trees in its path in incessant motion, while all elsewhere was still. Upon walking up to the spot to discover the cause of the commotion, a small ravine in the side of the main valley was found, down which air was pouring which had been cooled and rendered heavier than the surrounding air in the shade of great pine forests which crowned the heights; the cooled air was being drained off by a natural channel.

Photographic meteorological records, on the same system as at Kew, are made at Hong Kong in the Observatory there belonging to the British Government. The instruments at Hong Kong—properly called "Heung Keung"—to which meteorological recording apparatus is attached are the barograph and thermograph; there is no magnetograph on the premises. Bromide paper is used, as at home, but there is more difficulty in keeping it in the hot climate; some samples after a time get spotty. The Observatory was opened for work January 1st, 1884, at which time the waxed paper process was used, and this was superseded by bromide paper four or five years ago. The difficulties in working the old waxed paper process at Hong Kong were much greater than in working it at Kew; some kind of chemical change seemed to take place while the paper was on the cylinder, owing, probably, to the great heat. It developed irregularly, and seemed to lose sensitiveness in a manner it would not have done in colder regions. In Hong Kong there are about twenty photographers, and nearly all of them are Chinese. The chief professional photographer in Hong Kong, or the one who is generally recognised as such by the public, is A Fong. The great bulk of the population of China objects to photographic portraiture; an average Chinaman thinks that a photograph "takes away a portion of the soul of the sitter." In and about the treaty ports open to western barbarians, however, this superstition of the native population is breaking down.

We have lately received a letter from a photographic friend at Durban, Natal, who went out there about twelve months ago to try his fortune. He is just about to commence a photographic tour up country, and he says that "although the scenery is beautiful, there are few bits that make good pictures." This is possibly because of its vastness, and represents a source of disappointment to many a tourist who has taken a camera to other lands—to Norway, for instance. He further tells us that the country is in "an awfully depressed state, so if you know of anyone coming here, tell him

not to do so." We print this warning, as it represents a little piece of disinterested advice which may prove useful.

When Solomon wrote that "there is nothing new under the sun," he, of course, had no thought of photographic apparatus in his mind, because, as the old song has it, "it was not then invented;" but for all that the oft-quoted line is peculiarly applicable to so-called photographic novelties. The latest detective camera, for instance, takes the form of an opera glass, and the idea has been patented. But such a camera was constructed and shown to us ten years ago, and we have in our possession several photographs taken with it. We have often wondered why the notion was not revived, for it is certainly a good one.

We all know that, as a general rule, the simplest method of achieving a certain result is the best. One of the American humorists puts the matter in a quaint way by describing a prisoner confined in a dungeon who in vain tries to break the bars of his window, and to remove the stones from the walls, until a happy thought struck him; "he opened the door and walked out." Some such simplification has become desirable in chemical nomenclature, and the man who will suggest a way of "opening the door" to such a consummation will deserve the thanks of his fellows—and, we may say, especially fellows of the Chemical Society. Turning over the pages of the last "proceedings" of that highly useful body of workers, we come upon several terms which may be highly descriptive, but are certainly jaw-breaking. We will only quote one, and here it is: oximidolactone of xylylphenylacetoximeorthocarboxylic acid. We hasten to offer a prize to the first among our readers who will go to the nearest chemist's and ask for a pennor'th of it.

But seriously, cannot something be done in the direction indicated? Chemistry has always prided itself on the fact that its symbols convey in a simple manner a definite meaning, and not only give the composition of a substance, but the proportions in which its constituents are present. In this way it is far ahead of its sister science, botany, where the names of Smith, Brown, & Co.—that well-known quartette—are dragged in with other common surnames and turned into ridiculous Latin. The problem is a hard one, but it ought to be more easy of solution than some of the nuts chemists have had to crack.

Why does not the Government have the Hessian fly—when it is caught—photographed? A Government paper has been issued, in which illustrations of the usual character are given; but we are afraid that, to the average bucolic mind, these illustrations will not convey a vivid idea of the pest. A photograph slightly enlarged, on the other hand, would not only picture the insect in a recognisable form, but would bring home the truth, that there is such a thing as the Hessian fly; because, if it did not exist, how could it be photographed?

The late Sir Richard Wallace has to be included amongst those strong-minded, not to say eccentric, persons who object to sitting for their photographs, and it is said that it is doubtful if a photograph of this well-known patron of art is in existence. We are afraid that the old days of photography have much to answer for. The length of the sittings frightened a great number of people, and led to the stereotyped remark, "I always come out badly in a photograph." This kind of thing has, of course, long passed away, but the dislike, or prejudice, or whatever the feeling may be called, still remains among sitters who were photographed thirty years or so ago.

We do not know whether it is a practice of photographers who are fortunate enough to number among their *clientèle* a goodly proportion of celebrities, to keep an album in which their sitters can record their sentiments, but it would not be a bad idea. We believe that during Emerson's last visit to England he sat to Elliott and Fry, and wrote this in their album:—

"The man who has a thousand friends
Has not a friend to spare,
But he who has one enemy
Will meet him everywhere."

A photographic outfit is an indispensable adjunct to the "caravan" method of taking a holiday. One of these holiday homes upon wheels has lately been described by a society journal. Among other information, we are told of a photographic apparatus and a small photographic dark room. What we want to know now to make the picture complete is a little history of caravan photographic experience. To the ordinary villager a caravan is a caravan, and the difference between the peripatetic "likeness taker" and the aristocratic amateur photographer is not apparent. Hence very odd episodes must inevitably happen, and anyone who goes in for photography on wheels should have some curious stories to tell. We are inclined to exclaim with Sir Toby Belch, "Why are these things hid?"

It is rather rash to depend upon what is called a *post mortem* photograph as evidence of identity. A curious incident has just been reported. Some six months ago a man was found dead in bed in a common lodging house in Southwark. The body was photographed by the police, and buried as unidentified. About a month ago, a woman whose husband had been missing for twelve months was shown the photograph at Scotland Yard, and at once identified it as being the portrait of her husband, who was insured for £17. She forthwith made an affidavit, obtained the money, put on widow's weeds, and mourned her husband as dead. About a fortnight since she was startled by her husband—who had been to America—reappearing, and it is only fair to the widow to say that she at once recognised him, and received him in the most affectionate manner. The most disagreeable part of the business will probably be the returning of the £17.

THE STUDIO IN SUMMER-TIME.

BY JOHN A. TENNANT.

Now that the summer days are fairly upon us, a few remarks upon the studio in summer-time may not be out of place.

It is a great mistake to think, as many country photographers do, that the best way of obviating the difficulties supposed to be connected with studio work in summer, is to flee the glass-house and erect a temporary canvas arrangement in which to do what operating is required during the hot season.

The photographer should realize that in his skylight, and in his experience of the facilities of lighting which it offers, lies his chief strength as a picture maker. Furthermore, his past experience will show him that portraits taken in the open seldom or never equal those manipulated under the skylight.

Nor is there any real need to desert the carefully planned studio, for there are many simple contrivances by which it may be kept cool and attractive for summer patrons. The plan recently suggested in this magazine, of arranging a supply of water along the ridge of the glass roof by means of a perforated pipe through which the water could flow in a thin stream over the whole surface of the roof, is admirable, and will commend itself wherever practicable. Another plan is to erect a perpendicular screen above the roof so as to shield the glass area from the direct rays of the sun, by which coolness may be secured in some measure. A simple arrangement of hinged ventilating traps along the top of the walls, so placed as to secure a current of cold air along under the roof, would also be of great service; besides which the side-lights should be fitted in grooves, and be made to slide back, and so throw the whole side of the studio open if required. Much, too, depends upon the interior furnishing of a studio as to whether it appear hot or cool. In the first place, all heavy curtains, mats or rugs, surplus backgrounds, heavily upholstered furniture, dirty screens, and accumulations of apparatus should be cleared out, and clean, light-coloured curtains and screens, rush or rattan chairs, with straw matting, take their place. As little apparatus as possible should be allowed to stand about in the studio during summer. The bellows of the camera should also be dusted and oiled—somehow this item never seems to have any attention; in all the studios I have known the camera bellows was a perfect dust trap, save on new instruments. Then there should be plenty of big-leaved plants, such as ferns and palms, and these should have plenty of water and attention. Well looked after, a nice collection of such plants always makes a studio cool and inviting. The change of furnishing, if carried out as suggested, will give a new character to your photography, and make your specimen cases perfectly irresistible to would-be patrons, and is sure to bring more business.

Just as the studio requires different treatment at the varying seasons, so also with the other rooms. The reception room, with the aid of a few new pictures, and a light tapestry rug, with tasteful draperies (all of which may be obtained at a trifling cost) at the windows, may be made quite a pretty apartment. A point that should not be neglected is the providing of good, fresh literature for the amusement and recreation of your clients whilst waiting or resting.

The dark room also calls for special attention at this time of the year. Care should first of all be taken to test the non-actinic medium used to guard the room from white light. Often this medium becomes so much bleached as to be unsafe for the purpose for which it is intended. The shelves should be cleared of all unused bottles, empty plate boxes, paper wrappings, remains of winter experiments, and relics of dearly bought but worthless processes, old baths, and all other unnecessary rubbish or dust accumulators. The floor and shelves should never be dusted with a brush or dry cloth, but a damp cloth should be used to prevent any dust arising to work mischief in future hours.

The water-sink—generally a most convenient receptacle for spoilt plates and wrapping-paper—should now be frequently cleansed to avoid bad smells, and all the unmentionable rubbish *under* the sink should be cleaned right out. A continuous supply of water running over the sink, although forbidden by waterworks companies, is a certain cure for evil-doers, and has a wonderful cooling influence during spells of hot weather. The hypo fixing bath smells stale sooner now than in winter, and needs frequent renewal. It is a good rule in summer to mix only sufficient developer to last one day, and to keep it, when mixed, bottled and immersed in tins of water changed often. Another point is that the developer may be considerably weaker in summer than in winter with advantage. By using slower plates, and developing with weaker solutions than ordinarily used, softer and more detailed negatives of light-coloured stuffs may be obtained than otherwise. This point will be sufficient to help many to attain greater success in photographing ladies or children clad in light-coloured or white dresses.

The work-rooms and printing-room should be carefully overhauled before the hot, dusty days come. Such rooms, and the printing-room in particular, require a thorough cleansing to keep them sweet and in good condition. The suggestions here given, with others, which different circumstances will make evident to the thinking photographer, will go a long way to make the gallery in summer-time far from the stuffy, uncomfortable hole it generally is in small country towns.—*Wilson's Photographic Magazine.*

A Remedy for Green Fog.—Soak in a solution of bichromate of potash, and afterwards wash thoroughly in water.—*Wilson's Photographic Magazine.*

The peculiar branch of photography which consists of taking a series of instantaneous photographs of objects in motion, as developed by Anschütz, Muybridge, and others, and described in this magazine at various times, has received from the French the name of chrono-photography.—*Wilson's Photographic Magazine.*

Lantern Slides.—M. Lirondelle, of the Photographic Society of the North of France, gives the following process for making on gelatino-bromide plates positives for the lantern: A contact exposure is made; the light used is from a piece of ribbon of magnesium 3 centimetres in length by 2 millimetres in width ($1\frac{1}{4}$ inch by $\frac{1}{12}$ of an inch), and the pressure-frame is placed 40 centimetres (16 inches) from the luminous focus. To develop, plunge in a bath formed of two-thirds of neutral oxalate of potash at 30 per cent., and one-third of bromide of potassium at 12 per cent. At the end of a few moments pour, drop by drop, whilst agitating the bath, a very small quantity of a solution of proto-sulphate of iron, and wait a few minutes for the coming of the image. Use no more of this last solution unless the image is too slow in making its appearance, and allow the development to go on. If the image is too weak, increase the quantity of iron, but only at the end, and when it is found to be indispensable in obtaining the desired intensity. Fix, and afterwards wash. By this process the positives are clear and remarkably brilliant.—*L'Amateur Photographe.*

TREATING FLEXIBLE PLATES.

BY M. BALAGNY.

We have ascertained that the use of alum after development produced on flexible plates an effect that rendered manipulation difficult. It was necessary to first learn if it was the support or the gelatine film that caused cockling. For this purpose we made several negatives, and we detached the gelatine film from its support. The support remained absolutely flat, consequently it was the gelatine that caused the cockling. But we also discovered that this effect is produced more strongly when the gelatine film has been alumed before or after fixing. We have, therefore, done away with the use of alum. We have also done away with alcohol in the glycerine bath, which produces the same effect as alum, and which may sometimes, also, shorten the length of our negative. We want our flexible plate to be able, more than any other preparation, to give scientific results. For this it is necessary that the gelatine film should be rendered absolutely inextendible in the fullest acceptation of the word. To do this we have entirely modified the mode of drying. This is our present mode of operating: The negative, after developing, is washed and fixed. If we have reason to fear the yellow colouration, pass in citric acid at two per cent. before fixing, which is done in a solution of hyposulphite of twenty per cent. After fixing, wash well the flexible plates, and plunge them in a bath composed of:—

Water	1 litre
Glycerine	30 to 40 c.c.

Leave the plates in this bath two hours, or all night if not hurried in the printing. It is absolutely necessary that each negative should absorb a small quantity of glycerine, an operation that has for its object to give it more flexibility. It is well to change the place of the negatives in the dish of glycerinated water, especially if many had been placed together in this dish. This being done, varnish—a very easy operation—with lac varnish and water. This varnish, called hydrophite, is now found almost everywhere. It is poured over the flexible plates whilst they are still wet. The plate is taken from the glycerinated water and placed on a glass plate rather larger, so that the lower right-hand corner of the flexible plate exactly coincides with the lower right-hand corner of the other plate; the gelatine film should be on top, of course. Make the same disposition of a second, then of a third negative, and allow them to drain for about five minutes against the wall. Afterwards take the first and float on the surface a coat of varnish. With a badger blender, or with the finger, direct the liquid so that it covers the whole of the negative, and pour off the excess of varnish into a glass. Give at once a second coating of varnish, which has been placed ready for use on another glass, and pour off the excess into the first glass in order to prevent air-bubbles. Now drain. Each negative should be varnished in this manner. After a drainage of five minutes, raise each plate from the glass on which it is found, place it flat with the film on top on a sheet of bibulous paper. All the negatives are thus placed side by side, and allowed to dry on a table. Once dry, the negatives are absolutely plane, and show no tendency to cockle. Moreover, they have undergone neither extension nor shrinking; their dimensions are exactly similar to that of the flexible plates before being placed in the frame. It is possible to do away with varnishing, but we recommend it very strongly. In this case it is well to sponge the coating on coming from the bath, so that no trace of glycerine remains on the surface of the negative, as the glycerine might, later, at the time of printing on albumenised paper, give rise to spots. But in sponging with a fine sponge steeped in pure water, and then pressed between the fingers to free it from all excess of water, spotting is no longer to be feared.—*Moniteur.*

Literary Notice.

Leçons Elementaires de Chimie Photographique, by L. Mathet. (*Société Générale d'Editions, Paris*, 1890.)

This is a new dictionary of photographic chemistry, a volume of 726 pages, containing information on the subject down to the latest date. Its author, M. Mathet, is a *chemiste pharmacien de premiere classe*. In dealing in the book with chemical substances, he states what qualities they possess likely to be of use in photography, and the theoretical reasons why they should be so employed. He also tells how to manufacture the said substances when the method of manufacture is of a simple nature, likely to be within the means and grasp of the photographer. He also tells how to detect impurities in purchased photographic chemicals.

In the course of an article on toning with the salts of platinum, he says that the chloroplatinite of platinum may be purchased ready-made, or the common tetrachloride of platinum of commerce may be approximately reduced, and used for the same purpose, by boiling it with a weak solution of tartrate of soda, containing one gramme of the latter salt to every four grammes of tetrachloride of platinum. The weak solution has to be boiled until its yellow colour changes to dull grey; its volume is then made up to one litre with distilled water, and is acidified by means of five grammes—which seems a great deal—of pure sulphuric acid. Vegetable acids will not preserve the toning bath long, especially when it is exposed to light.

The experience of M. Mathet with eikonogen is:—

1. The time of development is notably shortened—we presume in comparison with that of ferrous-oxalate, the favourite developer on the Continent. Even when the exposure has been very short the image comes out well.

2. The bath does not, relatively speaking, discolour much by exposure to the air, and there is no fear of its staining the gelatine; the image keeps clear and without fog; the developer does not stain the fingers of the operator.

3. The colour of the reduced silver, not being modified by accidental staining of the gelatine, such as that given by pyrogallol, has a blackish blue tone which favours rapidity in printing; the colour of the image approaches that given by ferrous-oxalate.

4. Several plates can be developed successively in the same bath without any appreciable difference in appearance.

The author then devotes a few pages to the subject of getting density with eikonogen.

Altogether, the work is a useful book of reference for the photographer.

The London and Provincial Photographic Association.—The subject for August 7th will be "Home Portraiture;" the discussion thereupon will be opened by Mr. W. E. Debenham. Bank Holiday outing, St. Albans; train 10.24 a.m. from Moorgate Street. Visitors invited.

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

I.—WHAT IS A PERFECT NEGATIVE?—DENSITY, OPACITY, TRANSPARENCY.

THE production of a perfect picture by means of photography is an art; the production of a technically perfect negative is a science.

A perfect negative demands, in the first place, a perfect plate, and as the manufacture of dry sensitive plates is a large and rapidly growing chemical industry, we need offer no apology for bringing this subject before this Society.

Our researches, which have covered a period of over ten years, were made with a view to rendering the production of perfect negatives as far as possible a matter of certainty.

What is a perfect negative? A negative is theoretically perfect when the amount of light transmitted through its various gradations is in inverse ratio to that which the corresponding parts of the original subject sent out.

The negative is mathematically the true inverse of the original when the opacities of its graduations are proportional to the light reflected by those parts of the original which they represent.

Before we can clearly understand this definition, it will be necessary to state shortly the laws of absorption of light by opaque black substances, and to define clearly the meaning we attach to the terms opacity, transparency, and density of a negative. It is the more necessary to do this, as the whole of our investigations depend upon these laws.

For substances which do not reflect much light, such as black opaque bodies, or transparent coloured bodies, the relation between the light absorbed and the quantity of the substance present is very simple. If between the eye and a source of light we place a thin layer of dilute Indian ink, that layer absorbs light, and thereby reduces the intensity of the light transmitted. Assume that such a layer absorbs one-half of the light, then one-half of the light will be transmitted. Whatever may be the intensity of the original light, the intensity after passing this layer of ink will be one-half of what it was. The interposition of two such layers will reduce the light to one-fourth the original intensity; three such layers will reduce it to one-eighth, and so on, each layer reducing the intensity to one-half of what it receives.

Had the first layer allowed one-third of the light to pass through, then two such layers would reduce the intensity to one-ninth, three layers to one-twentyseventh, &c. In general, any number of layers would reduce the intensity of the light to a fraction which is equal to the fraction the first layer allows to pass, but raised to a power the index of which is the number of layers employed. If n equal layers were employed, and the first one reduced the intensity of the light to a fraction $\frac{1}{m}$, the n layers would reduce it to $\left(\frac{1}{m}\right)^n$.

If, instead of using so many successive layers, the first layer were made to contain as much Indian ink as the n successive layers contain altogether, we should find that the one layer now reduces the intensity of light by exactly the same amount as the n layers did. The reduction of the intensity is, of course, due to the black particles, and depends simply upon the number of them which are interposed per unit of area. We can thus replace the number of layers by the number of particles, and the law takes this form: The intensity T_x of light, after passing A molecules of a substance, is a fraction of the original intensity T, such that—

$$\frac{Tx}{T} = \left(\frac{1}{C}\right)^A.$$

For purely mathemathical reasons the fraction $\frac{1}{C}$ is usually expressed as a negative power of the base of the hyperbolic logarithms E, say $\frac{1}{C} = E^{-k}$, and we can write—

$$\frac{T_x}{T} = E^{-kA}$$

where k is called the coefficient of absorption. This form of the law we shall frequently use again. The fraction $\frac{T_x}{T}$ represents and measures the *transparency* of the substance. The inverse of that fraction, or $\frac{T}{T_x} = E^{kA}$, measures the *opacity* of the substance. It indicates what intensity of light must fall on one side of the substance in order that unit intensity may be transmitted.

In our investigations we use the letter T to denote transparency, and O to denote opacity, and the two symbols are related thus:—$O \times T = 1$.

We must further define what we mean by density as distinct from opacity. By density we mean the number of particles of a substance spread over unit area, multiplied by the coefficient of absorption; kA is what we term density, and mark by the letter D.

For our purposes, *i.e.*, in its application to negatives, the density is directly proportional to the amount of silver deposited per unit area, and may be used as a measure of that amount.

The relations between the three terms, transparency, opacity, and density, are the following:—

$$T = E^{-D}$$
$$O = E^{D}$$
$$D = \log_E O = -\log_E T.$$

The density is the logarithm of the opacity, or the negative logarithm of the transparency.

These relations hold good for some substances with regard to ordinary white light, for others only with regard to monochromatic light, and for others they do not hold good at all. We have satisfied ourselves that they do hold good for the silver deposited as a black substance in negatives as long as the silver does not assume a metallic lustre, and reflects but a very small amount of light.

By means of these definitions we are now in a position to trace the connection between the densities of a theoretically perfect negative and the light intensities which produced them.

Since the density is the logarithm of the opacity, and since, in a theoretically perfect negative, the opacities are directly proportional to the intensities of the light which produced them, it follows that each density must be proportional to the logarithm of the light intensity which produced it. (More correctly, the density is a linear function of the logarithm of the intensity of light and time of exposure.)

The result is this: In a theoretically perfect negative, the amounts of silver deposited in the various parts are proportional to the logarithms of the intensities of light proceeding from the corresponding parts of the object.

* This paper is quoted by permission from the *Journal of the Society of Chemical Industry*. The full title of it, as given by the authors, is "Photo-Chemical Investigations, and a New Method of Determination of the Sensitiveness of Photographic Plates."—ED.

The question arises, can such a negative be produced in practice?

In order to answer this question, we had first to find a simple method of measuring the density of the silver deposited in negatives. We have then to study the influence of the developers upon the density of the deposits, and we were then in a position to investigate the action of the light itself.

(To be continued.)

THE PHOTOGRAPHIC IMAGE.*

BY PROFESSOR RAPHAEL MELDOLA, F.R.S., M.R.I.

The photographic image is impressed on a modern film in an inappreciable fraction of a second, whereas the photo-salt requires an appreciable time for its production. The image is invisible simply because of the extremely minute quantity of haloid decomposed. In the present state of knowledge it cannot be asserted that the material composing this image is identical in composition with the photo-salt, for we know the composition of neither the one nor the other. But they are analogous in so far as they are both the result of photo-chemical decomposition, and there is great probability that they are closely related, if not identical, chemically. It may turn out that there are various kinds of invisible images, according to the vehicle or halogen absorbent—in other words, according to the sensitiser with which the silver haloid is associated. The invisible image is revealed by the action of the developer, into the function of which I do not propose to enter. It will suffice to say that the final result of the developing solution is to magnify the deposit of photo-salt by accumulating metallic silver thereon by accretion or reduction. Owing to the circumstance that the image is impressed with such remarkable rapidity, and that it is invisible when formed, it has been maintained, and is still held by many, that the first action of light on the film is molecular or physical, and not chemical. The arguments in favour of the chemical theory appear to me to be tolerably conclusive, and I will venture to submit a few of them.

The action of reagents upon the photographic film is quite similar to the action of the same reagents upon the silver haloids when exposed to the point of visible colouration. Reducing agents and halogen absorbents increase the sensitiveness of the film; oxidising and halogenising agents destroy its sensitiveness. It is difficult to see, on the physical theory, why it should not be possible to impress an image on a film, say, of pure silver bromide, as readily as on a film of the same haloid embedded in gelatine. Everyone knows that this cannot be done. I have myself been surprised at the extreme insensitiveness of films of pure bromide prepared by exposing films of silver deposited on glass to the action of bromine vapour. On the chemical theory we know that gelatine is a splendid sensitiser—*i.e.*, bromine absorbent. There is another proof which has been in our hands for nearly thirty years, but I do not think it has been viewed in this light before. It has been shown by Carey Lea, Eder, and especially by Abney—who has investigated the matter most thoroughly—that a shearing stress applied mechanically to a sensitive film leaves an impression which can be developed in just the same way as though it had been produced by the action of light. [Pressure marks on Eastman bromide paper developed by ferrous-oxalate.] Now that result cannot be produced on a surface of the pure haloid; some halogen absorbent, such as gelatine, must be associated with the haloid. We are concerned here with a chemical change of that class so ably investigated by Professor Spring, of Liege, who has shown that by mere mechanical pressure it is possible to bring about chemical reaction between mixtures of finely divided solids.* Then, again, mild reducing agents, too feeble to reduce the silver haloids directly to the metallic state, such as alkaline hypophosphites, glucose or lactose, and alkali, &c., form invisible images which can be developed in precisely the same way as the photographic image. All this looks like chemical change, and not physical modification pure and simple.

I have in this discourse stoically resisted the tempting opportunities for pictorial display which the subject affords. My aim has been to summarise the position in which we find ourselves with respect to the invisible image after fifty years' practice of the art. This image is, I venture to think, the property of the chemist, and by him must the scientific foundation of photography be laid. We may not be able to give the formula of the photo-salt, but if the solution of the problem has hitherto eluded our grasp it is because of the intrinsic difficulties of the investigation. The photographic image brings us face to face, not with an ordinary, but with an extraordinary class of chemical changes due entirely to the peculiar character of the silver salts. The material composing the image is not of that definite nature with which modern chemical methods are in the habit of dealing. The stability of the photo-salt is determined by some kind of combination between the subhaloid or oxyhaloid, or whatever it may be, and the excess of unaltered haloid which enters into its composition. The formation of the coloured product presents certain analogies with the formation of a saturated solution; the product of photo-chemical decomposition is formed under the influence of light up to a certain percentage of the whole photo-salt, beyond which it cannot be increased—in other words, the silver haloid is saturated by a very minute percentage of its own product of photo-decomposition. The photo-salt belongs to a domain of chemistry—a no-man's land—peopled by so-called "molecular compounds," into which the pure chemist ventures but timidly. But these compounds are more and more urging their claims for consideration, and sooner or later they will have to be reckoned with, even if they lack that definiteness which the modern chemist regards as the essential criterion of chemical individuality. The investigation may lead to the recognition of a new order of chemical attraction, or of the old chemical attraction in a different degree. The chemist who discourses here upon this subject at the end of the half-century of photography into which we have now entered, will no doubt know more about this aspect of chemical affinity; and if I may invoke the spirit of propheey in concluding, I should say that a study of the photographic film with its invisible image will have contributed materially to its advancement.

* Concluded from page 581.

* The connection between the two phenomena was suggested during a course of lectures delivered by me two years ago ("Chemistry of Photography," p. 191). I have since learnt that the same conclusion had been arrived at independently by Mr. C. H. Bothamley, of the Yorkshire College, Leeds.

PHOTO-ENGRAVING AS A BUSINESS.

During the past two or three years we have repeatedly drawn the attention of progressive photographers to the lucrative openings constantly recurring in the evolution of photo-engraving as an illustrative art. The ever-increasing demand for men skilled in this and photo-mechanical processes, together with the engaging prospects this youngest of professions holds out as inducements to its followers, have led us to embody here a few ideas which may help some who are looking for a better condition of things than photography in the studio affords.

Photo-engraving is a process by means of which a drawing in line or half-tone, a photograph, a water-colour or oil painting, or anything depicted by lines, colours, or tones, may be reproduced upon a zinc, copper, or steel base, and printed from the printer's press together with descriptive matter. The same end has, for many years, been accomplished, in some slight measure, by wood-blocks, upon which the design to be printed was cut by hand. This latter proceeding, however, had numerous disadvantages, amongst which we might mention that the success of the resulting picture depended wholly upon the fidelity of the work of the wood-cutter; also that the process was tedious and slow, requiring considerable skill on the part of the workman; consequently, the work was costly; and, beyond all this, there remained the fact that to obtain true likenesses of people, places, or things was generally impossible, because of the facilities offered in the wood-block to produce idealised representations of the objects depicted. Photo-engraving obviates all these difficulties, reproducing, as it does, with the actual fidelity of a photograph every detail of light and shade pictured in the original; and doing this, furthermore, within an incredibly short time.

Small wonder, then, can we express when we hear that this latest phase of reproductive art is driving all before it. We do not, however, believe that the spread of photo-engraving will result in the extinction of the branches of wood-cutting, steel-engraving, and the like. No! These have their own place, and will hold it, but without doubt photo-engraving is *the reproductive art of the future*, and, on that score, demands the earnest attention of all interested in photography, which is the fruitful source of this and all similar processes by which half-tone reproductions are obtained.

Now to the point. There are many photographers throughout our country who learnt the art in "wet-plate days," and who have never succeeded in the methods of dry-plate photography now in vogue. To such as these —and they are many—photo-engraving offers even greater inducements than to the modern dry-plate worker. Without a practical knowledge of the collodion process it is useless to try to accomplish anything in photo-engraving, but with this knowledge the workman is already half-way to the goal.

Some little time ago we called attention to an advertisement in a contemporary offering $50 per week to a skilled photo-engraver, and, so far as we know, that offer still holds good.

Anyway, it is absolutely certain that a man "worth his salt" in photo-engraving can obtain a salary all the way from $25 to $50 per week, whilst girls are employed in the lighter departments of the work at salaries ranging from $9 to $20 per week. What we particularly desire our interested readers to note is that, whilst photo-engraving as a comparatively new line of business is open to "live" workers from all allied trades, it is peculiarly open to photographers acquainted with the collodion processes of wet-plate days. The work is lighter and pleasanter than the general run of gallery work; the demand for good workmen is, and for some years will be, a steadily increasing one; the remuneration is greater than photography can offer under similar conditions to similar workmen, and the prospects of advancement are much more promising. In a conversation with Mr. M. Wolfe, of Dayton, Ohio, who produces the most perfect screen plates for photo-engraving purposes we have yet seen, he told us that if he had twelve competent men skilled in this class of work he could put them into good positions right away.—*Wilson's Photographic Magazine.*

MILITARY PHOTOGRAPHY.

Captain Curties, of the Royal Engineers, has written a series of articles on the above subject, which were published in the *Broad Arrow*. In the last of the series he gives a description of his photographic outfit. He says:—

"The one object I have kept in view all through has been to simplify the art as much as possible, and to make each photographic section complete in itself, and able to take, develop, and print a picture without any outside help, in the shortest time possible. Having this end in view, my equipment supplies, in the first place, two light knapsacks, to be carried in a reconnaissance by two mounted officers or men. One contains a very light fold-up camera, capable of taking pictures 10 in. by 12 in., round which is wrapped the focussing cloth. It has not appeared to me desirable to place before a general a view of a country smaller than this. The extra weight would be more than compensated by the comprehensive picture obtained; moreover, in a small plate, I take it, distance would not be fairly and distinctly portrayed. The other knapsack carries three dark slides, very light but strong, each containing two plates. This knapsack also contains the lens, instantaneous shutter, &c. Both knapsacks are made to fit close to the back, and, in addition to the straps passing over the shoulders, are secured to the sword-belt, thus preventing any injurious motion when riding. By the simple act of unbuckling one strap, each can be at once unslung ready to be unpacked. The tripod, which is made as light as can be consistently with strength and stability, is carried folded up in a packet attached to the saddle, and fixes immediately on to the camera. We next proceed to the all-important subject of "developing" in the field. For this purpose I use a tent composed of a large, folding, umbrella-shaped top, made of a material which admits a deep ruby light. When this is opened and fixed in the ground it stands just clear of a tall man's head. Over it is dropped a sort of sack, open at bottom ends, the top end being much smaller than the bottom end, and capable of being drawn together by means of two cords. This sack is lightproof and waterproof. The lower end is held down by means of a light iron hoop or ring, which also folds up to facilitate packing. The hoop is attached to the bottom of the sack in such a way that a border of the material extends beyond it, and rests upon the ground. This, in the ordinary way, is sufficient to keep out light, but should any find its way in, a few handfuls of earth or stones heaped up round the border will effectually keep it out. The stick of the umbrella is a hollow bamboo, open at the top. It is pierced with

holes to about half its length; this ventilates the tent. A cap placed over the top of the stick excludes light, but not air. We now have a complete tent in which a man can move about freely, and use his hands without constraint, and, above all, he is not half stifled, as one generally is in the usual run of developing tents. It can be taken down at a moment's notice, and packed in a very small compass, the whole being exceedingly light and compact. A few stays may be necessary in windy weather to keep it steady. The person about to develop a plate slings over his shoulders, knapsack fashion, a small metal tank, containing sufficient water to wash several plates; attached to it is a gutta-percha tube and tap. Round the waist is buckled a broad leather belt, in which are fixed bottles containing the developing solutions, &c. A light, fold-up trough, with a gutta-percha drain-pipe, carried outside the tent, and two light shelves, hook on to the stick of the umbrella. All that now has to be done is to lift up the walls of the tent, step inside, and develop and print the picture, which, by using bromide paper (undoubtedly *the* process for military use), would take something like a quarter of an hour; the printing, of course, to be done from the wet plate. I may mention that I use scarcely any glass beyond the plates (which I believe in); those articles which are made of glass are protected to prevent breakage. I believe myself that the whole of the articles now made of glass can be manufactured from a preparation of celluloid, which is strong, light, and durable. I hope shortly to have a complete set of bottles and measures made of celluloid."

On Saturday last Mr. Charles Knight, photographer, of Newport, Isle of Wight, had the honour, he says, of photographing H.R.H. the Duke of Connaught in Rifle Brigade uniform. The Prince is honorary colonel of the battallion.

The Fulgur Universal Lamp.—The Fulgur lamp consists essentially of a coal oil lamp whose reservoir contains a porous substance absorbing about two hundred centimetres of petroleum; it is furnished with a chimney of white glass, serving for ordinary lighting, enlargements, and magnesium flash-light, and with a chimney of red glass for lighting the dark room. The petroleum reservoir has over it a smaller reservoir containing magnesium in powder. By means of a faucet a small quantity of the powder is made to fall in a tube entering the flame, through which it is projected by means of a rubber bulb; the small quantity of magnesium smoke is entirely condensed on the chimney. The price of the lamp is 20 marks.—*Deutsche Photographen Zeitung.*

Phosphorescence Produced by Ozone.—Herr Ernst Fahrig says in *The Chemical News*:—"I was in a dark room, and having in my hand a sealed bottle about three-quarters full of a preparation of ozone (in this instance a solution of ozone in water containiug a small percentage of other substances, which I have found in the course of my experience are necessary to retain the ozone in solution), I, with no particular purpose in view, gave the bottle a vigorous shaking up; instantly I saw a soft, phosphorescent glow of light floating above the surface of the liquid and permeating the space in the upper part of the bottle. Its appearance was only momentary; but on shaking the liquid up again immediately afterwards it was observed again, but in much diminished intensity. Further repetition failed to produce any results, but after an interval of ten days the liquid had apparently regenerated its power, and the same effects could be observed, though weaker. I observed the phenomenon in another way, and obtained some especially remarkable results, by pouring a small quantity of an ozone solution into a glass beaker containing ordinary water. At first the cone-like projection of the solution where it falls into the water becomes luminous, and then the light suffuses the whole mass as the liquids become thoroughly mingled, and finally disappears."

PHOTOGRAPHING UPON WOOD.

The Magazinist, *The Century*, *Harper's*, and other popular monthlies use "process" engravings more and more. Photography on wood is their mainstay, and has almost superseded the draughtsman on wood. A sketch, say, a dozen times as large as the proposed engraving is made, reduced by photography, and then put upon the wood.

Photographing on wood by the wet-plate process is done thus: A slight modification of the collodion transfer will no doubt meet all requirements. First make a reversed collodion transparency in the camera from the negative. A tough and horny collodion should be used. Develop with—

Pyrogallic acid	100 grains
Citric acid	60 ,,
Acetic acid	2 ounces
Water	20 ,,

and fix in hyposulphite of soda. Coat the wood with the following hot solution of gelatine:—

Gelatine	4 ounces
Water	1 pint

Dissolve the gelatine by placing in a vessel of warm water, and then add 4 grains of chrome alum and mix thoroughly. The wood, having been coated, is allowed to dry. The gelatine surface is then moistened with water for ten or fifteen minutes, and the transparency, still wet from the washing water, is laid down upon it and pressed lightly in contact, and allowed to dry under slight pressure. When dry, the collodion readily leaves the glass, and remains in contact with the block.

Here are some further points: The plate is cleaned as usual, and dusted with powdered talc and polished off; it is then coated with positive collodion, sensitised and exposed as usual, fixed with cyanide of potassium, and placed in a dish of warm water. In the meantime, have your block blackened by rubbing drop black on it, or ordinary blacking, and coat and drain well with a solution of the commonest glue you can get, 1 ounce to 12 ounces of hot water; the common glues are the best, for they take a much longer time to set than better ones, and so you can get a much thinner coat with draining. Place your block in a vessel of water, having it immersed about three inches, then bring your photo from the dish, place it over the block and under the water. You will find by touching the edges of the film it will readily leave the glass; you can then turn it about any way under the water, and when in position raise your block gently out of the water, bringing the film with it; if it is puckered at all, it is owing to raising too roughly, and must be placed in the water again. If satisfactory, place at an angle to drain, and dry in warm, airy place. The whole operation, from focussing to getting the block ready for drying, will not take a practised hand more than twenty minutes. The common glue will not block the tool at all if you drain the block well, and when cut all can be removed immediately with a sponge and warm water. I may add that a very good way to black the block is to hold it over a petroleum lamp with its chimney removed. The glue-water will not come off it if applied in the same manner as applying varnish to a negative, and under no circumstances be induced to use a black varnish, for it is next to impossible to do a good job, for the graver slips as if it were cutting on glass.—*Wilson's Photographic Magazine.*

At the Photographic Club the following subjects will be considered:—Wednesday, August 6th, "New Hand-Cameras"; August 13th, "On Extemporising Apparatus."

Specifications Published.

14,220. *September 9th*, 1889. — "Photographic Focussing Magnifiers." FRANK BISHOP, of the firm of Marion and Co., 22 and 23, Soho Square, London, W., Dealers in Photographic Materials.

This invention, which has already been described in these pages, has for its object to provide a means whereby a focussing magnifier, sometimes used in focussing a picture in the photographic camera, may be temporarily fixed against the focussing screen in position for viewing the image, so that the hand of the operator, instead of being occupied in holding the magnifier, is at liberty to make the necessary adjustments of the camera.

The inveution consists in the combination with the focussing magnifier of a suction device in the form of an india-rubber cupped disc which, when pressed flat agaiust the focussing screen, remains adherent thereto by atmospheric pressure, in the manner of a sucker, with sufficient tenacity to support the focussing glass in position against the screen, and permit of its being shifted about thereon.

14,270. *September 10th*, 1889.—"Photographic Shutter." HENRI TRUNBERRY, Manufacturer of Photographic Shutters, 22, Rue de Bretagne, Paris.

This invention has for its object to provide a new form of shutter for photographic cameras.

This shutter may be employed at will for effecting instantaueous exposure, or exposures of which the duration may be regulated as desired. It is actuated by a compressed air piston, through an india-rubber tube terminating in a pear or ball as usual.

The piston alternately moves two slides, which constitute the shutter apparatus properly so called, from top to bottom, and which, in sliding vertically one in front of the other, alternately open and close the objective opening of the apparatus. The two slides are respectively actuated one by the other, each of them being provided on its side with a rack, the teeth of each of which engage at the same time with a pinion common to both, and which turns freely on its axis under the impulse given by either one of the said slides when itself actuated by the piston.

It will be understood that no matter which of the said slides is caused to move upwards by the piston, its movement in that direction, at the same time, through the action of the common pinion, imparts the opposite movement—that is to say, the downward movement—to the other slide. They therefore slide one over the other, and thus in succession produce the opening and closing of the objective opening. The alternate action of the piston upon the two slides is regulated by two springs in the form of elongated arcs, which alternately force the said piston under each of the slides. These two slides, in descending aud rising, themselves counteract the said spriugs, and render them free in succession.

. The above description applies to what is called instantaneous exposure.

For exposures of varying duration the travel of the slides is controlled to a given extent. Such limitation is effected by means of a bolt which arrests the upward movement of one of them, and through it the downward movement of the other slide, the action of the one being governed by the other, as above described. This bolt is actuated in a horizontal direction by a pin cut off slantingly, and which enters vertically a transverse slot formed in the said bolt, and which is also made slanting. An opposing spring placed in the bottom of the socket or box in which the bolt is confined pushes it automatically each time the pin in rising renders it free. This pin, and the slot which it enters in the bolt, are correspondiugly inclined, as above stated, and slide one over the other with a gentle friction. It will be understood by this that, when the finger of the operator presses on the said pin, the latter pushes the bolt which limits the travel of the two slides to the bottom of its socket, and at same time coupressess the opposing spring. When, on the contrary, the finger is withdrawn, the opposing spring, by expanding, then forces the bolt in the direction of the slides, and causes the pin to itself rise to its position of rest. In the latter position the shutter is adapted for what is known as varying exposure, the duration being, as it is easy to understand, regulated by the operator by means of the pin already described.

Besides what has been above described, a special arrangement enables the diameter of the objective opening to be reduced, with the object of enabling the shutter to be readily adapted to different sized apparatus.

This arrangement consists of a ring which is not entirely closed, and which forms the orifice itself, or the inner edge of the opening in the shutter, and which may be diminished or increased alternately under the pressure of two cylinders, screwed one over the other, and between which it is imprisoned. To produce the effect indicated, the said ring is broken at a point in its circuit, and its extremities are made so that when being decreased they slide one into the other. Further, the body of the said ring is triangular in cross section, the apex thereof being the external edge, while the base is, on the contrary, the internal edge of such ring. It will, therefore, be seen that the two cylinders, by screwing one on to the other, lessen the space left between them, and within which the ring for regulating the opening is enclosed, and consequently progressively press the said ring, and drive it towards its centre, thus producing its coutraction and diminution.

The reverse effect will, on the contrary, be produced by unscrewiug the two cylinders.

WE have reason to believe that one of the aluminium alloys will come largely into use in the photographic apparatus of the future.

A CELLULOID VARNISH.—It is not generally known that the best varnish for celluloid films of all kinds is a plain, spirituous celluloid solution. This is made of old celluloid film negatives from which the gelatine coating has been removed. The celluloid is cut into small trimmings and dissolved in common alcohol. This varnish is applied to the film in a cold state, and dried slowly without the application of heat. It flows smoothly and sets evenly, if made of the proper consistence. It has a greater degree of toughness than any resinous varnish, and has the additioual advantage of being entirely devoid of "tackiuess."—*Wilson's Photographic Magazine.*

LETTERING PRINTS.—M. Stravos Zellis, of Alexandria, recommends the following process for marking or lettering on the sensitised paper such uames as we wish to give the prints. He takes a piece of thin white paper, and traces upon it the words which he wishes to have at the bottom of his negative, and oils it on both sides. Having removed the excess of oil by rubbing it between two sheets of bibulous paper, he coats it with varnish on both sides, and allows it to dry. On the other hand, he removes from the bottoun of the negative a portion of the gelatine equal to the size of the paper, and substitutes for it the paper, which he sticks by means of a solution of gum arabic and water. He removes then the air-bubbles, which would prevent complete adherence, aud, this being done, waits for his work to dry. If, when printing on the sensitised paper, it is found that the letters do not show very white, the defective portions should be retouched on the back of the oiled paper. To write his name, M. Zellis makes use of a mixture of gum arabic, lampblack, and water. This process is simple, cheap, and gives excellent results.—*Annals Photographique.*

Correspondence.

COPYRIGHT LAW.

Sir,—In your "Notes" of last week, on page 575, you say: "This decision in the case of photography involves a certain amount of absurdity, because it is clear that one man may pose the sitter, and make all the arrangements, and be responsible for the art qualities of the picture; while the other man does no more than take off the cap and develop the plate. Yet the mechanical operator is deemed the author!" The decision you refer to is, I understand, that of Mr. Justice Wills in Kenrick *v.* Lawrence. If that is so, it seems to me that your note is somewhat misleading, as this case only decides that where one person directs another to make a drawing of a given subject, it is not the person by whose direction the drawing is made who is the author within the meaning of the Copyright Act. The judge did not decide who was the author, as it was unnecessary for him to do so, but at the end of his judgment he suggests that possibly they may both be joint authors.

The decision in this case is substantially the same as that in the other one to which you refer, namely, Nottage *v.* Jackson. It will be remembered that in that case the plaintiffs directed one of their assistants to go to the Oval and photograph the Australian cricketers in a group, and it was decided that the plaintiffs were not the authors of the photograph.

Who is the author of a photograph is a question of considerable difficulty, unless the whole of the work has been done by one person; but the Master of the Rolls, in giving judgment in the latter case, said, "The nearest I can come to is that it is the person who effectively is, as near as he can be, the cause of the picture which is produced, that is, the person who has superintended the arrangement, who has actually formed the picture by putting the people into position, and arranging the place in which the people are to be—the man who is the effective cause of that. Although he may only have done it by standing in the room and giving orders about it, still it is his mind and art, as far as anybody's mind and art are concerned, which is the effective cause of the picture, such as it is, when it is produced."

Hence, it seems that if one person poses and arranges the sitter, and another merely takes off the cap and develops the plate, then it is the former, and not the mechanical operator, who is the author of the photograph. In many cases, however, in which more than one person has been engaged in the taking of a photograph, it would probably be better to register them all as joint authors. C. Fleetwood Pritchard.

3, *Paper Buildings, Temple, E.C., July 29th*, 1890.

AMATEUR PHOTOGRAPHERS IN BOURNEMOUTH.

Sir,—At this time of the year you have, doubtless, many inquiries from amateur photographers as to facilities in this town for changing and developing plates, &c. I shall be glad if you will kindly refer such correspondents to me.

Stewart Hardwick.

21, *Commercial Road, Bournemouth, July 24th*, 1890.

Grey Bromide Prints.—To give a grey tone to prints on bromide paper, the *Photo. Mittheilungen* quotes M. Senier as recommending the alteration of the bromide to chloride by the use of a solution of chlorine (chlorine water), followed by redevelopment with oxalate or pyro, with the addition of considerable bromide. A red tone will be given by the addition of 4 parts of potassium bromide to 100 parts of the developer.

Photographic Periodicals.—The leaves of Vallombrosa and the multitudinous waves of the sea are simply not in it for numerousness with the new photographic periodicals which are sprouting hopeless around us. The latest edition—up to date of writing—which we have to welcome to the galaxy is the *Photographischen Neuheiten*, which appeared about the 1st of February in Berlin. It is under the protection of the house of Romain Talbot, and the editorship of Mr. Robert Talbot. It will appear monthly in French, English, and German editions.—*Wilson's Photographic Magazine.*

Proceedings of Societies.

London and Provincial Photographic Association.

At the meeting on the 24th inst. Mr. H. M. Smith occupied the chair. The subject for the evening's discussion was "Printing through Coloured Media."

The Hon. Secretary exhibited two slips of silver albumenised paper that had been sent to him by Mr. Otto Schölzig, showing the comparative actinic values of different coloured glasses. Different sections of the strips of paper had been exposed for a given time under dark yellow, ruby, blue, dark green, single green, and orange coloured pieces of glass. One strip of paper was left untoned for comparison of the colour of the deposits.

Mr F. A. Bridge read an extract from an article he had written in the Photographic News Year-Book of 1873, advocating the use of a thin sheet of green or pale red gelatine in printing from a thin negative, thereby getting a better result.

Mr. W. E. Debenham said that it had been asserted that with a certain class of negative a better and brighter effect was obtained by slow printing on a weak light than by exposure to a strong light; this he denied. He showed four prints on as many sections of a sheet of silver albumenised paper, all made from the same negative, using different coloured pieces of glass, and exposing from ten minutes to twenty hours in a weak light. No difference was noticeable in either of the prints except the exposure made under a piece of brownish orange glass. This Mr. Debenham accounted for by stating that the difference probably arose from the organic compound of silver being insensitive to orange light.

Mr. T. E. Freshwater showed some bromide prints developed with eikonogen of the last outing of the members at Wanstead Park.

Mr. F. A. Bridge showed an enlargement from a quarter-plate negative taken at Chester of some interesting carvings on one of the old houses.

The Chairman, as one of the delegates appointed to represent the Association at the Chester Convention, gave his report about the same.

The Bank Holiday outing on Monday next was arranged to take place at St. Albans.

Birmingham Photographic Society.

At the ordinary meeting of the above Society on July 24th, held at St. Edmund's College, Mr. W. Griffiths gave a very interesting paper on "Stereoscopic Photography." The lecturer described the different apparatus required and mode of working, and illustrated his remarks with a number of beautiful stereoscopic slides on paper and glass.

Mr. W. J. Harrison, F.G.S., who was in the chair, complimented Mr. Griffiths on his instructive paper, and said he was sorry a larger number of members had not availed themselves of the pleasure of hearing the paper.

Messrs. Karleese, Middleton, Taylor, and others took part in the discussion which followed.

The result of the first photographic competition towards the Warwickshire Photographic Survey was announced. A gold medal was offered by Mr. S. G. Mason, a silver medal by the Society, and a bronze medal by Mr. A. Constantine for six photographs taken in Warwickshire at places accessible to the general public; to be taken between March 1st and June 30th. Three to be open landscapes, part of each to be a river or stream, and three to be of a rustic cottage or cottages; the six prints to be exhibited on one mount. The awards were offered for excellence of the group of photographs, artistically and technically; the negatives of the prize photographs to be placed at the disposal of the Photographic Survey of Warwickshire Committee. The photographs were sent to Mr. George Bankart, President of the Leicester Society, to judge, who awarded the prizes as follows:—Gold medal—Benjamin Karleese, "Light and Truth;" Silver medal—Arthur J. Leeson, "Cannon;" Bronze medal—W. Jerome Harrison, "Avon."

On Saturday last a good number of members and friends took part in the monthly half-day excursion, Warwick being the *rendezvous* for the afternoon. A pleasant afternoon was spent under the leadership of Mr. George A. Thomason, when over 100 plates were exposed.

THE BATH PHOTOGRAPHIC SOCIETY.

ON Saturday, the 26th inst., the Society met at Prior Park, by invitation of the Rev. Canon Williams, the principal of the College. The grounds are some 200 acres in extent, and present many picturesque subjects for the camera. Prominent amoug them stand three handsome piles of buildings, with the mansion in central position, 150 feet wide, with a Corinthian portico of six columns, and the two wings used as colleges, and dedicated respectively to St. Peter and St. Paul. A church has also recently been added for the convenience of worshippers in the district. The interior is richly ornamented with carving in alabaster imported from Rome. It is lofty and well lit, a large and valuable Vandyke of Jesus being easily photographed along with the interior; when quite finished the floor will be of white marble throughout. There is also a private chapel, or chapel royal, in the mansion, said to have been intended for the use of George III; it is unique. These buildings take the form of a crescent, are situated ou a slope 400 feet above the Avon, and are generally considered to command a landscape full of Italian beauty. Far away down the slope so richly friuged with woods, and spanning the expansive fishponds, stands the Palladium Bridge, well known to visitors.

At five p.m. the party assembled under the portico of the mansion, where the Canon welcomed his fellow members to tea; Mr. and Mrs. Austin J. King and Miss King assisted in dispensing hospitality to the guests. After tea more photographs were taken, and the swimming bath, priory, and other points of interest visited. The sky being cloudy, with occasional showers, the light was too weak for many subjects, but some good and picturesque photographs were nevertheless obtained.

THE DAGUERRE MEMORIAL.

THE committees which have been appointed by the Photographic Association of America, with and by Chairman McMichael, of the general committee, are as follows:—

The General Committee.—H. McMichael, G. M. Carlisle, O. P. Scott, J. M. Appleton, G. H. Hastings.

The Washington Committee.—E. J. Pullman, Thomas W. Smillie, Hon. A. A. Adee, A. Dickinson Jewett, Dr. Griffiths, U.S.N.

The Chicago Committee.—Gayton A. Douglass, Richard Sweet, Thomas Pattison, O. P. Scott, Dr. John Nicol.

The St. Louis Committee.—G. Cramer, M. A. Seed, J. C. Somerville, H. A. Hyatt, F. W. Guerin, W. H. H. Clark.

The Philadelphia Committee.—W. J. Entrekin, W. P. Buchanan, John G. Hood, Edmund Stirling, J. Carbutt, J. Bartlett.

The Boston Committee.—George H. Hastings, W. H. Roby, T. H. Blair, Wilfred A. French, C. A. Chandler.

The New York Committee.—J. Wells Champney, H. Littlejohn, Edward L. Wilson, Ph.D., Dr. Arthur H. Elliot, W. 1. Lincoln Adams.

Each of these committees holds a book of certificates for subscribers to the fund, and is authorized to give receipts.

BICHROMATE OF SODA IN PHOTOGRAPHY.—J. Husnik recommends the employment of the bichromate of soda in place of the bichromate of potash in all the processes where a salt of chromium is used, such as zincography and photo-lithography. Not only, he says, does the soda salt contain more chromium in a given weight, and is more than a third cheaper; but it also has the advantage of being far more soluble in water than the other, thus has not its tendency to crystallize out when dextrine or gelatine is added to the solution. He states that he has used it with entire success in all his processes for some time past.

Answers to Correspondents.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and to the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

H. S.—*Cabinet Vignettes Showing Brush Marks.* Since communicating with you last week we have taken occasion to test the cards upon which the photographs are mounted. We can find nothing in them to account for such defects, for the boards are absolutely free from bleaching chlorides, sulphites or hyposulphites, and the edges are finished with pure gold. It would seem, therefore, that the mountant was at fault.

PHOTARGUS.—*Lead Pipes for Rain Water Supply.* Although it may happen that rain water acts slightly upou pure lead, the quantity of metal dissolved is so excessively minute that it is impossible to believe that such traces could exert any appreciable effect in photographic operations. Tin piping is absolutely safe, or even the alloy of lead and tin known as "composition pipe," but you must attach them to a slate cistern or water butt, for if put in contact with a lead-lined reservoir there is always increased danger of metallic corrosion, as the consequence of galvanic action being set up between dissimilar metals.

E. O. C. (Boston Photogravure Company, Mass.)—In a letter dated July 15th, our correspondent makes an excellent suggestion for overcoming irregularities in the development of celluloid films, by cementing them down with Canada balsam upon a plate of glass before proceeding to apply the chemicals. He thinks this idea may be worthy the attention of Colonel Waterhouse, who found difficulties in making enlargements from celluloid films in consequence of the varying thickness and opacity of the material he employed. The further details promised by our correspondent will be very acceptable; meanwhile we thank him for this letter already to hand.

J. M. B.—*Spots of Reversed Action.* Your communication is extremely interesting and important; we have never seen the effect produced in this way before, although the end windows of churches and other interiors very frequently show halation and reversal.

PERISHED.—*Red Rubber Bulbs and Tubing.* The pneumatic apparatus attached to instantaneous shutters very often gets rigid and rotten, and has to be replaced. A short immersion in warm water helps to make it serviceable for a time, but the change is due to oxidation of the caoutchoue, and is inevitable.

L. T.—*Liesegang's Fixing Bath.* The precipitate which you noticed may have resulted from the action of the alkali in the gold toning bath upon the magnesium salt, in throwing down the carbonate or hydrate of magnesia. Be careful to wash the toned prints well before immersion in the fixing liquor.

M. E.—*Pyro and Ammonia Developer.* This is very apt to stain the film wheuever the development is prolonged; try the substitution of carbonate of soda for the ammonia in the proportion of about one to five of soda.

R. S. (Ipswich).—*Measure Pipettes.* Provide a series of 1, 2, 5, and 10 c.c. pipettes; above this measure the graduated cylinders are better, say 50, 100, and 500 c.c. These, with a set of gramme weights, should meet all your requirements, or you might add to them a litre flask.

J. P.—*Storage of Rain Water.* There is nothing better than a well-cleaused petroleum cask or ruu puncheon; and if you can, by being always on the spot, allow the first washings from the roof to run to waste, and then collect only the pure rain water, you will be spared much trouble in filtering; but smuts so readily accumulate in towns that it will nearly always be necessary to filter the rain water before use.

W. T.—*Reducing Silver-Chloride.* Put in a few slips of zinc, and allow to remain for some days; then withdraw the excess of zinc, wash well by decantation, and lastly on a filter. Finally, melt the reduced silver in a Cornish crucible with a little dry carbonate of soda and borax as flux.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1666.—*August* 8, 1890.

CONTENTS.

TOURIST PHOTOGRAPHERS AND THE CHANNEL PASSAGES.

PHOTOGRAPHIC periodical literature on both sides of the Atlantic teems with items showing that the hot weather and the "dead" season are now upon us, and that those camera bearers who can do so are fleeing to the seaside or to the mountains. Within the last four or five years, as proved by the official returns, the passenger traffic between England and the Continent has been increasing by leaps and bounds, so altogether this seems an opportune moment to deal with the subject of the more frequented Channel passages, their boats, harbours, and subjects worth photographing from the deck of the ship.

The first question which troubles the tourist more than he cares to own, is whether he will suffer the horrors of sea-sickness on his coming journey. Some misconception is prevalent about liability to sea-sickness; most persons think that they will suffer less from it by taking the short passage between Dover and Calais, or Folkestone and Boulogne, instead of a longer route. The short passages have shallow harbours, especially on the French side, hence their passenger boats are all small, and draw little water, so that in the short "chopping" seas which are common enough in the narrowest part of the Channel, passengers are sometimes well tossed about, and made seasick upon breezy sunshiny days, when the same journey would have been altogether pleasant had they been upon a deep-sea boat. In a short passage of about seventy minutes the trouble is soon over, but passengers often have to leave the ship when they can scarcely walk, and if they say that they will remain on board for a short time, may be told that they cannot, as the boat will soon move away from the quay. A method of cheating the sea of its prey, sometimes adopted by those who have plenty of leisure, especially ladies, is to stay a day or two, if necessary, at the port of embarkation until the sea is smooth, and then slip across.

Beginning with the Dover-Ostend route, the boats are rather small, for the reason already stated, and the actual passage occupies in fine weather a little over three hours. The boats carry the mails, and are the property of the Belgian Government; they were built in Belgium, and engined by the Cockerill Co.; the engines are of first class workmanship, and of great power as compared with the size of the boat, consequently the speed of the latter is high. John Cockerill, an Englishman, founded the great Belgian iron works in the past generation at Seraing, near Liege, but for a long time past they have been the property of a Belgian Company. On those days when the sea is smooth, the restaurant department of the Ostend boat is much patronised; cooking goes on on board, and the charges fixed by the Belgian authorities and displayed for the benefit of the passengers are particularly moderate. The stewards are all in the employment of an hotel keeper at Ostend, who contracts for the vending of refreshments on the boats; hence it is no use consulting these officials in the expectation of getting disinterested information about Ostend hotels. At the present time Ostend is full of Germans, and all the hotels are, practically speaking, full. This is due partly to the circumstance of the German Emperor having visited the town a few days ago, and partly to the fact that there is an excellent railway service between Ostend and Cologne, which draws off from the Rhine districts and places eastwards thereof, those who seek rest and relaxation at the sea side. At Ostend there is little worth photographing from the deck of the boat; tall and roomy houses, with a sandy beach in front, represent Ostend as seen from the sea; the country around is absolutely flat. On the Dover side, the return boat approaches the Admiralty Pier in such a direction that admirable views can be taken in suitable weather of Dover Castle and the cliffs whereon it stands, with sea and boats in the foreground. A lens of moderately long focus is necessary. The Ostend boat reduces its speed when so close to its destination, and this is in favour of the photographer, who, at the same time, sees Dover Castle before him from perhaps the most picturesque point of

view. In fine weather this route across the Channel is exceedingly pleasant; in bad weather it is doubtless the reverse, what with the three hours' passage and the size of the boats.

Turn we now to the Harwich-Antwerp line to the Continent, which has the advantage of deep water harbours on both sides of the Channel; consequently deep sea boats are put on the service. Sleeping bunks and cabins are provided for the passengers; the cabins are illuminated by the electric light, and have "goose-neck" ventilators to keep the air pure. In times past this route was not spoken of in London with over-much respect; but of late years much money and care have been expended to make the service one of the best, and it is drawing a large share of the Channel passage traffic. The boats leave Parkeston Quay a little before ten o'clock at night, and reach Antwerp between eight and ten next morning; the direction of the tide in the Scheldt influences the time of arrival. Passengers liable to sea-sickness have (1) the advantage of being on board a large sea-going ship, which does not toss about like a walnut shell; (2) the advantage of not being exposed to the full force of the Atlantic in bad weather, being sheltered therefrom by the mainland of England; (3) the advantage, if sick at all, of being in a comfortable bed; (4) the advantage of ending the voyage with several hours' smooth steaming up the River Scheldt, giving abundance of time for recovery from sea-sickness before landing.

The steamers on this route are all twin-screw boats, and the largest of them is the *Colchester*. Twin-screw boats will rotate upon their vertical axis when the screws are moved in opposite directions, so the ship can turn in small space in a river. The breaking of the screw shaft is one of the most serious accidents which can befall a steamer at sea; but, with a twin-screw ship, if one shaft be broken, the boat can go ahead by means of the other shaft and the other screw.

Great speed is obtainable with twin-screw ships; indeed, our first experience with one was at the trial trip, off the measured mile, of a twin-screw vessel built to carry four guns, and scandalously rumoured to have been constructed to run the American blockade. She was, however, never used for that purpose, but was bought by the Brazilian Government to chase river pirates, because of her speed and power of turning in narrow places. The small Margate passenger steamers go at a good speed, yet the twin-screw boat rapidly caught and passed them, to the astonishment of the Margate passengers, who crowded to the sides of their boats to watch the strange vessel steaming with such rapidity down the Thames.

The Harwich boats have a smoking cabin on deck, and this locality is always the most sociable one on board ship. The Ostend boats are not so provided, but inferior cigars can be obtained on board the latter at high prices.

At Harwich is nothing worth photographing from the deck of the ship, unless the shipping in the harbour should chance to present favourable opportunities. The ship enters the Scheldt near Flushing, but that town is too far off to be made a prominent object in a picture. The river then for miles winds through Holland; flat country and occasional windmills present themselves on each side, and photographs worth taking are not obtainable except upon a day when fine cloud scenery forms the chief feature of the outlook. Sometimes the vessels passed on the river might be curious enough in their build or appearance to be worth photographing. Antwerp itself, however, offers food for the camera; the boat passes at such a distance as to be suitable for taking the lace-like spire of the cathedral and the intervening houses, and the Harwich boat passes along the whole of this side of Antwerp before it comes to the landing quay for its passengers. Abundant work for the camera, as many London photographers know, can be found in Antwerp, the great city which Napoleon I. had the idea of making a rival port to London.

(To be continued.)

Literary Notices.

The Stereoscopic Annual, by W. L. Chadwick. *(John Heywood, London,* 1890.)

This is a little book of 45 pages, by Mr. Chadwick, who is well known for the practical attention he has given to stereoscopic photography. Modern dry-plate workers are not so well acquainted with this subject as their elder brethren; to the latter the book contains little that is new. It contains full instructions about taking the negatives, and the more difficult work of cutting and mounting the prints, and of making from the negatives transparencies upon glass.

The Photographic Instructor, edited by W. J. Lincoln Adams. *The Scovill Manufacturing Company, New York,* 1890.

This book of 215 pages is written chiefly for beginners in photography, but is a useful book of reference for others. It deals with every branch almost of in-door and out-door photography, and while some of the chapters are full of necessary details, others are rather too meagre. For instance, few negatives exist which cannot be made to yield better than ordinary results in the printing, by the employment of various devices, and the four or five pages devoted to the branches of the important subject of "artistic printing" might have been exceeded with advantage. The book has an appendix by Dr. Ehrmann, on the nature and use of the various chemicals employed in photography, and some of the chapters are written by men of good standing in American photographic circles. Those who have thus assisted the editor are Mr. Charles Wager Hull; Prof. Randall Spaulding, of the Montclair High School; Prof. Karl Klanser, of Farmington; Mr. John Carbutt, of Philadelphia; Mr. O. G. Mason, of Bellevue Hospital, New York; and Mr. Maurice N. Miller, of the University of the City of New York.

Mr. R. Robert sends a sample bottle of what he names "The New Lavender Developer." Its action is rapid and energetic, and the photographer is warned not to be startled if the image appears immediately, inasmuch as there is no danger of fog, even with the most sensitive plate. The development, indeed, must only be stopped when the image begins to appear at the back of the plate. The action of the developer, which is made up in concentrated solution, may be controlled simply by the addition of more or less water. Other advantages are that it keeps well, and does not stain the fingers.

THE PHOTOGRAPHIC ANNUALS.

If any enthusiast of our art should require to possess a complete library of photography, he will want a very large book-case in which to keep the various books devoted to the one subject, and perhaps it is not too much to prophesy that at the end of a few years more the case must be expanded into a room; for books on every detail of the art, from stereoscopes to flash-lights, are constantly being produced—we do not say written, for in truth many of these works are sad examples of book-*making* as opposed to book-*writing*, which is, indeed, a very different thing.

Forming a principal feature in a collection such as that adverted to, would be those annuals which, at the end of every year, are produced with such regularity both in this country and by our cousins across the water. For these annuals represent the Encyclopædia of Photography, so full are they with information upon every detail connected with it. They also furnish the most ready means by which anyone may follow the modern history of sun painting, for not only does each volume contain a summary of the year's doings, but every advance is dealt with in sufficient detail by different writers to give it its proper value.

Photographers are most generous, and will, as a rule, tell all about their modes of procedure to any one who will lend them a willing and sympathetic ear. They have no trade secrets. Turning over a few of the pages of some of these back volumes, we can readily find out how such and such a well-known worker develops his plates; how an equally well-known hand spots, mounts, or retouches; and how somebody else says about something which he has invented, "This is a little device of my own which has long since paid its expenses;" and so on *ad infinitum*. How refreshing is this candour when compared with the difficulties one often meets with in getting at the correct way of doing things which prevails in other fields of labour.

The photographic annual professes to be a general summary of what has been going on in photographic circles during the year in which it appears, and although a great deal of its subject matter has been already, in the nature of things, threshed out in the press, it appears therein in more permanent form. A few decades back, when periodical literature was kept within smaller limits than it is now, the man who took in a weekly paper used, at the end of the year, to bind it. But things are different now, and the greater proportion of such literature eventually finds its way to the butcher's or the butter shop. The world has grown too busy to treat ephemeral things in any but an ephemeral spirit, and when the paper is read, away it goes to the waste-paper basket. But with the annuals it is different. The volume is worth keeping, if only for the sake of the advertisement columns, which, indeed, form a valuable photographic directory to all traders connected with the art.

But apart from this purely business view of the matter, we find in the annuals many things which are not to be found anywhere else, for there are a number of good workers who contribute their annual mite to this publication as their sole literary effort. In doing this, they unburden themselves of something good, for it is sure to be the outcome of practical experience, and is therefore valuable.

The annual is perhaps seen at its best when some epoch-making advance is nearly ready for general acceptance, and when men are hesitating whether to take up the new thing, or to leave it alone. Take, for instance, that period—now about fifteen years back—when the gelatine process was being experimented with and being improved gradually by many amateur workers. Let the professionals remember these pioneers when they feel angered against the ubiquitous amateur. But the amateur of that day was very different to his modern successor. He had to depend upon his own handiwork for nearly everything he required, and, besides making his own dry plates, made his silver nitrate as a preliminary and necessary operation. In those days the annuals were replete with all kinds of little details having reference to the making of emulsion and the coating of plates. Failures were common enough, a great many being due to the ignorance which prevailed as to the extreme sensitiveness of silver bromide under its new treatment. So much was this the case, that it was recommended by the pioneer dealer in dry plates that each plate should be washed in a preliminary bath of soluble bromide before development. It seems a laughable proceeding that the sensitiveness of a film should be purposely checked in this manner, but so it was in the early days of gelatine. In the meantime, professional photographers stuck religiously to collodion, and shook their heads incredulously when they were told of the merits of gelatine. They regarded it as a plaything only fit for amateurs, and not intended for serious work. And, in one sense, they were right, for a method must be out of its experimental swaddling clothes before it is of any use for really practical work. It is both amusing and instructive—to use the showman's formula—to look back through these annual volumes, and to see how these things have happened. We find in them the record of many an innovation which has soared upward rocket-fashion, and has come down speedily like the stick of the same noisy firework. We also find notice of the birth of improvements which have been announced in quieter fashion, but which are alive to-day. The photographic annuals are, in a word, necessary to the complete education of a modern photographer.

A "PHOTOGRAPHIC NEWS" SUPPLEMENT.

Next week we shall publish a pictorial supplement, representing the house at Eversley of the late Charles Kingsley, and executed by the photogravure process.

Ruby Light.—Ruby light, in spite of all that has been said in favour of the orange-green, continues to hold its own in the dark-room, and many who employ it continue to complain of its effect on their eyes. The remedy, says the *Beacon*, is the introduction of a pane of ground glass between the eyes and the ruby—*i.e.*, on the outside of the lantern.

THE PROGRESS OF THE PHOTO-MECHANICAL PRINTING PROCESSES.

BY HERMANN E. GUNTHER.

No. IV.

Collotype.—In consequence of the high perfection to which the photogravure process has attained of late, collotype seems to have been limited to a certain degree as regards book illustration. In this country (Germany) at least, photogravure is at present almost exclusively employed by the eminent publishers for the illustration of their splendid works, after "collotype, zincography and carbon printing have survived themselves," as one of them has quite recently declared; notwithstanding, our collotype establishments are fully engaged, there being so many other purposes—artistic and industrial—for which collotype is indispensable.

Great care has been devoted by the manufacturers to the perfection of the required machinery. The collotype steam presses are generally manufactured in three to four sizes, they being so constructed that the printing plate may be inked once, twice, or three times, each inking giving more vigour, though a corresponding decrease in the number of prints yielded.

The preparation of the plate for the steam press is generally identical with its preparation for the hand-press, but it will perhaps be of interest to note a formula for the preparation of the plates being adopted by a renowned collotype establishment, in which steam presses solely are in use. The substratum with which the plates are coated previous to the prepartion consists of 7 parts of stale beer, and 1 part of silicate of potash. The solution is filtered, and the plates are coated with it. After drying, they are placed for about half-an-hour in a warm, drying oven, when they are allowed to cool, and washed. The sensitizing solution is prepared of 25 parts of collotype gelatine, 300 parts of water, 7 parts of bichromate of potash, and chrome alum as required (4 to 20 drops of a saturated solution). The etching solution is the following:—50 parts of thick gelatine, 70 parts of water, 30 parts of ammonia (without the addition of hygroscopical salts). In order to keep the edges clean, to 50 c.c. of this etching solution a few small pieces of caustic potash are added, which solution is transferred to the edges of the printing plate.

With respect to the same subject, Mr. August Albert gives the following information. After the plate has been exposed in the printing-frame as much as required, it is fixed to the bed of the machine, but it is damped only as long as it is absolutely necessary with regard to the picture. Owing to the somewhat short damping process, a light tone will make its appearance in the "fond" of the picture; this may be afterwards removed in the following way:—Of a saturated solution of caustic soda 5 to 10 drops are, by means of a dropping-tube, added to 100 c.c. of the damping fluid in use; mix well, and cover with it, by means of a stout brush, and exactly following the outlines of the picture, the whole ground; allow to stand for a few minutes, and then take off the etching fluid carefully by means of a piece of blotting-paper. Care should, however, be taken that the fluid does not come in contact with the image itself, which in printing would at once become perceptible by lighter portions. The treatment of the printing plate with this strong etching fluid depends much on the kind of gelatine used, hard samples being much more resistant than soft ones, and it is therefore necessary to work very carefully, until the proportion of the addition of the caustic soda—the most favourable to the gelatine in use—and also the duration of the action of the etching fluid, have been exactly ascertained; otherwise the gelatine will be destroyed.

The preliminary coating process of the plate, though it seems to be very simple, is, notwithstanding, one of the more difficult processes in collotype. The old method with albumen and bichromate, though it is undoubtedly the most reliable one, is at present but sparingly used by German practitioners, on account of its inconvenience. The other method, with silicate of soda and albumen, is almost universally adopted; it is more easy than the former one, though in the case of limited experience it fails sometimes. After some experience it is not very difficult to see during coating the glass with the substratum if the preliminary coating is good or not. After it has dried up, there should be hardly anything noticeable in the glass, and after warming in the drying-box up to a temperature of 104° to 122° F., it should look quite even, like a very transparent opal glass, without being denser on one side; and after rinsing the plate in water and drying again, it should show the colours of the rainbow.

In one of our most eminent collotype establishments, an original and very efficient method of re-exposing the negative film is in practical use. Collodion plates are employed in this establishment for reproduction purposes, and in cases where a drawing or any other original in half-tones is to be reproduced for collotype, the collodion negative, after developing and well washing, is dried spontaneously. After drying, the negative is placed, film side down, on a piece of black velvet, and for about half an hour exposed to the action of strong but diffused light; only then is the negative fixed. This re-exposure is of importance, inasmuch as more softness and harmony in the tones are obtained by it. It would be interesting to try whether this method is also applicable in the case of gelatine plates; since, however, the gelatine film washes out with more difficulty than the collodion film, it would be well in this case to wash the gelatine negative for a comparatively long time after development, to remove every trace of the developing solution.

Hyposulphite of Soda, as a good febrifuge, has been mentioned; its antiseptic powers are not, however, very great. Cultures of chicken cholera do not lose their pathogenic properties by being kept for forty-eight hours in a 2½ to 5 per cent. solution of this salt, according to M. Perroncito.—*The Monthly Magazine.*

A Photographic "Every-Day Book."—*Scraps* says: "In no occupation, perhaps, does the Every-Day Book prove more serviceable than in photography. There is such a wealth of journalistic literature on the subject, that the average reader is apt to rise from his weekly study of it somewhat dazed with the quantity of matter, and consequently he is little able to carry away with him any of the details for future use. He has a vague idea that such and such a method is useful for such a purpose; but as nicety of working is necessary in our art, this imperfect recollection is useless. Let him then have always at hand his note-book to paste cuttings, or to copy into all such items as he cannot obtain cuttings of. Let him have an index carefully filled up from day to day, and if he can, let each extract be marked, "tried and found good—or bad," as the case may be. Such a book, looked over at leisure, will prove a source of infinite delight, and often recall some forgotten hint, and above all, will be a means of ready reference for some bit of information the details of which have slipped the memory." This advice of *Scraps* may be all very well in some cases, but scarcely applies to this journal, which is not usually cut up by its readers, but kept for binding.

PHOTOGRAPHY IN FLORENCE.

The *Bulletin* of the Italian Photographic Society for June has for its frontispiece an interesting phototype by the brothers Alinari from a negative by D. G. Roster of an enlargement of a diatom, Coseinodiscus oculus Iridis, &c., with a representative fraction of $\frac{1}{3000}$ diameter. The negative was obtained by Zeiss' photomierographic apparatus.

The letterpress opens with an account of the inauguration of the Society's place of residence on the 15th of June, on which occasion the president of the Society congratulated his fellow-workers on the great progress lately made in photographic knowledge, in art, science, and industry. Signor Cataldi then spoke on the process of photo-zincography, of which he gave a detailed and clear explanation; and Signor Golfarelli on the strict relation between the intensity of light, the aperture of the diaphragms, and the duration of the luminous action.

A new Italian photographic periodical is announced in the *Bulletin*. It is to have a "special physiognomy, and to respond harmonically to the tendencies of a distinct class," says the *Bulletin*, which adds, that as every day photography is making proselytes, and that there is a penury of Italian journals upon this subject, the foundation of a new periodical at a low price, which may circulate largely among professionals and amateurs, is a thing much to be desired. Signor Gioppi, the well-known photographic artist, will edit this new journal, which he has modestly named *The Photographic Dilettante*.

His Excellency Signor C. de Bildt, the Minister Plenipotentiary of Sweden and Norway at the Italian Court, a distinguished amateur photographer, and famous for his anxiety to obtain the latest news and discoveries in this branch of science, visited last month the President and Vice-President of the Italian Photographic Society, and had a long interview with them. He was much interested with the beautiful effects obtained by the stereoscopic apparatus of Professor Roster, and ordered one to be made for himself, proposing to employ it largely in his own country.

As a remedy against halation, or "aureole" as the Italians call this defect in negatives, the *Bulletin* proposes (1) the rubbing of the solarized portion with a tuft of wadding soaked in alcohol; (2) the covering the reverse of the plate with a solution of dextrine incorporated with black smoke and applied with a brush—this coating must be removed with great care before developing the negative; (3) the covering the back of the plate with a mixture of black smoke and cloves or cinnamon, taking care to clean the plate before development; (4) the gluing of a piece of dark flannel on the back of the plate, and detaching it before development; (5) the laying on of a light coat of burnt sienna or umber formed into a paste with gum. Other modes suggested are a sulphate of quinine in collodion, and the best results are promised from an application of collodion containing aurantia or chrisoidine. The backs of the plates may also be lightly coated with emery powder.

To prevent the separation of the gelatine from the glass plates in the hot weather of the present time, a simple recipe is given by Signor Vogel, consisting in immersing for a short time (say a couple of minutes) the plates, directly after development, in a solution of:—

Water...	500 grammes
Sulphite of soda	10 ,,
Tannin	1 gramme
Chlorhydric acid	5 grammes

This washing of the negative after development is only effectual when the tendency to separation is but slight. It can be also applied to the aristotype paper, but in this case it must be applied after the fixing of the image. The solution may be kept a long while without deterioration, and requires no special care, as, says Signor Golfarelli, "I myself am able to bear witness."

THE RECENT CITY PHOTOGRAPHIC EXHIBITION.

Last Monday we received a letter which had previously gone astray for some days through misdirection, from a correspondent, who gives the following particulars about the late Photographic Exhibition at the Drapers' Hall, London:—

The balance of £2 12s. 5d. was unanimously voted to the Photographers' Benevolent Association, it being a sum too small to be divided among the exhibitors who had paid for space; such a division would not have amounte d to more than twopence in the pound.

Having the magnificent rooms of the Drapers' Hall t the service of the Section, it was necessary to put the Exhibition handsomely before the public for the credit of the Section, and to do justice to the Drapers' Company. The preliminary expenses—printing, stationery, postage, and the services of an Assistant-Secretary—came to about £88. For the *soirée* the cloisters, which surround the inner square, had to be curtained in and ornamented; a cloak room, to accommodate 1,000 coats and hats had to be provided; also some first-class music and refreshments in corresponding style. The total expenses under this head amounted to £104. To provide handsome screens for mounting the pictures, a representative to superintend and direct the hanging, with advertisements in daily papers, &c., totalled to a little over £140.

The Photographic Section unanimously adopted the report and passed the accounts. A vote of thanks was passed to the Drapers' Company, to their Beadle, and to other servants for the great courtesy with which they received the Section and assisted in promoting the success of the Exhibition.

One Man Exhibition.—The exhibition of photographs by Colonel R. W. Stewart, which was promised, is now on at the Club. It is not only a "one-man" show, but also a "one-theme," the whole of the series, about sixty, being devoted to Westminster Abbey, almost entirely interiors. The prints are on matt-surface silver paper, and are of great interest, forming a very complete set, which all given to interior work will examine with much pleasure.—*Camera Club Journal.*

Artistic Photography.—Photography is, we think, now freely admitted to have much claim to the title of an art, and one special phase in studio work with the camera, where art comes into play, is in draping. The late Mr. Baden Pritchard has well pointed out that photography is more comparable with sculpture than with painting. Sculpture and our art are alike in absence of colour, and therefore light and shade and draping are the points which users of chisel and lens both have to study. Draperies not too light, not too dark, and not too stiff. Too soft and clinging they can scarcely be. Too old they cannot be. Soft greys, creams, and light browns for colours; and cashmeres, fine woollens, and soft muslins for materials. Taboo starch and glaze if you would hope for soft artistic pictures. Of course these are only aids to our artistic work; without them we can do nothing, with them we can do nothing unless we have eyes to appreciate and devise graceful poses and harmonious lighting.—*Scraps.*

GROUP DRAWBACKS.

BY MOSES BACK.

Burnet, in his *Essays*, often uses the term "group" in a technical sense, making it refer not only to groupings of persons, but to landscapes and even single portraits; thus conveying the idea that a picture is only a harmonious grouping of lights and shadows of various values.

In this sense a grouping of persons is no different from any other picture, and this is a point commonly overlooked by photographers; for while the good photographer will pose and light a single figure so as to give breadth and repose, few of the groupings so far exhibited have been anything more than meaningless conglomerations of spots, making the action uninteresting, because the means (light and shade) of expressing it was inharmonious; the group must be treated as a unit, and the light and shade grouped accordingly.

At this point, I think, is where photography meets its greatest obstacle. The artist cannot always get the individuals in his group to dress harmoniously; and even if that obstacle is overcome, a suitable background is not always available. Most of the backgrounds offered for sale are utterly unsuitable for anything. Not to mention windows on the shadow side of the group, and general daubiness of effect, most of them are arranged so as to bring the light side of the group against a dark ground, and *vice versa*, which is highly conducive of that spotty effect so justly denounced by Mr. Wilson. Therefore a carefully selected background is one of the first essentials in getting up a group. The difficulty of harmonising backgrounds and figures is appalling; but, as genius is only the ability to take infinite pains, I look for vast improvements in the facilities in this direction. Perhaps some one will invent a system of painting backgrounds whereby the operator can, with a brush and ready-prepared paint, modify the ground in its broad tints so as to suit the material in hand, and leave the general design more or less intact, and be able to go right on and use the ground at once.

As to composition, I think the fundamental principle of that branch is never to have any object in the picture chargeable with vagrancy—*i.e.*, without visible means of support or compensation.

The artistic eye is the eye which perceives the *harmony* of things. I just wish to call attention to the harmony—one might almost say unity—of pleasing effects of chiaroscuro and graceful action. As pleasing chiaroscuro has its focal point, so has the action in any incident its central point; and when these two coincide, and the accessories, both in action and values, are harmoniously grouped, we have a picture which is "attractive to our moral nature in its purity and perfection"—which is Ruskin's idea of a beautiful thing.*

As to how—pains, infinite pains. "For every one that asketh receiveth, and he that seeketh findeth, and to him that knocketh it shall be opened."

I fancy the best way is to portray what you see suggested. A man whose eyes are open, on the street or at home, will be constantly seeing new and interesting groupings and actions which are worthy of reproduction by the camera. Not that he can carry around a shot-gun camera and pull the trigger every time he sees something interesting; but in seeing an interesting group he shall set his inventive faculties to work, and bringing the composing elements together at the favourable time shall, with mature study, produce an unstudied effect.

As for portrait groups, as our lenses are now made, I don't see how one can avoid taking the licence of having most of the individuals looking at something not visible in the picture, as a group of profiles or people without eyes (looking down) is to my mind stupid.—*Wilson's Photographic Magazine.*

PHOTOGRAPHY IN GERMANY.

BY DR. H. W. VOGEL.

Photography in Natural Colours Again—Red Glass for Dark Rooms—Ready-Mixed Developers—How much Gold and Silver is used in the Printing Process—Recovering Gold from the Sulphocyanide Gold Bath.

Veresz' photographs in natural colours are still the daily talk. In regard to their durability I have given already my opinion. But one question seems to me still more important, that is, the resemblance of the colours to nature. Having been previously without the originals, I was not enabled to give a decision.

In the meantime I have obtained from the inventor Veresz a new photographic picture with the original, and I am now in the position to give a positive criticism about the natural resemblance of the colours. This refers only to the picture on paper which at present is before me.

The original is one of those transparent window-pictures in bright colours, brought into market by Grimme and Hempel, in Leipsic, as a substitute for glass painting. It represents a Cupid with yellowish brown hair and wings, and a small blue scarf around the waist, whose ends wave in the wind. He carries an arrow piercing two hearts of ruby colour; between the knees he holds a quiver with yellow ornamented opening, and in his left hand the upper part of a large brown cross-bow, with blue and yellow mountings, the lower part of which rests, with the figure, upon an idealistic thistle blossom of red leaves. The stem is of the same colour, and the plant shows fresh green leaves. The picture has a pale-blue background, and red, green, and yellow ornamentation around the border in very pronounced colours.

This border ornamentation affords an excellent means of comparison with the print. The latter, in opposition to the bright original, shows a greenish-grey, partly dark ground. At first look, one recognizes readily that of all the colours only the red of the original has been distinctly reproduced. But it is not true to nature; it has a copper-red colour, and differs decidedly from the vermilion and carmine red of the original. Besides this copper-red only the blue of the scarf and the mountings of the cross-bow and quiver come out as a very pale light blue, with no natural resemblance: the black lines of the border decoration appear alongside of this as a violet black. These are the tones which, to some extent, have a similarity of colour, but with the other colours it is not so favourable. The yellow squares and green trapezoids of the border decoration appear neither yellow nor green, but have a greyish-red tone. The blue fields are not blue, but greenish-grey like the ground.

It is most singular that several parts are reproduced in red—which actually are not red, but brown-yellow—as, for instance, the hair, the wings, the cross-bow, and the thistle. The green leaves in the print show no fresh colour, and

the red leaves of the blossom and the body of the Cupid show only a pale flesh-colour.

It is also remarkable that the thin lines of the shadows (black in the original) appear red in the print, even in those parts not coloured red; while the broad black lines, as remarked above, are black.

The resemblance of the new photographic pictures to natural colours is therefore not very favourable. Only two colours can be recognized distinctly in the copy, of which the red is the best, in a less degree the blue, which is weaker as far as the picture is concerned. The blue in the ornamentation around the border and all other colours either have not been reproduced at all, or are entirely unlike the original. It is possible that these discrepancies did not appear so prominently in the previously-described glass pictures, whose colours were decidedly more lively. I have no proper data at present to make a comparison to decide this question.

If I compare the sample before me with the pictures I have seen in 1867 of Niepce de St. Victor, Becquerel, and Dr. Zenker, I must confess that those much older productions were richer in colour, although the tones deviated likewise considerably from the natural ones. An essential progress I can therefore not recognize in the present pictures. But after all it is good to revive the problem, and thus animate to further experiments.

If other scientists, like Dr. Eder and Eugen von Gothard, express themselves more favourably about Veresz' photographic pictures, the reason may be that they have not seen the older productions, which I have.

Recently repeated complaints have been made about the coloured glass for dark-room lamps and windows, which are not without reason. Every dark-room glass should keep back that light which acts strongest upon the plate. This is particularly the blue light for ordinary plates, and the green and green-yellow for colour-sensitive plates. This is avoided most completely by a suitable glass of red, copper-flashed. It must not be too thin, of course. We have seen red glass lately which was so thin that a considerable part of green light could pass through. By looking through the spectroscope this defect could at once be detected, and I made the remark some time ago, that all glasses which we use for the dark room window should be tested spectroscopically. This can be done easily by anybody.

It has been proven that screens cut from the same sheet are not always alike. Some of them are correct, others are too thin again. To overcome this defect once and for all, and to furnish all buyers the certainty that they get good glasses, behind which the plates will not fog, the dealers should sell only glass which has been tested. Even if it is a little more expensive, the loss caused by bad and fogged plates is much higher.

At the Royal Technical High School we apply a pocket spectroscope, which can be had at the moderate price of 36 m. from Schmidt and Hoensch, opticians, in Berlin. This is focussed by drawing it out until the celebrated Fraunhofer lines can be recognized distinctly. Placing the red glass to be tested in front of the same, it should admit only red light; all other light should be absorbed. The only correct glass is copper oxide flashed glass. The red gold glass, which resembles the other very much, is not suitable—it transmits a considerable quantity of blue light.

Now, if the glasses of a weak red or gold red are a bad thing, the glass combinations of green and yellow should be discarded entirely. Besides the green they will transmit even greenish blue, and cannot be used even for ordinary plates. The combination of green and yellow is just as objectionable, as it will darken the laboratory in an extraordinary manner.

With an actually good red glass, ordinary and even colour-sensitive eosin silver plates can be developed. Only for red sensitive azalin plates it should be recommended to subdue the light somewhat in the beginning of development, and to keep the plate as much as possible in the shadow.

For several years ready-mixed developer, which is also sold by the dealers, has been in general use. This has also been done at the Royal High School. Lately it has been demonstrated that old developer, even if not used previously, will easily give silver glossy fogs, and this is particularly the case with the hydroquinone developer. This fog is also obtained if by accident some fixing soda should come into the developer. It can be wiped off with the fingers, but it is always disturbing. Eikonogen developer is always kept in separated solutions, as is well known. We do the same with the hydroquinone developer—that is, we keep the alkali (carbonate of soda) and the hydroquinone by themselves, and mix them shortly before use. After use, we keep the developer three to four days, and prefer to apply it for over-exposed plates.

About the consumption of gold and silver in the positive process, we had lately an interesting discussion in the *Verein zur Förderung der Photographie.*

The chairman reports, according to tests made by him and the experiments published in his text book, that if the silver bath has been freshly made, 2·6 grams will be used per sheet, but that by a continued strengthening of the bath the consumption will decrease to 2 grams. This, of course, was at a time when the paper was strongly salted. At present, when the quantity of the salt amounts to only 1 per cent., 1·2 gram of silver is consumed per sheet.

Mr. Haberlandt reports that in former years he used less silver, but that at present, in consequence of the many complaints made, the paper is again more salted, in consequence of which the consumption of silver per sheet would come to 2 grams. Mr. Bouck uses on an average 1·25 gram per sheet.

Mr. Haberlandt remarks that thinner baths, weakened by use, will make the paper fibrous. Mr. Vogel, Jnr., ascribes this to the circumstance that the albumen is not sufficiently coagulated by a weak solution of nitrate of silver.

About the consumption of gold, the chairman reports that 3 c.c. gold solution (1 : 50) are used per sheet at the High School.

Mr. Haberlandt dissolves 5 grams chloride of gold in 700 of water, and uses 4 to 5 c.c. of this solution per sheet.

Mr. Bouck used 20 grams chloride of gold per ream; therefore, per sheet about $\frac{1}{25}$ grm.—that is, two-thirds as much as at the High School.

Another subject of discussion was the precipitation of gold from old sulpho-cyanide gold baths. Sulphate of iron is not suitable.

The magnesium powder proposed by Mr. Haberlandt for this purpose would not work, but oxalate developer precipitated the gold to a great extent by heating.—*Anthony's Photographic Bulletin.*

TRUTH IN PHOTOGRAPHY.

BY H. COLEBROOKE.

There is a saying that "The noblest study of mankind is man." This seems to be one of those generally accepted truisms which needs no argument to convince anyone of its truth; and this truth, I think, should be still more patent to photographers, whose work is to reproduce in the form of photographs this noblest study, with all its characteristics and various aspects.

Many writers of the present day seem to resent as cant the necessity for absolute truth in a photograph, looking upon it as generally inconsistent with the necessary pleasing qualities. The author of "Modern Painters" says: "Some art is meant to teach and not to please," but of course this cannot be said to apply to photography, or rather, cannot be reconciled to business; but the same author says also, "Inferior art omits or changes all that is ugly," and this is the rock on which these writers split; one side insisting on truth in all its ugliness, the other insisting on the removal of the ugliness.

I think it should be necessary, before deciding such a point, for a man to prove to himself that he knows what ugliness means, and of what it consists. Let him look upon mankind as a book open to him to study—a study so free from monotony that it must be pleasing to all, and yet wider and deeper than all other studies. Let him realise that all men are not alike; that each and everyone has within him a something differing from others, this something being the very germ of the man, without which he becomes a nonentity. No two men see alike in all points, for they see with different eyes; no two men think alike in all points, for they think with different brains; and in all points where this difference is manifested this something is manifested also, and this something has a name that many use, yet of which few realise fully the meaning—individuality.

It is obvious, then, that if we want to *know* a man we must use comparison, not looking for those points familiar to us in other men—which we naturally do—but for those points wherein he differs from *all* men. I do not pretend that there is a possibility of any man mastering such a study; on the contrary, I should say that few get to any depth, and that the position of the deepest is as a shallow lake compared with an unfathomable ocean. Yet let the knowledge gained be never so small, it is priceless to the photographer. It teaches him to grasp somewhat the meaning of a face; ugliness becomes something more than the mere opposite of beauty; beauty contains more than colour, outline, or expression; truth means more than the harsh outline of ugliness; while every line and feature breathes out something that proclaims *the* man as distinctive from *a* man. The deeper into this subject the photographer goes, the wider and more acute becomes his vision, until at last it dawns upon him that truth is not incompatible with beauty. Each detail of a face becomes of significant value, and, naturally, the more the value increases, the less anxious is he to part with it; but, at the same time, as his knowledge increases, these details resolve themselves into positions of more or less importance, which he carefully enforces or reduces according to their degree of importance.

It is decidedly useful for a photographer to have a knowledge of the bones and muscles of the human frame, but it is decidedly not useful for him to possess a diagram, either literally or mentally, by which to correct all mistakes Nature has made according to that diagram. Human nature is contradictory, and refuses to be reduced to a table or chart (and herein lies the fallacy of attributing, *absolutely*, to certain shaped heads and faces qualities differing with that shape). The student must invest each anatomy with individual life, and seek a purpose and significance in those very points his diagram proves to be incorrect. Let it be understood I do not speak of malformation or disfigurement; these, it is true, possess a decided significance—so does a black eye—but a significance not necessary to individuality, or the reproduction of individuality in a photograph. This statement, however, requires a little qualification. Because a man is deformed, it need not be essential to enforce that deformity in a photograph; but to untwist a twisted neck, to balance a one-sided face, or to straighten a crooked nose, is to produce an absurdity, because it does not exist. Let the photographer conceal what he pleases, for that is part of his art, but let it be truly and only concealment. Take, for example, a person one side of whose face is deformed, By turning the deformed side away from the camera it does not appear in the photograph; yet it still exists. Such means are legitimate, because it is not altering nature, but showing her best side; in other words, not destroying, but concealing ugliness. To cut and pare a man according to a model is to prove one of two things—either a conviction that all men should be alike, or that the photographer is working against conviction—that is, doing what he knows to be wrong; and a man working against conviction is a half-hearted creature at best.

To begin at the beginning, the human race represents a whole which is split up into many parts; first, say, nations, each of which possesses some characteristic points that distinguish them from the others. These in turn are divided, sub-divided, and divided again into degrees, orders, classes, and families, each claiming some distinguishing mark, until we reach the individual. A comparison might be made to a peal of bells of such number as to allow an incalculable number of combinations and changes; the whole human race being represented by the peal, the many types by the groups of combinations, and the individual by the incalculable changes. Now, it follows that as the brain of man cannot receive anything incalculable, he may grasp an idea of the many types or groups of humanity, yet certainly not the faintest of individual humanity.

Dickens is said to have drawn all his characters from life, and the chief fascination these characters possess is, I think, that, apart from the actual story they tell, they present types of humanity that all are more or less familiar with, and therefore are accepted by all as a reality. A photographer has to present an individual, and therefore has less to do with type—which will manifest itself to a certain extent—than individuality. He must, therefore, free himself from all classification, and deal solely and only with the individual before him as apart from the whole race. If he can do this he can realise that absolute truth is essential, and will characterise as balderdash any attempt to prove otherwise.

The face is naturally the chief study. The figure, of course, possesses many important points, more in action, less in repose; but in either, the photographer has less scope. There is much in a movement or gesture, but until instantaneous photography becomes practicable in more senses than one in the studio, the portrayal of such is impossible. The face has been called the index to the mind, and what greater study can there be than this? Let the photographer study outline and form, and classify them if he will, but there is a subtle something shown by this index that defies classification and beggars description, breathed out by and impregnating every line and feature. What stronger argument can there be for absolute truth?

Let those who would excel, study their fellow-men, and strive to fathom their minds and thoughts. Let them seek bad qualities or good qualities, it matters little—one will manifest the other. Let them only desire to reproduce what they see and understand, and, though much of this be impossible, the result will certainly elevate all that it is in their power to reproduce.

What is a beautiful landscape to an uneducated eye, and what would a picture of that landscape be produced by the owner of that eye. So it is with a face. A man is dead to outward beauty until he receives sight, and even then he requires education before he reaches a full appreciation of what he sees.

In conclusion, I quote from a comic paper—there is many a true word spoken in jest—the following lines, as an instance of a good deal of sense contained in a very small space: "To know others, study thyself; to know thyself, study others."

London and Provincial Photographic Association.—Subject, August 14th, further adjourned discussion (third evening) on "Printing under Coloured Media."

THE METRIC SYSTEM IN PHOTOGRAPHY.

BY W. H. SEAMAN, M.D.

A priori the units of the metric system are just as easy to form thought elements as those of the other, and, when formed, the translation required is from the English units to the metric for comprehension, and not *vice versa* as assumed. This is the case with most of our German friends, who form no small part of our scientific population. But, farther, the metric system is used by the whole civilized world, except English speakers, and among the latter is used by all chemists. It is actually in universal use by chemists throughout the world. This is a good reason why all arts dependent on chemistry should use it, such as photography, medicine, and pharmacy; and it modifies the personal equation, because most English chemists think in grammes. In my own case, I always translate the English units, not the metric. I know many chemists and physicians who do likewise.

It may to some look like an extravagant statement, but it is simple truth, without exaggeration, that the English system is a relic of barbarism which impedes general education.

It has been calculated by teachers, published by the Metric Bureau, and never traversed in the writer's knowledge, that the substitution of the metric for the ordinary system would save a year of the school-life of every child. What labour-saving machine ever invented is equal to this? There are about fifty factors to be memorized in our system. In the metric but one; and this is the same as our ratio of notation. Hence, as a practical matter of education, the whole time spent in learning by heart tables of weights and measures is wasted.

In a piece of work now in progress here, in which a comparison of many analyses is required, in which the results have been mostly published in some form of the old system, because of supposed public utility, it will cost hundreds, if not thousands, of dollars to bring them into a common form adapted for mutual comparison with each other. Precisely the same confusion exists in photographic formulæ, as the writer well knows from a late attempt to compare a number. Mr. Wallace's article cites the unity of minim and grain as an advantage, but it is the sole instance of correlation between weight and measure in the old system, while every measure and weight corresponds in the metric. Why use a bad thing when a good one is at hand?

I think very few chemists, at least of the younger class, would accept the statement of "uncertainty in rapid calculation." On the contrary, it is the metric system that would be preferred, because of the greater rapidity and certainty of calculation.

Definite ideas of weights and measures come by actual use, and not by thinking about them. And if the use is begun early in life, the idea is formed more easily and perfectly than when commenced later.

Our professional schools are responsible for the continued toleration of the "American" system. At the present time nothing but the metric system should be taught in such schools, and every druggist should be required to possess a set of metric weights.

This would not interfere with the practice of those too old to change. The old system is well called the American system. No other nation uses it. The Imperial pound and gallon are the officinal measures of England, and the pound troy is no longer in English text-books, while the Winchester or American gallon disappeared long ago. When we use imported measures or graduates, they are not the same as ours.

A small part of the metric system suffices for the photographer. The following table represents a form the writer has found well adapted for professional students:—

1,000 millegrammes make one gramme.
1,000 grammes or cubic centimetres make a kilo or litre.
1,000 kilos make one ton.
65 millegrammes make one grain.
15½ grains make one gramme.
31 grammes make one ounce troy.

The last table is only because of our present transitional state. Millegrammes, grammes, and kilos are weights, and the metric ton is 2,204 pounds, between our long and short ton. Cubic centimetres (usually written c.c.) and litres are measures. The actual weight of any measure of liquid, if its spec. grav. is known, is got by multiplying the corresponding weight by the s.g.

In writing metric formulæ, the point should stand between the grammes and millegrammes. Three figures on the right of the decimal point are millegrammes, all on the the left grammes. In the arts the millegramme is never divided.

The present Pharmacopeia uses parts by weight. The Washington Camera Club prints its formulæ in parts per hundred, thus:—

Hydroquinone ... ... 2·25 per cent.
(In metric terms it would be 22·500.)
Sodium sulphite, C.P. ... ... 10 per cent.
(In metric terms it would be 100·000.)
Distilled water ... ... 87·75 per cent.
Make up to one litre.

POTASH SOLUTION.

Potassium carbonate, C.P. ... ... 15 per cent.
(In metric terms it would be 150·000.)
Sodium sulphite, C.P. ... ... 10 per cent.
(In metric terms it would be 100·000.)
Distilled water ... ... 75 per cent.
Make up to one litre.

For use dilute No. 1, half, add 3-6 drachms, or 10-20 c.c. potash.

The change from per cents. to grammes needs only a change of the decimal point. Hence no advocate of the metric system has any objection to a percentage system. Duplex graduates are for sale with c.c. on one side and fluid ounces on the other, and the c.c. are good for percentage. Chemists generally make up their formulæ on a basis of one litre, *i.e.*, 1,000 c.c., as a convenient quantity.

Another change that seems to be greatly needed in the mode of stating photographic formulæ is to give the strength actually used, and not that of the stock-bottle. Every man with brains enough to be a photographer at all, can make his stocks of a degree of concentration to suit his convenience, or the size of his bottles. What must be known is the strength of the solution actually applied. Much space would thus be saved in description, and different formulæ could be compared directly, which now require many figures. Thus the Washington formulæ as used is half the given formulæ. Or the water can be doubled.

I am pretty sure that anyone who will actually use the graduates and weights of the metric system in compounding solutions for a short time (not attempt to translate equivalents) will soon find them satisfactory.—*The American Journal of Photography.*

Notes.

Owing to American legislation and other influences in relation to silver, the price of nitrate of silver has been varying of late, and is now high as compared with prices of recent years. New sources of supply of the metal are coming to the fore, and if they increase may possibly have some little influence on the cost of nitrate of silver in the future. At the metallurgical and mineral exhibition now open at the Crystal Palace is a vast trophy, silvered outside, and reaching nearly to the roof of the building, representing the output of silver of the Broken Hill Proprietary Co., New South Wales, between May, 1886, and July, 1890, amounting to 16,500,000 ounces. The exhibitors are Messrs. Vivian, Younger, and Bond, of London, one of the principals of which firm we believe to be Mr. Vivian, the well-known copper smelter, of Swansea. Other firms also furnish particulars at the Crystal Palace about their output of silver in New South Wales. The Crystal Palace now looks more attractive, and has less the aspect of faded gentility than was the case some years ago, betokening in its improvement evidence of good management.

Mr. Ferrero is *par excellence* the business man of the Camera Club in matters financial, and displays ability in paying polite attention to those members whose subscriptions may be in arrear. An article from his pen will be found on another page about the new premises of the Camera Club in London, which are in such an advanced state that the girders of the fourth floor are now on the point of being laid. The Camera Club has thoroughly efficient officials, who put their hands well to the plough, and get all work done expeditiously. Mr. George Davison, for instance, is noted among London photographers as a model secretary.

In relation to the ever-smouldering subject of amateur *v.* professional photographers, there has been in this country a marked improvement in tone on both sides for some time past. It is evident, on the one hand, that because many utilize photography as a business is no valid reason for preventing others following it as a hobby; on the other hand, there is no desire on the part of the majority of amateurs to do harm to the professional photographer, but rather to put business in his way whenever possible. Some of the ill-feeling of the past was largely due to the vagaries of individuals of vulgar wealth, who think in their inexperience that money can do everything, until they find to their astonishment that it is no passport to the inner circles of refined society, so try to assert themselves by being as offensive as possible to those over whom they think they can exert any influence. All persons of this class would form good photographic subjects for Mr. Gambier Bolton, Mr. York, and other camera men interested in zoology. There is no more pitiable object in nature than an individual without mental resources or natural refinement, who has been left large sums of money instead of cultured education; such individuals of their own accord go straight to their father, the Devil. People of this class who give themselves airs, are rather more plentiful than is pleasant to those competent to estimate them at their true value.

Last week we spoke of the difficulty in working the old waxed-paper process in the tropics, as evidenced at the Hong Kong Observatory; yet this process has still merits of its own for certain classes of work in meteorological observatories. This week we have received a copy of the official report for 1884 of Mr. W. Doberck, the Government Astronomer at Hong Kong, who says therein: "Unfortunately a large stock of waxed paper had also been supplied by the Secretary to the Meteorological Office, who was not aware that argento-bromide paper had for years been successfully adopted in India. Now the necessity for iodising and sensitising every photographic sheet has caused a deal of trouble during the damp and hot season. The sensitised sheets were found not to keep for two days on the barrel. The sheets had then to be changed every day. Even the iodised sheets did not keep for any length of time. Only freshly iodised sheets could be sensitised with any degree of success, and this added enormously to the labour, a great part of the time of the second assistant being taken up in the work. Even when every precaution was taken, the result was not nearly so good as during the winter. Tannin as recommended by Chambers, was tried, but made no improvement here." At present, commercial argento-bromide paper is used in meteorological observatories.

The packing of dry plates for touring has occupied the attention of many photographers, both professional and amateur, and we have often received letters asking for guidance in this matter. We believe that the best plan to adopt is to allow the plates to remain in their original boxes until they are transferred to the dark slide or changing-box. After exposure, they may be numbered on the film side with an aniline pencil, so that they may be identified before development, and can then be packed film to film with nothing between them, in packets of four, and after being wrapped in red paper can be restored to the cardboard box from which they came. This box should also be wrapped in red paper, fastened up with some gummed postage stamp edging, and labelled with the name of the district in which the plates have been exposed. We have adopted this method for some years, and have never yet had a plate injured, either mechanically or chemically.

Many persons advocate the practice of placing a sheet of paper between each pair of plates, and although this looks plausible enough, and would be desirable in the case of ordinary plates of glass, we cannot approve of it for photographic plates. Common paper is known to be contaminated with substances injurious to the sensitive coating of the plate, but even if a pure paper

were attainable—as of course it might be by using that of which chemical filters are made—then comes in the question of unequal pressure on the film, which leaves a record which is revealed by development. Most photographers have had to learn this by sad experience, and know now that a slip of paper will leave its mark behind it.

There are some good people whom we have read about who absolutely refuse to travel by rail, so firmly are they tied to the traditions of their youth. In the same way, people are met with who refuse to acknowledge the march of modern events, and, in detriment to their own interests, will close their ears to remonstrance. We are led into this train of thought by a letter from a tourist at Deal, Kent—a place which has refused the modern call to "move on." Things go in a primitive way there, and the old town is much the same as it was fifty years ago. However, it has a railway and a pier, and it is about this latter structure that our tourist friend pours out the vials of his wrath. Armed with his peaceful camera and tripod, our friend presented himself at the gate, and the man at the wicket demanded of him the sum of half-a-guinea before that camera could be allowed to pass. Our friend expostulated, but to no purpose; the fatuous authorities had named that prohibitive sum against the entry of such a profane thing as a camera upon their sacred premises, and its bearer had to go away lamenting.

We sympathise with our correspondent, and console him by the information that there is really very little lost by his exclusion from Deal Pier. One or two steamers call there daily, but that is all. The rest of the shipping never get near enough to it to have their portraits taken. We advise him to betake himself and his camera to Lowestoft, where the single payment of one penny will give him the right to traverse the pier for a whole day, with a camera or without. There the sea is alive with picturesque fishing boats, and he will find enough indeed to interest him, and to make him forget the short-sighted policy of the wiseacres at Deal, which drives tourists away instead of attracting them to the town.

There is much virtue in flattery. The photographer who is adroit in paying compliments may expect a large business, other things being favourable. An experienced photographer of our acquaintance says that the first thing towards securing a good photograph is to make the sitters thoroughly pleased with themselves, and the next to make them forget all about themselves. It is hard to say which is the most difficult task. The photographer must be a combination of the courtier and philosopher. He must humour the vanities of his sitter, and be charitable towards them. That man was skilful who, when a particularly austere lady with an expression of iron asked him for how much he would take her, replied, with an engaging air of innocence, "About five and twenty, madam." She was five and thirty at the very least, and she remarked sharply, she did not mean that; but, nevertheless, the muscles of her face relaxed, and she was fairly amiable for at least half an hour.

The foregoing is an example of the sitter being pleased with herself. The proper time for gently inducing this feeling is of course previous to any preparations for taking the picture. Having got your sitter into a pleasant frame of mind, then comes the next operation, the bringing about of the forgetfulness of self. The time for this is when the eventful moment for making the exposure is approaching. Reserve your best story, your most sparkling epigram, your quaintest paradox for this crucial juncture. To carry this off successfully you want to be something of an actor, for there are times when, to use Jack Point's words, "you can't let yourself go;" but if you have successfully accomplished the first condition mentioned, the second will not be difficult. Sitters who are pleased with themselves are not likely to be very exacting.

The detective camera has placed a new pleasure and a new power literally in the hands of the tourist. We are told that a large party of American excursionists lately visited the Parliament House in Edinburgh. They were all heavily armed with hand-cameras, and one of the party, a young man, had the hardihood to take a "shot" at the Judges of the First Division, unknown, of course, to their lordships. We foresee in this the beginning of what may be called a photographic epidemic among American tourists. These energetic ladies and gentlemen are the most systematic and pertinacious of sight-seers. They are always in such a hurry, and are so anxious to "tick" off everything they have got down in their note-books, that they have no eye for the real beauty of scenery or architectural charm, and no time for enjoyment. They are only happy when the sight is "ticked" off. To these the camera will be indispensable. They will use their eyes less than ever. The tomb of Rubens at Antwerp, the Venus of Milo in the Louvre, the headsman's block in the Tower of London, and a hundred other notable things more or less celebrated, will all be "shot" at in haste, and developed at leisure. It is hard to say where the pleasure in this mode of enjoying oneself will come in.

In the opinion of some sensitive people the sale of Gibson's Tinted Venus to the enterprising soap firm for advertising purposes is a degradation of art. This is by no means so certain. The dissemination of copies of a beautiful statue or picture, though the object may be an advertisement, can do no harm. We may expect to hear of the Tinted Venus being photographed from every point of view, as was Focardi's "You Dirty Boy." The photographing of this popular statuette was not an easy undertaking, as to do justice to both the old woman and the boy involved great care and judgment in the lighting. Gibson's statue will be much less difficult.

WASHING PRINTS.

In putting into shape a few thoughts on print washing, I have before me, as a text, an observation of Andrew Pringle, at a recent meeting of one of the London, England, societies, to the effect that prints should be subjected to the action of the squeegee and plenty of elbow-grease, and then transferred to the washer.

It may be taken for granted that the object of washing is to remove all traces of, not hyposulphite of soda, which would do little or no harm, but of the double salt of soda and silver, which, on exposure to light, would certainly degrade the whites, and probably also the coloured silver substance of which the picture is composed, and the question is, how much washing is required for that purpose?

I do not suppose that anyone at the present day considers it necessary to soak the prints for twenty-four, or even twelve hours, as was at one time the almost universal custom, but I know that there are many who still adhere to a needless system of prolonged washing, and needless waste of, in some localities at least, valuable water, and the object of this article is to show such photographers that both time and water may be economized without danger to the prints.

I may say at the outset that the following statements are the outcome of a series of carefully conducted experiments, and may be relied on as being correct, so far as the "trained observer" is worthy of confidence, subject, of course, to the variations incident to all commercial articles.

A sheet of albumenised paper, coagulated by sensitising on the nitrate bath, will absorb half an ounce—four drachms—of water, and, therefore, when after toning and fixing it is drained and placed into the washing water, it carries with it, on the supposition that the strength of the fixing solution was one to eight, just thirty grains of hyposulphite of sodium and silver. If the prints—*i.e.*, the one sheet of paper—be covered with thirty ounces of water, and kept moving about for, say, five minutes, the thirty grains will, in consequence of the diffusion of liquids, be spread over the thirty ounces of water, and if the prints are removed and drained, they will retain only half a grain of the salt. The prints so drained and immersed in another thirty ounces of water, the second charge will, when diffusion is complete, be in a solution of only one-sixtieth of a grain to the ounce, and when lifted and drained, will carry into the third water only one-hundred-and-twentieth of a grain. Repeating the washing process in this way, it will be evident that by the third or fourth change of water, if the diffusion has been anything like uniform, the trace of silver hyposulphite that can remain is so small as to be unworthy of notice.

But theory and practice do not always go hand in hand, and in this case diffusion is sufficiently protracted to make a more than theoretical washing necessary, and the following experiments were undertaken with a view to ascertain just how much more. The sheet of paper, drained from the fixing bath, was placed in a tray, covered with four pints of water, and the prints kept in motion for five minutes. They were then removed and allowed to drain—the last drops being received in a test glass—and again immersed in another four pints of water. Two of the drops from the prints were found to discharge the feeble colour from a drachm of iodide of starch solution. The process was repeated, and this time at least twenty drops were required to discharge the colour. Of the third washing, more than equal parts of drippings had to be added to the test solution before a perceptible effect was produced, and of the fourth washing even three of the drainings to one of the iodide solution showed little more than the effect of dilution, while the fifth water had absolutely no action on the delicate test.

From those experiments, then, I think I am warranted in assuming that ordinary silver prints may be thoroughly washed in six changes of water, at the rate of, say, four pints to each sheet, each change, or twenty-four pints altogether, for each sheet. The changes may be made at intervals of five minutes, and the whole washing be completed in thirty minutes from the time of removal from the fixing bath. Of course that implies a constant movement of the prints during each of the five minutes' soakings, so as to promote, as far as possible, the diffusion of the solution in the washing water.

Those, of course, who can arrange for running water can do much better, and without much trouble. All that is required is to see that the prints are kept separate, and that the water enters at the top of the washer and escapes at the bottom. In such a water, with a flow from a quarter-inch pipe, fifteen minutes' washing will be found sufficient. —H. G. in *The Beacon*.

ENAMELLING.

BY F. TARNIQUET.

Use very clean plates and rather larger than the prints to be enamelled. Wipe them well, rub them with tale, and remove the excess with a soft brush passed lightly over the surface. In a dish, half-filled with ordinary water, immerse the photographs and allow them to soak. This being done, coat one of the talced plates with enamelling collodion in the ordinary way, agitate to cause the ether to evaporate, and when the film has set—that is to say, in a few seconds—steep this plate, the collodionized surface up, in a second dish containing pure water; now take one of the prints in the first dish and apply the printed side to the collodion, remove the plate from the dish, keeping the print in its place with the finger of the left hand, and remove the air-bubbles by lightly rubbing the back of the photograph with the forefinger of the right hand. Care has been taken beforehand to prepare some very pure starch paste passed through a cloth, and some thin cardboards, or simply thick paper the size of the plates used. The air-bubbles having completely disappeared, and the perfect adherence of the print ascertained, dry with bibulous paper, and spread over the prepared cardboard on paper a coating of the collodion by means of a flat brush. Apply this sheet on the print, pass the finger over it to obtain complete adherence, and give it twenty-four hours to dry. At the expiration of this time, cut with a penknife the cardboard or paper even with the print, and detach by one corner; if the plate has been well cleaned, the print will come off of itself. We get in this manner a very brilliant surface, and as solid as that obtained by the use of gelatine, which, as it is seen, is entirely done away with in this process. The prints are afterwards mounted on thick cardboard in the usual way. It is possible, by mixing with the collodion some methyl blue dissolved in alcohol (a few drops are sufficient), to obtain moonlight effects, especially if a rather strong negative has been used. For sunsets make use of an alcoholic solution of coccinine.—*Science en Famille*.

THE NEW PREMISES OF THE CAMERA CLUB.*

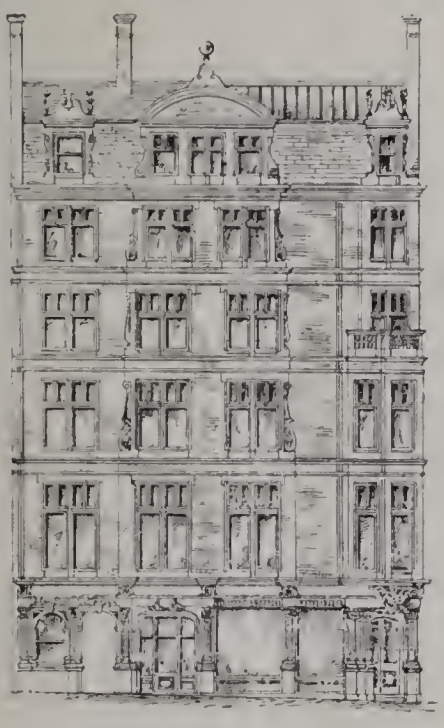
BY E. FERRERO.

The new club-house is being built according to plans prepared specially for the Club. At the outset a plan of the ground was given by the lessor to the new premises sub-committee (who had the fortune to have amongst its members an architect in Mr. J. Gale), and the plans prepared and proposed on behalf of the Club were substantially accepted by the lessor's architect, Mr. F. T. Pilkington.

In making the arrangements for the building, the committee gave their first consideration to the requirements of a photographic club, and it will be seen from the set of plans sent with this number of the *Journal*, that ample provision has been made for them. It was decided to have a number of separate dark rooms as well as a larger room, where work not requiring the absolute exclusion of white light could be carried out. Then a studio and an enlarging room were provided for. A large well-ventilated room for meetings was also considered a first necessity. Then the claim of the honorary librarian to a good room in which the collection of books could be displayed and used to the best advantage had to be considered, and the second best room was devoted to this purpose. Finally, a workshop was provided, which will be fitted with a table, cabinet-maker's bench, and a complete set of tools, which have been kindly presented to the Club by Sir David Salomons.

Having thus supplied all the possible wants of photography, it was decided to use the remaining space to provide on a moderate scale the usual attractions and conveniences of a social club. How far the committee have succeeded in their endeavours to give the Club as useful and comfortable a home as circumstances would allow, will be seen from the plans, and we now propose to take our readers over the whole of the premises.

The building is situated on the south side of Charing Cross Road, London, at the corner of Cecil Court. It is



of red stone and red brick, and it has a frontage of 51 ft. on the Charing Cross Road, and 50 ft. in Cecil Court.

* From the *Journal of the Camera Club.*

The entrance to the club is near the left corner of the building. On passing the glass swing-doors, the porter's lodge will be found on the left, and beyond that a stone staircase leads to the floors above. We will, however, proceed first to the basement. On reaching the bottom of the single flight of stairs, we find on our right a room containing the furnace, which will supply hot water to the whole of the house, and, beyond that, the servants' lavatory and dressing-room.

The second door on the right leads to the cellars. The passage from which these doors open will contain a number of lockers, where members can keep their photographic materials. Turning to the left we enter the daylight work-room. This is lighted from the roof, and will contain a sink, extending along one side of the room, with a number of taps for cold and hot water. This room is intended for washing negatives, developing platinotypes, toning, and all other operations not requiring a dark room. Opposite this room is a long passage, giving access to nine dark rooms, which will be provided with good ventilating arrangements, and lamps encased in concrete, so as to minimise the radiation of heat.

Proceeding to the first floor, we find on the left of the landing the cloak-room, whilst the door on the right leads to the still-room. Opposite the staircase is the entrance to the principal room, a handsome hall, 43 ft. by 26 ft., and 14 ft. 6 in. high. Special provision has been made for the ventilation of this room, and the manager of the optical lantern has obtained his heart's desire in having a space of the wall, 9 ft. square, painted white, in place of a movable screen, for showing slides.

Above the cloak-room a mezzanine has been arranged, which provides further accommodation for hats and coats.

On the second floor a third cloak-room, with lavatories, is provided. The passage leads from the landing to the dining-room on the right, the billiard-room on the left, and to the library at the end. The height of this floor is 12 ft. On the third floor the building becomes much shallower. A corridor similar to the one below leads on the right to the committee and secretary's rooms, on the left to the leads above the billiard-room (which leads will have a trellis floor, and will be useful for printing), and finally to the workshop or lathe-room.

The fourth floor is entirely taken up by the kitchen and other offices, and a bedroom and a living-room for a resident servant.

On the fifth floor is a good enlarging room with a dark room attached, and a fine studio 27 ft. long by 16 ft. wide, with a dark room.

A lift large enough for carrying coals and communicating with each floor from the basement to the kitchen will be provided, also speaking-tubes and electric bells. The house is to be wired for electric light, and a sufficient sum has been provided for the decorations, which will, however, not be added until next year.

The fitting and furnishing will now occupy the attention of the committee, and suggestions from members are invited, and will be carefully considered.

Phospho-boric Glass for microscopes is a new kind of optical glass, which contains phosphoric acid and boracic acid, and is designed specially for the construction of object glasses. It is asserted that by means of this new glass, lately produced in Germany, an object possessing no more than the one-eight-hundred-and-twentieth part of a millimetre can be distinctly recognised.—*The Monthly Magazine.*

PHOTOGRAPHY IN NATURAL COLOURS.

BY J. GAEDICKE.

Our present time is so much imbued with sensational novelties, that it leaves hardly any time to the normal development of science, and it gathers already, precipitately, the discoveries of future days. So it is with the photographic reproduction of natural colours. A notice passed through the journals, according to which the problem of colour-photography had been solved, and that the honours of this invention belonged to a photographer in Klausenburg, Mr. Veresz. But a close examination reveals the fact that said photographer has done nothing more nor less than what was already published by Niepce de St. Victor in 1852, and Poitevin and Simpson in 1866. He cannot show the least progress, as his preparations are much less sensitive, and the pictures are much less durable than those of his predecessors.

The practical significance of the matter and the progress may be sufficiently estimated, considering the necessity of exposures of "several weeks," and a fixity which had not been shaken "after lying in a lighted room" for several hours. In the face of these exaggerations of the Klausenburg accomplishments to the solution of the problem of colour-photography, and the fact that by such manœuvres the public is only led astray, it seems in order to recapitulate in a few words what has already been accomplished in the above-mentioned field.

The first observations about the printing of a coloured spectrum upon chloride of silver were published by Dr. Seebeck, in 1810. Sir John Herschel made also mention of colours upon chloride of silver in 1839.

Becquerel was the first who obtained a spectrum with all colours. After having been occupied with this matter since 1838, he presented, in 1848, his first report to the Paris Academy of Sciences. He employed a highly-polished silver plate, which, fastened to the positive pole of a battery, he immersed in diluted muriatic acid (1 : 8) and passed a platinum wire, connected with the negative pole, into the solution. The silver plate became tarnished by absorbing chlorine, and took up gradually a number of colours. By prolonged action there was a repetition of the colours, these representing the number of the second degree. He continued this until he obtained a colour number of the fourth degree, whereupon, later on, according to experience, the most brilliant colours developed. Becquerel determined also the quantity of the chlorine which was taken by the plate by inserting a voltameter, and measuring the hydrogen gas developed in the same, which gave the quantity of the utilised chlorine. He determined that the best results are obtained if about 6·5 c.c. hydrogen per square decimetre of the plate are absorbed. Becquerel found further that, if the chlorinised plate was exposed for a longer period to a temperature of 30 to 35 degrees C., it would give much lighter colours, and that the action of the temperature can be matched by exposing the plates under a combination of ruby and cobalt glass for one to two hours to sunlight. The film becomes hereby dark violet, and is bleached in the camera by white light, and is coloured correspondingly by coloured light. The colours appear here light upon dark ground. In the camera one has to expose for several hours with a very bright light, and the pictures so produced are said to be visible in the dark, while they disappear gradually in light. Herschel reports, in 1855, that a coloured spectrum picture which he obtained from Becquerel, but which he kept in the dark and examined only by lamplight, was not decomposed after several years, although it had bleached a little.

The next progress in colour photography was made by Niepce de St. Victor, who presented his investigations about this subject in 1851 and 1852 to the Paris Academy of Sciences. Niepce used also silver plates as a basis, but simplified the chlorination by using baths containing chlorides in place of the galvanic battery, and found that additions of certain flame-colouring salts increase the capacity of reproduction of the corresponding colours and the sensitiveness. As the best of chlorinizing means he used a mixture of chloride of magnesium and sulphate of copper. Afterwards the plate is heated until it shows a bright red colour.

In this way he obtained camera pictures in fifteen to thirteen seconds in the sun, or sixty seconds in diffused light with rapid objectives. The durability was also increased by Niepce by applying for fixing a solution of chloride of lead with a subsequent coating of tincture of benzine. At the Paris Exhibition of 1867 there were heliochromic pictures, produced by Niepce, which, according to the records of the French Photographic Society, had kept well preserved during the seven months' exhibition, and which suffered only a little in the brilliancy of the colours. The pictures were exhibited in a case, which was opened for inspection, and then closed again.

According to Niepce, the spectrum colours will appear truly, while the pigment colours do not appear always in the same shade. Emerald, for instance, or arsenic copper, shows green, but a green mixture of chrome yellow with ruby blue will come out blue. Orange produced by yellow and red glasses placed together will print as red.

In 1866 Poitevin appeared with a new heliochromic process, in which he used paper as a support. He floats plain paper on a chloride of sodium solution, and after floating on the silver bath, washes with water in a dish, and pours into the last water a solution of chloride of tin, exposes the dish to light, and lets the paper become dark violet in from five to ten minutes. He washes now with water and dries in the dark. The paper is now made sensitive by immersing the same in a bath consisting of an equal volume of a 5 per cent. solution of bichromate of potassium and a concentrated solution of sulphate of copper, after which it is dried.

Under a coloured diapositive this paper will give, exposed for half an hour to the sun, or for one and half days to diffused light, a clear coloured picture upon dark ground.

Poitevin obtained also coloured pictures with collodion. Simpson produced in 1866 coloured-light impressions upon chloride of silver collodion by printing under aniline colours and coloured glasses.

Saint Florent communicated to the French Society of Photography, in 1882, his process for producing colours photographically upon paper.

During later years a more extended research was published by Carey Lea, in which he designates compounds of chloride of silver with very little chloride of silver as photo salts, and proves that with different descriptions of chloride compounds different colours will originate.

The final result is, that twenty years ago we were more advanced regarding the sensitiveness and durability of the products than Mr. Veresz is at the present day, and that there is no reason yet to consider the problem of photography in natural colours as practically solved.—*Photographisches Wochenblatt.*

HOW TO MAKE A GROUP.

BY CHARLES P. MARSHALL.

"How to make a group." One might as well ask how to compose a nocturne, or try to describe the process. The art of composing must be inborn; it is a gift. No amount of art education will develop what is not there.

One may learn to imitate, but does he compose? He may vary another work, yet is it composition? However, there are a few conscientious persons who can look upon another's composition, and, without trespassing, use the variations of some well-known principle set forth. On the other hand, there are many who, without scruple, literally copy mass for mass, and line for line. They create a new title, and with great aplomb dash in their autograph. Is such an act a composition? No, it is not. Then it smacks very much of plagiarism.

We often borrow from another when we think we do not. Friends of the craft, be on your guard, lest in your picture, when deeply interested, you thoughtlessly incorporate another's idea. Watch your work, that the fruit of another's toil creep not in. In your admiration for some choice passage you may unconsciously borrow it, thinking it your own, because it so thoroughly coincided with your taste. The above is written from experience.

It is difficult for the young artist to produce a meritorious composition, all his own. If he has devoted only a year to picture-making, then he lacks experience; and if he finds that the latent composer is not within him, better seek another vocation.

The reader will please consider what has just been written as simply observation and experience, and not a tirade against the fraternity.

How many of us in our younger art-days have passed through a similar experience. How many of us can look back to a heterogeneous mass of light and shade, our first picture, and recall the trials, struggles, and disappointments over that first effort, and many subsequent ones. In our crude manner, how we gauged our production by the work of some well-known artist of repute—not in principle, but in minutiæ. Disappointment seized us if we could not lay our ideal over our own work, and make it coincide in light, shade, and line. We were too apt to give the greater share of our study to certain little points, which, in reality, were only individualisms. We omitted to search out the principle of our ideal, and hastened on to study detail in finish.

We tried to saturate ourselves with someone else's individuality; that is how so many of us drifted into plagiarism. When we step out of that rut only can we progress. Study the principles in other's works, but let alone their individuality. Is your own not worth cultivating?

Education of the eye is the pivotal point in picture-making. But to educate the eye takes time. It cannot be done in one year, or two, or three, or four. Don't expect too much within a period of seven years. And before this, one should be well schooled in the alphabet of art; that is, should be able to draw well, understand colour, harmony, and artistic anatomy. All this is simply getting your tools together.

The eye becomes educated when you are thoroughly conversant with them; when you can look at a picture and fully understand it, without the necessity of revolving in the mind all the rules of proportion, balance, line, breadth, and perspective; to speak vulgarly, when it becomes "second nature."

We have thus educated the eye sufficiently to start with; now let the young artist turn his thoughts to a composition. First choose something thoroughly comprehended—let us say a small group. Select a situation from something you have actually seen, not what you have observed in some one else's picture. In making choice of a subject, choose one where the story can be well told without difficult arrangement. Think it all out before you attempt the first thing. When you have mentally digested it, then you may trust it to paper. Sketch in first a general outline, then lay in with stump the great masses of shade. Every stroke will offer a new idea. Gradually give your sketch more form. At this point, if you decide that a radical change is better, start a new sketch, only improve it in form as compared with the first.

Now, once more take the stump, and, with more ease, mass in your shade, carrying it somewhat farther toward good form, then sketch number one. (Never destroy an original sketch; you will prize it in the future as a valuable note.) Compare your two sketches; be harsh in your criticism; sit in stern judgment on your work; always be ready to *cut out* rather than *add to* a composition (I refer to accessories). Many a good production is spoiled by a so-called *coup de grace*, which literally *was* a *finishing stroke*. Stop where you are for awhile; take several days to think what you have done; something may present itself to alter your ideas.

We will now consider your main plans as permanent. Now make as fine a drawing of your picture as you possibly can. Make notes of the time of day necessary to proper lighting, of age and size of models, of accessories needed. If your models are not too young, always instruct them as far as you can all about the picture. Many children, and most grown people, can get a pretty good idea of your picture and the *rôle* they are to play, if you will take pains to carefully explain it to them. Under these conditions your model will be enabled to assist you. If your model does not understand *why* you place him or her in such and such a position, why you ask for such and such an expression, then he certainly cannot perform his part naturally. What to you may seem a bright idea, to him will appear silly and affected, and the brilliant situation you had in mind will be rendered in burlesque. In choosing models, never take one that is shy, for no amount of coaxing will overcome it. Choose a willing one, though he be made of pepper and snuff.

One or two rehearsals is always best; it imparts more to the models than simple words without action. Avoid fatigue by giving long positions. In short, I consider these rehearsals as indispensable, because the novelty of the situation must wear off before you can get the best effort from your models. Even when your models are not around, it is well to rehearse your accessories, more particularly the lighting. By a thorough study of *this* point you are enabled to light the model better. Remember that in most compositions you are seeking a harmonious whole, and not the individual lighting of any particular face or figure. Here you must lay aside portraiture lighting, for you are about to tell a story in light and shade, to illuminate many objects, and not to produce a picture all in one face.

You are now ready for your final work—lines decided upon; time and lighting in mind; and models in place. It is expected at this point that you are thoroughly satis-

fied with all arrangements (size of picture, elevation of camera, lens necessary—rapid long focus variety—distance, and kind of plate.) Now bring out your camera, and not before. Remember your camera is a whole set of instantaneous drawing pencils, stumps, blenders, parallel rulers, proportional dividers, and paper; the picture is in you, in your mind's eye, not in the camera-obscura. Never torture your subject by doing your work on the ground-glass; fetch it forth only when all is ready. Carefully but quickly focus, the critical moment arrives. If you thrash around, and dance all over the room, squinting this way and that, you will upset your model's choicest effort. Stand by the "casel," the camera, where the picture is about to have birth. Now you are a manager, with so many actors before you. In gentle voice, give your final coaching; wait a moment for it to take effect. "Still now, please;" remove the cap easily and moderately slow; it will be less observed by the models; your heart beats in sympathy as the seconds slowly pass, and if your magnetism has gone out with your kind words, then you may hope for a successful "group."—*Wilson's Photographic Magazine.*

ALUMINIUM IN THE CONSTRUCTION OF PHOTOGRAPHIC APPARATUS.*

BY ERNEST SEYD.

In 1856, according to Maugin, the price of aluminium in its metallic state was about £5 10s. per grain; its present price, owing to the exertions of the Aluminium Company, has been reduced to 6s. per pound, and the value of the pure metal is being slowly recognised in this country by the makers of philosophical apparatus where extreme lightness combined with strength is required. Aluminium can now be obtained in sheets, bars, or drawn tubes, and, from its extraordinary ductility and tenacity, wire as fine as a hair can be produced. Its specific gravity is 2·56; the metal fuses at a dull red-heat. It is asserted that cannon have been made from it, and it is known that the Emperor William III. had a suit of armour constructed entirely out of the pure metal.

To those members of the Camera Club who combine a mechanical genius with the lighter labours of the hand camera, and who may be debating within themselves the possibility of constructing an apparatus which shall combine *all* the perfections claimed by the different advertisers, with *none* of the imperfections invariably discovered afterwards, a few words on the working and adaptability of the metal may not be unwelcome. Aluminium should be turned on the lathe at a quick speed with a very low-angled tool, and, to avoid the clogging that takes place, paraffin oil may be used freely as a lubricant. It will not stand too much hammering, and cannot be soldered, and although the Aluminium Company are, it is stated, about to bring out a receipt for this purpose, it may be doubted, with justice, if the same satisfactory results will be achieved as in the case of other metals and alloys.

Aluminium, being nearly four times lighter than brass, and almost as strong in proportion, its adaptability for large cameras is unquestioned. It has no effect upon silver salts, and is quite unaffected by damp; does not tarnish; and, with the exception of hydrochloric acid, remains unchanged in the presence of the strongest acid fumes. Messrs. Beck, of Cornhill, show some lenses, where the metallic casing is entirely aluminium, and by comparing the weight of these with others of the same size mounted in brass, the difference is much in favour of the white metal, and there is no doubt that a saving of some fifty per cent. in weight could be effected in a photographic outfit by the substitution of aluminium for the metallic fittings of our cameras; and it is to be hoped, therefore, that some enterprising maker will bring aluminium into practical use, for although some attempts have been already made in this direction, it would seem that amateurs are not expected to pay so much for the small differences in cost of workmanship as for the novelty of the application itself.

To the practical man, however, the metal presents some drawbacks in its manipulation; it cannot be cast, on account of its extreme lightness, with the same ease as the copper alloys: it tarnishes in sea air, and is more easily damaged and scratched. Weight for weight it is stronger than iron; but bulk for bulk it is not so strong as brass. It is possible that this difficulty might be overcome by the addition of tin, or other alloy, as the tensile strength of an impure kind of aluminium. Bronze produced by the smelting of a mixture of copper and corundum, through the agency of immense dynamos in the Cowles process, is from 103,000 up to 129,000 pounds to the square inch. There is a certainty, however, that the application of pure aluminium to photographic purposes is capable of considerable extension, and it is to be hoped that the mechanical portion of the Camera Club may be induced to show themselves to more advantage by experimenting with what is practically a new metal, first known as a greyish powder by the German chemist Wöhler, in 1828; reduced through the medium of sodium to a metallic form by Sainte-Claire Deville, some thirty years later; and, finally, produced as a marketable commodity, some two years ago, by the Castner process.

* From the *Journal of the Camera Club.*

Light for the Developing Room.—We have often said that ruby was the only safe and suitable light for the development of the modern gelatino-bromide plate, and still maintain that theoretically it is so. But practice and theory do not always go hand in hand, and the result of a series of experiments that we saw conducted by one of our friends a few days ago has induced us to somewhat modify our opinions. The dark-room in which the experiments were made has three windows, each about 22 by 16 inches, and filled in with deep ruby glass. Two are "borrowed" lights, and so safe enough; the third faces the west, and at the time of operation was in full sunshine. In addition to those, there was a small window about 9 by 7 in one corner, and it was close to this, or about six inches from it, that the plates were developed. This window is lighted by a gas jet, a No. 3 burning within four inches of the glass, which is one sheet of green between two of yellow, or yellowish orange, but altogether so pale that at first we thought it was merely a sheet of ordinary glass, and refused to believe that plates could be developed under it without fog. But "the proof o' the pudding is in the preein' o't," and we saw half a dozen of Cramer's "40" plates that had been snapshotted on groups of children, and consequently requiring protracted and pushed development, successfully developed, and without a trace of fog, under the light. The owner of the dark-room has for some time been suffering from weak or easily inflamed eyes, and with her it was simply a question of finding a light other than ruby, or giving up the pleasure of the dark-room altogether. The comfort of the greenish-yellow light is greater than can be believed by those who have not tried it; and while, as no light is absolutely safe, it is so nearly so that on putting an unexposed plate into the developer, leaving it for fully five minutes close to the window, with the burner turned on full, it showed on being fixed only a hardly perceptible opalescent trace of fog.—*The Beacon.*

THE BRITISH ASSOCIATION AT LEEDS.

The next meeting of the British Association will be held at Leeds, and open on Wednesday evening, September 3rd, under the presidency of Sir F. Abel, of Woolwich Arsenal. There will be a reception and *conversazione* by invitation of the Mayor of Leeds: on Friday, at 8.30, a discourse on "Mimicry," by Mr. E. B. Poulton, M.A., F.R.S., F.G.S.; on Saturday, a lecture to the operative classes *(members not admitted)*, by Professor John Perry, M.E., D.Sc., F.R.S.; on Monday, at 8.30, a discourse on "Quartz Fibres and their Applications," by Professor C. Vernon Boys, F.R.S.; on Tuesday, a *soirée*. The work of the Association will be divided into the following sections, which will meet daily at 11 o'clock for the reading and discussion of addresses, reports, and papers: special facilities being afforded for the discussion of subjects of local interest:—

A.—Mathematical and Physical Science, including pure and mixed mathematics, astronomy, sound, heat, light, and electricity. President, Mr. J. W. L. Glaisher, D.Sc., F.R.S., V.P.R.A.S.

B.—Chemical Science, including applications to manufactures, dyeing, and agriculture. President, Professor T. E. Thorpe, B.Sc., Ph.D., F.R.S., Treas. C.S.

C.—Geology, including applications to coal and other mining. President, Professor A. H. Green, M.A., F.R.S., F.G.S.

D.—Biology, including anatomy, physiology, zoology, and botany. President, Professor A. Milnes Marshall, M.A., M.D., D.Sc., F.R.S.

E.—Geography, including recent explorations. President, Lieut.-Col. Sir R. Lambert Playfair, K.C.M.G., F.R.G.S.

F.—Economic Science and Statistics, including applications to educational and social problems. President, Professor Alfred Marshall, M.A., F.S.S.

G.—Mechanical Science, including applications to civil, mechanical, and marine engineering. President, Captain A. Noble, C.B., F.R.S., F.R.A.S., F.C.S., M.Inst.C.E.

H.—Anthropology, including the characteristics and distribution of the various races of men. President, John Evans, D.C.L., L.L.D., V.P.R.S., Pres. S.A., F.L.S., F.G.S.

We understand that many of the principal manufacturers have already kindly promised to open their works for inspection, and from the great variety of trades carried on in Leeds, the courtesy will be appreciated by all members and associates. The manufacture of iron in all its varieties from clay ironstone, and its application to the construction of stationary and locomotive engines, of pumps, tools, machinery for every purpose to which machinery can be applied, of weighing and testing machines, of arms; the manufacture of cloth, flannel worsted, and other woollen goods, of ready-made clothes and caps; the operations of dyeing, tanning, and leather dressing in all its branches; the manufacture of sanitary tubes, quarries and firebricks; brewing; soap making; flax spinning and linen weaving; the manufacture of sulphuric acid and other chemicals, of glass bottles, artistic pottery, boots and shoes, soda-water; the operations of milling and sawing wood and stone, of making writing, wall, and other papers, afford the most varied opportunities to those interested in industry.

The Photographic Club.—Subject for discussion on Wednesday, August 13th, "Extemporising Apparatus;" August 20th, "Actinometers and Photometers."

Patent Intelligence.

Specifications Published.

11,416. *July 16th*, 1889.—"Photographic Cameras and Shutters." Benjamin Joseph Edwards, The Grove, Hackney, London, Manufacturer.

This invention relates to improvements in the shutters used for exposing the sensitive plates or films, and in the appliances for changing them, also in the holders or sheaths used for carrying such plates or films. My objects are, first, to facilitate the regulation of the time of exposure so that the same instrument may be successfully used for extremely rapid or for prolonged exposures, and that better protection may be afforded from the light previous to exposure.

Second, to combine in one operation the setting of the roller blind shutter and the removal of the plate after exposure.

Third, to provide a means for holding flexible sensitive films so that they may be curved to form the arc of a circle of any required radius, thus bringing the sides of the picture, which is formed on the hollow side, more into focus of the rays from the lens, so obtaining better definition than is possible with films used in the ordinary way.

In carrying out the first part of my invention, I combine the shutter known as the "roller blind shutter," which was described and shown by me in 1882, and which has since been extensively used for what are known as instantaneous exposures, with an ordinary pivoted or flap shutter in such a manner that both may be used in combination, or the flap shutter may be employed separately. The mechanism which I employ for working the shutter or shutters may be hand, pneumatic, hydrostatic, or other convenient style, and is so arranged that when the flap is lifted, a catch which holds the roller (the spring of which has been previously wound up) shall be released, and the shutter allowed to descend. When the pivoted shutter is to be used alone for time exposures, the roller shutter is set so that it shall be open, and is fixed in that position by a clamp catch or other convenient arrangement. I do not confine myself to any particular position for the roller shutter, which may be in front of or behind the lens, but I prefer to place it immediately in front of the sensitive plate. The use of the two shutters in combination forms an additional protection to the plates previous to exposure, the flap covering the lens, while the roller shutter is set, and until it is brought into use.

In carrying out the second part of my invention, I combine with the roller blind shutter, used separately, or in combination with the flap shutter, an arrangement for exposing a succession of plates by removing the plate which has been exposed, thereby leaving the next plate in position for immediate use; this I do by securing in a suitable position on the flexible blind one or more projections or hooks which fall with the shutter when the plate is exposed, and engage with the plate or its frame or carrier; thus when the roller shutter is again set or wound up, the plate is drawn or raised with it. In adapting my camera, which may be of the type known as the "detective," to suit this part of my invention, I divide it into two compartments longitudinally, each of which will hold a number of plates, each plate being fitted into a sheath or carrier of paper, wood, metal, or other suitable material, and these I place one behind the other, and keep in position by means of a spring or other contrivance in one of the compartments (preferably the lower one) after having wound up or set the shutter. On releasing the shutter the plate is exposed, and the hooks or projections engage with it, ready to draw or lift it into the second compartment when the blind is again set, the operations being repeated until all the plates are used, and removed to the second chamber, when they are taken out and a new set placed in the first.

In carrying out the third part of my invention I do away with the flat surface now used as a support for the flexible film or sensitive paper, and I make the holder, or sheath, or support curved to the required radius, or I leave a sufficient space at the back of the flexible film to allow of its being bent to the required curve, and held in such position by pressure at the

edges ; when continuous bands or separate pieces of sensitive paper or films are employed, they may be placed or drawn round a curved plate of glass, and thus held to the required radius, the photograph being taken through the glass.

The other parts of the camera may be of any convenient form or type such as are at present in use.

7,010. *May 6th*, 1890.—"Photographic Cameras." BENJAMIN JOSEPH BARNARD MILLS, 23, Southampton Buildings, London, Patent Agent. A communication from LOUIS LOUMIERE, of 21 and 25, Rue Saint-Victor, Lyon-Montplaisir, France.

The invention is particularly applicable to portable photographic apparatus, and has for its object to present successively and at will behind the lens a certain number of plates previously enclosed in the apparatus, and to shut them up one by one—as they have been used—in the bottom of the camera, whence they are withdrawn only in the dark room. This result is obtained by simple apparatus worked from the exterior.

The inventor claims :—

An arrangement of camera in which a number of plates contained in frames furnished with trunnions are suspended one behind the other in front of the lens, and are pushed by a spring, the first frame, and in succession the following ones, being capable of removal by a notched disc operated from the exterior, and then of swinging on to the bottom of the camera by turning on their lower trunnions.

9,058. *June 11th*, 1890.—"Lamps for Enlarging or Copying Photographs." JAMES CHAPMAN SHENSTONE, 13, High Street, Colchester, Essex, Chemist.

This invention relates to lamps used for enlarging or copying photographs and the like, with the aid of an ordinary photographic camera, without the use of a lantern or condenser, the object being to render these lamps more handy in use and efficient in operation.

With these ends in view, the invention consists of a lamp having an oil lamp and a spirit lamp with magnesium ribbon burner, capable of being moved transversely across the lamp to bring the one or the other into a central position, as required for focussing or printing.

The inventor claims :—

1. The improved lamp for enlarging or copying photographs and the like, substantially as and for the purpose set forth in the specification.

2. In a lamp for enlarging or copying photographs and the like with an ordinary photographic camera without the use of a lantern or condenser, adapting the focussing oil lamp and the printing magnesium ribbon burner to move transversely across the lamp for the purpose of bringing the one or the other into a central position.

9,062. *June 11th*, 1890.—"Treating Emulsions in Centrifugal Machines." CARL DIDRIK HELLSTROM, Engineer, Stockholm, Sweden.

This invention seems to be intended to apply chiefly to the making of butter, but as it contains curious results of scientific research as to the motions of particles in emulsions subjected to centrifugal force, we quote the portion of general scientific interest.

In an emulsion the particles of fat are in the form of spheres of very different sizes ; for example, in milk, the largest are of about twenty times greater volume than the smallest. Each sphere of fat is surrounded with a zone of the surrounding liquid. The zone lessens the flotation of the spheres of fat in proportion to the size of the latter, so that the smaller spheres no longer possess any flotation ; these cannot be separated by centrifugal action alone, except when the larger spheres draw them in a manner with them. The path of the larger spheres through the mass under the influence of centrifugal action will be an unbroken line. When, however, the mass also receives a motion parallel to the axis, the larger spheres which possess flotation will, on account of their small density, receive a relative motion in an axial direction. If the axial motion continually changes its direction, the larger spheres will travel in a zig-zag course about the line which in the absence of axial movement would have been the path. The larger spheres so travelling will continually collide with the smaller spheres of fat, which on account of the surrounding zones do not take part in the relative motion. The separation of the fat is rendered more complete by this method. As the axial movement in the mass gives rise to pressure, the particles will coalesce, and the enlargement of the at first small particles of fat takes place fairly quickly throughout the mass. On the surface this enlargement of the spheres of fat is hastened by the movements originated by the axial motion. In centrifugal action the surface places itself normally to the resultant of the centrifugal force, and gravitation ; if there be also axial motions the surface tends to place itself normally to the resultant of all three ; as, however, the axial motion is variable, both as regards amount and direction, the particles on the surface have a wavy motion. This takes place quite symmetrically round the axis, so that a section which is placed perpendicular to the axis will be alternately extended and compressed, and by this means the particles of fat will be made to unite. By each union of two spheres a portion of the liquid which envelopes the spheres will be liberated ; the fat, therefore, is more thoroughly freed from liquid than by centrifugal action alone.

When the temperature of the emulsion is such that the fat is cool, the transition to a firmer state of aggregation is hastened by the repeated variations of pressure ; if, for example, milk is treated at a temperature under 23° C., in this way, butter is produced. With continuous inflow and outflow the process is made continuous.

The inventor claims :—

1. The process substantially as described for the separation of fat from emulsions, wherein the emulsion is exposed to the simultaneous influence of rotary motion, and of motion either quite or nearly parallel with the axis of rotary movement.

2. Apparatus substantially as described and illustrated by the drawings accompanying the specification.

52,750. "An Improvement in Transferring from Zinc or Copper Plates to Lithographic Stones or other Metal Plates, so that the Transfer will Print Exactly in the Original Size" (German Patent).

The invention, which is hereafter described, has for its purpose the transferring or reprinting of engravings, or of designs on copper or any other metal plates, in exactly the original size, and this, up to the present time, people were never able to get. The process is the following :—The engraving or the drawing, on a plate of copper or other metal, must first be coloured after the manner known to most printers. Place then, upon such a plate, transfer paper, and upon this transfer paper place a sheet of unsized copper-plate paper. Pull the plate under a moderate pressure through the press, which will cause the transfer paper to adhere firmly to the plate, and place then upon the transfer paper a sheet of strong paper that will not easily stretch, after having previously gummed the lower surface of it ; before placing the latter paper on the transfer book, dampen both slightly. Now pull the plate again through the press, but under stronger pressure. This will cause the upper paper to form one layer with the transfer paper. Then place upon this, without removing it from the plate, a folded blanket, or any other elastic layer, and pull it several times through the press again, under heavy pressure. Only after the printing plate or stone upon which the transfer is to be made is fully prepared for this purpose, this layer, the preparation of which has just been described, is lifted from the other plate and placed upon the prepared plate to be treated as usual. Whoever will try this process will find that it will yield an absolute exactness of size in all directions. The patent claim is : A process to transfer engravings or any other kind of printing from metal plates in absolutely exact original size to lithographic stones or metal plates for the purpose of printing ; and this process consists of connecting the paper which is used for the transfer, after it has become adherent to the stone or metal plate by once pulling through the press, with the upper layer of strong paper, or other material which will neither stretch nor shrink (after the latter has been gummed on its lower side) by repeated pulling through the press.

Correspondence.

"THE TREATMENT OF SUBJECTS BY FOCUS."

Sir,—Mr. W. K. Burton's letter in your last issue requires a lengthy answer. It is to be regretted that Mr. Burton is so far away from England for controversial purposes. Had he seen my letter sent to you a week or two ago, pointing out his error in regard to what he deemed a new aspect in spherical aberration in its bearing on the formation of images, he would probably not have repeated—had he understood it—the errors which he has only emphasised in his article in your last week's issue.

Mr. Burton certainly has very much misunderstood me and the subject too, but still he suggests: "If Mr. Dallmeyer had confined himself to claiming one phase of the question, he would have been on safe ground, but he has tried to prove too much." I shall show Mr. Burton in an article—if you can afford the space—that I have succeeded in proving *fact*, and I cannot help thinking it a pity that Mr. Burton should give himself away in connection with a subject which he probably has not had the same opportunities that I myself have had of investigating; but I understand Mr. Burton to be a gentleman whose sole object in all controversies is to arrive at the truth of a question, and under these circumstances it will be a pleasure, and not an irksome duty, to point out the errors into which he has fallen.

I hope to have my article ready for your next issue, and then and for ever "lay this ghost!"

Thomas R. Dallmeyer.

25, *Newman Street, London*, W., *August 4th*, 1890.

THE LANTERN SOCIETY.

Sir,—The Lantern Society has obtained the use of the rooms belonging to the Royal Medical and Chirurgical Society at 20, Hanover Square, and, through the courtesy of their committee, at a very moderate rental.

These rooms are centrally situated, and are frequented by several scientific societies, amongst whom are the Royal Microscopical and Quekett Clubs.

Meetings will be held for the purpose of reading papers and exhibiting lantern slides on the second and fourth Mondays in each month, from October to April inclusive, at 8.30 p.m.

Several applications for membership having been received from ladies, the Council desire it to be known that they are eligible for election.

Charles E. Gladstone, R.N., *Hon. Sec.*

6, *Bolton Street, London*, W.

The informal but pleasing gatherings on Thursday evenings continue at the Camera Club. A few members regularly meet to discuss photographic affairs, and to examine any apparatus or pictures presented. During the past month the Club has had upon the walls some of the platinotype prints of hunting scenes sent by the Vienna Club.

Perfumed Photographs.—To meet the fastidious taste of some of their customers, English photographers are perfuming their photographs before sending them out, and Mr. A. H. Norman suggests for the purpose keeping the mounts in a box along with a few of the scented sachets sold by perfumers, Photographers on this side might adopt the notion, and perhaps get an additional half dollar a dozen for the novelty. They can do better, however, than pay fancy prices to the perfumer, and at the same time have a perfume to their own tastes, or even to the tastes of their customers, for that matter. All that is needed is to take, say, four ounces of powdered orris root, and incorporate with it thoroughly, small quantities of various essential oils. Of course, in the selection of the oils and proportions, each photographer will be guided by his own taste. By ringing the changes on the following, any desired style may be obtained. Bergamot, true cinnamon, citronell, clove, geranium, lavender, neroli, and sandalwood. The *pot pourri* may be placed in a thin muslin bag the full size of the bottom of a tight box, and the mounts for to-morrow's use put into the box to-day.—*The Beacon.*

Proceedings of Societies.

London and Provincial Photographic Association.

At the meeting on the 31st ult. Mr. J. J. Briginshaw occupied the chair.

Mr. J. B. O'Connor was elected a member of the Association.

The adjourned discussion on "Printing under Coloured Glass" was proceeded with.

Mr. Otto Scholzig exhibited a strip of sensitised albumenised paper which had been printed in sections under various coloured pieces of glass. In each case the printing was continued until the same depth of colour was reached. The paper was then toned, the following bath being used:—

Borax	1½ drams
Uranium nitrate	4 grains
Gold	3 ,,
Water	24 ounces

A difference of tone in the various sections of the paper was noticeable, those portions of the paper that had been printed under green and dark yellow glass appearing to give the best results. Mr. Schölzig said he had tried printing under various coloured sheets of celluloid, the brownish-yellow and green producing excellent tones; but prints exposed under other colours he found difficult to tone. Printing through a green medium gave a bluish-red colour, which toned rapidly to a rich black, and did not fix out. He believed a perfect substitution of the gold took place. He had placed plain paper prints, after toning to this colour, in a five per cent. solution of nitric acid without any appreciable detriment to the image. In printing from a negative, one-half through green glass, and the other half exposed to white light, the printing being continued until both halves of the print were of the same depth, a great difference was found, to the advantage of the half exposed under green glass.

Mr. Scholzig also showed two strips of sensitised paper, toned and untoned, that had been printed in different sections under coloured pieces of glass, showing alteration of tint caused by the various media through which the light had passed. The difference in the time of printing under green glass, he stated, would be about three times that of white light. A print but just rinsed in water previous to toning would take up more gold and yield a much blacker tone, and, in consequence, would be more permanent, than a print that had been thoroughly washed previous to toning.

Mr. W. E. Debenham said, referring to the last statement, that the published experiments of Mr. W. K. Burton proved exactly a reverse conclusion. A print that had been thoroughly washed previous to toning, although of a different colour in the bath, continued to tone, whereas in the second case the blue stage would be reached before all the silver was replaced. He thought these conditions might apply in some way to printing under green glass. Mr. Debenham referred to the results of his experiments in this direction exhibited at last week's meetings. Printing under green glass certainly produced another colour in the finished print, but he maintained that in the majority of instances a loss of richness of tone was the result.

Mr. J. S. Teape showed three prints, two of which had been printed under green glass, and one under white glass. With the former he was able to get a rich black tone which he was unable to produce in the latter. He also exhibited a series of prints from the same negative ranging over various lengths of exposure, with the result that the shorter the time of printing the more it became necessary to prolong the toning operations. In printing through green glass, he had found that the print did not appreciably lose its bluish tint in toning; the bath he used was as under:—

Saturated solution borax	1 ounce
Gold	1 grain
Water	6 ounces

Mr. H. M. Hastings showed some sheets of sensitised albumenised paper, portions of which had received a preliminary exposure; part of the paper was then washed, and further exposed under green glass. It was found that with the part of the paper that had received a preliminary exposure, the printing

proceeded more rapidly than the remainder of the sheet. Ruby glass was also tried with a similar effect.

Mr. W. E. DEBENHAM said that a possible explanation why printing in a weak light might yield a better result was that the length of time necessary to print in a weak light allowed the chlorine given out during printing to escape; whereas with rapid printing it would be evolved too quickly to admit of this, to the injury of the richness of the print.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

AT the meeting in the Association's Club Rooms, 3, Lord Street, on Thursday evening, the 31st July, Mr. PAUL LANGE presided, and expressed the great pleasure it gave him in once more meeting the members of the Association after his trip to Iceland. He had undergone as extraordinary an experience as it was the lot of any man to undergo, and he had passed through much hardship and fatigue. He thought he had accomplished a feat no man had done before in managing to climb up 5,200 feet and photograph the Crater of Hecla, which he had done successfully.

The following candidates were elected members:—Messrs. Herbert E. Cox, Arthur Workman, Herbert T. Mallabar, Rev. A. M. Lewis, C. R. Jones, and Edward King Ellison.

Mr. C. B. READER reported about the excursion to Bolton Abbey, and gave some interesting information as to the progress of the "Liverpool Illustrated" return set for the Boston Camera Club (U.S.A.)

A novel tripod, the invention of Mr. William Tomkinson, and designed by him for hand-camera work, was exhibited and explained by the inventor.

Mr. A. TYRER exhibited a number of photographs taken at Bolton Abbey by Messrs. Tomkinson, Phillips, and the hon. sec. (Mr. E. M. Tunstall), views of the interior of Eaton Hall; the last named showed some whole plate prints of Moreton Old Hall, secured during the excursion in the Convention week.

Mr. Watmough Webster's photographs of the Convention groups were handed round.

Mr. H. H. Williams was elected an honorary member.

Mr. T. W. WADE, Vice-President of the Manchester Amateur Photographic Society, was then called upon to give his paper entitled, "Landscape Photography," which he illustrated with rapid sketches in charcoal, and for which a hearty vote of thanks was accorded.

The PRESIDENT announced the excursion for the month of August, viz., to Rufford Hall, on Saturday 9th inst. (half day), and to Haddon Hall on Wednesday, 20th inst. (whole day).

THE WEST LONDON PHOTOGRAPHIC SOCIETY.

AN ordinary meeting was held on the 25th ult., Mr. CHAS. BILTON (President) in the chair. Dr. St. Clair Buxton, and Messrs. Lynn, Ward, Holmes, and Kendall, were elected members.

The question of the advisability of removing the *locale* of the Society from the Addison Hall to the Lecture Hall, Broadway, Hammersmith, was considered, and a motion in favour of the suggested change was carried. The remainder of the evening was occupied in exhibiting and criticising work done at the summer excursions.

It was announced that the next outdoor excursion would take place on the 9th August. Members to meet at Greenwich Pier at 3.30. On 23rd August the members meet at Hanwell Station for an excursion up the Brent. On Sept. 26th a meeting will be held at the Broadway Lecture Hall, Hammersmith.

RECEIVED:—Messrs. John J. Griffin and Son's Illustrated Catalogue, consisting of nearly 200 pages, neatly printed in chocolate ink. In addition to the well-arranged trade catalogue, there is a large amount of useful information in the shape of formulæ and descriptive matter.——Messrs. Gauthier Villars forward a copy of "La Photographie Judiciaire," in which M. Alphonse Bertillon, of the Prefecture of Police, sets forth the general principles of his photographic and authropometric method for the identification of criminals. This interesting little book of 116 pages is richly illustrated, the photographs published being anonymous portraits of individuals deceased or transported to the Colonies.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

L. E.—*Glycerine in the Developer.* With pyrogallol it seems to play the part of a mild restrainer, and, when employed in the stock solution, helps to keep it from decomposition. It assists, likewise, in promoting the easy flow of the developer over the plate. Mr. B. J. Edwards's formula is as follows:—

No. 1.—Pyrogallol	... ...	1 ounce
Methylated spirit	... ...	7 ounces
Glycerine	... ...	½ ounce
No. 2.—Bromide of potassium	... ...	120 grains
Distilled water	... ...	7 ounces
880 ammonia	... ...	1 ounce

The above are stock solutions, which require to be diluted for daily use, each with fifteen parts of water. Then, for developer, mix the two together in equal parts.

R. D. (Skipton).—*Silvered Glass.* Assuming that you mean looking-glass (tin amalgam), and not real silver deposited from solution, details for which were given in these columns a year ago, proceed as follows. Procure a flat wooden board, on which lay a piece of tin-foil a little larger than the glass to be silvered, then amalgamate the tin surface with a drop of mercury and a hare's foot; flood on more mercury, and then slide in the glass plate, apply weights, and rear up the board to drain off all excess. This done, again lower it to the horizontal position, and leave it for a few hours under pressure to harden.

L. N.—*Magnesium Chloride Fixing Bath.* Since replying to you on the 18th ult., we have been trying to procure a fixing bath by the concentration of sea water. Leaving a pint of sea water to evaporate spontaneously in the open air, it is not even now sufficiently reduced in bulk to make it worth while trying the experiment of using it as a fixing bath. The liquor, besides, is so charged with black smuts from the London atmosphere that it requires to be often filtered and put back again into the cleared dish.

A. NEALE (Nottingham).—The portrait group of Council and Officers of the Society of Chemical Industry is admirable, and will serve as a most interesting memento of the Tenth Annual Meeting recently held in your town. We thank you for the blue paper print sent subsequently as an index, which enables us to identify a few faces in the group of twenty-four who were not personally known to us. We congratulate you on your success; the portraits of Sir Lowthian Bell, Mr. Ryder Cook, and the other Past Presidents—Sir John Turney, Professor Clowes, and the Mayor of Nottingham—are excellent.

J. M. S.—*The Weather of July.* The rainfall, amounting to 1·25 inches, was considerably above the average (2·51 inches), and corresponded exactly with the wet July of 1888. When not raining, the sky was so gloomy and overcast with high winds, that we doubt there was ever so unpropitious a summer month for out-door photographic operations. By the rule of compensation, August and September ought to prove more favourable.

M. G.—*Glass Clips.* We do not know where they may be procured, but with a few slips of glass, and elastic rings or sections of india-rubber tubing, it would be very easy to make them for yourself. Be sure and wash them frequently, or there would be no advantage in use over the ordinary wooden clips.

T. W. (Bexley).—*Nitrate of Lead in Printing Bath.* The addition of five grains per ounce has been recommended to help out the silver, but we cannot say with certainty that any good purpose is served by putting in the lead. A claim is made for it on the ground that the whites of the print are better preserved, but in the absence of direct comparative experiments we must not affirm that such is actually the case.

THE PHOTOGRAVURE PROCESS.

WITH A PICTORIAL SUPPLEMENT.

THE highly artistic results obtainable by the photo-etching process in half tone, originated by Klic, and employed with modifications by Goupil & Co., Annan & Swan, and others, are well known. To-day we issue as a supplement a picture by this process representing the late Charles Kingsley's rectory at Eversley, reproduced in photogravure from a painting by Mr. Alfred Dawson, by Messrs. Dawson, of the Hogarth Works, Chiswick, whose excellent prints by this process of some of Mr. Gale's photographs issued with the first number of *Sun Artists* may be known to many.

At the Chiswick establishment the art-worker is Mr. Alfred Dawson, and the scientific department is under the charge of Mr. Charles Dawson. They began photo-mechanical printing in 1869 in Queen Square, Westminster, and their present works were built in 1872. The Chiswick works consist of a number of buildings dotted over a considerable space of garden ground, rich at the present time in flowers. A brick wall separates it from Hogarth's house and grounds, for which Mr. Charles Dawson is now in treaty with a view to the purchase thereof, and it is highly probable that shortly one of the most artistic and costly of the photo-mechanical processes will be carried on in Hogarth's old house. In Chiswick churchyard, near at hand, is the grave of Hogarth.

Klic's process will be found described in detail in the PHOTOGRAPHIC NEWS of January 28th, 1887. There was a previous notice of it in the NEWS of February 1st, 1884; and the first publication was made in the *Photographische Mittheilungen* of December, 1883. Briefly stated, the process consists in covering a chemically clean copper plate with finely powdered asphalt, upon which is then developed a carbon negative; both are then subjected to the action of an etching fluid, which is usually perchloride of iron. The carbon negative causes the etching fluid to act with different degrees of vigour upon parts of the copper plate, and the asphalt gives the grain. It is thus an intaglio process, and the printing is done in the same presses as those used in turning out ordinary copper-plate engravings. The machining is slow work, and it took some weeks to print the accompanying supplement.

In the photo-mechanical processes there is little or nothing of a secret nature; many beginners fail in their attempts because they do not persevere long enough to gain the great experience necessary for the production of high-class results; others fail in the machining; exceedingly perfect machines, under the control of skilled workmen, are necessary for printing proofs from plates produced by several of these processes; indeed, in some instances, the necessary machines are made in France and Germany alone.

Every firm, as might be expected, introduces some small modifications of its own into the process employed, as the result of its particular experience. Mr. Charles Dawson says that he rarely uses asphalt in working Klic's process, but a powdered compound of various resins; the bitumen grain is too fine for most purposes; it necessitates passing from stage to stage in the operations too rapidly, whereby a tendency to flatness and hardness obtains. "Pits" give trouble in Klic's process, and experience is necessary to avoid their production.

In copying paintings for the photogravure process at the Hogarth works, orthochromatic methods are employed; in fact, Obernetter's orthochromatic plates are used. As a yellow screen, a sheet of perfectly plane glass coated with solution of golden aniline in collodion is used. The golden aniline is difficult to dissolve therein, but it can be managed with time and care. When dry, another sheet of plane glass is cemented over the yellow film by means of melted Canada balsam; optical defects are thereby minimised, and the film protected. Yellow glass has usually an amber or brownish tinge, and appears somewhat dingy by transmitted light; it cuts off rather more light than is necessary for getting an equal amount of orthochromatic effect. The golden aniline film has, by transmitted light, more the pure yellow colour of a

solution of chloride of gold. At the works ordinary Ilford plates are used for copying, but all line work is copied by the wet process. Mr. Dawson states that the firm makes about four hundred photogravure plates a year.

The last Oxford and Cambridge boat race was photographed by Messrs. Dawson at 5.15 p.m., and at 9 p.m. some photogravure plates thereof were made ready for printing. By 9 o'clock next morning 500 prints were ready and on sale in London at the offices of various newspapers interested in the boat race. This is perhaps the quickest commercial work which has ever been done by Klic's slow and highly artistic process.

CHARLES KINGSLEY'S HOME AT EVERSLEY.

Our supplement this week represents the home at Eversley, Hampshire, of the late Charles Kingsley, who was so universally beloved and respected that it is unnecessary to say anything as to his writings or claims to public attention. He was born at Battramsley, in the New Forest, on the 12th of June, 1819, and died at Eversley on the 23rd of January, 1875. On July 17th, 1842, he settled as curate at Eversley, then a place described by his widow, in her book on his life and letters, as mostly a parish of common land on the borders of Old Windsor Forest, containing three hamlets surrounded by moorland, the population consisting of "croppers" and poachers from time immemorial. He once described his typical parishioner as the descendant of "many generations of broom squires and deer stealers," who occasionally spent a little time over a crank in Winchester gaol, but was "a very good fellow, nevertheless." In 1842 he described the view from Eversley Rectory thus:—"Can you understand my sketch? I am no drawer of trees, but the view is beautiful. The ground slopes upwards from the windows to a sunk fence and road, without banks or hedges, and then rises in the furze hill in the drawing, which hill is perfectly beautiful in light, and shade, and colour. Behind the acacia on the lawn you get the first glimpse of the fir-forests and moors, of which five-sixths of my parish consist. Those delicious self-sown firs! Every step I wander they whisper to me of you, the delicious past melting into the more delicious future. 'What has been shall be,' they say." Mrs. Kingsley remarks:—"Outside the pastoral work, and yet as part of it, his aim was to be 'all things to all men.' He could swing a flail with the threshers in the barn, turn his swathe with the mowers in the meadow, pitch hay with the haymakers in the pasture. He knew every fox-earth on the moor, the 'reedy hover' of the pike, the still hole where the chub lay, and had always a kindly word for the huntsman or the old poacher. With the farmer he could discuss the rotation of crops, with the labourer his hedging and ditching; and in giving sympathy he gained power."

The London and Provincial Photographic Association.—Subject, August 21st, "Cloud Negatives"; opened by Mr. J. S. Teape. Subject, August 28th, "Pictorial Definition"; opened by Mr. P. Everett. Visitors invited. R. P. Drage, hon. sec.

PHOTOGRAPHIC TOURISTS AND THE CHANNEL PASSAGES.

II.

The Folkestone-Boulogne route is perhaps the most fashionable one to the Continent, and the boats traverse the Channel from pier-head to pier-head in about an hour and a-half; although this is about twenty minutes longer than the time taken by the Dover-Calais boats, nearly thirty miles of railway travelling in France are saved by taking the Folkestone-Boulogne route to Paris. The boat trains from Calais to Paris all pass through Boulogne-sur-Mer.

Both Folkestone and Boulogne are picturesque places, affording suitable opportunities for camera work. One advantage of Folkestone as a seaside resort is, that unlike many watering places on the South Coast near London, it has no chalk cliffs, so that in the dog-days, while the sun is blinding and baking the visitor on the one side, he does not have white cliffs reflecting the sun's rays down upon him on the other side. The dark, precipitous cliffs to the east of Folkestone harbour are of soft material, and portions fall into the sea occasionally; the dark cliffs to the west of the harbour are partly covered with herbage and small trees. The departures and arrivals of the Boulogne boats present animated scenes for photographic work, so also do fishing smacks entering and leaving the harbour, and from the south side of the harbour views may be obtained of the cliffs, and old houses on the tops thereof, with boats in the foreground. To the north of Folkestone, stretching away to Canterbury, lies what may be called the Ingoldsby country, containing occasional picturesque "bits" for the camera, and some of the old village churches in the district have an interesting history of their own.

The old part of Folkestone is interesting, and abounds in the smuggling dens of the past; some of the smugglers of the old school are still living in Folkestone, and several of them tell tough yarns, which lose nothing in force or incident with lapse of time. Folkestone is a place not much invaded by excursion trains, and altogether, it is one of the most pleasant seaside places near London—although on points like these tastes differ. At Folkestone there is a slow motion of the beach from west to east, tending to choke the water area of any harbour there with shingle, and special engineering devices have been adopted at Folkestone to arrest or divert this motion, that the shingle may do little harm in the manner just stated. In 1635, in the days of Charles I., the corporation of Folkestone ordered that on the blowing of the horn "every householder," or his deputy, "provided with shovelles, or other fittinge and meete tooles," should set to work to clear the shingle out of the harbour so long as the Mayor might deem necessary, or, in default, should pay a fine of sixpence. The horn used in those primitive times by the town crier is now suspended behind the Mayor's chair in the Council Chamber at Folkestone.

The chief passenger steamboats on this service are

the *Albert Victor*, the *Louise Dagmar*, and the *Princess Beatrice*. The two former are each 250 feet long, 29 feet beam, 15 feet depth, 350 nominal horse power, and 8 feet draught; they were built by Samuda Brothers, and engined by Mr. William Penn, of Greenwich. The *Mary Beatrice*, one of the fastest steamboats afloat, is 255 feet long, 29 feet broad, 15 feet 6 inches depth of hold, 8 feet 1 inch draught, 1,063 tons burden, and 2,800 indicated horse-power; she was built by Samuda Brothers, and engined by John Penn and Sons. Her boiler pressure is 32 lbs., her cylinders 72 inches in diameter, the pistons have 5 feet stroke, and there are 6,500 feet of condenser surface, with two engines to drive the water through. The three boats already mentioned are much alike, and, small as they necessarily are because of the shallow harbours in the narrow portions of the Channel, are so well built that they would be likely to do well in very bad weather. If, however, the weather gets so bad as to be dangerous the boats stop running for the day, in order not to expose the passengers to risks. The roomy deck saloon is a special feature of these boats. The engines are of the ordinary oscillating description.

In mid-channel, by this route, the Varne lightship is seen in the distance to the west, but not near enough to get an effective photograph thereof. These lightships are exceedingly safe, although they often have to bear the full brunt of Atlantic storms; on rare occasions they have broken from their moorings in bad weather, but they are so well built that practically the men on board are as safe as upon dry land. A Trinity House boat visits them occasionally with provisions and stores.

Boulogne-sur-Mer is a pretty place as seen from the sea, and a few photographs of it may be taken with advantage. Prominent is the dome of the cathedral on the top of the hill; two long piers of timber painted white and stretching out to sea, have a waterway between them which forms the entrance to the harbour; in front of the piers the observer upon the deck of the ship may sometimes see one or more of the Dutch pneumatic dredging boats of Messrs. Volker and Bós, with appliances for drawing up the sand and stones from the sea bed by suction, and discharging them into barges alongside.

The arrival of the Boulogne boat forms a subject for pictures often given in newspapers, and will equally well suit the photographer. The sea-side scenery and cliffs of Boulogne are pretty, and, as the sea-shore faces the west, glorious sunsets at sea are sometimes visible. The cathedral, inside and outside, is picturesque. Occasionally there are some grand ecclesiastical processions at Boulogne, affording subjects for the camera unobtainable in England. One of these processions takes place on the day of the "first communion" of children. The venerable archbishop brings up the rear, upraising his hands at times and "blessing little children." The other annual display of ecclesiastical pageantry is connected with ceremony peculiar to Boulogne, known as "the blessing of the sea."

VARNISHING.

"I NEVER trouble to varnish my negatives," is a statement more often made by the amateur than by the professional photographer, for the latter is careful, by every precaution, to give permanence to his work. He never knows how valuable a negative may prove to him in after years, when, perchance, the original has gone over to the majority, and loving friends want duplicates of the picture. With the amateur it is different. He takes his negative, and, after a few positives have been printed from it for his album and that of his friends, he ceases to take much further interest in it, and it is either broken by careless handling, or stored away to be forgotten.

In wet plate days the unvarnished film, although more sensitive to mechanical injury, was of a far more permanent character, and suffered no change if it were kept with reasonable care. But that which is formed of gelatine, although much harder to the touch, is subject to change by even a moist atmosphere, and, as this is the common condition of the air in these islands, the worker should do his best to render his negatives proof against it. The varnish, in fact, acts as a moisture-proof coating, and keeps the enemy out; but, as all photographers know, it will not protect the film against actual wet, such as rain-drops, which will, if left to themselves, soon act upon the gelatine underneath.

Strange to say, the principal reason why varnishing is neglected is because the large majority of amateur workers find a difficulty in performing the simple operation of applying the fluid to the face of the negative. They try once or twice, and, after finding that the sticky liquid will somehow run over their fingers in preference to the plate, they give up the matter in disgust, and vote it a bore. The operation certainly requires a steady hand; but, beyond this, varnishing presents no difficulty whatever, if it be done while the negative is fresh from the drying rack. What we mean is this; if the negative to be treated has been handled to any great extent, the surface becomes repellent to the varnish, and it is difficult to make it flow regularly over the surface. Some persons cannot handle anything without leaving a perceptible trace of their fingers upon the thing touched, and even those who are blessed with those dry and extra-sensitive finger-tips which distinguish artists and other skilled workers, will leave an imperceptible trace which the flowing wave of varnish will discover. All difficulty disappears if the plate be handled by its edges only, and if it be varnished as soon as it is perfectly dry.

Few men care to compound their own varnish, for that which is sold by the dealers answers every purpose. But for all practical purposes the ordinary "white hard," which is obtainable at any good oil and colour warehouse, if diluted with about half its bulk of methylated spirit, can be recommended. It lends itself readily to the retouching pencil after treatment with the usual media, and it forms a good protection to the film. In the case of a negative from which an unusually large number of prints may be required, it is

as well to flood the film with a coating of plain collodion as a preliminary step, but for ordinary work the varnish is sufficient by itself.

Apart from the mechanical business of pouring the varnish on the film, some workers make a muddle of the after-work of heating and drying, and get streaky marks which show in the printing. Others, again, get dust, hairs, and all other abominations upon the varnish, and these are sure to stick in some place where they can make themselves evident in the print. With care all these disasters may be easily avoided. In the first place, the plate must be made gently warm only, by which we mean a warmth which, in the case of a liquid, would be called tepid. Next, after the varnish is poured on, the surplus should be run off into a separate bottle kept for the purpose, and finally, the plate should be rocked as it is made quite hot before a clear fire, or, better still, a vertical gas stove. All these operations should be conducted with an entire absence of hurry, for there is no need of haste; indeed, the slower the operation, the greater will be the evaporation of the solvents, and the better the coating. We believe that this old and well-tried method of varnishing a plate is the best, although it involves some little trouble; the heat hardening the coating so thoroughly that it can be printed from as soon as the plate is cold, which is hardly the case where a varnish is employed which requires no heat in its application. Several of these have been introduced of late months, and they will be productive of good if only they induce those who did not varnish their negatives to amend their ways. We have tried more than one formula for a varnish of this latter description, and the one with which we succeeded best was made by dissolving an ounce and a half of gum dammar in half a pint of good benzole. The mixture must be shaken at intervals until the gum is dissolved, and must be left until all sediment has subsided. It can then be carefully decanted for use. We give this recipe for those who like to try it, but we repeat that we prefer, in our own practice, a varnish which requires heat in its application.

Rules for Amateur Photographers.—A great deal is said about the amateur photographer that might just as well have been left unsaid. Those who never were amateur photographers do not realise that there is anything to it but pull the string and press the button. They do not know how it feels to sneak through the streets with a camera under one arm, and encounter the suspicious gaze of every man, woman, and child who knows that such a thing as photography exists. There is nobody who gets within sight of an instantaneous machine who does not promptly reach the conclusion that he is to be made the victim of a photographic conspiracy. Sometimes this self-selected victim will stand around in an effort to look pretty, and make it as pleasant for the picture-taker as possible, and sometimes he will issue a peremptory challenge to mortal combat. You never can tell. After the photograph is obtained, it is as likely as not that the houses will look like Chinese pagodas in a horrible whirl of dissipation, while the pictures of your friends make you sorry that they are not your enemies. There are lots of rules that go with amateur photography, but the only truly reliable way to deal with a camera is to take it out somewhere and carefully break it.—*Washington Post.*

PHOTOGRAPHY IN FRANCE.

BY LEON VIDAL.

French Photographic Society: Modification of its Statutes—New Instantaneous Shutter—Models of Moessard's Cylindrograph — Imitation Limoges Enamel—Yellow Fog, by M. Metreux—South-West Photographic Club at Lyons: Preparation for a Competitive Exhibition — General Syndicate of Photography — Consideration of the Question of Property in Photographic Work—Spread of Orthochromatic Photography in France.

French Photographic Society.—The death of M. Péligot, ex-president of the French Photographic Society, has been the cause of certain modifications being made in its statutes. It has been decided that the presidential office shall not continue beyond three consecutive years. Up to the present time the office has been filled by members of the Institute. We have had successively in the presidential chair MM. Regnault, Bolard, and Péligot, all belonging to that learned association. At the present time there are amongst the members of the Photographic Society several members of the Academy of Science—MM. E. Becquerel, Janssen, Cornu, and Marey. Probably the choice for the new president will fall on one of these. M. E. Becquerel having retired from the council as an active member, and being now only an honorary member, it is not likely that he will be elected to the presidency; and it is probable that upon M. Janssen, who has presided over the International Congress of 1889, will devolve the title, of which he is so well worthy.

MM. Béza, Hausser, and Co. showed a new shutter constructed on an American plan. It is evidently a good instrument, but it is one more among such a large number that are already open to our choice. There ought to be a special exhibition of shutters, so that one might study and compare all these systems and settle upon the best. There are, however, still so many shutters being produced that it is probably better to wait awhile before thinking of organizing such an exhibition.

Commander Moessard has had cylindrographs constructed in all sizes. He has shown some of extremely limited dimensions, one truly small in itself, permitting us to execute prints up to a metre in length.

M. Schirm described a process fit, he tells us, to imitate the enamels of Limoges. It is, in fact, only a sort of transfer not capable of enduring firing, and is produced by the carbon process; nothing particularly new or interesting in this.

The question of yellow fog has been once more brought forward. M. Métreux thinks that it may be avoided by using copious washing. To think that so much should be said about such a small matter! We believe that we have shown that sufficient washing will prevent this evil, and that it is useless to theorise much about it. After this meeting the society was adjourned till the month of November.

The Photographic Club of Lyons had had the intention to prepare for the month of October a great exhibition and set of conferences, but it has recoiled before the material difficulties of such an enterprise, and has limited itself to an exhibition of prints and a competition. The present moment is not favourable to the organisation of a complete exhibition. As for the conferences, they are deferred to a later period, and doubtless there will be one at the time of recommencing the meetings. We believe

that on this occasion one of the honorary members of the Photographic Club of Lyons resident in Paris will be applied to.

The question of the protection of original photographic works continues to occupy the general syndicate of photography; its last meetings have been given over to the study of this question in connection with the projected law concerning literary and artistic property deposited by M. Philippon at the bureau of the Chamber of Deputies. This project assimilates photography to the other methods of production of works of art. It seems to us difficult to suppose that it will not be adopted, and it would be really dangerous to create an exceptional law with regard to photography.

Orthochromatic photography is spreading more and more in France; plates from the establishments of Monckhoven at Ghent, of Engel and Feitknecht in Switzerland, and others, are on sale everywhere. At the establishment of MM. Poulenc Brothers, and at other warehouses, pellicular colour screens, sensitocolorimeters, and chemicals for sensitising plates by the bath process are now on sale. The house of Lumière is also preparing, we hear, to supply orthochromatic plates. All this is of good augury, for the day is not distant when the use of these plates will be insisted upon for the reproduction of polychromatic subjects. We shall then be surprised that we have waited so long before making use of a process that enables us to reproduce the value of diverse colourations with their true effect.

THE TREATMENT OF SUBJECTS BY FOCUS.

BY THOMAS R. DALLMEYER.

Spherical Aberration.

In this paper I shall confine myself to answering Mr. Burton's comments on spherical aberration. He makes this the *pièce de résistance* of his letter, and I therefore propose to settle this question first. To make the matter clear, I would invite those who are interested in the question to refer to Mr. Burton's paper and the two diagrams therein.* First, he says I say that "in the case of a lens with diffusion of focus introduced in the form of positive spherical aberration, the effect, if a middle distance object is focussed, is that the falling off in definition, although greater for a near object than in the case of a thoroughly corrected lens, is less for the distance, and that, the important aim being to reduce the contrast between the definition of the object focussed for and that of the distance, diffusion of focus is a useful thing." Mr. Burton says in reply to this, "that the facts are *the direct opposite of this.* Positive spherical aberration favours near objects at the expense of distance," and proceeds to say that he thinks he can prove it.

Now as a matter of fact, the diagram of Grubb is not properly disposed for accurate comparison, in that the point of best definition does not lie in the plane of the least circle of aberration, *but beyond it:* but it will suffice for the purpose. If, as I have stated before, the sole measurement that concerned the practical as well as theoretical introduction of spherical aberration into a lens was to be ganged by the *transversal measurement* of the circles of confusion, then it would be found that the planes nearer than that focussed for would be benefitted by the introduction to the detriment of the distance, as the transversal measurements shown in the diagram would convey to a casual observer.

Taking Grubb's diagram as it stands, there is a locus of five hundred units, within which there is partial definition and an *inward* concentration of rays even beyond this in the lens containing spherical aberration. In the corrected lens there is only one point of absolute definition, and a uniform distribution either side of the focus; in the lens with spherical aberration, therefore, there must be *improved* definition in these out of focus planes along that locus, and where there is the inward concentration. The most important bearing that the introduction of spherical aberration has on the formation of the image *depends on where the image-forming rays are most concentrated.* Imagine, in both cases, that a point of light has been focussed for. A mere glance at the lower figure shows the vast amount of inward concentration that occurs on the *further side* of the least circle of aberration; it is the *inward* concentration of rays that tends to form the image. Mr. Burton, simply taking into consideration transversal measurement, entirely overlooks the fact that although the transversal measurement *is less nearer to the lens, that here the concentration is outward*, and the point of light that is desired to be represented would be represented by a bright ring with a comparatively dark centre. On the further side of the best focus it will be a bright point surrounded by faint halos, but, comparing the two, the inward concentration of these image-forming rays where concentrated along the axis will produce a *better* image than an uniformly illuminated disc. When spherical aberration is introduced, I repeat, the distance is favoured at the expense of worse definition for the foreground. If Mr. Burton had carefully examined the prints of the grating in my paper read at the Camera Club Conference, he would find, in the case of excessive spherical aberration, the *tendency* I have pointed out of *outward concentration* is clearly illustrated, in that for a nearer plane than that focussed for the image itself becomes absolutely *reversed*, whereas the distance simply, more or less, maintains the *structure* without the reversal.

The second error in Mr. Burton's letter is where he says:—"Mr. Dallmeyer assumes that the bundle of rays nearer the lens than the plane of focus represents the distance, those farther from the plane of focus, foreground. *Now the exact reverse is the truth.*" I find this rather comical, as Mr. Burton immediately proceeds unwittingly to prove by his diagram that I am right and he is wrong. The plane of the plate, A B, is a fixture, and is focussed for an object, C. Viewing the two diagrams of Grubb and this together, supposing the object is moved nearer to the lens at E; the result is, that upon the plane of the plate the *outward* concentration of rays will fall; if, on the other hand, the object C be moved away from the lens, for parallel rays, as represented in Mr. Burton's figure by the fine lines, the *inward* concentration of rays will fall upon the plate. Had Mr. Burton introduced spherical aberration into a large diagram, he would have seen that what I have above pointed out is fact. I say it is comical because Mr. Burton becomes so hopelessly muddled that he does not see that if he puts his *two* clauses, "the exact reverse of this is the case," together, that the two negatives make a positive, and, if correct, would prove that, with positive spherical aberration present, the *distance must be favoured.*

In order that I may make myself perfectly clear, I would like Mr. Burton to try the practical experiment for him-

* We are unable to reprint this week the two large cuts published in the News last week, and referred to in this article by Mr. Dallmeyer. Readers are therefore requested to refer to our last number.—Ed.

self. Taking a lens with a large amount of spherical aberration outstanding (for simplicity), and obtain the best focus possible; then, referring to Grubb's diagram, with the spherical aberration outstanding, let him remove the bright object, such as a lamp flame, some distance off without altering the plane of the focussing screen. He will there see that the continuation of the *inward concentration* of the image-forming rays is brought forward and registered on the plate, the image still, according to the distance to which it has been moved, remaining more or less distinct. Then, on the other hand, let the lamp be brought forward without altering the plane of the focussing screen; he will there see that, instead of having the same indication of the image, the rays going to form a focus at a *longer* conjugate, the *outward* concentrated rays will fall upon the screen. If, in any case, Mr. Burton cannot follow my arguments, let him, at any rate, prove this for himself by the experiment; he will then be convinced of the truth of the position I have taken up.

In conclusion, Mr. Burton says that he does not know at all that he agrees with me when I lay it down that it is always most desirable to reduce the lack of definition of the *distance* without reference to the foreground; then he says, "I think there are many cases in which the reverse is the case." My reason for thinking that improved background is better than improved foreground is, that as visually there is less falling off in discrimination of distance *beyond* what the eye is concentrated upon than there is for foreground, that this condition is preferable; for we know in vision that there is a distance beyond which everything is apparently in focus; and Mr. Burton also possibly knows, for a given distance either one side or the other of the plane focussed for, the definition would be better for an object a certain given distance *beyond* the point focussed for, than for the like distance in *front* of the point, even when employing a perfectly corrected lens.

In my paper read before the Camera Club Conference, I mentioned that there was a means of improving foreground, if necessary, by the introduction of *negative* spherical aberration; and if Mr. Grubb's diagram be turned upside down, Mr. Burton will have the representation of the condition of things if negative spherical aberration were introduced.

Had this subject not been fully thought out many years ago, there is no doubt, in my late father's patent portrait lens, there would have been a means by bringing the back flint lens *closer* to the crown than the condition for aplanatism now allows of to introduce negative as well as positive spherical aberration. With that construction either the one or the other class of aberration could be introduced at will, there being one definite position in which the lens as a system is entirely free from aberration.

I hope next week to reply to the other points contained in Mr. Burton's letter.

Photographic Club.—Subject for discussion Wednesday, August 20, "Photometers and Actinometers." August 27, "Printing Through Coloured Media."

A Simple Printing-Frame.—*Photographisches Wochenblatt* gives the following directions for making a cheap printing-frame; viz., take any old or spoiled glass negative of the proper size, and cut it in two; then paste a strong piece of black muslin over both pieces; when thoroughly dry this will form a hinge. For use, place the sensitive paper on the negative to be copied in the usual manner, then a piece of blotting-paper, after which lay the cut negative, muslin side up, on the paper, and secure the whole with four spring clips or clothes-pins, and print in the usual manner. This device has been published before.

THE PHOTOGRAPHER'S HOLIDAY.

BY JAMES MEW.

"To everything," says the author of the book known as "Ecclesiastes," "there is a season, and a time to every purpose under heaven." To every separate work which goes to make up the great aggregate of human activity, to every operation in the vast sum of human travail, there is, according to this inspired authority, an appropriate time appointed.

The time to take a holiday seems, by a general consensus of opinion among the inhabitants of Great Britain, to be the month of August. It is in this month that everybody—everybody, at least, in the social world of fashion—is out of town. It is in this month that we hear the familiar observation, however inaccurate, that the streets of London are nearly empty.

It is in this month that a drizzling shower of advertisements from the various railway companies in England invites us to Blackpool, and to Leicester, and to the Lakes, and to Margate, and to Southend-by-the-Sea, and to more places of holiday resort than could be easily compressed into a column of the present paper in the smallest type.

It is in this month that the modern development of Virgil's harpies swoop down upon the carefully provided fodder of the family commissariat, and confound her frugal mind with large slices cut out of the cold leg of mutton intended for the Sunday dinner. Finally, it is in this month that the photographer is bound by laws akin to those of the Medes and Persians in their immutability, to take his holiday, if he can take a holiday at all. And here arises a painful doubt, Can a photographer take a holiday at all?

First, let us take the case of the ordinary man of photographic business, with whose neat glass case in the High Street—a case full of portraits of the seven ages—we are all so familiar. This bourgeois photographer will take up his parable, and complain in this wise after the fashion of Sterne's starling: I can't get out. I cannot take a holiday. If I leave my wonted habitation, what will become of my custom? Those who seek me will not find me. They will go elsewhere; there will they obtain their hearts' desire, and I shall be altogether forgotten like a thing out of mind. Thus he complains, and not altogether without cause. It is idle to suppose that his customers will reason in the following syllogistic fashion, neatly provided for them by the inexperienced: Our photographer, from extreme pressure of work, has lost his health, and has been compelled to recover it by a little change. This extreme pressure is the result of his popularity; his popularity, again, is the result of his excellent workmanship. Therefore we will wait to have our portraits taken till such time as he returns. No! human nature, particularly, perhaps, female human nature, which pants after carte-de-visites as the hart panteth after the waterbrook, is impatient; it is also illogical. An idea of business, and of a consequently failing health, does not arise in the lady visitor's mind before her favourite photographer's closed door. She is rather disposed, from the little irritation born of disappointment, to associate his absence with indolence or with pleasure. In any case, the lady visitor cannot waste her valuable time; she cannot wait. Human nature, it has been said, seeks to attain the difficult, but that is only where the easy is impossible of access. There is no aspiration for the attainment of the difficult where it is simply a matter of crossing the road from Mr. Jones, on his holiday, to Mr. Brown, still hard at work

in his studio. Bob Sawyer's device to obtain patients was not destitute of ingenuity, but it is also probable that he lost them by his absence from his surgery.

Let us hear the conclusion of the whole matter. The ordinary photographer—the man whose business it is to furnish counterfeit presentments of his fellow creatures all day long—can hardly take a holiday without a considerable loss of custom. This is a misfortune which, it may be urged, he shares with every other professioual man; but it is hardly so. The lawyer, for instance, loses little by not attending to legal business in the long vacatiou; the grocer may leave a substitute behind him. The photographic artist has in this particular an unique crown of exclusive glory. But if Mr. Jones is willing to behold with uo jaundiced eye those who once purchased their pictures from him passing over the road with one accord to buy of Mr. Brown; if in the magnauimity engendered of the Margate air he chooses to let pecuniary considerations slide, then let Mr. Jones take holiday to his heart's content. He may sit in the blinding sunlight upon some unfamiliar shore, and do nothing but contemplate the sea all day long—a leading feature of happiness in a holiday—if he is content to forget his camera, which is not so difficult, and his customers, which is not so easy.

But a real photographer, a true lover of his art, one whose soul is occupied with his profession, a photographer *jusq'aux ongles*, as the French say, a man whose whole being, as we say, is in his work, can a man of this kidney ever obtain what is generally and correctly understood by a holiday. The old sense of this word, which is a consecrated day or a religious anniversary, a day set apart for the commemoration of some important event or egregious person, has long since passed by. Its meaning is now not necessarily even au occasion of joy and gaiety. It is rather a time of exemption from labour, a time comprehending a day, or a number of days, during which a person is released from his ordinary toil. It is in this sense in which the word is used in the well-known passage which Shakespeare puts into the mouth of Prince Henry:—

> "If all the year were playing holidays,
> To sport would be as tedious as to work."

The never failing condition of a holiday is that there must be some variation of a man's common occupatiou.

The essence of a holiday is change. For the true photographer this condition is difficult, if not impossible. He who practices photography solely for the sake of making money by it may be no true lover of the art. It is easy for him to obtain his holiday by leaviug all photographic considerations behind him. But he who loves his art for its own sake, for the pleasure which it brings him, quite apart from any consideration of pecuuiary profit, cannot so easily divorce himself from its charms. Before the commencement of what is called, for convenience of nomenclature rather thau for exactitude of description, his holiday, he will earnestly consider what photographic impedimenta it will be necessary or conveuient for him to pack up and take with him, constant companions wherever he goes, like the bells on the fiugers and bells ou the toes of the lady in the nursery rhyme. His study will be to simplify his baggage, to take such articles as are light and yet of approved solidity, such pieces of photographic machinery as are proof against heat and moisture. Then comes the choice of plates, of objectives, of chemicals; then a selection from a series of excellently well written papers from the Photographic News on the arts of retouching, of printing, on the possibility of the reproduction of natural colours, all of them papers which he has put aside to read carefully at a convenient season. These he reads, or some one or two of them, as the train conveys him to the haven where he would be, the place he has chosen to inhabit during his so-called holiday, and so his so-called holiday begins.

With such a commencement of his holiday, it is possibly needless to enlarge upon the method of its continuauce. The recreation which arises from change of employment is not his. He alters—perhaps not without some considerable inconvenience, paying all the while heavily for the alteration—his hours of rising aud going to bed, of exercise, of eating and of drinking. He varies his meals, but not his meditations. Photography, which is the great business of his life at home, is also the great business of his life abroad. The unwonted dress of the foreigners he meets fills him with a burning desire for the Kodak he forgot to pack up and bring with him in his portmanteau. The most picturesque scenery of hill, or champaign, or wood, or waterfall, in dewy morn or dusky eve, scenery which is supposed, in the slang jargon of our day, to lift a man out of himself, only plunges him into a troubled consideration of lenses, and lights, and sensitised papers, and diaphragms, and printing, and toning, and filters, and oxalates, and hyposulphites, aud the uumerous other matters which enter the ordinary routiue of the photographer's existence. The Chinese, who, as we are told, object to having their portraits taken lest they should at the same time lose a portion of their soul, are uot, perhaps, so silly in their apprehensious as they might at first blush appear. If the soul of the sitter suffers not from the taking a portrait of the whole or a part of his body, the art which instructs the photographer to take him is guilty of no petty larceuy in the matter of the soul of the photographer himself. You have robbed me of my soul, is the intelligible though impassioned language of the lover to his mistress. In like manner may the fervid photographer arraign that dear art which is his constant occupation as well as his dearest delight.

The lawyer may forget for a season his parchment and his leading cases, the churchman his Chillingworth and his chasuble, the doctor his drugs and his drachms, but the photographer to the manner born is reminded by his very pleasure of his well-beloved business. It is impossible for him to escape from his camera.

In their daily work, people become tired of repetition, of routine, of sameuess. They know their work so well; there is nothing to surprise them; they can reckon so exactly on what is coming. They get tired of it all, and wish for something varied, something unknown, something unusual, somethiug surprising. This is the chief factor in the sense of delight alike for the holiday maker in Lucerne or the Lakes, and the urchin who plays at pitch and toss in the street with a dirty halfpenny; and so far as the photographer here pictured can obtain pleasure from unexpected effects, so far he may enjoy a holiday without locomotive change. But other holiday it is not his to know. Like the merchaut Abudah in the Tales of the Genii, the wealthy tradesmau of Bagdad who, travelling in search of the talisman of Oromanes, was accompanied everywhere by the mysterious box containing a familiar spirit, so is the lover of his art accompanied in his search after health or pleasure abroad by the ubiquitous presence of the spirit of photography, which at home is his household god.

Notes.

M. Nadar has been inviting newspaper men and others in Paris to become amateur burglars, and to try their prentice hands at breaking or filing open his iron safe. At a certain stage these operations complete the circuit of a galvanic battery, which then fires off some magnesium explosive powder, and releases the shutter of a concealed camera. The result of this is a portrait of the burglar in the act of "burgling." The correspondent of one French newspaper says that he was careful to bring his portrait, so taken, away with him; it was too compromising to be left out of his own possession.

The people of the more civilised nations of Continental Europe have been visiting each other more and more in holiday seasons for the last twenty or thirty years; but only of late years has the average Briton begun to take the same course. The small extent to which the teaching of living languages was aforetime encouraged by British scholastic authorities had much to do with this comparative isolation. Within the last six or seven years a remarkable change has been taking place in the amount of Continental travel performed by the English middle classes, and the statistics of the traffic across the Channel just published show that during July the number of passengers between Calais and Dover was 28,207; between Dieppe and Newhaven, 13,631; and between Boulogne and Folkestone, 8,757. The traffic for the first seven months has amounted to—Calais and Dover, 141,333; Dieppe and Newhaven, 47,217; Boulogne and Folkestone, 44,251. The total of these figures shows a decrease of 67,252 compared with last year, which was an exceptional year on account of the Exhibition; but, in comparison with 1888, there is an increase of 18,392 passengers.

Now that the question of the revival of stereoscopic photography is occasionally cropping up, some of the leading causes of its going out in the past may be considered. One was the large number of bad stereoscopes in the market, unprovided also with means for adjusting the lenses to suit the eyes of different observers; the eyes of some persons, for instance, are much farther apart than the eyes of others. The lenses of a stereoscope should be adjustable to any position, in addition to the usual means of fixing them at any desired distance from the photograph. Badly mounted stereoscopic views were plentiful, and those which were printed on albumen and imperfectly fixed, tinted also with fugitive colours, soon became wretched objects on a drawing-room table.

An idle rumour has reached us from different sources that a shop for the sale of photographic goods is to be opened on the ground floor of the new premises of the Camera Club, not that the Club is going to keep the shop itself, but that it will let the "location" to some dealer. This would come pretty much to the same thing, because shops in main London thoroughfares are commonly enough let at rather more rent than the tenant can pay, so that actually he is often but the slave of his landlord. Supposing, however, that the ground floor were let at a moderate rental, the tenant—and we have not heard that one has been unwise enough to accept the ticklish position—would be obliged to be mightily civil to his governing customers upstairs, and the latter are aware that there are two ways of controlling a donkey. One way is to beat him with a stick, or, when a lady is on his back, to run hairpins into him between the ribs, because that method does not look so cruel as the use of a cudgel, and might not be noticed by passing observers; the other way is to hold at the end of a stick a bunch of carrots in front of his nose. Whichever way you put it, the fact remains that the animal is not free, and that the governing powers are the morally responsible agents. If the Royal Society tolerated a shop on its premises at Burlington House for the sale of scientific instruments, or if the Travellers' Club encouraged a map-shop down below, what effect would it have on the influence and *prestige* of the organisation? Such a line of action as that rumoured would seem to us at the first glance to be the first mistake in public policy yet made by the Camera Club, an excellent organisation which has greatly promoted intellectual activity in photography. Probably the rumour is false.

Many of our readers have, doubtless, been somewhat amused by the highly coloured pictures of sea-side places and tourist resorts which are exhibited by our various railway companies. The lines which run to Scotland are particularly demonstrative in this way, and, in spite of stern reality, depict mountain and lake bathed in everlasting sunshine, as if in those regions the rainfall, instead of being in the nature of things more abundant than in any other part of Britain, were absolutely *nil*. In like manner the Lakes of Killarney and the western coast of Ireland are made to tell a flattering tale of continued fine weather. Of course the railway companies must not be blamed for showing their territory under the best conditions, and fine weather landscapes will, no doubt, continue to attract customers.

But some railway companies seem to be alive to the fact that these pictures may be thought by some to be too gorgeous in their colouring, and to approach too nearly to the pictorial efforts of the theatrical manager. So they are invoking the aid of photography in their efforts to gather tourists under their wings, and they are wise in exhibiting pictures of real merit. In the first class carriages of the Great Eastern Company, for instance, are now displayed some capital pictures of the Norfolk Broads, &c., which bear the well-known name of Payne Jennings. The Midland Railway is also to the fore in showing at their stations some good pictures of the magnificent limestone scenery of Yorkshire. These latter are platinotypes, and are evidently meant to stay.

A notable result of the adoption of photography by the tourist is the large number of dark rooms which are now at his disposal throughout the kingdom. Dealers have long ago seen the advantage of providing this accommodation for their customers, the enterprising London Stereoscopic Company having been first in the field. In every large town there are several who allow tourists to change plates on their premises, and even to develop as well. This, of course, brings them business, for the worker is sure to want both plates and chemicals to supply the place of those which he has used up, and will often make a point of wanting something in order to make a little return for the hospitality which he has received.

But, beyond mere dealers, there are others who are glad to place the attraction of a dark room before their customers. These are the hotel keepers, who are beginning to understand why so many of their clients have from time to time made enquiries as to the accessibility of their empty cellars. In a very useful hand-book issued for the use of members of the Cyclist's Touring Club, such hotels as afford this accommodation have the letters D.R. (dark room) or D.C. (dark cupboard) placed against them. An explanatory note says that some of these places are mere cupboards, without any kind of fittings, and the tourist is therefore advised to carry his own red light with him. In the near future the hotel proprietor will find it to his interest to pay particular attention to this necessary adjunct to his house.

Our own Post Office authorities are occasionally afflicted with eccentricity; but they have not, so far as we know, perpetrated such an enormity as a well-known French photographer, M. Balagny, complains of. M. Balagny had sent to him, from America, a number of film negatives for development. They were forwarded by parcels post with all possible precautions, and marked "Photographic plates; to be opened only in a red light," but seem to have met with a series of misfortunes. Firstly, they took two months to arrive; secondly, the postage amounted to eight francs, seventy-five centimes; and thirdly, the packet had been opened and all the plates spoilt. A second parcel of films, marked "Sample of photographic pellicles, of no value," arrived to time, cost but thirty centimes, and developed without the least sign of deterioration. After this experience, M. Balagny has come to the conclusion that the best way of sending photographic films is in the form of a registered letter, with a declaration of its value.

The incident certainly points a moral. Until the Post Office authorities employ photographers, and set up dark rooms, it will be unwise to inscribe packets with the intimation, "To be opened only in a red light." Some officials might take this announcement as a direct invitation to break the paper cover, and as their notion of a red light might be very different from that of a photographer, the result would be disastrous for the contents of the parcel.

Photographers, like doctors, are perpetually differing. Perhaps it is as well; the various opinions and experiences prevent monotony. The paper on "Eiconogen," read by Mr. Chapman Jones recently at the Photographic Society of Great Britain, has attracted the attention of the Society Francaise de Photographie. M. Davanne does not concur in Mr. Chapman Jones' opinion that eiconogen does not stain. M. Davanne's experience was that eiconogen did stain, but he added that the cause might be due to the developer having been prepared for some time. M. Ton, on the other hand, did not think the staining was due to the developer at all, but to the difference in the mode of preparing the plates.

There are no less than three pirated photographic editions of the "Encyclopædia Britannica" selling in the United States at about one-seventh of the price of the authorised edition. The decision in the recent action brought by Messrs. A. and C. Black and their American agents, Messrs. Scribner, against an American firm which had published a pirated edition from photographic plates, will probably cause the other three firms some alarm, as a verdict against them is certain should Messrs. Black decide to proceed for damages.

France and America are running a very close race in regard to photo-astronomical work. The Brothers Henry have lately turned their attention to photographing stella spectra, and with such success that from statements made by Admiral Mouchez in a report to the Paris Academy, it appears that their results compare favourably with those obtained in the United States. The photographs were obtained by placing prisms of 22° or 45° in front of the object glass of the photographic telescope. The Paris Observatory, Admiral Mouchez also stated, will henceforth include spectroscopic observations as a part of its regular work.

Are the public getting tired of photographs of celebrities? There is a decided falling off in the demand. One photographic firm which used to go in largely for this branch of publication now attaches no value to it as a source of income. A well-known shop, not a hundred miles from Temple Bar, which for years was exceedingly useful to artists in want of photographs of celebrities, is closed; and it may be presumed that there was no inducement for a successor to continue the business. The Automatic Photographic Supply Company has discovered that there is not the fascination in photographs of actors and actresses, even at a penny a piece, 'as it supposed. And as for the peripatetic vendors, they have almost wholly disappeared from the streets, though this, of course, may be due to the fact that in the summer time they may have more profitable articles of merchandise. Anyway, all the indications point to a curious cessation of interest in the counterfeit presentments of popular personages.

THE AMERICAN PHOTOGRAPHIC CONVENTION.

At the American Photographic Convention, which opened in Washington three days ago, the list of prizes for 1890 is as follows:—

The grand prize is a group in bronze, entitled "Nearing the Goal," value $225, and governed by the following rules and regulations:—

Competitors for this award shall exhibit three plain photographs illustrating Tennyson's poem, "Enoch Arden," the picture not to be less than 13 or more than 22 inches in length.

The pictures must be framed, either with or without glass. The award to be made for the most meritorious collection.

Class A.—A beautiful silver "plaque" mounted in plush, representing "Victory," for the best exhibit of genre photographs. The subjects are to be chosen by the photographer, and appropriately inscribed; size not less than 13 or more than 22 inches in length, and framed, with or without glass. The award to be made for the best collection.

Class B.—One gold, one silver, and one bronze medal for the best collection of portrait photographs, size 14 by 17 inches, or larger.

Class C.—One gold, one silver, and one bronze medal for the best collection of portrait photographs, size 11 by 14 inches, or smaller.

Class D.—One gold, one silver, and one bronze medal for the best collection of landscape photographs; one silver and one bronze medal for the best collection of marine views; one silver and one bronze medal for the best collection of architectural views.

Class E.—One silver and one bronze medal for the six most artistically retouched negatives, any size; prints made before and after retouching to be exhibited with the negatives.

Class F.—One silver and one bronze medal for the six best plain enlargements, either in silver, bromide, albumen, carbon, or platinum, size not less than 18 by 22 inches.

Class G.—One silver medal for the best improvement in photographic appliances introduced since the last Convention.

Class H.—One gold, one silver, and one bronze medal for the best foreign exhibits of portrait photographs, framed or unframed, but delivered to the Association free from all charges.

Mr. R. P. Drage is the new hon. secretary of the London and Provincial Photographic Association. The life and soul of any organisation have no means of adequate public expression except by means of its secretary, and we think, as aforetime, that in this case the Association has another good one.

Gelatine Plates Developed in Water.—Dr. Backelandt gives the following formula for making sensitive plates which, after exposure in the camera, can be developed in water. These gelatino-bromide or gelatino-chloride of silver plates are prepared in the following manner. The back of the plate is coated with a mixture composed of:—

Water	20 c.c.
Salicylic acid	1 gramme
Gum or dextrine	10 grammes
Alcohol	5 c.c.
Pyrogallic acid	1 gramme

The plate is allowed to dry at the ordinary temperature. To develop, steep it in water to which a few drops of ammonia have been added.

THE VALUE OF SILVER WASTE.

BY GEORGE BRINTON PHILLIPS.

It is rather surprising that there should still exist in the minds of many practical photographers a good deal of uncertainty with regard to the true value of their silver and gold wastes. In the early days of the art very little attention was paid to the systematic saving of the precious metals in the waste, although Dr. Vogel, in his "Handbook of Photography," in 1871, gave some interesting estimates of the amount of silver in the finished print, and the quantity that goes to waste in the wash-water, hypo, and clippings. Of late years, however, close competition has compelled the photographer to consider his wastes as a source of revenue, and now, when the proper systematic care is exercised in saving them, but little that is valuable of the precious metals is actually lost. The writer, some years ago, made a number of experiments and assays to determine the amount of silver that went to waste during the process of silver printing. The results, which were published in a pamphlet, called attention to the very trifling amount of silver in the finished print, amounting to only about 6 per cent., and the large proportion which, with care, might be saved.

It is, perhaps, a little unfortunate that the possibility of recovering so large a percentage of the silver used has led a good many to expect to get back really more than they have actually consumed. There are some photographers who, with a laudable desire to save all their paper waste, sweep into a corner of their printing room everything that falls upon the floor, and in a short time a pile accumulates, consisting of some clippings, with a varied assortment of old newspapers, card mounts, dry-plate boxes, broken negatives, nails, and pretty much everything, down to old hats and shoes. This heap is regarded with a jealous eye as a possible mine of great wealth; when the meagre return from the refiner comes in the photographer is much disgusted, and, in his ignorance of the simple facts of the case, believes he is the victim of gross fraud. There are others who, through lack of time or interest in the matter, delegate the proper care of their wastes to some one in their employ. Of course the conscientious printer will do the best he can, if he has the proper instructions, but an intelligent supervision is always necessary in looking after the details of any business to insure success. Although it should not be the principal effort of the photographer to make the saving of his wastes the chief aim of his business, yet it is a matter which is worth a little personal attention, as he will then be able to form a pretty accurate estimate of the value of his wastes, and, having a knowledge of the amount of nitrate of silver purchased during the time, he can compare, with some degree of fairness, his expectations with the actual returns when they come in.

To do this, it is most important that the waste paper and residues should be kept clean and free from foreign matter. A barrel or large box in a convenient corner in the printing room may be made the receptacle for all clippings, proofs, and spoiled paper, and nothing else should be allowed to get in but silvered paper. Under such circumstances it will be easy to form a close approximation of the actual value of such waste. It must be borne in mind, however, that the presence of bromide paper, and especially blotters, will considerably lessen the value of the waste, while, on the other hand, many rich filters, or papers which have become saturated with the

drippings of nitrate of silver for a long period, will noticeably increase it. It has generally been conceded that 1 ounce of nitrate of silver is consumed in sensitising 20 sheets of paper. As 20 sheets of silvered paper will be found to weigh 16 ounces, or 1 lb., it follows that it will be impossible to get from a pound of such paper more than 1 ounce of nitrate of silver. Now, as 1 ounce of nitrate of silver contains 63·5 per cent. of metallic silver, the one pound of paper will contain 277 grains of metal. The value of metallic silver varies from day to day, so that the value of the waste will fluctuate in a corresponding manner. Supposing that fine silver were worth 95 cents. per ounce (the average price for some months past), the value of the 277 grains of silver would be $54\frac{8}{10}$ cents. This $54\frac{8}{10}$ cents, then, is the actual value of one pound of perfectly clean silvered paper. Of course it stands to reason that there must be some expenses and profit to the refiner in recovering the silver from the waste, which must be deducted before the net value to the photographer is reached. These expenses may be great or small, but there must be some charge for refining, and as few photographers have the time or knowledge necessary to successfully refine their own wastes, they should not begrudge the modest charge deducted from the returns.

The experience of a number of years in the reduction of silver residues has enabled the writer to verify the above figures.

Paper silvered upon a 60 grains bath has been found by careful assay to contain 11 grains of metallic silver to each sheet, five grains existing as free nitrate of silver, which is removed in the washing before toning, the balance being chloride of silver, the bulk of which is dissolved out by the hypo. As 14 grains of silver are present in one sheet of paper, twenty sheets (or one pound) would contain 280 grains, a close approximation to the theoretical calculation. In another paper will be shown the value of the wet residues, toned prints, and gold waste.—*American Journal of Photography.*

An Optical Pyrometer.—In the Official Report on War Material in the Paris Exhibition, *The Chemical Trades' Journal* finds an interesting application of optical polarimetry to the determination of high temperatures. We refer to the Lunette pyrometrique or pyrometic telescope, in which polarisation is applied to the rays of the spectrum. The instrument consists of a small tube of brass having a conical enlargement at one end. The smaller and cylindrical portion is divided into two parts, the first containing an arrangement of lenses, constituting the eye-piece, and a Nicol's prism. This is called the analyser, and is fitted to the second tube or part so as to rotate axially and independently. In the second part is fitted a plane of quartz, cut perpendicular to its optical axis. Behind this is a second Nicol's prism called the polariser, while in the enlarged end of the instrument is placed the object glass. When an incandescent body is observed through this instrument, the colour visible for a given rotation of the analyser varies according to the temperature, and the passage from one tint to another requires an angle of rotation varying according to the luminous shade observed. A small turn brings the change from green to red, and the angle of rotation indicates the temperature. The test is said to be far more accurate than any judgment based upon observation with the naked eye. Cherry red at about 900° C. requires an angle of 40° on the instrument; white heat at 1,500° C. an angle of 69° to bring about the change of colour. The small illumination produced by temperatures below 900° renders it difficult to accurately determine them, and an extra large objective is employed. It is stated that this instrument is "largely" used at the St. Jacques Works, and we await further particulars based on actual experience of this interesting application of polarised light.

SPECIAL UTILISATIONS OF HYDROQUINONE DEVELOPMENT.

BY T. ARCHDALE POPE.

Hydroquinone has not hitherto been much used as a substitute for pyrogallic acid in the development of dry plates, at least in this country; but when the advantages which it possesses over the latter substance come to be more fully recognised, it is not unlikely that, for certain classes of work, and in particular for the development of extremely rapid plates, it will supersede pyro altogether. I have lately been hunting up and trying the different published formulæ, and have found one in a book published last year (*Traité de Photographie parles Procedés Pelliculaires*, by Balagny, Vol. I.) lent me by Colonel Waterhouse, which will repay the trouble of making up. As it is not so much the composition of the developer as the method of applying it, according to the particular qualities desired in the negative, which conduces to good results, it will be necessary to describe exactly how the author himself proceeds.

The chief advantage claimed for hydroquinone is that it yields a negative of remarkable softness, and at the same time of sufficient density to give a good print; and that such negatives can be produced by means of hydroquinone much more readily than with pyro, the latter only yielding equal results if the proportions of the several ingredients of the developer—pyro, bromide of potassium, and alkali—are regulated exactly. No such extreme nicety of proportion is necessary with hydroquinone development. Once the solution is made up, it only remains to employ it in the manner to be described, and it will be almost impossible to spoil a plate, provided the exposure has been fairly correct. Moreover, the colour of hydroquinone negatives leaves nothing to be desired; yellow stains and green fog, so often resulting from pyro and ammonia development, are impossible with it, and the delicate silver-grey tone which it imparts is very conducive to rapid and successful printing.

The quantities are given by the author in the French metric system, but I have converted them into English weights and measures as being more likely to be useful to readers of the *Journal*.

The developing solution is made up as follows:—

Water	30 ounces
Sulphite of soda	2·5 ,,

When dissolved, heat the solution to about 70° Fah. and add—

Hydroquinone	150 grains

The hydroquinone should be in powder; great care should be taken that it is completely dissolved, and no grains left at the bottom of the glass; otherwise, the subsequent addition of the alkali will redden the solution slightly, and ultimately spoil it altogether. Next add—

Carbonate of soda (crystals)	4·75 ounces

which completes the developer.

This solution is so energetic in its action that it should never be used in its freshly prepared state, except to develop highly sensitive plates exposed with the most extreme rapidity. When several such plates have been developed in it the solution becomes partially charged with bromide of soda from the sensitive films, and this exercises a restraining effect upon it, rendering it slower in its action and more suitable for the development of less sensitive plates. As the solution alters very slowly, the same quantity may be used to develop five or six plates in succession, after which it should be poured off into another

bottle, and kept for future plates of a less high degree of rapidity.

But if, having made up the solution as above, it is only desired to develop plates of the slower class, to which ordinary drop-shutter or longer exposures have been given, it will be necessary to modify the developer, so as to give it the restraining effect of one which has already been used. This may be done by adding to a sufficient quantity of the unused developer an equal quantity of water, and to each ounce of the mixture three drops of glacial acetic acid.

Thus, we have two formulæ; one for a developer which is too strong in its action for ordinary plates, but can only be used in cases of very special rapidity, and another for a modified developer, which is precisely similar in its action to the stronger one when the latter has been used a few times, and become partially charged with bromide of soda. These two developers may be used either separately, the first for very quick, and the second or modified one for very slow exposures, or they may be mixed together in various proportions for exposures ranging between the two extremes. For instantaneous plates, not of the special class mentioned above, the proportions of the mixture would be about seventy per cent. of the strong developer, and thirty per cent. of the modified one. So much latitude, however, does hydroquinone permit that, if we suppose a series of six plates of the same kind to have been exposed two, four, six, eight, ten, and twelve seconds respectively, there would be no need to vary the strength of the solution for each plate, but it would probably be found that a mixture of equal parts of the strong and modified developers would develop all the six plates equally well. If the light at the time of exposure was weak, it would be advisable to increase the proportion of the strong solution and decrease that of the modified one, and *vice versâ*. Different makes of plate will, of course, require different treatment, but a few trials will show what strength of solution works best with the particular kind of plate used.

After developing five or six plates, the bath should not be thrown away, but poured off into another bottle, and it can be used afterwards in place of the modified developer to mix with the original one. It will not grow weaker, because every time it is employed it is strengthened by being mixed with the strong solution. If, however, from long use it becomes of a deep red colour, it should be thrown away, and a fresh portion of the strong solution modified with water and acetic acid as already explained.

It should be remembered that, when the strong solution preponderates in the mixture, the resulting negative will be of a very soft, harmonious character (*grey*, in fact, when used unmixed), and that an excess of the modified or old developer will tend to produce a hard black and white negative; and this principle should be borne in mind in settling the composition of the developing bath.

The negatives are washed and fixed in the usual manner. Five minutes in a 15 per cent. hypo bath are sufficient, after which they are well washed again and placed in the alum bath.

Only glass dishes should be used as developing trays. Those made of *papier maché* have a tendency to darken the solution and render it useless.

Prints on bromide paper may be developed with hydroquinone, and, according to my experience, there is less difficulty in obtaining pure black tones with it than when ferrous oxalate is used.—*Journal of the Photographic Society of India.*

PHOTOGRAPHIC TERMS AND THE GERMAN LANGUAGE.*

As quite a number of photographers who attend the Convention in Washington have expressed a desire to take a trip to England and the Continent after the Convention has adjourned, for the express purpose of extending their photographic knowledge, and to become thoroughly familiar with the latest European methods, we consider it our duty to the craft to sound a note of warning to all such as contemplate an extension of their trip to Germany. As will be known to many, a systematic effort has been made ever since the termination of the Franco-Prussian war to expunge from the German language all words, expressions, and terms of foreign origin. How thoroughly this has been done will be apparent when we take for example the German substitutes for the two universal words telegraph and telephone—viz., *Electrischer-fernschreiber* (electric distant writer), *Fernsprecher* (distant speaker). For some reason still unexplained, photography and its attendant terms escaped for the time being. It is now stated, on apparently good authority, that one of the first edicts issued after the resignation of Prince Bismarck was an order relative to the expurgation of all foreign words which crept into the German language in connection with photography. The result of this is, that the tourist who visits Berlin and looks for the formerly familiar signs *Photographisches Atelier*, looks in vain. Nor would the uninitiated stranger be much the wiser if he gaped for an hour at the brand new sign over the entrance to one of Berlin's most celebrated galleries:

FRIEDRICH WILHELM RECHTECHTTEUTSCH,

H. u. K. Hof.-Lichtbildner

LICHTBILDNERWERKSTATT.

If his curiosity should overcome him, and he should enter the establishment, he would be surprised to find himself in an every-day photograph gallery. But even after entering the portal with the sign *Eingangsstube*, and being met with a polite reception from the *Empfangsfraulein*, he would not be less confounded, if he should point to a cabinet size and ask the price, and be told that *silber-pauslichtbilder* in *schlafstubengrösse* costs so much, but in *damenzurückziezimmergrösse* the price is so many marks higher. All this confusion is merely the result of the improvement in the German language. If the seeker after photographic knowledge would have a personal interview with the proprietor, he would send his card to the *Herr Hauptlichtbildner*, or if his business laid with the operator, he would simply ask for the *Dunkelkammersachverständigen*. The much abused amateur is known no more within the Imperial realm; he has vanished for ever. His successor is the *Herr Liebhaberlichtbildner*—a just punishment for his many shortcomings.

For the benefit of such members of the Eleventh Convention as propose a trip through Germany, we will give a few of the new German substitutes for our familiar terms: viz., skylight, *glasshaus*; printing-frame, *abklatschrahmen*; printer, *lichtpauser*; retoucher, *bildverschöneror*; burnisher, *heissglanzvorrichtung*; carte, *besuchsbrustkarte*; transpareney, *durchsichtsbild*; mount, *pappe*; negative, *gegenbild*; albumen paper, *eiweisspapier*; positive, *lichtpause*:

* From the *American Journal of Photography.*

photography, *lichtbildnerei*: photographer, *lichtbildner*; tripod, *stativ*: printing, *lichtpausverfahren*; silver printing, *silberpausverfahren*: blue print, *eisenpausverfahren*; orthochromatic, *farbenempfindlich*: leimtype, *leimlinienhochdruck*; and photogravure, *lichtgalvonotondruck*. Before passing this subject another word of caution: should any one of our photographic friends at any time be in a German dark room, and have the misfortune to be out of reach of the lid of his dry-plate box, and wish his brother *Dunkelkammersachverständiger* to hand it to him, let him be sure to ask for "*deudeckeldesbromsilberleimsubzdrockenplattenkästen*" if he wishes to be understood.

It is stated that, in view of these changes in the nomenclature, there has been a marked falling off in the photographic industry; further, that since the introduction of these synonyms there has been a steady increase of the population of the various lunatic asylums throughout the Fatherland from photographers who tried to comply with the Imperial edict. One fatal case is also announced, that of a German photographer who returned to Berlin after a long sojourn in the Congo basin, and who knew nothing of the expurgation during his absence. It is stated on the day of his arrival he stepped up to a news-stand and asked for a copy of the *Photographisches Wochenblatt*. The attendant told him she was sorry not to be able to serve him, but perhaps he meant *Das Lichtbildnerische Wochenblatt*, which was the leading *Zeitschrift für Lichtbildnerei*, handing him at the same time a copy of Dr. Meithe's well-known publication, resplendent with its Germanised title.

The old German gave one gasp, and expired.

J. F. S.

Picture Framing.—A very large percentage of the pictures used to decorate our walls is ruined by the framing. Why this should be so, what particular fault has rendered this or that picture so disappointing, requires a power of analysis and nice discrimination few of us have time or ability to exert. The decorator frequently knows no more of the proprieties in the case than the carpenter who saws out and fits the moulding, and is firmly persuaded that the most expensive is necessarily the handsomest frame. At an army post, with its meagre resources, one does not expect to find everything *comme il faut*, but a few months ago a parlour was furnished by a bride on the frontier that in many respects might serve as a model for more ambitious surroundings. The pictures especially attracted attention as something very superior, but a closer inspection showed that, though carefully chosen, much of the beauty was due to the appropriateness of the settings. The etchings were enclosed by a mat three to five inches in width, beyond which was a strip of oak about an inch wide, not varnished, but polished. If the etching and mat made a picture, say, a foot and a half long, the frame was two inches wide, with a very narrow gilt strip next the mat. A picture blue in tone had a darker blue mat and a very narrow white frame with a bit of gilt beading. A fruit piece with black background was very handsome without a mat, but with a dark, old-oak frame, flat, and fully four inches in width. A black and gilt beading ornamented the outer edge. Small water colours were framed in the same manner as the etchings, and were equally effective; while two photographs, larger than cabinet size, were simply framed in a two-inch board, covered with deep crimson velvet. All this sounds commonplace enough; yet one has but to compare two copies of an etching, engraving, or photograph framed, the one as indicated above with broad white margin, and simple strip of wood moulding, and the other with the old, florid, gold leaf square of plaster and wood, rising like a wall from the edge of the picture, to be convinced that half the pictures are spoiled by the mode of framing.—*Good Housekeeping, U.S.A.*

Specifications Published.

14,701. *September 18th*, 1889.—"Hand-Drawn Negatives." John Malloch, 306, Lawnmarket, Edinburgh, Mapmounter.

My invention, which consists of a glass plate or other transparent substance coated with a non-actinic film, has for its object to produce a negative for photographic, photo-lithographic, photo-mechanical, and like printing purposes. By scratching off the non-actinic film from the glass plate with a needle or other sharp pointed instrument, fine lines of clear glass with non-actinic background are produced. I can thus scratch out sketches which yield a fine negative for the purposes before-mentioned.

If desired, the non-actinic film may be coated with, or have incorporated with it, substances sensitive to light which, when used, would provide a photographic impression on the plate previous to etching.

12,972. *August 16th*, 1889.—"Improvements in Magic Lanterns." James Henry Steward, 406, Strand, London, Optician.

Improvements in magic or optical lanterns, consisting, first, of an improved method of adjusting the fronts and lenses (the optical system); and second, improved oxy-hydrogen lime-light jet for the more perfectly centreing, adjusting, and controlling the light.

The mechanical details of this invention are explained in the specification by means of drawings.

15,714. *October 7th*, 1889.—"Photographic Shutter." Charles Hoddle, 258A, Mare Street, Hackney, London, Boot and Shoe Maker.

My invention is a shutter made to provide a simple and ready means to expose photographic dry plates when in the camera. It is made to work either before or behind the lens, but mostly in the diaphragm slot. The novelty in this shutter is, that it requires no setting or winding of springs, as all other shutters do, before an exposure can be made. To make an exposure it is only necessary to press a small button; and immediately the pressure is made it automatically sets itself ready for the next exposure.

To effect this I make a shutter of thin sheet brass, or other material, shaped so as to cover the lens, and made with a short arm projecting at right angles to the lens, and pivoted at the far end of the said short arm; close to the pivot I fasten on to said arm a small slip catch, which is acted upon by a short, stiff, upright spring which is attached to a thin brass driving rod running in guides, which has a small button at bottom. This thin brass is held back just underneath the said slip catch by a spiral spring of suitable strength. The shutter is also held over the lens by a second spiral spring. Now on pressing the small button the shutter is lifted to a sufficient height to uncover the lens. The short spring at top of driving rod then leaves the slip catch, and allows the shutter to spring back to original position; then, on removing the pressure from the said button, the driving rod springs back to its original position

also, and is immediately ready for the next exposure. The shutter can be made to travel that it can be loosened or tightened at will. The shutter can be adapted to any kind of photographic apparatus, but it is invented chiefly for use with the detective kinds.

239. *Jan. 7th*, 1890.—"Photographic Cameras." WILLIAM SNOW ROGERS, 7, Addison Road, Bedford Park, Chiswick, Middlesex, Engineer.

My invention relates to photographic cameras of the type known as "hand" or "detective" cameras, and particularly to the means for effecting the transfer within the camera of any plate, film, or other sensitised surface from its place within the storage reservoir to its position for exposure, and its removal therefrom, its replacement within the reservoir, and the substitution of another unexposed plate, the operations providing for the exposure of any or all of the plates as desired.

To carry this invention into effect, I employ a light-tight reservoir with vertical parallel grooves to contain the plates, forming a backward extension of the camera. This reservoir can be filled through a door provided for the purpose, or by means of the valve to be described hereunder. I also provide in the camera proper, and immediately in front of the reservoir, a single groove to carry the plate whilst it is being exposed, and a spring or springs to keep the plate against the side of the groove or rebate nearest to the lens. Above the space occupied by the exposing groove and the set of storage grooves is an opening provided with a sliding light-tight shutter constructed as follows :—

The fore part of the shutter is rigid, and slides beneath the camera top, and in light-tight contact with it. The centre part consists of a valve and changing reservoir, to be described more fully hereunder, and the back part of the shutter consists of a hinged or flexible portion.

The range of movement of the shutter is such that the valve and changing reservoir can be brought successively over all or over any groove, including the exposing groove, at will, and the hinged or flexible part of the shutter is guided vertically downwards at the back of the storage reservoir by means of a curved groove, as the shutter is moved in that direction.

The valve consists of a cylindrical part slotted through in a plane passing through its axis to allow a passage for the plate, and capable of moving about its axis over an angle of about 180° upon a curved seating covered with velvet, or otherwise made impervious to light.

This valve seat also is slotted for the passage of the plate, to correspond with the valve slot when the latter stands vertically.

Forming a continuation of the valve slot is a light-tight reservoir of sufficient size only to contain a single plate in grooves.

The action of the camera is thus : Having placed in the storage reservoir its full complement, or any less number, of plates, the sliding shutter is moved along until the valve comes above the first groove ; the changing reservoir is then moved so that it stands at right angles to the camera top, by which means the valve is opened, and on turning the camera up side down the first—or any selected—plate falls into the changing reservoir. The sliding shutter is then moved forward to its full limit, when the valve will have come immediately above the exposing groove, and the plate may be made to drop therein by turning the camera right side up. The operation is reversed to return the exposed plate to the reservoir, and the next plate can then be dealt with.

A ratchet, pointer, or other registering device is used to indicate the position of the grooves in the storage reservoir, and to register the exposed plates.

The valve may be used as the means of filling the reservoir if so desired, and when not in use the changing reservoir may be folded down flat upon the camera.

On Wednesday last their Royal Highnesses the Prince of Wales and his daughters, the two younger princesses, honoured Mr. A. Debenham with sittings on board the royal yacht off Cowes.

Correspondence.

SAMUEL FRY AND COMPANY, LIMITED.

SIR,—Will you kindly allow us to notify the public, through your columns, that we have purchased the business, goodwill, and stock-in-trade of Samuel Fry and Co., Limited, of Chandos Street, London, and Kingston-on-Thames.

The business will be continued at both places, as before, under the style of "The Fry Manufacturing Company," of which we are the proprietors.

Full announcement will be made in your advertising columns to all our customers and friends generally.—Thanking you in advance for your courtesy,

S. HERBERT FRY,
A. E. HAYMAN.

WHAT ARE THE BEST USES TO WHICH PHOTOGRAPHY CAN BE APPLIED?

SIR,—For the first time in my life I went in for a prize competition of the *Tit Bits* model. This not because I was very anxious to gain the prize, a £7 or £8 amateur's outfit in photography by the good firm of Mawson & Swan, at whose warehouse in Soho Square the articles were on view. I never went, however, to inspect. My chief object was to test the value of this competition, and to expose it if not fairly conducted.

I confess I felt there was really no guarantee that the best would win. All these competitions seem to be managed in a very "hole-and-corner" manner.

As the editor of *Short Cuts* announced that if this competition was extensively taken up a more important one in photography would follow, and as he states that 2,291 replies had been received for the present one, I think photographers should be warned not to waste their time and brains over a competition of this kind, where they have no assurance that the judge who is to decide is acquainted with the subject, and is, above all, suspicion of partiality or unfairness.

Believing that after many years' experience I was not unfamiliar with the best applications of our noble art science, I determined to try my luck and test Mr. "Short Cuts." Soon after the announcement I sent in the short article which follows this.

The competition was to close on June 12th. Here was unfairness No. 1 ; the editor arbitrarily extends it to July 12th. Let that pass, however.

Seeing, some time after I had sent in my communication, a "outlet" by the editor informing "Photographer" that it was not an essay but something short that was required, and thinking that perhaps my tolerably brief communication might be considered not "short," and perhaps classed as an essay, I sent in a second as-short-as-I-could-make-it answer. I give this also below.

Some time after this Mr. Editor makes a new condition, viz., that all communications must be accompanied by the printed notice of the competition cut from a copy of *Short Cuts*. To this no one could object had it been stated at the outset. It was not, so here is unfairness No. 2. However, I duly sent the cutting with a note to the Editor mentioning my two communications.

At length, in *Illustrated Short Cuts*, August 2nd, the award is made. The prize is given to a gentleman who has written an *essay* more than *a fourth longer* than mine, and who has named specifically only two of the best applications of photography, both of which I had named specifically in my second communication, and inferentially in my first. He says not a word of lantern slides—perhaps *the* most important of the applications of photography, embracing, as they do, astronomy, microscopy, portraiture, landscape, architecture, &c., and invaluable as a means of education.

Now, I do not mean to say that there may not be some one who has "spotted" still more important applications of the art than I have done, but I do most distinctly assert that the prize winner has not given such a specific and practically exhaustive reply as I have done in my second communication, sent in in order to comply with the editor's own conditions. I hold also

that my first communication, in pointing to the value of photography as a means of training to good habits and acquiring knowledge, is more to the point than a pious dissertation about "the Great Cause of All" and the mystery of nature. I purposely kept my essay, if such it can be termed, as brief as possible, although I could easily have dilated on the points stated.

That your readers may judge for themselves whether the award has been fairly made or not, I append first the prize-man's article, second my first communication, and third my last.

The prize was awarded to D. Hanneford, 30, Avenue Terrace, Forest Gate, E., to whom a complete photographic set, by Messrs. Mawson & Swan, of Soho Square, valued at £7 16s. 6d., has been sent.

His answer is as follows :—

"The Best Uses of Photography.

"It has been well said by Sir William Hamilton that 'On earth there is nothing great but man : in man there is nothing great but mind.' To broaden and elevate the mind of man, then, must be a work of paramount importance, and to employ anything to that end must be to make the best use of it.

"In replying, therefore, to the question, 'What are the best uses of photography?' we must consider how that wonderful discovery can be best applied to ennobling the human mind.

"The answer, in my opinion, will be found in the application of photography to the furtherance of the sciences, especially astronomy. The telescope, armed with the highly sensitive photographic plate, has revealed to the modern observer a universe of which Newton and Herschel had not the faintest conception. It has drawn for us the picture of suns whose distances and dimensions are inconceivable in their greatness. Nor is this all ; with the assistance of the spectroscope we are enabled, by comparing observations of the heavenly orbs made at various times, to learn their composition and the changes taking place in the evolution of worlds and systems separated from us by infinitude.

"Here, then, the mind is enlarged by the contemplation of the stupendous grandeur of creation.

"Again, photography has lent its aid to the microscope in revealing to us the other extremity of the infinite—the infinitely small. A drop of water, which to the unaided eye is scarcely visible, is shown by the microscope to be a world teeming with life the most complex and wonderful. For years these wonders were for the eye of the wealthy observer only, a microscope being a luxury only for the few ; but photography steps in, and with little expense hundreds of the most accurate pictures of life in this universe of the infinitely minute are ready for distribution, and thousands who before knew nothing outside their own commonplace sphere are made acquainted with the marvels of nature.

"To what a grand extent must these uses of photography act upon the human mind to expand it. When we contemplate the infinities around us, and ask the questions, Whence comes it all? and whither does it tend? we find ourselves in the presence of an awful mystery, and we re-echo the cry of the Psalmist, but with greater meaning, 'The Heavens declare the glory of God, and the firmament showeth His handiwork.'

"Our ideas of the Great Cause of All are also raised, and with greater knowledge comes greater reverence and greater charity, and each fresh agent of science lends its aid to exterminate those twin sisters, ignorance and bigotry, and herald the millenium of peace and goodwill to mankind."

My first article was as follows :—

"Speaking generally, I think the best uses of photography are :—

"1. The production of slides for the optical lantern to be used for educational and scientific purposes. Accompanied by oral description in the form of lecture or otherwise, good photographic lantern slides impress the minds of children and adults through the most effective combination of senses—seeing and hearing.

"2. The practice of photography in any of its numerous branches is also eminently educational for its votaries as regards technics, science, art, and mental training.

"No one can be a good photographer who does not endeavour to understand the 'why' and the 'wherefore' ; no one can be a good photographer who has not learnt to be careful and systematic in working ; no one can be a good photographer who has not learnt the 'power of littles' ; and lastly, no one can be a good photographer who lacks perseverance.

"3. Another *best* use of photography : it promotes brotherly feeling ; there is a good deal of freemasonry among the members of the craft where it is practised not for lucre, but for love ; even among professionals there is some solidarity.

"4. Yet another *best* use. Memorials of the living and the dead—*vera effigies*, which bring before us individuals ; memorials of past and present—the monuments of Assyria, Egypt, Greece, and Italy ; or life and scenes in the present 'Darkest Africa.'

"There can be, however, no best uses of photography singled out from its numerous applications. There is only one best use of anything—its efficiency for the object in view. Photography is found invaluable to the astronomer ; it is also invaluable to the producer of tintypes on Ramsgate sands. Perhaps one of those tintypes of a 'puling infant' will bring more joy to the heart of its loving mother than she would get by looking at Common's splendid photographs of nebulæ.

"We are all tempted to consider that to be the best use of anything which we use, the way we use it, and the good which its use brings us. The best uses of photography are, therefore, legion."

My second communication, sent July 1st, 1890, was as follows :—

"Sir,—In case you may consider my answer sent you in May last to be not sufficiently short—the word 'short' is as indefinite as the proverbial 'piece of chalk'—I send below more briefly what I consider the best uses to which photography can be applied :—

"1. Lantern slides for educational, scientific, and recreative purposes.

"2. Portraiture.

"3. Views—landscape and architecture.

"4. Photographic engraving, collotype, &c., for book, periodical, or newspaper illustration.

"5. Astronomical and microscopical work.

"To sum up in one short answer : —

"6. Every use of photography which brings pleasure or profit to man, woman, or child." Duncan C. Dallas.

Proceedings of Societies.

London and Provincial Photographic Association.

At the meeting on the 7th inst. Mr. W. Ackland occupied the chair.

Mr. Otto Scholzig and Mr. D. Hurst were elected members of the Association.

At the previous meeting prints were shown by Mr. Otto Scholzig, some of which had been well washed, and the remainder only slighted rinsed in water previous to toning ; the contention was that the latter, from toning much quicker than the others, and being of a richer black, absorbed more gold, and consequently were more permanent. This being disputed, it was agreed to subject the prints to test solutions.

Mr. A. Haddon now handed to the chairman three bottles containing solutions for this purpose.—1. Cyanide of potassium 10 per cent ; 2. Nitric acid 20 per cent ; 3. Bichloride of mercury saturated solution. A piece of each of the prints referred to was immersed in these solutions, and marked A and B respectively. A, slightly washed ; B, well washed. In the first solution the print marked B commenced to change in one minute after immersion. In No. 2 solution, the immersion was continued for three minutes, the print marked B again showing, in comparison with A, greater deterioration of image. In No. 3 solution, the prints remained to the end of the meeting without incurring any material change.

The subject of home portraiture being introduced, Mr. W. E. Debenham dwelt upon the importance of the

position of the reflector used; this should be placed a little forward and raised considerably; a crumb cloth spread on the floor would assist to reflect light upwards. He contended that a large reflector placed at a distance from the sitter gave a better illumination than a small one placed nearer.

Mr. F. A. BRIDGE suggested placing the reflector at an angle to reflect the light upwards. A sheet, suspended and fastened at each bottom corner to chairs, answered capitally, as the chairs could be drawn backwards or forwards until the best effect of lighting was secured.

[Mr. H. M. Hastings writes that in our last report of this Association's meetings the word "washed" is a misprint for "masked."]

THE SHEFFIELD PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of the above Society was held at the Masonic Hall, Surrey Street, on Tuesday evening last, with Mr. B. J. TAYLOR in the chair. After the routine business of the meeting, the award of Messrs. Geo. Davison and Lyonel Clark—the judges in the recent competition, subject, a "Genre Study"—was made known, the result being that the president, Mr. B. J. Taylor, was declared the winner. No other picture was deemed of sufficient merit for the awarding of a second prize; that prize was, therefore, withheld.

THE "CROTONWANZE."—The *Photographisches Wochenblatt*, ably edited by Dr. A. Miethe, of Berlin, has received several communications or inquiries in regard to the article in the *American Journal of Photography* in reference to a new danger which threatened the American dry plate industry, and in which the *Wochenblatt* is quoted. Dr. Miethe thus disposes of the subject in his reply to an "Anxious Inquirer":—"Herrn P 117.—We have the article also now read, and ourselves much amused. You wonder yourself even so as we, that the smart Yankee our notice and warning against the 'Crotonwanze' for real earnest have taken. The dressing up of the jest is, however, very pretty. Our notice originated, however, as a matter of fact, in one American periodical, where it on an important place to find is."

LIGHT AND SHADE.—Light and shade, independent of its effects in rendering objects more distinct and intelligible, has other properties, and those of a higher quality; when portraiture has to take a station in the ranks along with music and poetry, these properties are the means of giving breadth and grandeur of form, the effects of bustle or repose, which portions of a picture require. Light and shade, or the conduct of the chiaroscuro of any work, is entirely given up to the control of the artist, to be used for the express purpose of rendering his design complete; where he departs too much from the arrangements observable in nature it becomes capricious, and loses its effect upon the eye; when, on the other hand, the every-day occurrences are adopted, his work becomes common and feeble. Reynolds says justly, "When we are required to paint broad, it is not understood that we should paint broader than nature; but objects are to be so placed that there is scarcely any limit to their breadth of light and shade." In the earlier stages of painting, relief and distinctness were the only requisites sought after. But whatever way the student takes to get an insight into this great charm of painting, either in arranging his composition so as to suit any particular effect of light and shade, or in trying various means of distributing light and shade over his design, let him carefully watch, both in nature and in art, its various combinations, and endeavour to find out the latent cause of beauty. As the etchings of Rembrandt embrace this quality in the highest degree, from a mere outline to the most extensive depth of shadow, they ought to be constantly before him when he has it in his power; they ought to be viewed in every direction, to enable the eye to get acquainted with the proportions of light, dark, and half-tint; he ought also to engraft the scheme of chiaroscuro on designs of his own, that the harmony which exists in these wonderful productions may be transferred, if possible, into new inventions.—*Burnet.*

RECEIVED.—Notice of change of address of Messrs. H. C. Lewis & Co., formerly of Ranelagh Street, Liverpool, to 31, Bold Street, Liverpool.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

V. B.—*Performance of Copying Lens.* Paste a sheet of the *Times*, *Standard*, or other clearly printed newspaper upon a drawing board, focus the lens upon it, and observe the definition at centre and margin, using a small stop. When the field appears flat and all in good definition take a photograph, and if the picture comes out sharp all over, or good within a certain area, there is no doubt about your being able to use the lens for copying up to that size.

G. P.—*Gold Toned Prints.* It is perhaps doubtful, notwithstanding the statement on page 623, whether the *whole* of the silver is replaced by gold in what is called a "rich black" print. Special experiments have hitherto shown that for this to be the case, the toning process must have gone on to the point of furnishing a green (overtoned) print. By burning one of the rich black impressions, and boiling the ashes with dilute nitric acid, the presence or absence of silver in the solution could at once be decided.

L. E. M.—*Effect of Ruby Light on the Eyes.* In summer time one ought to be careful to close the eyes for a few moments when coming out of the dark room, so as to avoid sudden transition from this trying light to brilliant sunshine. There is no doubt that the strain put upon the retinæ by incautious exposure is often very prejudicial to the visual organs, and may eventually produce decided and permanent ill effects. The temporary use of neutral tinted spectacles might be advantageous.

E. DARWELL.—*Alkali Equivalents in Developers.* It is by no means certain that the work done by different caustic and carbonated alkalies will be exactly proportional to their atomic weights; but here are the chemical equivalents in case you would like to try experiments for yourself:—·880 ammonia contains 27·3 per cent of real NH_3, the atomic weight of which, without water, is 17; pure sodium hydrate, NaHO, is 40; potassium hydrate, KHO, is 56; dry carbonate of soda, Na_2CO_3 (halved), is 53; dry carbonate of potash, K_2CO_3 (halved), is 69. In our view of the case 40 parts of caustic soda would go very much farther, as an alkali, than 53 parts of dry carbonate of soda.

W. TULLY.—You might get Mr. W. T. Wilkinson's "Photo-Engraving and Photo-Lithography," published by Messrs England Brothers, Charles Street, Notting Hill, W.; or Lietze's American work, "Modern Heliographic Processes," New York, Van Nostrand Company.

C. N.—*Varnish for Bright Silver.* Gum sandarac is dissolved in methylated spirit, to which an equal bulk of amylic acetate is added. The silver articles, freshly polished with a leather, are slightly warmed and then painted with or immersed in the varnish; they are then dried off in the open air, to allow the amyl fumes to escape, for if inhaled they are almost certain to cause severe headache. It is important to go over the whole surface very thoroughly if done by hand, as small patches of the silver left uncoated will only be detected, after a time, by the tarnishing of the metal at those parts; hence the method of total immersion is often the better plan.

CITRO (Shide).—*Testing Citric Acid for Tartaric Impurity.* Add a small quantity of carbonate of potash, stir well, and allow to stand at rest for some time. In the event of any appreciable quantity of tartaric acid being present, a white crystalline deposit of tartar will separate out and partly adhere to the sides of the test tube.

GLASGOW.—*Platino-Mechanical.* We have no knowledge of any such combined process as that referred to in your letter, but see no objection to working the two distinctly different operations successively.

Other correspondents in our next.

VOL. XXXIV. No. 1668.—*August* 22, 1890.

CONTENTS.

CLOUDS.

If it were possible for photographers to bring an action against the clerk of the weather for business opportunities lost in consequence of his vagaries during the present year, they would stand a good chance of obtaining exemplary damages. From all parts of the country have there been complaints of long periods of wet, when, according to past experience, it should have been dry, and of unsettled conditions where sunshine should reign undisturbed. Bad weather means stoppage of business all round, but, hard as their lot may appear to be, photographers are not by any means the most to be pitied, for although their hands may be idle during the bad time, they have not the mortification of knowing, like the poor farmers, that the fruit of their past labours is rotting for want of harvesting.

Photography is an art that is full of disappointments. We all of us know how something is apt to go wrong at the last moment, and how fond hopes are thus shattered. But it also has an advantage in giving its votaries plenty to do indoors, such as in the after-treatment of negatives and enlarging, when camera work is out of the question. Even unsettled weather brings with it a compensation in the opportunities it affords of obtaining cloud negatives, for at no other time does the firmament offer a more lovely field for this kind of work than it does when the barometer is on the move.

And it is necessary that the advanced photographer should have at hand cloud negatives to wed to his landscapes. Under certain happy combinations of circumstances it is possible to get a natural sky above a landscape on the same negative, but this desirable event very seldom occurs, and we may take it as a rule that the sky must be separately recorded. Excellent sky negatives can now be purchased, and their existence shows that there is a demand for such things. But the photographer who considers himself an artist, and even the conscientious man who cannot lay claim to that distinction, will refuse to be beholden to another hand for any part of his pictures, and will insist on using cloud negatives of his own production, or none at all. In this resolve he is wise, for setting apart all question of ethics, he will not care to run the risk of exhibiting a picture in which may be recognised the same sky which appears in somebody else's work. It is obvious that if two men purchase the same set of sky negatives, they must be prepared to run such a risk.

Cloud negatives are certainly troublesome things to produce, not because there is any particular difficulty in making them, but because much time is likely to be consumed in running down the quarry. In the same sense, we might say that it is not very difficult to shoot a stag, but you must spend much time in seeking him out. The expectant photographer may spend all his spare time in looking out for a sky which will photograph well—that is to say, a sky which presents much contrast of light and shade; heavy masses of cumulus against deep blue, or a dark cloud with its silver lining brightly showing. Such contrasts are common enough, but they generally seem to come when the camera is not at hand, or when there is no plate in the dark slide. A sportsman knows full well how the birds rise almost from his feet when he happens to leave his gun behind him, and he generally ascribes the provoking circumstance to the artfulness of the feathered bipeds. It would almost seem that the clouds treat the poor photographer in the same way, and mock him by their presence when he is unarmed, and therefore unable to be revenged upon them.

At the last exhibition of the Meteorological Society several very fine cloud pictures were shown. These were taken for scientific purposes, and possibly in the hope that they might help in the matter of weather study. But, apart from the scientific value of such works, they are objects of great beauty, notwithstanding the absence of nature's wondrous range of tints, for clouds take every diversity of form, and their shapes, owing to the veil of atmosphere through which they are seen, are never harsh, and are seldom cut with hard outlines. Cloudland is, indeed, full of fairy

forms, which change and change again with such rapidity that it is often difficult to catch the effect which it is desired to record. Before the camera can be set up the effect is gone, and it may be a long time before anything like it is seen again.

A cloudy sky through which the sun now and again endeavours to pierce an opening is the finest effect of light and colour which nature offers to the delighted eyes of men. And when the firmament has below it the ocean, which reflects upon its troubled bosom every delicate tint and shade, and which is occasionally crossed with bars of burnished gold where the rays can touch it, the beauty of the scene is enhanced a thousand-fold. Such scenes are not uncommon on our western coasts when the sun sinks to rest, and equally lovely visions are vouchsafed to early risers on our eastern shores. Mere sky and sea are sufficient to make up a picture, the loveliness and glory of which are without parallel, although some may prefer to endow it with human interest by the presence of a fleet of fishing boats going to or returning from their dangerous quest.

For the benefit of those who have not had much experience in making cloud negatives, we may offer a few words of advice respecting the manner of going to work. If the sun is to be included in the picture, as it commonly is in so-called moonlight effects, films or ground glass backed plates should be used. Any lens which will take a good landscape can be used, and its smallest stop should be employed. As a rule, the exposure will be about one second on a slow plate, but in the case of red sunrises and sunsets, this may often be increased to as much as eight or even ten seconds unless isochromatic plates are available. The development must be very carefully watched, and not carried too far.

Photographers who desire to help their distressed fellows would do well to send a donation to the Photographers' Benevolent Association, which is sadly in need of funds.

The Advancement of Photography.—Photography has seen much advancement of late years, and a vista of discovery and improvement, boundless and wonderful, stretches before it, which time alone will be able to define. If we to-day could but see photography as it will be fifty years hence, we should doubtless be equally if not more astounded than Wedgwood, the father of photographers, would be were he recalled to life now and shown the amazing heights of improvement his art has reached to. Thanks to its many seductive characteristics, than photography no science has acquired greater popularity, nor secured under its banner more ardent amateurs. —*Liverpool Echo.*

Photography in Florence.—Dark room accommodation for pilgrims is becoming common all over, not only our own, but also other countries. We have received from Signor A. Anghinelte the prospectus of a dark room company, which has organised a completely fitted up establishment, including laboratory, studio, finishing room, lecture room, and library, with all necessary teaching appliances, under the direction of Signor G. Moretti, for the use of amateurs at via della Scalla, 15 piano terrano, Florence. Members of the Photographic Society of Italy, and amateurs resident in Florence, may have the use of the establishment daily from 10 till 4 for a small annual payment, and practical instruction on the development of negatives or finishing of prints at very moderate charges; while members of photographic societies from any part of the world, who may visit Florence, are invited to use the laboratory free of charge.—*The Beacon.*

THE PHOTOGRAPHIC SOCIETY OF THE NORTH OF FRANCE.

I.

The Society bearing the above title has its headquarters at Douai, and is nearer to London than any other photographic society in France; in fact, it may be reached *via* Calais in five or six hours. Another route lies partly through Belgium, *via* Ostend, for Douai is on the main line from Ostend to Paris, along which run about two fast trains every day each way. Along the latter route the country is practically flat the whole way, but is slightly undulating just after passing the French frontier. Lille, said by some to rank fifth, and by others seventh, among the greater cities of France, is passed *en route*. By the slow trains the Belgian city of Courtrai may be visited on the way to Douai, and it is worth attention for photographic purposes, because of specimens of old ecclesiastical architecture, and from the new bridge across the river a picturesque view of the old bridge with ancient towers at each end is obtainable. Lille, for its size, has not many specimens of remarkable public buildings, ancient or modern, but there are a few. The people in these regions, and as far south as Lille, differ scarcely at all from the Belgians; Van Damme and other highly respectable Flemish or Dutch names are often to be seen over the windows of the shops in these parts, but French characteristics are rather more pronounced than farther north. The "Golden Lion" is a common hotel and inn sign about Belgium, and in the north the French also use it frequently, but display originality of thought by introducing also the sign of the Golden Ape. The Photographic Society of the North of France possesses the Golden Ape himself, secured by a light chain, which allows him to run some distance in the garden, and to climb up the windows of the house; the chain is not long enough to let him get at the printing-frames. We do not say that this active little ape is golden to the vulgar eye, but that he is golden by virtue of his numerous intellectual and moral qualities. Why should he not be trained to attend to the printing operations, and to take out the papers when the exposures have been sufficient? It is a fact that an ape has been trained to do the signalling, under direction, at one of the railway stations in Natal.

The Belgians in the villages between Ostend and the French frontier make up for the flatness of the land in which they dwell by constructing high spires to their churches, but the spires do not usually come to a point at the top, because the natives wish to see the view. The church spires, therefore, frequently have at the top what from the ground looks like a pigeon-house with a balcony running round the outside; close at hand, this elevated house is seen to be large enough to accommodate several sight-seers.

When the lines in these parts are not cleared for the few quick trains, some nondescript, slow-travelling vehicles occasionally appear upon the rails,

but get out of the way again before the times of their fleeter brethren draw near. A few days ago, at a junction station called Roulers, we alighted and explored the village, then waited for a slow train to Courtrai. A great vehicle of a blood-red colour came "lumbering" into the station, and it proved to be a train made all in one piece; the whole of it was mounted on one rigid framework. The first part of the frame supported the engine, close behind which was the luggage compartment, in which the luggage was kept comfortably warm. Behind that was a passage across the train—if train it may be called—for the entrances to the carriages were at the ends. Then came the third class section, next the second class section, then the first class section, and lastly, the guard's brake compartment. In this ponderous, but economical and useful vehicle, which travelled slowly and stopped at every station, Courtrai was reached.

Douai, which is situated on the Scarpe, covers an unusually large area in proportion to its population, so many of the houses have good gardens attached. The town is surrounded with the ruins of the ancient wall and fortifications; it has a noble belfry tower and Hotel de Ville, and some picturesque old churches, consequently a certain amount of photographic work can be done therein, and some of the members of the Photographic Society there tell us that there is no impediment in the way of anyone taking photographic views in Douai.

The town and surrounding country are flat. At the last Paris Exhibition the members of the Photographic Society of the North of France exhibited an album containing work done by its members. One photograph represented the *Géant Gayant* with his wife and family; the giant and his wife are each thirty feet high, and have moderately handsome faces; these giant dolls are made of osier, and each is worked by eight men inside. The family of giants is carried through Douai in a curious procession, which traverses the streets of the town early in July every year, according to ancient custom.

Of the work done by the Photographic Society of the North of France, we shall have something to say in the next article upon the present subject.

Photographic Conventions.—The oft-quoted saying that "the child is father to the man" is, to a large extent, applicable to the relation existing between the British Convention and her mother, the Photographers' Association of America, as, although only in her fifth year, the daughter has objects in view and ways of going to work that might be advantageously adopted by the mother. For one thing, the distinction between professional and amateur does not exist, and those who live by the practice of photography leave the "shop" behind, and meet those who only practise the art for the love of it on equal terms, and with but one, or rather two, objects in view, the advancement of photography as a science and art, and the cultivation of good fellowship by social intercourse. The offices are positions of honour and not emolument, and as there are no axes to grind, and no party factions to be considered, there is neither contention nor contest, the best man for each particular office being generally appointed *nemine contradicente*. — *The Beacon.*

THE CAMERA CLUB AND TRADING IN PHOTOGRAPHY.

There is a certain amount of truth in the prevalent rumour to which we gave publicity last week, about the Camera Club having the idea of letting a part of its new premises to a dealer in photographic goods. We have been told that the part of the ground floor let as a shop is entirely detached from the Club; there is a corridor belonging to the premises at the back, severing the Club from the shop. The entrance of the shop is at the corner of Cecil Court; the entrance to the Club is away at the other extremity of the façade. The Club will have nothing to do with controlling the dealer on the premises, and "the Club Company will give him a lease of seven or fourteen years," says a member of the Club, "just as we ourselves will have," and the Club will not think of making any kind of arrangement with the occupier. "The shop had to be let, and anyone could have it. It may be a convenience to some members to have a general photographic depôt near at hand, but the tenant will be entirely independent, and can snap his fingers at the Club if he so wishes." Such may be taken to be the view of some of those members of the Club in favour of the scheme.

For particular purposes the tenant is unlikely to draw any nice distinctions between organisations so closely allied as the Camera Club, and the Camera Club Company, Limited, and should he obtain but a seven years' lease, his freedom from the influence of members of the Club would be small, so the expression of opinion about the matter which we made last week, from our present point of view holds good. Should, however, he obtain a fourteen years' lease, doubtless he will have a greater proportion of freedom, at all events during the first seven or eight years. In accordance with the not over-elegant parable we put forth last week, but in terms "easily to be understanded by people," a seven-years' tenant at a moderate rental will look upon the possible obtaining of another seven years' lease upon the same terms, as a prospective "bunch of carrots" before his nose, and the non-renewal thereof on those terms as "the stick," so is not likely to regard any one of his numerous landlords with club voting power who may deal with him, in quite the same light as he would regard an ordinary customer not connected with the Club.

So long as the shop is on the premises at all, its exact geographical position thereon, and where its doors may be situated, seem to have no bearing on the question at issue. Perhaps it would be better were the shop in front rather than in a less prominent position. Once, in some discussion at the Club about professional and amateur photographers, Mr. Lyonel Clark made a statement to the effect that if anyone were "fool enough" to want to buy one of his pictures, he would sell it without hesitation. That was a bold, clear statement, to be respected. On like principles, with any shop at all on the Club premises, it might better be in front than elsewhere, and rendered

as prominent and attractive as possible. Once upon a time, shortly before the Paris Exhibition opened, in many of the shop windows of Paris might be seen a picture of the back of an elderly and stout peasant woman passing one of the *octroi* officers, to whom she shows her basket containing a few eggs, and declares that she has no game in her possession. The leaning forward to display the contents of the basket, revealed to the spectators behind, the head of a hare with its long ears dangling between her ankles. It would have been better had she displayed that hare with the eggs in her basket in front.

No doubt, with all the photographic conveniences provided on the new premises of the Camera Club, a shop in the basement at which photographic goods could be purchased would be additionally handy, but the convenience may be bought at too high a price, and give rise to various complications in the future. The meaner the individual, the more likely is he to impute unworthy motives, because he judges others by himself, and knows what he would do under similar circumstances, so with the somewhat strained relations between amateur and professional photographers, a few among the latter are likely to be found who will consider this shop not to have been started without ulterior objects.

No doubt much more time has been devoted to the consideration of these points by the members of the Camera Club than we have had an opportunity of giving, and as they have not yet published any official statement on the subject, it is judicious for everyone to wait until that statement is issued before forming a decided opinion.

The question at issue is one which concerns the members of the Club more than anyone else, because it affects the influence of the organisation. In any large organisation there is small power of controlling the erratic actions of some of the members, but as regards the Camera Club we have thought that its well-deserved influence would be increased, were there some rule that no member who has shares in any company—except the Camera Club Company, Limited—commercially connected with photography, shall be eligible to a seat on the Council, or to the position of an office-bearer connected therewith. With this rule, and with no shop on the premises, it is probable that decisions of the Club in relation to anything connected with photographic science and art would carry additional weight with both amateur and professional photographers, who might sometimes like to have a tribunal to which to appeal, about the disinterestedness of which tribunal all felt satisfied; and even "appearances" would have an influence in promoting the growth of such confidence.

THE PHOTOGRAPHIC CLUB.—The subject for discussion on August 27th will be "Printing under Coloured Media;" September 3rd, "Supplementary Exposures." Monthly Saturday outing August 30th at Pinner; train from Baker Street at 2.26.

PHOTOGRAPHY IN GERMANY.

BY HERMANN E. GUNTHER.

TIMING FLASH LIGHTS—SILHOUETTES—IRIDIUM PAPER—LIESEGANG'S PHONOGRAPH.

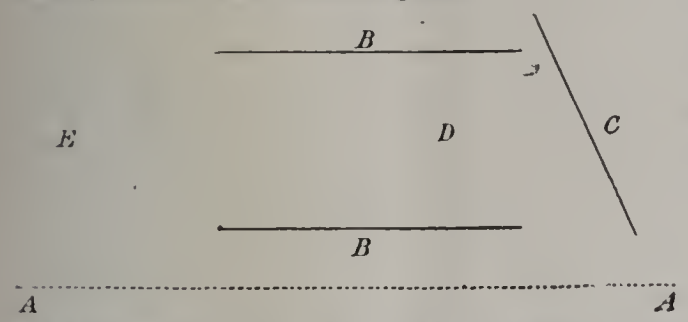
Timing the Duration of Flash-Lights.—Professor Eder has made some interesting experiments, together with Captain von Reisinger, for the purpose of timing the duration of the flash produced by various modes of burning the flash powder. He employed a heavy wheel of black wood of about twenty-six inches diameter, which is caused to revolve around its axis by hand. At the centre of the wheel a silvered hemisphere of glass was attached, and a similar one at the circumference of the wheel. The latter was caused to revolve at the rate of one revolution a second. At first the image reflected by the hemispheres was focussed by means of a candle-light, then the room was darkened, the sensitive plate inserted, the lens uncovered, the wheel caused to revolve, and the flash produced. The plate was then developed, and showed a sharp point at the centre of the wheel, and a sharp black line extending partly round the circle made by the rim of the wheel. This was the reflected light of the flash, and showed the arc through which the wheel had turned while the flash was produced. If this arc amounts to one-fourth of the circumference, the duration of the exposure has been $\frac{1}{4}$ second. The results of the experiments are as follows:—

Explosive magnesium mixture; 30 parts of perchlorate of potash, 30 parts of chlorate of potash, 40 parts of magnesium powder, containing 8 grains of magnesium... ...	$\frac{1}{20}$ to $\frac{1}{30}$ second.
Pure magnesium powder, blown as fast as possible through a glass tube into a spirit flame by means of an india-rubber tube held in the mouth; containing 8 grains of magnesium	$\frac{1}{8}$ second.
Pure magnesium powder, burnt in Mr. Von Loehr's flash lamp; 8 grains of magnesium	$\frac{1}{4}$ second.
Pure magnesium powder, burnt by means of Dr. Hesekiel's flash lamp; 4 grains of magnesium	$\frac{1}{13}$ second.
Pure magnesium powder, burnt in Prof. Schirm's flash lamp; 4 grains of magnesium	$\frac{1}{7}$ second.

These experiments show that the charges of magnesium powder mixed with chlorate of potash (the so-called explosive mixtures) are much quicker in combustion than those of pure magnesium powder alone. To those operators who have experience in flash-light photography this result will not be surprising, but it is well known that the various flash-light mixtures in which the magnesium is kept stored in mixture with potassium chlorate, picric acid, or other compounds acting as supporters of combustion, have occasioned serious accidents, so that it is doubtful whether their use is to be recommended generally.

Photographic Silhouettes.—A number of charming photographic silhouettes, produced by E. Stumman, a Russian photographer, is excellently reproduced in the last number of the *Phot. Correspondenz.* Mr. Stumman describes his mode of working as follows. Two dark coloured backgrounds are required, which are placed parallel to the glass side of the studio at a distance of about 3 feet from the latter and $5\frac{1}{4}$ feet distant from each other. The two backgrounds are covered with a black cloth, which then forms the roof of the tunnel produced. In front of one of the openings of the extemporised tunnel is placed

a perfectly white background at a distance of 3 feet, so that it reflects as much light as possible. The size of the white background corresponds to the size of the opening of the tunnel, or it may be a little larger. The sitter is placed in the centre of the tunnel, the face directed to one of the parallel backgrounds, but nearer to the white background, so that the side of the face directed to the camera is shaded as much as possible. The annexed sketch gives an idea of the arrangement.



A A the glass, or light side; B B two parallel black backgrounds; C the white background of an inclined plane; D the sitter; E the camera. As the white background reflects plenty of light to the camera, a very short exposure is sufficient.

A New Sensitive Positive Paper.—On behalf of Mr. A. Moll, of Vienna, Mr. von Zamboni has tried the new iridium paper, introduced by a French firm. It is a printing-out paper similar to the gelatino-chloride papers, and is said to give prints of the character of platinum prints; but it keeps better than the platinum paper, and is much cheaper. After removal from the printing frame the paper is washed in several changes of water, and then placed in a toning bath consisting of—

Chloride of gold	1 part
Bicarbonate of soda	3 parts
Distilled water	6,000 ,,

The toning bath should be prepared a few hours before use, but it keeps for any time. According to the duration of the action of the toning bath various tones may be produced. At any rate, the toning proceeds quickly, a rich sepia tone being obtained after the lapse of a minute, a bluish one after 1½ minute, and a velvet-brown tone within about two minutes. The prints are placed, after toning, in the fixing bath, consisting of—

Hyposulphite of soda	8 parts
Water	100 ,,

After about ten minutes they are removed and thoroughly washed. Mr. von Zamboni has found that the prints may as well be treated with the combined toning and fixing bath which is used in connection with the gelatino-chloride papers. They are placed in this bath directly after removing them from the printing frame, and allowed to remain in it until the desired tone, varying from sepia to brown, has been obtained. The paper is prepared with chloride of iridium; it keeps, if protected against moisture, at least six to seven months, and its sensitiveness is about equal to that of the gelatino-chloride printing-out paper.

Liesegang's New Phonograph.—An ingenious invention has been made of late by Mr. R. Ed. Liesegang in connection with phonography, showing clearly how the photographic camera and the phonograph can be made mutually helpful. It will be known that in Mr. Edison's phonograph the phonogram is recorded on a cylinder prepared with a wax solution. The wax film being, however, very delicate, it has been found in practice that this feature of Mr. Edison's apparatus renders its general introduction difficult. In Mr. Liesengang's phonograph the wax cylinder is entirely omitted, the sound-curve being written by means of a drawing-pencil on a paper or blackened-glass support, and the writing being afterwards made conductive by photo-chemical means. The arrangement of the apparatus is about the following. A diaphragm which is set into vibrations by sound transmits them to a lever, at the end of which the drawing pencil is fixed. The latter writes the vibrations of the diaphragm on an enlarged scale down on a sheet of paper or on a blackened-glass plate, evenly driven by clockwork. At the same time, a fixed pencil attached to another lever at the side of the first one records on the support the progress which is made by the paper or by the glass plate.

(*a*). Line drawn by the fixed pencil.
(*b*). Sound-curve transmitted by the diaphragm.

If the phonogram is recorded directly on paper, an ink is used for writing, which consists of a metallic salt which is easily reduced. If, however, a blackened-glass plate is employed, a photographic impression is taken from it on sensitised paper, after the image has eventually been previously enlarged. The printing process suited best for this purpose is the carbon process or the collotype, a well-conducting metallic powder being substituted for the carbon, which is mixed with the printing ink if collotype is applied, or dusted on if an impression in fatty ink is made. The prints can then be stored in book-form. To transform the curved lines into sound-waves again, a very thin platinum wire is used, being a little larger than the largest distance between the two lines recorded by the apparatus. A thick copper wire is placed around the platinum wire on its upper side, as near as possible to it, but isolated from it by a thin film of gutta-percha, a similar copper wire being placed around the platinum wire at its lower end. The two copper wires come up to another closely without touching one another. This instrument is passed over the lines with as even a pressure as possible, so that the copper wire at the lower end of the platinum wire is placed always over the straight line *a*, the copper wire at the upper end always over the curved line *b*. The electric current from the battery enters the lower copper wire, passes through a short way of the straight line, then through the platinum wire up to the curved line, and through the latter in the upper copper wire passed over it. Thence the current passes through a telephone of any construction, and runs back to the battery. It is evident from this description that the electric current has to pass through various extents of the platinum resistance, according to the form of the curvature, and that it is weakened thereby more or less, producing, consequently, the vibrations of the telephone-diaphragm.

A New Verb.—The new verb, "to kodak," is becoming assimilated. The Rochester edition of the *Elmira Telegram* of July 13th has an interesting article on the State Fish Hatchery, near Rochester, in which it incidentally mentioned that numbers of the finny tribe were attracted to the clear water surrounding the feeding house by the vibration of the meat-cutter, set agoing for the purpose, and successfully "kodaked," as were also a number of large salmon trout, in the act of jumping for food thrown to them.—*The Beacon.*

SPHERICAL ABERRATION, AND THE TREATMENT OF SUBJECTS BY FOCUS.

BY W. E. DEBENHAM.

As Mr. T. R. Dallmeyer remarks, in his letter appearing in your issue of the 18th inst., it is to be regretted that Mr. W. K. Burton is so far away from England for controversial purposes. One particular reason for this regret is, that readers who have not made such a special study of optical subjects as to enable them to go into the question and appreciate the arguments brought forward, may be induced by Mr. Dallmeyer's style of writing of "the errors into which Mr. Burton has fallen," of his having "certainly very much misunderstood the subject" of his (Mr. Dallmeyer's) article "for ever laying the ghost," and so on, to do injustice to Mr. Burton during the time that must elapse before he can reply.

The main question is, whether the planes not in focus are better defined when spherical aberration is introduced than when it is absent: whether, by sacrificing definition at the focal plane, better definition is obtained at the planes not in focus. The claim put forward by Mr. J. H. Dallmeyer, when introducing a certain lens to the public, was, that "by such diffusion, objects in planes wide apart were defined better, not simply relatively, but absolutely." The denial of this claim, made by Mr. T. Grubb and by me at the time, and I believe by Mr. Burton and others since, is the "ghost" which Mr. Dallmeyer would do well to lay, if that is possible.

I considered that Mr. Dallmeyer had practically abandoned the claim for improved definition when he recently admitted that, with spherical aberration, definition was worse on one side of the focal plane, but claimed that it was improved on the other. If the total range of definition is not greater, it is of very secondary consideration whether there is a little improvement on one side or the other, balanced by a decided diminution of sharpness on the opposite side. If, for instance, the eye of the sitter were focussed, some persons might prefer that, in accordance with Mr. Dallmeyer's latest contention, the back hair should be somewhat better defined, and the moustache more distinctly out of focus, whilst others might take the contrary view, and prefer the foreground plane represented by the moustache to be better defined, at the sacrifice of some additional fuzziness in the back hair.

If it is assumed that Mr. T. R. Dallmeyer's recent contention is correct, and that at the sacrifice of near objects distant objects are better defined with spherical aberration, and that to an extent that can be detected in the resulting photograph, there would still be no justification of the original claim, unless it could be shown that for planes wide apart the definition was better with the "diffusion" lens than with the other when both are focussed to get the best available definition on these planes simultaneously. Had Mr. J. H. Dallmeyer's claim been that now put forward by Mr. T. R. Dallmeyer, it is probable that neither Mr. Grubb nor I should have thought it worth while to discuss it. The claim was, however, for increased "depth of focus," a condition which cannot be said to exist if "increase" in one direction is counter-balanced, or more than counter-balanced, by "diminution" in the other direction.

Mr. Grubb, however, seems to have anticipated that such an argument as that lately propounded by Mr. T. R. Dallmeyer might be used "as a last resource," for after saying, "In short, in whatever way we make these comparative measurements, provided it be done fairly, we shall find the advantage with respect to 'depth of focus' to lie on the side of the corrected lens," he adds that it will probably be advanced that in the uncorrected lens—that with spherical aberration—the rays beyond the focus are more condensed in the centre than in the corrected lens, but that the antidote will be found at the opposite side of the focus where the rays are concentrated as much outwardly in the pencil as they are after crossing the axis concentrated inwardly.

Depth of focus does not mean an increase in one direction which may or may not be the more desirable one, accompanied by a counter-balancing or more than counter-balancing decrease of definition in the other direction. It means, as put by Mr. J. H. Dallmeyer, that objects in planes wide apart are defined better, and this is what Mr. Grubb and I have contested. Mr. T. R. Dallmeyer has inferentially, as I considered, abandoned this pretension. It would be well if he would either abandon it specifically, or re-affirm and prepare to defend it.

It would be no reply to affirm that when a certain plane is focussed as nearly as may be with a lens possessing spherical aberration, some particular background plane is better defined than it would be by a corrected lens focussed at its sharpest on the foreground. The corrected lens might be—and would be by a photographer desiring to secure these two particular planes—focussed at some intermediate plane, and if this can be done without more sacrifice in sharpness in the foreground plane than necessarily results from the presence of spherical aberration in the other lens, whilst the background plane is also as sharp as with the other, and the intermediate ones all better than with the "diffusion arrangement," there is clearly no greater depth of focus with the latter.

Mr. Burton's article in the current Year-Book, which originated the present discussion, is well worth the consideration of those interested in the question of sharpness in photographs. His main arguments are, I think, incontrovertible. A point less easy to concur with is the disposition to yield his reason and assent to the dictates of others in a point where, as he says, every argument they have produced is defective. This question, however, may form the subject of another article.

Wayzegoose.—On Saturday, August 16th, the employées of Messrs. Percy Lund and Co. held their wayzegoose at Morecambe. The party had engaged a Pullman car, which was attached to the usual Morecambe day trip, and arrived in Morecambe soon after nine. In the afternoon the company assembled at the Summer Gardens, where tea was provided. Fifty-five sat down, after which the whole of the party were photographed by one of the firm's employées. A short programme of vocal and instrumental music and recitations was afterwards gone through, and brief speeches were made by Mr. Percy Lund and others.—*Bradford Observer.*

Cleaning Soiled Engravings.—It frequently happens that fine engravings, notwithstanding every precaution, become soiled and stained, and a recipe for restoring them is valuable. Put the engraving on a smooth board and cover it with a thin layer of common salt, finely pulverised; then squeeze lemon-juice upon the salt until a considerable portion of it is dissolved. After every part of the picture has been subjected to this treatment, elevate one end of the board so that it will form an angle of about forty-five degrees with the horizon. Then pour on the engraving boiling water until the salt and lemon-juice are well washed off. It will then be perfectly free from stain. It must be dried on the board, or on some smooth surface, gradually. If dried by the fire or sun it will be tinged of a dingy yellowish colour.—*Wilson's Photographic Magazine.*

THE STATUE OF DAGUERRE.

BY JAMES MEW.

When the marble statue of the Komthur, or Commendatore, or Commander of the order of Knighthood in the fifth act of Don Giovanni, pale, and terrible, and solemn, stalks into the supper room of the libertine hero, and, with sombre majesty of demeanour, seizing him by the arm with his stony fingers, drags away that unfortunate man from what seems to be an exceedingly sumptuous supper, in the direction of a place not mentioned to polite ears, the spectators are commonly conscious of a feeling of commiseration which they would be scarcely likely to experience were some of our own public statues to be endowed with life, and in like manner to drag away those gentlemen who had designed, or carved, or cast them. The spectators of such an incident would regard it very probably with cool complacence, not only devoid of any sentiment of remorse, but with some slight satisfaction arising from a sense of the general fitness of things, and the recognition of a late but wholly righteous administration of retaliative justice.

A statue, it is said, is about to be erected to Daguerre in front of the Smithsonian Institute at Washington. It may be permitted us to enquire why in front of the Smithsonian Institute? Our ignorance is complete as to the nature of the Smithsonian Institute, but we hope and charitably suppose that this Smithsonian Institute may be in some way connected with the photographic art. For it is occasionally necessary to reverse the aphorism of De Ségur, and say that statues, like men, should be seen in their proper places. That they are not always so seen our own metropolis bears pregnant proof. "Things" which it would be polite and moderate to call only ill-natured, have been said about our own statues and their positions. These "things" it is, happily, wholly needless to recapitulate. A statue has now, indeed, become a doubtful mark of honour, and it is much to be desired that the ghost of the deceased Daguerre may have no cause to regret this public recognition of his artistic service.

Rollin relates that some good folk one day enquired of Cato why, in a country adorned with so many statues, not a single statue had been erected in his honour? To which that stoic philosopher is said to have replied that he preferred that people should ask why he had not a statue, than why he had. About the deserving a statue, supposing it to be a desirable award of honour, there can, in the case of an inventor of photography, be little doubt or discussion. It is needless at this time of day to expatiate on the many advantages which this wonderful art has conferred upon almost every section of the globe—an art for which nothing is too high and nothing too low, an art which is no less interested in earth and its most delicate organisms, than in heaven and its most distant stars. It shares, indeed, with the steam engine and the electric telegraph, the honour of being, in the words of the Photographers' Association of America, one of "the three great discoveries of the age." The close of its first half-century of existence is to be commemorated by a statue of Daguerre.

In what position is the great photographer to be presented? Sculptors are, as the public knows to its cost, compact of idiosyncrasies. It may be the sweet will of the glyptic artist to seize the forelock of the present occasion to deliver to posterity a portrait of Daguerre on horseback, or seated in the magisterial siege, but neither the cavalier nor the occupant of the curule chair is a statue in the strict etymological sense of the word. A statue is clearly something standing, not sitting, whether on a horse or on a stool. The first statues, from which our present expression "stiff as a statue" seems to have been derived, were always upright, with joined feet, legs well glued together, and arms perpendicularly pendant on the figure's sides. Such, according to Grimm, was the original statue, whether the material were gold, or silver, or marble, or bronze, or wood, or clay. It represented man in the dignity of his nature, not prone as other animals, but erect and raising his face to the firmament.

It will be interesting to learn whether the artist who has Daguerre's statue in hand has considered the chair, or the column, or the curtain, or the book, which are almost constants in the old Daguerreotypes, in any way necessary or advantageous to the monument of him who pictured them. There is no doubt that in any case the utmost pains will be taken to secure a personal resemblance, so as not to detract in any way from the privilege of the statue to be the nearest of all copies to the object it represents. In this respect the verbal description and the picture are of inferior power, and though the latter, like the statue, can speak in all languages, yet the statue alone, of all the secondary pleasures of the imagination, as Addison has called them, can convey, by the sense of touch, information and delight.

Louis Jacques Muadé Daguerre was born at Cormeilles, in the department of Seine-et-Oise, and began the earning of money for the support of that life to which his parents had assumed the responsibility of introducing him in the somewhat prosaic employment of an inland revenue officer. But the artist in Daguerre soon rose superior to the accountant, and he deserted the inquisitorial inspection of kegs for the more congenial occupation of painting the visions of his imagination upon canvas. He became a scene painter for the Opera at Paris, and in his remarkable power of exhibiting the effects of light and shade, threw into the latter not only his predecessors, Munich and Bibiena, accomplished as they both were, but also his own tutor, Degoti. The Chapel of Glenthorn, at the Ambigu, and a pellucid picture of sunrise in "Les Mexicains," are still quoted as the most marvellous of his inspired manifestations. He supplemented his theatrical work with panoramic views of Athens and Jerusalem, of Rome and London, and other great cities, and followed step by step the leading genius of his life, the spirit of the contrasts of light and darkness, in a dioramic exhibition which he opened in Regent's Park. The picture of a Midnight Mass at the Church of Saint Etienne du Mont was his penultimate effort before he appeared as the inventor of the Daguerreotypic photography.

Hos ego versiculos: It was I who wrote these little verses. A stormy autumn at Rome, some nineteen hundred years ago, on the occasion of a spectacular exhibition of the time, when the storms confined themselves—as people in these later degenerate days have often wished, when bent on pleasurable excursions into the country, that storms would confine themselves—to the night, and in the morning all again was bright and fair. And Virgil, then a young man, wrote in Latin the following lines, and placed them high on the theatre of the spectacles and sports, where all who ran might read—

> "Rain rules the night, with day our sports arise,
> So seems it right in Jove's and Cæsar's eyes."

And those who read inquired after the author, and one

Bathyllus, a poetaster, not devoid of audacity, rose up straightway and said, "I am the man," and received in due course royal flattery's rich reward. Then Virgil grew wroth, and wrote under the lines, "I wrote these lines," and left a blank space, and then "For others so," four times repeated, and left after them four blank spaces, one in every line, and publicly asked Bathyllus to fill up the blank spaces. Bathyllus, finding himself in an intellectual quagmire, with floundering thoughts which in vain attempted to gain a poetic foothold, gave up the attempt in despair, and so, we are informed with some looseness of logical deduction, was found to be an impostor, and Virgil gained reputation, an inadequate substitute, perhaps, for the payment already secured by Bathyllus, by concluding his commenced verses thus:—

"I wrote these lines—the laurels others bear,
For others so—steers drag the heavy share,
For others so—bees stock their cells with care,
For others so—sheep fleecy raiments wear,
For others so—birds build their nests in air."

It is an old story, but it comes pat to the purpose, for Niepce, of Châlon-sur-Saône, and Daguerre, of Cormeilles, in the matter of the founding of photography stand in somewhat the same relation to each other as Bathyllus and Virgil, though which is Bathyllus it is no easy matter to determine. It seems that Nicéphore Niepce, who, since 1814, had been seeking a means of obtaining permanent pictures by the sun's assistance, learned in 1826 that Daguerre was similarly occupied. These are the dates given by the historians, but, of course, they are a little difficult of proof. We are told that in the following year Niepce communicated to Daguerre particulars of his own method of fixing the images produced in the camera lucida by making use of metallic plates "coated with a composition of asphalt and oil of lavender; this, when acted on by the light, remained undissolved when the plate was plunged into a mixture of petroleum and oil of lavender." The two investigators, it is fairly certain, continued to labour conjointly in the production of their photographs, or, as they called them, heliographic pictures, from 1829 till the date of Niepce's death in July, 1833. Daguerre, building on the solid foundation of their joint travail, erected some little time after his fellow student's death the edifice—since so much enlarged—which he called after his own name. A chief point, it has been well said in favour of Daguerre as the discoverer of photography, lies in his familiar development of the latent image by means of the vapour of mercury, which he discovered, we are told, by accident. That the French Government had some doubt about the relative merits of Niepce and Daguerre appears clearly from their consideration of a bill according to the provisions of which Niepce's heir was, on certain conditions, to receive an annuity of 4,000 francs. But the discoverer of photography must depend upon what is understood by those words. Schulze may have this title, and Thomas Wedgwood and Fox Talbot, to whom is owing the first transparent paper negative. History, like many other matters, suffers from the bias of patriotism.

Daguerre died in July, 1851, at Petit-Brie-sur-Marne, a suburb of Paris. Two books written by him will interest the photographer, his "Historique et Description des procédés du Daguerréotype et du Diorama," published at Paris in 1839, which passed through several editions, and has been translated into English, and an octavo work published at Paris, in 1844, entitled, "Nouveau moyen de préparer la couche sensible des plaques destinées à recevoir les images photographiques."

ARTISTIC EDUCATION FOR CHILDREN.*

BY ADA M. LAUGHLIN.

All children should be taught enough drawing to be able to express themselves readily with the pencil; not with the purpose of making artists of them, but because such power is an enrichment of ordinary daily life. This study awakens an appreciation for beauty and truth, and leads to higher ideals in conduct and workmanship. There is a yearning toward beauty in form and colour as well as in sound and morals, and it is to this upward tendency of the mind that the wise educator will address himself. The higher our conception of material beauty, the higher will be our ideal of moral beauty.

We, as a nation of peace, maintaining the smallest standing army in the world, in our public education are doing nothing compared with Europe to advance and ennoble peaceful occupations. What is being done in America toward fitting the people for adjustment of their relations to peaceful labour is being done wholly by private enterprise. Pratt Institute in Brooklyn, whose varied work is illustrated so beautifully in our city to-day, is maintained wholly by private enterprise, and is training 1,500 young people to self-reliance and skill, the expense to them being merely nominal. Mr. Philip Armour, of Chicago, has in view the establishing of a similar enterprise in his own city.

With the diminution of hours of labour for the working man rises the demand as to how he shall spend his time. Because more leisure is coming to people, we must create, foster, and nourish the desire for pure and elevating amusements, and this fostering of correct tastes must be begun in childhood, and cared for under the state and civil authorities. Few studies can claim to do as much as music and drawing toward advancing children in paths of peace, obedience, and order, giving them present happiness, future occupation, and a constantly elevated enjoyment.

America must not judge herself nor her arts by standards of Greece and Rome, for the conditions of life now are vastly changed and much improved. We cannot do, even if it were a thousand times better worth doing, anything well except what our American hearts shall prompt and our American skies teach us, for all good workmanship is the natural utterance of its own people in its own day. The art life which is the result of this new industrial activity will come from the sure and gradual elevation that is the necessary outgrowth of universal purity of thought and action. Inspired by the purpose to educate and thus redeem the masses, to awaken and stimulate an appreciation of nature as the externalisation of God's thought—dominated by the Christian idea—the leavening of the entire lump, the nation's aim shall be, not the development of intellect for intellect's sake, nor science for science's sake, nor art for art's sake, but everything for humanity's sake—to make humanity godlike.

Prices of Paper and Platinum Salts.—Mr. Otto Scholzig writes that owing to the continued rise in price of silver nitrate, he has been obliged to raise the price of his sensitised paper by 10s. per ream. The price of Dr. Jacoby's platinum paper has also been raised from 2s. to 2s. 6d. per sheet, owing to the high price of platinum salts.

* A paper read before the American National Convention of Teachers at St. Paul.

SUCCESS IN PORTRAITURE.

I am going to offer a few more remarks upon the portrait branch of photography, and I will ask all experienced workers to give what I have to say the go-by, recollecting that, while what is here told may be familiar enough to them, there are a great many enthusiastic ladies and gentlemen providing themselves with cameras every day, and scanning photographic literature for help, to whom assistance will, I am sure, not come amiss.

There are a few broad principles underlying success in the taking of portraits, which, if properly understood at the outset, lead rapidly to success, and without a knowledge of which the aspirant will inevitably waste his time and materials, and find himself disposed to set aside in disgust an occupation which ought to prove, with proper guidance, an endless source of interest and pleasure to himself and his friends.

First let us call attention to the importance of simplicity in our arrangements and effects. In mechanics, it is well understood that simple contrivances are generally better than more complicated ones, but the mistaken impression seems now to prevail in relation to artistic productions, that the more complex and over-crowded they are, the higher they must stand in the scale of excellence.

The mind should be impressed, not distracted, and a work of art, to be impressive, must tell its story simply and directly. Its objects should be suitably grasped, and its light and shadow collected into broad masses. All that we admit, as we proceed, to give fulness and interest to our subject must yet remain subservient to the larger and simpler parts, and it must be constantly remembered that the more we introduce by way of embellishment, the more we are likely to drive away the attention, and destroy the breadth and unity of purpose in our picture. When we set out to make a portrait, we must bear in mind that the head and bust of the individual are the aim and end of our work. Anything else that is introduced must not only be entirely subservient to this main end, but should be as far as possible in harmony with it.

It is very difficult to secure about residences and homes generally the breadth of lighting and repose of background that are necessary to the production of a good portrait, and it is for this very reason that I am particularly induced to urge the necessity of bestowing a little time and pains upon a few necessary arrangements before attempting to expose plates upon heads.

First, as to the matter of lighting. Good portraits can never be made in any situation where the lighting does not extend above the level of the head, because all under-shadows are destroyed, and the important modelling which gives expression is lost. For the same reason, outdoor pictures taken in a diffused light are seldom good, and we may here add that, under the latter condition, it is impossible to secure a calm, tranquil expression, owing to the effect of the glare of light upon the eyes. Whether the work be attempted in an apartment or out-of-doors, the conditions should, in a general way, be the same, namely, the direct light should come upon the sitter as nearly as possible at an angle of forty-five degrees, and somewhat from the front. It matters little whether the amount of light be great or small. It may be merely what may proceed from a little window near the top of an apartment with a high ceiling, or the whole of an outdoor light which happens to be cut off eight or ten feet from the ground, and sheltered still higher on two sides. It will be seen that the former condition is absolutely unattainable in an apartment with a low ceiling, while the latter may readily be got in the city, in back yards where there are high walls and high board fences with big spaces of overhead light, and in the country where walls and shrubbery very often give us virtually the same conditions.

Heads taken under porches can never make good pictures, because all the overhead light is cut off, and if the sun happens to be shining upon the floor of the porch or light earth in front of it, we have a lighting precisely analogous to that produced by the stage footlights upon the players, which is abominable to artists.

After lighting, the next most important matter is to see that we secure a quiet background. The beginner in portraiture is apt to be so absorbed in his sitter that he rarely thinks of what may happen to be back of the latter, and if there should be a combination of strongly-defined objects near enough to be in focus, the head is lost in them, and the picture is spoiled. It so rarely happens that we find a quiet space in front of which to pose a sitter that it is much better to provide ourselves with a suitable piece of quiet, grey drapery, or to stretch some muslin on a slight frame a couple of yards square, and tint it with a coating of distemper, and this gives us the additional advantage of being able to grade our background from a light tint on one side (or corner, rather) to a darker at the other, which not only varies it and prevents monotony, but will enable us to relieve the light side of our head by a dark ground, and *vice versa*.—*American Journal of Photography.*

Decomposition of Eikonogen.—Eikonogen in crystals kept for a long time becomes greenish in colour, then black. This partial change does not prevent its use as a developer. The solutions then obtained have a more or less green colour, whilst the substance freshly prepared yields solutions of a pale yellow. It is easy to remove from the affected mass the portion which has remained uninjured. Make a cold and very neutral solution of sulphite of soda—that is to say, containing less than 500 grammes of the salt for 1 litre of water; boil, and add an excess of the affected eikonogen reduced to powder. Agitate with a glass rod until complete solution. Decant, and cool rapidly the liquid in a bottle exposed to a flow of cold water, and continually agitating, so as to avoid the forming of large crystals of eikonogen, which rapidly crystallises. Filter the whole and wash the crystals on the filter with a little alcohol. Allow the mass to dry, and we have an eikonogen that is almost colourless.—*Journal des Sociétés Photographique.*

Solar Activity.—Prof. Tacchini gives the following results of solar observations during the second quarter of this year (*Comptes Rendus*, August 4):—

	No of days of observation.	Relative frequence of spots.	Relative frequence of days without spots.	Comparative area of spots.	Comparative area of faculæ.	No. of groups of spots per day.
April	19	2·08	0·75	1·40	10·40	0·44
May	20	2·55	0·54	2·58	25·83	0·71
June	26	1·35	0·76	0·86	8·10	0·25

A comparison of these figures with those of the first quarter of this year shows that the spots are slowly increasing in magnitude, and that the number of days without spots is diminishing. The following results have been obtained for the prominence:—

	No. of days of observation.	Mean number.	Mean height.	Mean extent.
			"	"
April	19	1·90	35·2	1·5
May	20	1·55	37·9	0·9
June	26	2·42	27·7	1·3

Notes.

The great statue of "Liberty Enlightening the World," on Bedloe's Island, New York Harbour, has been photographed at night by an enterprising Yankee by the aid of the magnesium light. A wire was stretched from the Torch of Liberty to the mast of a ship in the neighbourhood, and by this wire the pot containing the magnesium compound was slung under a pulley wheel, which was made to travel to the desired position. Twenty-four ounces of magnesium compound were used with an ounce of the pure powdered metal on the top, and the compound was fired by electricity from the electric light plant on the island. The photograph was taken from the dock on the east side of the island. The ambitious photographer who did this work was Mr. S. R. Stoddard, of Glens Falls, New York. The result is said to be much the same as if the picture had been taken in daylight, but the sky is darker.

Great preparations are being made in France, both by ecclesiastics and the laity, for the coming festival in honour of Joan of Arc, and soon a great change will come over the little village of Domremy, in which she was born. At present it is in its primitive state, but half a mile or more away is a new church on the borders of the wood in which she heard the voices; this church was erected from the plans of Parisian architects, and is a handsome structure. Before new national buildings are erected in the village itself, the latter should be well photographed from different points, although it is not a picturesque place, and is interesting chiefly from its historical associations. The little cottage of Joan of Arc, which has long been kept in order by the Government as a national monument, is about the most picturesque subject in the village; we photographed it once in a storm of wind and rain, which had kept on for two days previously, and then showed no signs of abating. The old church bears no resemblance to its representation in theatres; it is no majestic pile rearing its head in the moonlight, whilst the pealing organ adds to the solemnity of the scene, but it is an ugly little white building, like some of the plainest Little Bethels to be found in back streets in London; in front it has an ugly black statue of the Maid of Orleans. A narrow street runs by its side, and at the opposite corner to the church is a small *cafe*; French "Cheap Jacks," sometimes put up their travelling vans against the wall of the church, then turn their horses out to grass. The inside of the little church is interesting, but badly lighted for photographic purposes. Banners and wreaths, dusty with age, wrought by the hands of fair ladies in France, abound; many of these came from the great city of Orleans, which always turns its eyes with affection towards Domremy. This historical village is not an easy place to get at; it is down a branch line in the Vosges district, along which line a few slow passenger trains pass during the day; the nearest large city is Nancy. No authentic portrait of Joan of Arc exists. The oldest representation of her is a time-worn stone effigy in the wall of her cottage; if she bore any resemblance thereto, she was a rather pudding-faced, obstinate-looking young woman. It is doubtful whether Joan of Arc was burnt.

The East Dulwich and Peckham Photographic Society has changed its name to the South London Photographic Society—a title borne by an organisation of the past, which died after a long career of usefulness and of honour. The new Society seems to have taken the name of the old one of its own sweet will and pleasure—not that there is any actual connecting link between them. Having taken a good name, the new Society would do well to act up to the traditions connected therewith.

Our American brethren have a neat way sometimes of describing ordinary events. Recently, it will be remembered, Voigtlander had conferred upon him by the Emperor of Austria the Ritterkreuz of the Franz-Joseph Order. About this an American writer says:—"We congratulate Herr Ritter von Voigtlander, and trust that he may bear his honours meekly, and that the glitter of the knightly star upon his manly breast will not prevent him from continuing in his efforts to give us a perfect photographic lens. Farther, that the escutcheon of the new Baron Euryscope von Voigtlander may never be fogged by the Bar-Sinister, and that the results of his labours may always prove absolutely rectilineal and free from distortion, with a flat field and sharp definition."

Hogarth's illustrated moral story of the industrious and the idle apprentices is often called to mind by living illustrations which we see around us. The man who is conscientious and careful in his work gets to the top of the tree, while his fellow worker who is slovenly grovels at the root. We came upon a case in point the other day at a certain country town which boasts two photographic establishments. In one of them everything was spick and span, the reception-room was garnished with flowers, the specimens were good, and everything wore the aspect of prosperity. The other establishment was the reverse of all this, but perhaps the worst point about it was the sorry condition of the show cases which lined the entrance hall. The pictures could not have been renewed for at least a couple of years, and were afflicted with measles, yellow jaundice, and all the other ills to which photographic flesh—on albumenised paper—is heir. We learnt incidentally that the other man had all the best of the business, and we had no need to ask why.

The condition of the show-case is of the utmost importance to a photographer, and yet some seem to think that it is not worth troubling about, and that its proper rôle is to form an interesting exhibition of the fashions which were in vogue ten years back. Others, again, depend more upon quantity than quality, and cram their cases with hundreds of portraits, mostly of an

indifferent kind, as much as to say, "Look how many I take," instead of, as it should be, "Look at the excellence of my work." The best photographers know better than this, and are content to exhibit one or two really good portraits set tastefully on little easels. A real work of art will immediately attract a passer-by, who will stay for a moment to look at it, while the large collection of indifferent ones will only attract the idle residents of the place, who will point out Miss So-and-so, and criticise the portrait of Mr. Somebody else for the amusement of themselves and their companions.

The itinerant seashore photographer is, perhaps, the man who is most commonly blind to his own interests in exhibiting portraits which should be consigned to a photographic room of horrors. Poor fellow, he often lacks the means to alter this condition of things, and open air portraiture, generally done in blinding sunshine, is hardly conducive to good work. But even he might eliminate the pictures which have turned all kinds of colours except a pleasing one, so as not to advertise too strongly the want of permanence in his wares. He might, indeed, refrain from exhibiting any paper proofs at all, seeing that his work is wholly on ferrotype plates; in fact, he goes out of his way to show faults of manipulation.

While we are discoursing of faded prints, we may note a curious case of fading which came under our own observation a short time ago, for which it is difficult to discover any sufficient cause. We have in our private album the portrait of a child which was taken about twelve years ago by one of our best professional workers, one whose honoured name is known throughout the photographic world. It is covered with spots, has turned to a sickly yellow hue, and is altogether a most miserable example of a faded silver print, while the rest of the pictures in the book—some of much older date—are in fair condition. In a friend's album we lately had an opportunity of seeing another copy of this same picture which was printed at the same time, by the same hand, and presumably with the same materials. It is as bright and good in every respect as the day it was printed. This second picture, too, has been kept in an album, but why the difference in their appearance?

Automatic photographs are still in the dim and distant future. The statutory meeting of the company, which was held this week, did not disclose much which was cheering either to the shareholders or the public. Though the company has been in existence nearly three months, not one of the machines has yet been placed, nor could the chairman state exactly when it would be. He hinted somewhat vaguely at about thirty days; so that at the earliest the public cannot have their photographs taken for a penny until the autumn is well advanced. As light will have been considerably reduced in its actinic value by that time, and is likely to get worse during the next four or five months, a considerable proportion of failures may be expected. It is to be hoped, when an irate sitter fails to obtain a flattering portrait or even no portrait at all, that he will not wreak his vengeance upon the unoffending machine. Possibly the directors had some fear of this kind before their eyes, as Lord Kilmorey, the chairman, spoke of a new lens which was being constructed, by which photographs would be taken in a dull light equally as rapidly as in a good one. Photographers will be delighted to hear of this. In fact, what with the "secret" chemicals which the company is going to supply them with, and what with the new lens which it is about to introduce, the Automatic Photograph Company promises to be quite a benefactor to the profession. The curious thing is that it is so modest in offering the said chemicals for sale. We should be very glad to hear of a single photographer who has been able to secure a single pennnyworth. Mr. W. E. Debenham addressed the chairman on the question of the price of the chemicals, asserting that what the company was going to pay a halfpenny for would cost but the sixteenth part of a penny. The chairman, however, discreetly avoided answering the question, and the world is still left in darkness as to what the "secret" of the company is. No doubt in time the shareholders will discover for themselves.

The President of the Photographic Convention has been taken to task for his statement that "colour printing in photogravure will produce water-colour drawings with a fidelity so great that it must deceive even the artist of the original drawing." While admitting the great advance made in fine art progress by the aid of photography, the critic of the *Sunday Times* doubts if the almost infinite gradations in tone and tint of a good water-colour can be exactly reproduced. It is to be hoped that the critic is right. The possibility of reproducing a water-colour drawing so faithfully as to deceive the original artist places a dangerous power in the hands of unscrupulous persons, who are always ready to avail themselves of a chance of piracy in art.

Photography has invaded the music hall. We do not refer to the photographs of the lion comique, the sister ducttists, and the marvellous acrobat, with which the entrance halls are plentifully ornamented, but to the comic song. The latest effusion is sung by a young lady in a fancy costume who comes on the stage holding a bundle of cabinet photographs in her hand. The song is of a topical character, each verse relating to some well-known personage, such as the Prince of Wales, Mr. Gladstone, and others, but without any mention of the name. The key to the allusions is given by showing the photograph of the person sung about, with the refrain, "Do you not think so?" to which the audience are expected to reply with a stentorian "Yes." The song seems to take, whether through the popularity of the personages, or the exhibition of their photographs.

THE KEEPING QUALITIES OF GELATINE PLATES.

The question is often asked, How long will gelatine plates keep? And the answer, of course, must depend on the experience of the particular individual, or on evidence gathered from the experience of others. As every item of experience in this direction must be of more or less value, we proceed to note down a few facts, impelled thereto by the result of an experiment made to-day—a repetition of a series made at intervals during the last five years. The experiment was simply the exposure of a plate on a fairly well lighted subject, with *f*/22, for a little less than a second, and its development into a fairly good negative, with a solution of pyro three grains and sodium carbonate twelve grains, in about eight minutes; the history of the plate alone giving interest to the experiment. During 1875-6-7 we had been experimenting extensively, numerically at least, with gelatino-bromide emulsions, and naturally accumulated a large quantity of "bottoms" when the results were promising, and larger quantities when the experiments were, as happened more frequently than not, unsatisfactory. Our method was to make batches of five ounces, no two of course being made alike, and after coating a number of plates, and otherwise examining each batch, the remainder was set aside in a dark closet in the laboratory. By the August of 1877 the shelves of the closet became crowded with bottles aggregating sufficient to fill three Winchester quarts—a gallon and a half—some containing alcohol, some carbolic acid, some salicylic acid, thymol, &c., and all with varying proportions of iodides and bromides, and made at different temperatures and with shorter and longer subjection to the "cooking" process. Some samples were white and solid, apparently unchanged, while others were of the consistence of thin syrup, dark as molasses, and smelling abominably.

The whole was turned into an earthenware jar as the first step toward the recovery of the silver, and as it occurred to us that the haloid salt could not be injured, or probably changed to any great extent, by contact with the decomposed gelatine, we placed a few ounces in a water bath and added sufficient of Heinrich's gelatine to make a firm emulsion. This was set and thoroughly washed in the ordinary way, melted, and a few plates coated, which, on exposure and development, proved, to our surprise, to be in every respect excellent, and very much more sensitive than any one of the samples, or than any emulsion that we had heard of. The experiment was repeated on a larger scale, and about a gross of plates coated, all of which, except three dozen, were used in our ordinary course of practice. The three dozen were put up in packets of four, each pair face to face, and wrapped in yellow paper, the common commercial yellow demy, two half sheets being employed for each four. Each three packets were placed in boxes made to order, and of a better quality of board than is now used, and the boxes were simply wrapped in brown paper and fastened with a string. In this way they remained until 1885, having in the meantime made three voyages across the Atlantic, and on one of the boxes being opened and a plate tried it was found in good condition and apparently as sensitive as at first. From time to time, from then till now, the experiment has been repeated, and the plate exposed to-day is apparently in as good condition as its neighbours were thirteen years ago.

On critical examination by an expert, the plate would not be pronounced equal to those by our best makers at the present. The negative is on the thin side, and slightly wanting in contrast. This is caused partly by over-exposure, no doubt, but it also arises in part from lack of silver, emulsions being less rich then than now. A careful examination also shows at one end and one edge a faint trace of the well-known metallic appearance that some plates assume even within a few months after being made, but it does not extend to the breadth of the rebate, and the picture is clean, crisp, and full of delicate detail, without trace of fog or other fault.

We believe the fact that these plates have retained their good qualities for such a length of time is due mainly to the way in which they were packed. The only objection to their being placed face to face is the possibility of their being scratched or rubbed; but when tightly bound together in fours—perhaps twos would be better—each packet is as solid as a single plate, and, while there may be vibration between the packets, the surfaces are not injured.

Some of the negatives made on the thirteen years old plates are in our office, and will be shown to those who are sufficiently interested in the matter to favour us with a call.—*The Beacon.*

A Transformation of the Physiognomy.—Physiologists assert that a married couple having reached a certain age, having ideas in common, in sympathy with each other and leading the same life, end by resembling each other facially. The Geneva Photographic Society has taken the photographs of seventy-eight couples to see to what degree this resemblance is developed. The result was that in twenty-four cases the resemblance between husband and wife was greater than between brother and sister, and as great in thirty cases.

Silver Malonates.—G. Massol.—This salt, $C_6H_3O_8Ag_2$, is obtained by the double decomposition of potassium malonate and silver nitrate. It is a white or faintly yellowish powder formed of fine microscopic needles which blacken on exposure to light. When dried in the open air, but in the dark, it yields 67·11 per cent metallic silver. If heated it blackens slightly, takes fire, and burns with brisk deflagration, leaving a residue of metallic silver. It is slightly soluble in water; at 20° 1 equiv. dissolves in 559 litres of distilled water, absorbing —9·8 cals. The formation of this salt by double decomposition is accompanied with a liberation of heat.—*Comptes Rendus.*

Electioneering Photographs.—Mr. G. T. Teasdale-Buckell, editor of *Land and Water*, is circulating the following letter among country Conservatives:—"I intend to publish some special editions of *Land and Water* relating to your county, and in each of these editions I desire to give the photograph of a Conservative or Unionist member of Parliament, or a candidate for the next Parliament. The photographs will be done in the best possible manner, and for this purpose it is necessary that the sitters should be taken specially for the purpose. I have already had a number taken, but many members have sent me their photographs previously taken which I unfortunately cannot use. It is my intention to deal extensively with the industries of your district by the assistance of experts, and to get out the photographs and literature some time in advance of the next general election, so that when this event does occur reprints of the photographs and literature can be made, if desired, and sold at a low price—perhaps 1d. The photographs will be superior to anything ever published in a newspaper. My object in writing to you to-day is to ask you to induce your member to call on us for this purpose at the earliest possible date, and before Parliament rises, if possible, as I cannot start with your county until I have taken the whole of its Conservative and Unionist members and candidates. I think that the earlier it is done the less like electioneering it will appear if it should be reprinted at the time of an election."

THE CAMERA THE HISTORIAN OF THE FUTURE.

BY JULIUS F. SACHSE.

Among the manifold uses of the camera and photography in the various departments of the sciences and arts at the present day, both as a profession and pastime, no field opens wider nor shows greater possibilities than that of photo-historiography. With the great improvements which have lately been made in portable apparatus, and the simplification of the various manipulations and formulæ, together with the perfection of permanent processes, photography is destined soon to take its place, we may well say, as the historian of the future. The camera, with its great recording eye, will not alone pictorially depict the passing events of the day, but retain the appearance of the fast crumbling landmarks and monuments of the past; it will duplicate the features of the present generation, as well as permanently renew the old fading portraits and yellowing parchments, thus preserving them for the students and searchers of the future. That such photographic records will before long become the one thing needful in connection with every country, society, or other body having any interest in its history being handed down to posterity, will be apparent to all.

This fact is being recognised in different parts of the world. We already read of photographic surveys of various localities, castles, and historic buildings in England; of the "Ausflüge" of the photographic societies in Germany; the efforts made to reproduce old paintings, documents, and engravings in Vienna; the glorious photographic detail survey of the Basilica of St. Mark, at Venice, in Italy, consisting of six hundred and fifty plates in five large portfolios, executed under the patronage of H. R. H. Margaret of Savoy, Queen of Italy, the work having been commenced in 1878 and completed in 1885, by Fernando Ongania, and a large corps of assistants. The majority of these plates are reproduced by the heliotype process; others in colours by chromo-lithography. How thoroughly the work was done may be surmised from the fact that the entire facade was divided into twenty-one sections. Yet so exact is the work that the plates fit together exactly, forming one large picture, 8 ft. 9 in. long by 5 ft. 9 in. high. This valuable collection of plates shows completely all the decorative features of both the interior and exterior of the grand ecclesiastical edifice. Every detail being taken directly from the actual object by the camera, and reproduced by the phototype process in printer's ink, this collection, besides serving as a basis for any renewal or restoration that may be necessary in the course of time, will transmit to students in all parts of the world, as well as to posterity, a faithful record of the splendid ecclesiastical monument in the state of preservation in which it is found at the present time.

A somewhat similar work has been done on the Alhambra, in Spain; while from far-off Australia comes the news that some hundreds of photographs have been collected of the leading men who assisted to lay the foundation of Victoria, and which have been reproduced in uniform size, thus forming an interesting volume which, in time, will prove one of the most valuable historical records of the colony. In our own country this subject has not received the attention which it deserves; it is true a few individual efforts may have been made in different parts of the country, but in most all cases without any definite system, or without any intention to thoroughly exhaust the territory. A work of this kind, to be of future historic value, must be done conscientiously and intelligently, as well as in a systematic manner, and those who undertake the task should be thoroughly posted, not alone in the general and local history of the territory and subjects at which they wish to point their camera, but also train their eye for the salient and important parts, to say nothing about the picturesque bits of the subject, no matter how unpromising it may appear from an artistic standpoint at first sight.

In a work of this kind, negatives are apt to increase in number rapidly, and at the very outset, after the survey is completed, a new difficulty presents itself, viz., how to utilize the prints to the best advantage for future use and availability; and it is here where we must look to the expert book-binder, as well as the photographer or silver printer. As is well known, the regular albumen prints are so apt to twist or warp as to make them almost useless for book-work. Turning to the new "permanent" processes, where the plates could be printed on heavy plain paper, masked so as to show a wide margin, same as an etching or steel engraving, all difficulties were thought to have been overcome. This was notably the case with the platinum process, but here again a difficulty presented itself from the fact of the prints having to be developed in hot chemicals; the paper loses its sizing, opens the fibres, and becomes tender, and the white margin soon turns yellow. The same may be said of some of the bromide papers. Phototypes would seem to present the best results for our purpose, but as at present produced, and on account of the small editions, would be out of question on account of the expense involved. The welcome news, however, comes to us from Vienna and Paris that the process of producing these reproductions has been much simplified. In Paris, amateur outfits for "phototypie" are already offered for sale. If this process is practicable and cheap it may solve the problem, especially as there can be no question as to the permanency of printer's ink.

The first complete copy of a photographic survey which has been made in this country, so far as has come to the knowledge of the writer, was shown a short time ago at the rooms of the Historical Society of Pennsylvania. The subject was the old religious community at Ephrata, and consisted of fifty silver prints, 4 by 5, mounted on heavy cards, 7 by 10, a print being mounted on each side of the mount. They were burnished by a peculiar process, so as to overcome as much as possible the twist of the cards. These pictures reproduced all the different buildings still standing which had formerly been used by the community; the various interiors were also portrayed, together with the mystical inscription upon the walls; then came the various details of the construction, such as unique portals and quaint staircases; then followed some specimens of their peculiar musical MSS., so highly valued by all bibliophiles, the series concluding with the mossy and crumbling tombstones which mark the resting-place of these old religious pioneers, who unto death upheld their Sabbatarian doctrine. Between each two cards a page of heavy bond paper was inserted, upon which was engrossed a short sketch or description of the picture on the page opposite. A title page and full index preceded the illustrations. The mounts were hinged at the back, and the whole was bound in a rich morocco cover. The volume formed a unique book, which may well be classed as an "edition de luxe," irrespective of its great historical value. As a matter of course, the limited demand for any such a work would debar the average professional

from undertaking the photographic part. The same reasons apply to the printing of the descriptive pages or inserts.

In the meantime, until the difficulties which so far present themselves shall be overcome, we would suggest that wherever a photographic society or historical association exists, work of this kind should be encouraged, and some provision be made for preserving such negatives as may be given them, or means taken at least to obtain a print from any such negatives of value. These prints, when properly mounted, classified, and indexed, must prove of great value and interest in the near future.—*The American Journal of Photography.*

FIXING PHOTOGRAPHS.

BY ELLERSLIE WALLACE.

IT is now conceded by all good authorities on bromide paper printing that stability or permanency largely depends upon thorough fixation of the print. This same assertion has often been made concerning the ordinary silver print on albumenised paper, and is also quite true.

The conditions involved in the making of bromide prints are so different from those in silver printing, that it will not be amiss for us to compare them and see why the necessity for thorough fixation is so specially urgent in the case of the bromide print. Almost every one knows that the bromide print is made on a gelatine emulsion, while the silver print is made on a surface of albumen. The bromide print is the result of a process of development, while the silver print is "printed-out" as the phrase goes. The albumen forming the vehicle for the sensitive compound in the silver print is an exceedingly thin layer; while the gelatine, which correspondingly forms the vehicle for the sensitive salt in the case of the bromide print, is very much thicker and heavier. The gelatine layer absorbs a large quantity of water, and swells to still greater thickness during the development and finishing, while the increase of bulk of the albumen layer of the silver print when wetted is so slight that it may be practically disregarded. Lastly, the silver print depends for good quality largely upon the keeping of the picture upon the surface, while the bromide print is rather one of those kinds where the image penetrates more deeply.

For the benefit of those of our readers who have never made silver prints, we may say that one chief point requiring attention is the condition of the fixing bath of hyposulphite of soda. This salt, although highly soluble in water, is quite unstable chemically, and is particularly susceptible to decomposition in the presence of acids or acid salts. Every care is taken that nothing of the kind is introduced into the bath. When the prints are "reddened" by means of acetic acid, they are always well washed before reaching the fixing solution.

This brings us now to one of the points that we feel sure is often overlooked by makers of bromide prints. Everyone conversant with the process will remember that when the development is concluded, it is necessary to rinse off the developer with weak acetic acid in order to prevent foggy deposits and general discolouration of the print. The extreme weakness of the solutions generally used—say one drachm of the acid to thirty-two ounces of water—being overlooked, the prints are hurried into the hyposulphite without sufficient washing, and a highly undesirable decomposition is forthwith set up. The products of this decomposition are numerous; sulphur, sulphurous acid, and sulphide of silver being the chief ones. Supposing that the developer had been but imperfectly removed by the acid, there would also be more or less oxalate of iron present.

Even if the bromide print were thus carelessly and ignorantly made, it would nevertheless have fair chances of permanency when compared to the ordinary silver print. It has long been known that photographic images produced by development are more permanent in their character than those which are "printed-out."

But there is another point connected with the fixing of bromide prints that we must not neglect to speak of. If permanent results are expected, *time* enough for the hyposulphite to fully do its work must always be given. And it should not be forgotten that the hypo really has a double task to perform: first, to convert the unaltered portions of the gelatine-bromide of silver into a soluble form; and secondly, to take them up or dissolve them. Besides this, the process has to be done throughout the whole mass of a tough gelatinous layer that is comparatively slow to receive chemicals, but slower still in parting with them.

Those who can look back to the early experiments with gelatine negatives will remember how many failures were caused by imperfect fixation of the plates. To those used to working collodion plates, it seemed impossible that so long a time was required for thorough fixation. But painful experiences taught us what we now know about the matter.

Before concluding, let us give a few words of practical advice. If silver prints are being made, see that before fixing they are well washed free from acid, if this be used for reddening. Let the fixing bath be rather large in quantity, *not too cold* in winter, and see that the prints are well worked about in it. Twelve or fifteen minutes would be a fair time of immersion. If bromides are the work in hand, see that the prints are likewise well washed front and back in running water before laying in the hypo pan, and do not hurry the prints out when once they are in. The mere disappearance of the yellowish tint of the unaltered bromide of silver is not proof that the print is fixed. Additional time should be allowed, just as in the case of negatives, which cannot be safely removed from the fixing bath as soon as the shadows clear. Twenty minutes' immersion for the bromide prints would, in most cases, be none too long. The prints should never be allowed to stick together so that the solution will not pass freely between them, but, as we before said, they should be well moved about. Care must be taken that while doing this the soft gelatine surface is not injured or scratched. Silver prints will bear rougher handling, the albumen surface being thoroughly coagulated and hardened.

The first washing waters for both varieties of prints should be rapidly changed, and the prints not allowed to stick together in batches, or sink down to the bottom of the vessel, and lie on the bottom. Neglect of this caution in silver printing often makes yellow prints.—*Ibid.*

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—Subject August 28th—Demonstration of Mr. Varley's Magazine Camera, and discussion on the uses and abuses of Hand-cameras; September 4th—"Pictorial Definition," opened by Mr. P. Everett. Visitors invited.

SNAP-SHOT PHOTOGRAPHY.*

The young man whom you see sliding along the street with a peculiarly shaped grip in his hand is not a commercial traveller, nor is he just about to begin a journey. Follow him at a distance, and you will see him glide into a hall-way, open his grip, pull out something that looks like a flat board, turn what appears to be a long screw, slam down the cover, throw up a diamond-shaped piece of leather in one end of the box, and then step jauntily into the street. Suppose it is in Mott Street that you encounter him for the first time. He appears to be watching the entire neighbourhood, and you might be inclined to think that he is a detective, with several assumed names about his person, except that he doesn't wear a cloak. Opposite the Chinese joss-house he stops, lifts his queer box up to the level of his breast, and lo! every Chinaman in front of the building takes a dive below, out of the way of impending danger; for he believes that the man with the grip is going to riddle the building. The mysterious individual has noted all this, but even while the pigtail of the last Celestial is whisked about as its owner disappears in the hall-way the man with the grip has pressed a button and his work is done. He has caught an exposure of the building and the flying Mongolians, and he knows that under good conditions he will have as a result of his labours a very good photograph of the joss-house. The mystery of the man and the box stands revealed in all its hideous proportions. Its owner is an amateur photographer, and the little grip is a detective camera.

It is astonishing to consider the number of snap-cameras now in use in New York. Turn where you will, you are likely to run against a man mooning around with one of these machines. He is relentless and terrible. He will take you so that you will appear in the worst possible light to your friends if only he can get you in a good one to snap his weapon. No cowboy in the wilds of Texas takes greater pleasure in punching an ugly steer than does this gentleman of the gelatine film when suddenly there bursts upon his vision a group of boys playing "craps," toughs discussing politics, Chinamen paddling about, or a pretty girl posed on a curbstone waiting for a horse-car.

The snap-camera man is not always skilful. In fact, he works for weeks before he can secure an exposure with that deftness and swift accuracy so characteristic of the veteran photographer. His first efforts, as a rule, are generally failures, and he spends a large share of his patrimony in plates and chemicals before he learns how to get a really good negative.

It was a Parisian who hit upon the novel idea of a detective camera. He made a small camera, which he concealed in his hat. A shutter in front was so cleverly arranged that the joint could not be seen. At first he used wet plates, but he soon saw the disadvantage he was labouring under. About that time the lightning dry plates were put on the market, and the Frenchman's hopes rose high. He could take his hat anywhere with him, and no one, at a glance, would suspect its double purpose. Placed on a table facing the person to be taken, the little button at the back could be pressed, and the exposure made. In some respects the hat camera was immeasurably superior to the toys now on the market.

The perfect detective camera should be all that the name implies, and the name manifestly becomes a misnomer when the camera is encased in a yellow wooden box. There are certain kinds of satchel cameras made that to all outward appearances are simply "grips," but by far one of the best of the late inventions is a camera in the shape of a book. It has three compartments, each supplied with a lens, and when a roll of gelatine film is placed in each section, the capacity of the book reaches 300 exposures. Carried under the arm, a camera of this description has such an innocent appearance that no one gives it a glance. It could be carried among a gang of thieves, exposures could be made, and the operator could depart without suspicion of the real use of his book.

Another detective camera that has met with considerable success lately is in the shape of an opera glass. It is really an opera glass with the larger glasses removed and dise plates substituted. The shutter is in the smaller end, and a nicely concealed spring operates it. The focus can be adjusted easily, as the screw in the centre is arranged for that purpose. Of course the negatives are small, but they can be enlarged by any of the many appliances known to the photographic world. Two meniscus lenses of equal focussing powers should be substituted for the concave glasses at the narrow end.

On the principle of enlarging, a neat camera has been invented which can be carried on the person and its presence remain practically unknown. It is placed inside the waistcoat, and the only external evidence is the lens, which is easily mistaken for a button. The picture taken by a camera of this kind is an inch or an inch and a half in diameter, and it can be easily enlarged without losing any of its essential details.

It might be well here to give a few pointers to amateurs who have recently supplied themselves with detective cameras. Never carry your box as though you were conscious of its ulterior purpose, or as though you were looking around for the express purpose of "snapping" some one. Strike an average focus, and in the quiet of some friendly hall-way set the shutter, open the slide, and take out the slide-plate, and there you are. When you are abreast of the object you desire to take, level the instrument on a line with your breast, touch the spring, and lo! once more, there you are! Then go along to another hall-way and readjust the plate slide, reverse the plate-holder, and once more you are ready to "scoop" another crowd. Do everything neatly and with the utmost despatch possible, and you will never be troubled. This rule is too often violated by amateurs, and they are subjected to all sorts of petty annoyance by street urchins.

An all-important fact in connection with photography lies in the illumination. There are good days and bad days; days when the sun shines so brightly that shadows are distinct and outlines are sharp and perfect. To obtain a negative under the best conditions the exposure should be made when the sun's rays have attained an angle of about 35° on an object situated about twenty feet from the operator, who should have the sun behind his back. The general tone of the light should be blue; a yellow, hazy atmosphere will never give a satisfactory negative.

Remember this, that while you have an apparatus that will work much better automatically than a slot machine, the success of the exposure depends mostly on your appreciation of the laws of light and shade. No matter how perfect a machine may be, good results cannot be obtained if the operator is not careful to observe the needs of the moment. The camera may be pointed too high or too low, directly in the sun's path, or the hand may press the button at the wrong moment, or with a tremor that will cause the shutter to slide unevenly.

The enthusiastic student of photography may obtain a good deal of amusement, and not a little knowledge, by experiment with the "paste-board camera," as it has been called. Take a long cigar box and blacken the inside. Make a pin-hole in the centre of one of the ends, and place a sheet of carbon paper beneath the lid and jam it down. If a 4 by 5 dry plate is placed at the end opposite the pin hole, with the sensitive side toward the latter, the lid jammed down and the box taken from the dark room to an open window, where there is a view of some building or other object, a very fair picture will be obtained on returning the box to the dark room and developing the plate at the end of half an hour's exposure. By interposing a meniscus lens the aperture of the pin-hole may be greatly enlarged, and the taking of the picture much quickened.

It may be added that thousands of good exposures are ruined annually by fault of developers. Not enough attention is given to this subject, and the result is a general condemnation of all the cameras in existence. The first and most important rule is not to permit a ray of light to enter the dark room; second, see that your hands are clean, and wash them thoroughly after each immersion in the separate baths. The trays should be perfectly clean, and that one used for the oxalic agent in the development of bromide prints should be used for no other purpose. The hypo is so cheap that it is really no saving to use a wash of it more than once. One of

* From the *New York Sun*.

the best developers has for its fundamental part a quantity of eikonogen, a German product, very costly, but quite cheap when compared with the work it does. After the plate has been developed it should be thoroughly washed in clear, cold water, and then immersed in the hypo bath until it is thoroughly fixed—say ten minutes. Then it should be immersed in a running bath of clear, cold water for half an hour, until all the hypo has disappeared. Then put the plate aside to dry, a process that cannot be hurried up if you want a good picture.

THE ABOLITION OF LONDON SMOKE.

THE dirt in the air of London and other great cities—which not alone forces the inhabitants to take filth into their lungs, but commercially injures professional portrait photographers in the winter months by increasing the time of exposing plates, because dirt in the atmosphere specially cuts off the actinic rays of the sun—will cause this letter by Mr. T. Howell Williams, F.C.S., L.C.C., to be of interest to our readers. We publish it but as one means, perhaps, of solving the problem. There are others.

MY DEAR WREN,—In reply to your enquiry of some months ago for a fuller explanation and a more detailed account of a scheme which I brought before your notice as to the abolition of London smoke, and the future prevention of London fog, I have much pleasure in taking this opportunity of placing before you further particulars regarding a project which, I believe, would result in the removal of evils that are a disgrace and reproach to a scientific age. I have observed that Lord Rosebery, in his recent able review of the first year's work of the London County Council, stated that "as regards fogs, which was a subject on which the Sanitary Purposes Committee had built some hopes, they found it impossible to make any practical suggestion." Both the questions of London fog and London drainage are serious problems, which the administrative body for the metropolis must face at some early day; and it is exceedingly probable that any further delay means not only additional expense to the community, but also a menacing danger to the comfort and health of Londoners.

The plan which I have the honour to submit to you at the present moment is one which possesses all the elements of practicability, and, I think, will deserve some consideration. Briefly stated, this plan is the production of gaseous fuel, for the use of Londoners and those who reside within the metropolitan district, at such a low price that it would be impossible in the future to burn coal economically in London. This would, I propose, be accomplished by making two kinds of gas—heating gas and lighting gas—*at the coal fields*, closely adjacent to the coal pits, conveying the same, when manufactured, to London in separate systems of main pipes; storing it in convenient gas holders, and then distributing it for the two distinct purposes of heating and lighting, thus making it a matter of absolute impossibility that coal should be economically consumed within the radius of the metropolitan district for the purpose of heating, and preventing its import as a matter of profit, tolerating specimens of the precious but uncleanly mineral as curiosities in our exhibitions and museums.

It will be a convenient method of laying the scheme before you if I proceed to discuss the question in the following order:—

I.—I shall endeavour to state and summarise the present odious disadvantages ensuing from the indiscriminate, ill-regulated, and wholesale combustion of coal in London.

II.—I shall next place before you the main lines of my scheme, leaving the *minutiæ* to be worked out later on when required; and I shall endeavour to sum up shortly the undoubted advantages which, I believe, it would bring to a patient and suffering public.

I.—*Disadvantages and Evils of the present System.*

It will be unnecessary for me, in the first place, to do anything more than state as briefly as possible what are the present disadvantages of London life in this respect. You have, in your able pamphlet on the "Causes and Cures for London Fogs," stated them more fully than I shall have the opportunity; and Dr. Alfred Carpenter, in his pamphlet "On London Fogs," has dealt also with the question in a comprehensive manner. Although it is true that a smoky atmosphere is the creation of modern times, yet it must be recollected that the question has always been one of public interest. From early times the citizens of London have been of opinion that the fumes produced by coal combustion corrupt the air, and are injurious to public health. In 1306, Parliament petitioned Edward I. to prevent that fuel being burnt, and it was made a capital offence to burn "secole" within the city, its use being permitted only in furnaces. It is said that a man was actually executed for burning it contrary to law in London; and it may be not difficult to imagine that, with the ever-increasing area of London, the fog nuisance will become so unbearable and injurious that a severe punishment will inevitably be provided for those who contaminate the already overladen air with the deleterious products of coal combustion under the present arrangements. Theodore Hook, fifty years ago, described London as that "sink of sin and seacoal." But of late years London fogs have been becoming more intolerable and frequent. The unhappy inhabitants are compelled to grope their way too frequently amongst the darkened streets, quite unconscious of the beautiful weather which may, perhaps, prevail only a few yards above the fog, through which the rays of the sun cannot even penetrate. Fog damages the public health. It fills the lungs with choking, repulsive vapour, impedes respiration, lowers the vitality of the individual, and fills the air passages with dirt, producing the most irritating sensations. It spoils our libraries; it injures our property; it diminishes the value and beauty of our public buildings. It corrodes and destroys the appearance of our perishable articles and pictures; and the gaseous, as well as solid, impurities which are to be found in the air give a most unpleasant taste, which prevents free breathing. Added to these discomforts, there are the exhalations of human beings and animals becoming concentrated in the great blanket overlaying the huge city. The money cost of each fog must be enormous and incalculable. Traffic everywhere is paralysed by it, precious time is wasted, and outdoor business practically is at a standstill. During its occurence, the prevailing discomfort is made worse by the thousands of fires kept up on the railways emitting black smoke, necessary, however, to keep the signalmen from perishing from cold. The metropolitan district area is over 300 square miles. "There are at least, probably, 4,000,000 domestic fireplaces in this area, and about 1,500,000 lighted fires of every description in full operation daily during the winter months. It has been estimated that about 30,000 tons are daily burnt in London. About 13,000,000 of tons are brought every year into the metropolis, and, taking the percentage of one-tenth of a grain of carbon to each cubic foot of smoke escaping from London chimneys, there are, perhaps, sixty tons of unconsumed coal hanging over London every day. An immense amount of unconsumed hydrocarbon is also wasted, owing to unscientific methods of combustion, principally due to the use of the old-fashioned English fireplace and cheerful hearth said to be so dear to the peculiarly conservative people of these realms."

With these ingredients hanging over us, there is mixed up such products of coal as tar, itself the most unpleasant quality in fog. It is asserted that 200 tons of sulphur—the principal portion of which is in combination with ammonia as sulphate of ammonia—are daily thrown into London air, involving an enormous waste, and representing a dead loss of a very valuable fertilising agent.

The injury to life which fog creates was seen in that terrible season of the winter of 1879-80. For six weeks, ranging from November to February, there was a continuation of dense and protracted fog, doubling the number of deaths; asthma increased 220 per cent., bronchitis 331 per cent., and in the week ending February 13th, 1882, the death-rate, owing to the dense fogs, rose from 27·1 in the previous week to 35·3,

diseases of the respiratory organs rising to 994, the corrected weekly average being 430.

The dangerous element in fog is the smoke. There is as much fog sometimes in the English Channel as in London, but a great difference exists between the two varieties. In the Channel it is a clear, white mist; in London it becomes mixed up with carbon and other ingredients, which come out of our coal fires, and on each little water particle there is a layer not only of carbon, but of sulphuric acid and other choking compounds which make the "London particular" so deleterious and objectionable. In an article on waste in the *Quarterly Review* of April, 1889, the "filthiness of smoke" is well set forth. The household waste brought about is incalculable. The injury to the poor is shown to be the result of the pollution of the atmosphere. They are condemned to live, or die, in continual obscurity and dirt. Their surroundings are steeped in a perenuial filth. They have been born to dullness; it seems natural and appropriate to them, and it increases just as they increase. This deluge of coal smoke is permanent and desperate. Four million people of all ages, similarly ill-conditioned, live in the smoke supplied by chimneys, and they demand to be liberated from their grimy misery. To Londoners, accustomed to their present cloud of smoke, it is hardly conceivable that seventy years ago their city was a bright and sunny town. In 1817 the residents in the then well-conditioned quarter near the "Angel," Islington, would, sitting in their gardens, watch the shipping at Blackwall; and fifty years ago a favourite summer evening's walk was to the slopes of Highgate, to see over London to the Surrey Hills, with Banstead Downs and Epsom Stand, the woods of Anerley and Shooter's Hill, and the returning Margate steamboats on the river. But I think enough has, perhaps, been said about the nuisance and evils of fogs.

Another direction in which we discover enormous waste is in the work and worry attendant upon the present system of coal combustion in open fire-places. We have all the evil effects arising from these fires, producing dust, dirt, and deposits of soot in rooms and houses. There is the daily problem of dealing with the ashes and refuse of the grates, the great amount of constant and unremitting attention which must be paid by domestic servants to the fires and the cleansing of the grates and stoves. Indirectly, the reform of these fire-places would act upon the great social problem of domestic labour. Many of the present infelicities of household life, caused by the carelessness and behaviour of domestic servants, could be removed by making them not so necessary as they are at present. An immense saving of labour would at once result in this direction, as it would also by the abolition of chimney sweeping and its accompanying discomforts.

The quantity of coal which is brought into the metropolis annually, as before mentioned, is about 13,000,000 tons. The cost of transit of this coal, together with the profits obtained by the middleman and retail dealers, amounts probably, in the aggregate, to at least six million pounds sterling. Here there is an enormous waste of money, capital, and labour which cannot well be avoided under the present system of coal consumption. Added to this waste, we have the additional disadvantages of coal bays, wharves, and stations in the heart of the metropolis. There are the grimy waggons and waggoners to be considered as adding to the dirt and discomfort of Londoners. The atmosphere is daily polluted by the supply of private houses and manufactories with this fuel. Large coal yards, and a hugh army of highly paid labourers are utilised in the trade, and thus we have a further direction in which enormous waste is found.

It can easily be shown how extravagantly wasteful Londoners are in the present method of artificial lighting and warmth. Most persons agree in the present discomforts and terrible unhealthiness of London during a foggy season, and sigh at the same time for remedial measures that will carry away the evils which I have endeavoured to sketch. Further than these discomforts, is the serious question of persistent waste of resources going on, threatening the material prosperity of the citizens as well as imposing physical burdens upon them. "If coal smoke were avoided by complete combustion," says the *Quarterly Review* (April, 1889, p. 372), "and were houses scientifically warmed, the saving in the cost of coal, and in the labour and sickness, the destruction and depreciation caused by smoke, would in one year yield all the sum that is immediately required to provide sufficient parks and playgrounds, gardens, boulevards, and avenues for the metropolis; and London would then be as bright and cheerful as it was three-quarters of a century ago." The main remedy must be sought in the reform of our fire-places, and in a more scientific consumption of coal, a small proportion of which is now only used in giving forth heat. Five-sixths at least of the developed heat is lost, and much of the fuel passes away unconsumed. Dr. Carpenter and others have proposed a tax in the nature of a hearth-tax. I venture to submit that the preceding disadvantages which I have enumerated, and the hostility to any hearth-tax, will be obviated by the scheme which I propose herein.

Specifications Published.

13,697. *August 13th*, 1889.—"The Preparation of Alkaline Cyanides." Hermann Gruneberg, Dr. Phil., Holzmarkt 25, Cöln; Hugo Flemming, Dr. Phil., 165, Haüpstr, Kalk; and Wilhelm Siepermann, Dr., Elberfeld.

If quantities of coal and alkaline carbonate are heated together to a dark red heat, and ammoniacal gas be added to the same, then a quantity of alkaline cyanate is formed together with a little alkaline cyauate; if the same experiment be made at a light red heat, then alkaline cyanate alone will be formed, but with less profit.

If, however, ammoniacal gas be first introduced at a dark red heat, and be afterwards heated to a light red heat, then the alkaline cyanate which is formed at first is reduced to alkaline cyanide, and the gain of alkaline cyanide will be considerably more.

For a continual performance of these reactions of the preparation of the alkaline cyanates in two phases, the inventors describe apparatus.

The two reactions are effected in different parts of one and the same retort, of which a certain number are put in an oven at the same time, whilst a part of each of the retorts is heated to dark red, another part is heated to light red. For this purpose vertical retorts are used, so that the substance submitted to the tests sinks down by its own weight from the more heated to the less heated part.

For the manufacture of cyanide of potassium the inventors employ a special method, viz.:—The salt formed is dissolved out, until the resulting solution shows 40° Beaumé.

This solution is then supersaturated with carbonate of soda at ordinary or at higher temperature; in the former case the potassium cyanide precipitates at once, in the latter case it does so as soon as the solution cools.

The inventors claim :—

1. The employment of upright retorts for the manufacture of the cyanides of the metals of the alkalies, arranged in a furnace in such a manner that the passage of the heating gases round them brings the upper portion of the retorts to a dark red heat, while the part below is at a bright red heat.

2. The employment in the retort of a movable tube for the introduction of a current of ammonia.

3. The precipitation of potassium cyanide from its aqueous solution by sodium carbonate.

Correspondence.

ANIMAL STUDIES AT THE EDINBURGH EXHIBITION.

SIR,—Some of those who make animal photography their speciality have been working for a long time to get their studies removed from the instantaneous class at exhibitions—where they are mixed up with yachting scenes, breaking waves, and street scenes—to their proper place, viz., under the heading *scientific;* and as the executive of the Edinburgh Exhibition have just written to say that they will do this, I hope that all who can will enter as many as possible, and make a good show, as it is the first time that we have been thus rightly classified.

May I urge this point upon hon. secretaries of other exhibitions, as unless one tells a direct untruth by entering photographs under the heading instantaneous which have had from one to two seconds' exposure, he rarely has a chance to exhibit them at all. GAMBIER BOLTON.

Camera Club, 21, Bedford Street, W.C.

MORLEY AMATEUR PHOTOGRAPHIC SOCIETY.

SIR,—I am glad to say that the amateurs of this district have succeeded in forming a society entitled "Morley and District Amateur Photographic Society," of which I forward you a members' card and syllabus of meetings, hoping you will do us the favour to publish the same in your columns.

MORLEY AND DISTRICT AMATEUR PHOTOGRAPHIC SOCIETY.

The object of this Society is for the mutual improvement of its members in the art of photography, by reading of papers, the exhibition of work and apparatus, and by rambles in search of the picturesque. Meetings are held every alternate Tuesday evening. *President*—Samuel Atkinson, Esq. ; *Vice-President*—Mr. Illingworth ; *Treasurer*—Solomon Tomlinson ; *Secretary*—Lionel Lawton, 3, Bank Top, Morley ; *Committee*—J. H. Spencer, Henry Leathley, J. W. Smith. *Syllabus*—September 2nd, Mr. Sanderson ; September 16th, Excursion ; September 30th, Mr. Richardson. G. W. LAWTON, Hon. Sec.

3, *Bank Top, Morley, August 16th*, 1890.

WHAT ARE THE BEST USES TO WHICH PHOTOGRAPHY CAN BE APPLIED?

SIR,—I can quite sympathise with your correspondent, Duncan E. Dallas, in his complaints about the unfairness of the award in the recent *Short Cuts* photographic competition, in which I also foolishly entered. In my paper (of which, unfortunately, I kept no copy), besides enumerating the uses of photography as given by your correspondent in his paper, I also pointed out its use in warfare, and especially in reconnoitreing from balloons ; for multiplying copies of pictures by the old masters and other famous artists ; for aiding artists in securing bits of street life or rustic views, to be afterwards worked up in the studio ; for the *facsimile* copying of old and valuable books and manuscripts, and for the copying of important documents in legal cases, as well as its older and well-known use in the detection of criminals.

My paper was much about the same length as that of the prize-winner, and although I had very slight hopes of being successful (in the face of the fact that I knew of several photographers who were competing), yet I must say that I was utterly astounded at the character of the winning paper, which, however good as a piece of English composition, was in no sense an exposition of the best uses to which photography might be put, but the rather showed the writer's want of knowledge on the subject.

To the other grievance—that of changing the date—there was also added at the last moment a condition that a coupon cut from the paper was to accompany each contribution. Whether this was for the purpose of disqualifying those who had sent in their papers previous to the 12th of June or not I will not pretend to say ; but, judging from the result, I should imagine that all the good papers had been disqualified.

The same periodical is now offering prizes for instantaneous photographs, but I fancy the result of the previous competition will deter many from competing until they know who is to judge them, as good men will not submit their specimens to the arbitrament of persons who evidently know very little of the art-science of photography. GEORGE BROWN.

Walworth, August 18th.

Proceedings of Societies.

LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

August 14th.—Mr. A COWAN in the chair. A portfolio of prints was received from Dr. Emerson.

Mr. J. GOTZ exhibited McKellan's hand-camera, and directed attention to some novel points in its working, more especially to the method of changing the plates. The plates, twelve in number, are fitted into sheaths, and placed in the camera from the back, the back of the sheath holding the last plate having a strong circular spring affixed to keep the plates in position. After exposure, a lever arm at the side of the camera is brought round a distance of half a circle ; this action releases the spring that holds the front plate, and at the same time raises a receptacle into which the plate drops. Pushing the lever back to its original position carries the box containing the exposed plates to a recess at the bottom of the camera. The camera was not fitted with a finder, which Mr. Gotz thought was not really necessary, an opinion which the majority of the members did not share.

Mr. J. J. BRIGINSHAW had tried hand-cameras with and without finders. Admitting that a fairly accurate aim, with some practice, could be taken of general objects without a finder, there were many pictures—architectural, for instance—that it would be almost impossible to photograph properly without a finder.

The adjourned discussion (third evening) on printing through coloured media was resumed.

Mr. OTTO SCHOLZIG said that matt-surface prints but slightly washed would lose in toning, but not in the fixing ; prolonged washing would cause a deterioration of image. He showed two matt-surface and one albumenised prints ; half of each of these had been printed under green glass ; the remaining halves in the ordinary way without any medium, all to the same depth as near as it was possible to judge. The prints were then divided lengthways, and half of each toned. After a close comparison, the general opinion was in favour of those printed through green glass, as showing the greater amount of detail.

Mr. J. S. TEAPE had received three half-sheets of sensitised paper from Mr. Scholzig. He showed prints from this paper printed in white light and through green glass from the same negative ; the latter were considered to show better detail.

In a similar set of prints, printed under the same conditions, on paper freshly sensitised without any preservative, the difference was not so marked. Two matt-surfaced prints were also shown, one printed in bright light under green glass, and one in the shade in white light, both toned in the same bath, and for the same length of time. The result was in favour of the green glass medium.

Mr. W. E. DEBENHAM held that experiments of this kind could not be considered identical when freshly sensitised and preserved papers were used ; in each case a different result being obtained. The colour of the glass used had also to be taken into consideration. He showed three pieces of green glass of varying depths of colour, which he had used in the course of his experiments. Using paper freshly sensitised in a sixty-

grain bath, four prints were made from a thin negative, two having an exposure of three and a half minutes; one printed for the same length of time in bright light, but at intervals to allow the chlorine to escape, and one printed in the shade, taking two days; three others were printed under light and dark green glass and white light respectively under a dense negative. Mr. Debenham was of opinion that with dense negatives printing under green glass brought out more detail, and that the prints were more amenable to toning effect.

Mr. ATKINS showed two prints, one of which had been printed under green glass, but little difference was noticeable. It was pointed out that the sheet of glass under which the print had been exposed, which was handed round with the prints, had a tendency to a blue colour.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

A MEETING was held on the 13th inst., Mr. W. BENHAM in the chair.

There were seven applications for assistance, of which six were granted. The amount of grants voted was £15 4s. 6d.

THE SOUTH LONDON (*late* EAST DULWICH AND PECKHAM) PHOTOGRAPHIC SOCIETY.

THE usual meeting was held on Friday, August 15th, at 76, Peckham Rye, the PRESIDENT in the chair. One member was elected.

After the transaction of the ordinary business, the meeting was made "special" to take into consideration a proposed change in the title of the Society. On the motion of the President, it was unanimously resolved that the Society in future be called "The South London Photographic Society." On and after the meeting on October 3rd, the Society will meet at Hanover Hall, Hanover Park, Rye Lane, S.E., the number of members the Society has enrolled since its foundation necessitating increased accommodation. The new meeting place is within three minutes' walk of tram or train (Peckham Rye, L.C D.R., and L.B.S.C. Railway Company).

The following is the syllabus for the winter session, 1890-91 :—

September 5th—"Mounting and Finishing," Mr. C. Hoddle; September 19th—Exhibition of F. W. Hart's patented apparatus for Flash-light, with demonstration; also Stands for Optical Lantern Screens, Photo Backgrounds, Studios, &c., Mr. F. W. Hart; October 3rd—Lantern Night, Mr. Boydell and other members; October 17th—Demonstration with Alpha Paper, the President; November 7th—Lantern Night (A Tour to the Channel Islands), H. Banks; November 21st—The Annual Exhibition; December 5th—Photographic "Dodges," discussion to be opened by the President; December 19th—Experiments with Optical Lantern, H. Banks and S. W. Gardner. During the month of January, 1891, Mr. Leon Warnerke has consented to give a demonstration on "Mechanical Printing as applied to Photography."

The following medals are offered for competition at the Exhibition for work done by the members: One silver medal for the best general work, and one for the best six pictures taken at the Society's excursions: one bronze medal for the second best six pictures taken at the Society's excursions; one for the best of six local views; and one for the best series of lantern slides consisting of not less than six nor more than twelve.

HACKNEY PHOTOGRAPHIC SOCIETY.

MR. ROBERT BECKETT gave a paper on "Intensifying, Reduction, and Varnishing," on Thursday last, Dr. ROLAND SMITH presiding. His formula for intensifying was :—

Mercuric chloride	...	...	...	¼ ounce
Hot water	...	...	...	1 pint
Hydrochloric acid	...	...	...	60 minims

The great thing was to give plenty of washing to the negative. For blackening, he used a 15 per cent. solution of ammonia, but if denser negatives were required, he advised sulphite of soda. He had been very successful in intensifying under-exposed plates. For reduction he used Mr. Farmer's formula, a 6 per cent. solution of red prussiate potash and hypo. For local reduction, Mr. Beckett advised methylated spirit. He then reduced a negative, preferring to demonstrate, which he did very successfully.

The SECRETARY showed paper made by Messrs. Geering & Co., of Stamford Hill. He had tried their pyro developer successfully.

Mr. POULSON showed the Quadrant hand-camera, which is simple and compact.

At the monthly excursion to Carshalton, under the guidance of Mr. W. L. Barker, there was a good muster, and successful exposures were made.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

August 11th.—Mr. PAUL in the chair. Messrs. Norris, Gosling, and Cox were elected members.

Mr. WALKER said that he had found that nearly all the automatic arrangements for changing plates in hand-cameras were defective, causing the plates to get fixed at awkward times. The methods of changing plates with various cameras were discussed, as also changing bags for use with dark slides.

The advantages of a turntable fixed to a camera were considered.

On Monday, September 8th, the Secretary will read a paper on "Collotype," contributed by a producer in the trade. Visitors are invited to attend.

The following is the syllabus of ensuing meetings :—September 22nd—"Lantern Slide Making," a demonstration by Mr. C. Beadle; October 13th—"Pictures of Egyptian Life," an evening with the lantern, by Mr. D. P. Rodgers; October 27th—Lecture on "Stereoscopic Photography," by Mr. Bishop; November 10th—An evening with the optical lantern; November 24th—Mr. Friese Greene will occupy the evening with a description of his latest experiments; December 8th—Conversazione and exhibition of members' work; December 22nd—Meeting for the nomination of officers for ensuing year; January 12th—Annual general meeting. Members of kindred clubs and visitors are invited to attend any of the above meetings.

DUNEDIN PHOTOGRAPHIC SOCIETY, NEW ZEALAND.

THE first annual exhibition of this Society was opened on June 28th, and continued for a week, during which time it was visited by a large number of the public. The Society is composed of amateurs only, and though it is young the show of work by members was considerable, and called forth praise. On the walls were many specimens of enlargements, embracing portraits, landscapes, yachts, and animal life. Although prints on albumenised paper largely predominated, there were not wanting examples on other papers—platinotype, aristotype, and bromide. Perhaps one reason for the small number of platinotypes and aristotypes is to be found in the bad keeping qualities of the materials, both papers deteriorating to a great extent before they reach the Colony. Silver prints were represented by an extensive collection in all sizes from 10 by 8 to quarter-plate, illustrative of New Zealand scenery—yachts, portraits, and groups. Artistic taste seems to have been exercised by some members in their pictures, noticeably in the beautiful cloud effects, reflections, and atmospheres. It is intended to hold an exhibition annually.

This Society enjoys the reputation of being the most southerly photographic society in the world, and as its location is amid some of the most beautiful scenery south of the line, the work of the members may be expected to be, in views at least, interesting and pretty.

NORTHERN TASMANIAN CAMERA CLUB.

At the first annual meeting of the Northern Tasmanian Camera Club there was a good muster of members; Dr. H. A. ROOME occupied the chair. Mr. Walter Brickhill was unanimously elected a member.

The SECRETARY then read his report, in which he stated that during the year the list of members had increased from ten during the first month to twenty-eight at the present time.

The meetings had been fairly attended considering so many members reside in the country, and that next year the committee would endeavour to make the meetings even more attractive. One field day was held, in November, and it is hoped that more of these pleasant and useful excursions will take place. Two prize competitions have take place, one in landscapes and one in out-door portraiture. The winners of the first certificate were, in landscape, Dr. Roome; in portraiture, Mr. F. Styant Browne; second in landscape, Mr. F. Styant Browne; in portraiture, Dr. Roome; third in landscape and portraiture, Mr. R. L. Parker. Mr. S. Spurling acted as judge in landscapes, and Mr. Carl Burrowes in portraits. The circulation of collections of photographs, the work of members, had proved satisfactory; a good number contributed; the criticisms were given in a fair and good-natured way, and some changes are about to be made which will make these circulations even more popular.

Papers were read, and practical work in enlarging and developing considered, and lantern slides exhibited, all tending to make the meetings interesting and instructive. One death had occurred among the members, that of the late Captain Arthur, R.N., whose loss was deeply regretted. The income and expenditure were submitted in the treasurer's statement, and it was satisfactory to find that a substantial balance was left to carry forward to the new year. The library was well patronised, and thanks were given to the president (Mr. Wm. Aikenhead), Messrs. R. L. Parker, and S. Spurling for donations of books.

At the conclusion of the secretary's and treasurer's report office-bearers were elected for the ensuing year, with the following result:—*President*—Dr. H. A. Roome; *Vice-President*—Mr. R. Lewis Parker; *Secretary, Treasurer,* and *Librarian*—Mr. F. Styant Browne; *Committee*—Rev. A. H. Champion, Mr. R. Kermode, and Mr. A. C. Bonner.

Dr. ROOME then read a paper entitled "Practical Hints on Photography," and after a discussion upon some of the points in the paper, a vote of thanks was carried.

The Camera Club have reason to be pleased with the result of their first year's work, and it is hoped and expected that at the close of the second year the secretary and treasurer will be able to give a still better account of the prosperity of the Club.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—The monthly technical meeting will be held on Tuesday, August 26, at 8 p.m., at the Gallery, 5A, Pall Mall East.

PHOTOGRAPHS ON GRAVESTONES.—Mr. Charles John Tozer, of 27, High Street, Plymouth, has brought out a device to be attached to gravestones, vaults, and such like, for displaying photographs, and for holding visiting, mourning, or memorial cards, flowers, and similar articles. It is intended by this ingenious inventor to attach the photographs of the deceased, or suitable mottoes, to a disc revolving by means of a button projecting from the face of the apparatus at the back of the device, which is locked at the back to a rebated ring fastened to, or suspended from, the head-stone, vault, or other place. The face of the device is provided with a glazed aperture, behind which the photographs appear successively as the disc is revolved. The disc can be covered at will by means of a flap or door, the inside of which may be fitted with a small mirror. A small lock-up box with glazed front is also attached to the face of the disc, the said box being provided with a longitudinal slit for the reception of visiting, memorial, or mourning cards, and with shade or canopy or hinged sloping roof over the said slit to prevent the rain and snow from entering the box through the slit. Double vases also are secured to brackets on the face of the device, the inner vase being watertight for the purpose of holding cut flowers, the outer vase being perforated to enable trailing plants to grow over the sides, thereby decorating the otherwise plain appearance of the stone. A hook is fixed just above the top of the ring for the purpose of hanging a wreath upon. Thus it will be possible in future to have the likeness of the deceased ever present to the mourners, and to provide a record of the visits to the grave.—*Invention.*

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

MUCKROSS.—*Stains of Fading in Prints.* From the purely local character of the stains, and shape of the marks, we should unhesitatingly say they were due to splashes of hypo, which must have dropped upon the prints when the washing was nearly if not quite completed. This explanation is more probable than to suppose that they arise from original defects in the paper.

S. M.—*Time Indicators for Developing.* The common egg boiler is sometimes employed in studio practice, and if this does not give the exact period required, it is easy to guess the variation within or beyond this definite limit; at any rate, it is much more convenient than working by a clock dial or stop watch, the sand column being clearly visible by transmitted light if set on the window ledge.

SUTTON.—Received your letter. Leave the matter in our hands for a few days, to give an opportunity of making the necessary inquiries.

T. S. B.—Failing the course already taken, your want ought to be immediately met by inserting an advertisement.

L. E.—*Non-Corrodible Spatula.* A silver coin flattened out and elongated by passing several times through rollers makes a capital spatula, and for photographic use is almost as good as platinum. Any assayer will do it for you in a few minutes in the event of your own rolling-press proving unequal to the task.

M. G.—*Stripping Films.* After fixing and washing, immerse in dilute acid (three drops of strong hydrochloric to the ounce of water), then cut off the extreme edges of the paper, and heat up to 120°-140° Fahrenheit in a dish of hot water. Done in this way the stripping ought not to present any difficulty, although old exposures may demand the exercise of a little patience.

R. T.—*British Association Meeting.* At Leeds, on Wednesday evening, 3rd September, Sir Frederick Abel, president, will deliver his inaugural address, and the sectional meetings will occupy about a week. Mr. J. W. L. Glaisher is to preside over Section A (Physics), and Professor T. E. Thorpe has charge of Section B (Chemical Science).

LUTON.—*Interchangeable Albums.* If we rightly understand your description, Messrs. Marion and Co. will show you the identical thing already in stock. It is no novelty.

C. B. H.—*White Shellac.* This is always held to be a chlorine compound, and not bleached by sunlight exposure, as you seem to imagine. Deflagrate a little white lac in pure melted nitre, and you will be able to detect chlorine in the aqueous solution of the fused mass.

STUDIO.—*Fire Insurance Policy.* By paying for the odd time, in addition to the annual premium, you need not wait until Michaelmas day. The office takes the risk immediately on acceptance of your proposal, and may even do so before inspection.

NEMO.—*The Cantor Lectures.* Inside the wrapper of the *Society of Arts Journal* you will find a priced list of all the reports which are now procurable, and that which you are inquiring about is one of them.

C. N.—*Silver Varnish.* If you refer again you will find that last week we mentioned amylic acetate, and not amylic alcohol (fusel oil), which is a very different thing. The former is made from the latter by distilling it with oil of vitriol and fused acetate of soda.

DR. GUNTHER.—For the information of S. P. and another correspondent, will you be so good as to say what is to be understood by "thick gelatine" for etching solution, about the middle of your first column, on page 608? Further down, if the exposed plate be submitted only to a "short damping process," how is the excess of bichromate to be removed?

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1669.—*August* 29, 1890.

CONTENTS.

THE CAMERA CLUB AND COMMERCIAL PHOTOGRAPHY.

OF late years, the chief standards in photography have been rising; platinum prints have been gaining ground as compared with the position of their fading silver brethren; the artistic effects obtainable by photo-etching are daily more and more in demand; higher artistic excellence in landscape and portrait work has become a necessity for those professional and amateur photographers who wish to make a name in the world; lastly, as regards public organisations, high intellectual activity and culture, combined with freedom from bias by commercial considerations, form one among the requirements of the times.

In relation to the last-mentioned item, in the course of the past two weeks attention has been called in these pages to the Camera Club letting a portion of its new premises to a dealer for the sale of photographic goods, and as the Camera Club virtually, if not in set terms, professes to stand before the world as a body able to speak its mind freely without bias from commercial considerations, a public discussion about the relations of the Club to this shop became, sooner or later, inevitable.

A letter in our correspondence columns to-day settles the whole matter as regards the sale of goods on the premises, completely and satisfactorily. The shop is not let on a seven years' lease to a young dealer just starting in business, as might have been the case for aught we knew last Friday to the contrary, but to Mr. Adams, of the firm formely known as Abrahams and Co., who will use it but as a branch establishment, who has a seven years lease of the shop, and can get another seven years' lease at his own option and not that of the Club, and who is strong enough and experienced enough to take care of himself, or to "snap his fingers at the Club" if he likes, but which would be an extremely ill-bred line of action.

Thus the action of the Club stands clearly revealed; it has merely let the shop to a photographic dealer for the sake of the convenience of being able to buy photographic goods on its own premises, and in this matter cannot and does not desire to exert any undue influence whatever over the said dealer.

Mr. Adams tells us that, although his shop will have no door in the front of the Club premises in Charing Cross Road, it will have two windows there, so there is no hiding away of the shop at the back of the premises, as might have been the case for aught that we could gather to the contrary from the information afforded up to last Friday. Thus, prevalent rumours about the relationship of the Club to this commercial matter may now be decently buried for fourteen years.

THE VIENNA INTERNATIONAL PHOTOGRAPHIC SALON.

WE have just had the pleasure of receiving definite particulars about the forthcoming International Photographic Exhibition at Vienna from Mr. Carl Srna, the president, and Dr. Frederico Mallmann and Mr. Carl Ulrich, the vice-presidents of the Exhibition Committee of the Club of Amateur Photographers at Vienna. Special interest attaches to this Salon, because its managers will make the first influential attempt in connection with photographic exhibitions to reject all inferior work, irrespective of the amount of wall space they may have at command. A competent jury will decide whether each photograph proffered has sufficient merit to deserve exhibition at all. The promoters of this Exhibition care nothing for quantity, but regard only quality; they care not how small in number the pictures exhibited under their auspices may be. The coming Vienna Exhibition will be open from April 30th to May 31st, 1891.

The Exhibition will be held in the Imperial and Royal Austrian Museum of Arts and Manufactures, and the question of the admission of pictures will be subjected to the decision of a competent jury of artists and photographers. Each admission is an honour which

will be certified by special diploma bearing the signature of the "Patroness of the Exhibition, Her Imperial and Royal Highness the Archduchess Maria Theresa."

The jury will have the privilege of recommending competitors for special good work for the silver-gilt Maria Theresa medal, which, says our informants, "will be awarded by Her Imperial and Royal Highness." The number of these medals is not to exceed ten, and must be awarded unanimously.

The approval of two-thirds of the jury is required for the admission of a picture. No scientific section will be opened this time.

All photographs of artistic merit will be admitted, including landscapes, studies of flowers and of animals, genre pictures, portraits, and so on, besides diapositives, lantern slides, and stereoscopes. Every picture not smaller than 12 centimetres by 9 centimetres must be mounted on a separate sheet of cardboard, with or without a frame. Suitable frames will be supplied by the Club free of charge. The subject and artist's name must be on each picture.

Pictures previously exhibited in Vienna, in 1888, cannot again be exhibited.

Applications for admission of pictures must be made not later than the 15th of January, 1891, and exhibitors will kindly forward their photographs before the 1st of April, 1891, to a London address, which will be made known in time, whence they will be forwarded and returned at the expense of the Club, and no farther charges, as for wall space, and so on, will be incurred by exhibitors. The names of the members of the jury will be published before the 1st of January, 1891. No exhibits will be allowed to be removed before the close of the Exhibition. The jury will decide where the pictures are to be fixed.

The committee reserves the right of issuing farther rules, if necessary. All communications to be addressed to the President of the Club, Mr. Carl Srna, VII. Stiftgasse 1, Vienna.

The officers of the Exhibition Committee of the Club of Amateur Photographers in Vienna, other than those we have already mentioned, are the *Secretaries*—Anton Einsle, Dr. Julius Hoffmann, and Carl Winkelbauer; *Cashier*—Friedrich Vellusig; *Librarian*—Robert Ritter von Stockert; *Members*—Gustav von Dürfeld, Fritz Goldschmidt, Carl Hiller, Baron Alfred Liebieg, August Ritter von Loehr, Baron Nathaniel Rothschild, Dr. Eduard Suchanek.

The professional photographers of Holland have just formed an association, the Nederlandisch Photographen-Verein, at Amsterdam. They expect shortly to issue an organ of their own.

Sub-Fluoride of Silver.—A subject of interest to photographers was treated of before the Academy of Sciences at Paris, on 23rd June, by M. Guntz, who read a paper on the sub-fluoride of silver. The existence of this salt was indicated by the analysis of a precipitate produced on the negative pole, on the subjection of a hot saturated solution of silver fluoride to electrolysis, with the aid of a very strong current and silver electrodes. By heating finely-divided silver, with a saturated solution of silver fluoride on a bath, to a temperature of from 50° to 90° C., the pure salt may be obtained plentifully, which, on analysis, proves to be the sub-fluoride of silver, Ag_2F.

THE LIGHT OF THE FUTURE.

It would not be altogether an unprofitable task to search the newspaper files of past years in order to see how many of the inventions, loudly exalted by them, have survived their early infancy. We allude to those inventions which, like that of the phonograph, the penny-in-the-slot photographic camera, and others, are calculated to tickle the public taste, and for that reason have called forth all the flowery language that a daily leader writer has at his command. We venture to think that not a few of these children which, in their early years, showed such promise, have since died off from sheer want of strength of constitution.

Supposing that we made such a search as that indicated, we should find about every tenth year a crop of patents having reference to electric illumination, and in company with them we should have the inevitable leading article consisting, half of a condensed *Encyclopædia Britannica* account of the history of the thing, and the other half of a prophecy that Jones's new device would now bring electric lighting within the reach of the poor man. About every ten years has the subject cropped up since, at the beginning of the century, *Mr.* Humphry Davy showed that the terminal wires from a powerful battery would, if fitted with carbon points, emit a most brilliant light. Scientists have told us that spots on the sun have their periods, and that they very probably exercise some effect upon the abundance of our harvests and vintages. It would almost seem as if the sun-spot theory ought also to be applied to the periodic appearance of electric illumination patents; and there would be the more reasonableness in this, seeing that father Sol must be personally interested in the doings of a powerful rival in his own particular line of business.

But now, after many decades, during which the instant coming of general electric lighting has been as often prophesied as the end of the world has been forewarned by another class of enthusiasts, we are within measurable distance of seeing the prophesy fulfilled. Inventors have been busy, old patents have been re-patented and furbished up anew; novelties have been introduced; our American cousins, more go-a-head than we, have taught us what to adopt and what to avoid; the legislature has withdrawn many restrictions which it had imposed in the righteous endeavour to prevent such another monopoly as the gas and water companies represent, and at length the ground is cleared. The era of electric illumination has commenced, and it behoves us to consider how far the new departure will affect the work of those who—of all bread-earners—depend most upon light for their subsistence.

In endeavouring to glance into the future, it is always best to look back upon what has already been done in the same direction. Many of our leading photographers have long had the electric light in use, both in their studios and in other parts of their premises. They have been wise in taking first advantage of a method which is most effectual for portraiture,

and which offers many other minor advantages in its use. These pioneers have not been able to instal the electric light without considerable outlay of capital, and they certainly deserve all the kudos and more substantial return which the change has brought to them. A dynamo machine, and a gas or steam engine to work it, together with the rest of the apparatus necessary to produce the light, represent rather a costly enterprise, but one which—in London, at least, where there are so many days when the sun is hidden in clouds of smoke—would soon repay the speculator; and hence we find that several of the West-end houses have for some time been independent of daylight, and have actually been working in studios from which daylight is carefully shut out.

In the various London houses which are devoted to photo-mechanical block work the electric light is also installed, not only for copying the line drawings from which most of these blocks are prepared, but also for exposing the sensitised zinc plate beneath the negative. It would never do for such works to be dependent upon fickle daylight, and even if natural light did not deserve the charge of inconstancy, it would be the same, for the work has generally to be carried on during the dark hours. This is, of course, imperative for newspaper work, which is done, as everybody knows, when the rest of the world is asleep.

The electric light has also been long recognized as the best that can be utilised for the work of enlarging. The Eastman Company, at various exhibitions, have shown wonderful life-sized portraits which have been taken from half-plate originals, and we may say that this work would have been next to impossible in the absence of a light which is at once small in area and intensely brilliant in quality. The allied business of projection, optical lantern fashion, by means of electricity, is yet quite in its infancy; but we may mention, in passing, that a lantern lighted by this means has for some time been in use at the large theatre of the Society of Arts, in the Adelphi, and that at other places the electric arc light has been tried for this purpose with most promising results. For microscopic projection work the light is unequalled, as it is also for spectroscopic experiments. In these various ways it is coming into use in our leading schools and colleges.

But it is not until the electricity is "laid on" to us like gas and water is at present, that the photographer of humble aims can make use of it. It is then that he will have his perfect dark-room, which can be illuminated by incandescent lamps in red globes by the touch of a button. Then he can laugh at the occurrence of dull weather, for the arc lamps in his studio will place constant brightness at his disposal. He may possibly, for a time, be still dependent upon daylight for printing purposes, but we venture to predict that, before the new light comes into general use, a quick printing process by development will have cast out the older methods.

It it stated that the Photographic Society will take new premises for its meetings, and use its present ones for exhibitions only.

TOURIST PHOTOGRAPHERS AND THE CHANNEL PASSAGES.

III.

The great historical route to France by Dover and Calais now demands attention.

Dover is a highly picturesque place, and, as its heights are monopolised by fortifications, and its lower portions near the sea have been largely under requisition for railways and docks, the town is of straggling form, so that but small portions of it can be seen at any one time or from any one spot. Some of the oldest parts of the town have been pulled down in times past to give extra railway accommodation. The streets are so laid out that not a few of them at the southern end of the town, and some others all the way thence to Dover Priory, lie in such a direction that the view at the end of each street aforesaid is closed by the Castle Hill and old Dover Castle on the top thereof. Good instantaneous views of busy streets in Dover, with this picturesque termination, would make striking lantern slides. One of the best views of the Castle is to be obtained from the Admiralty pier. The photographs of the town in the shop windows of Dover are of mixed quality, and are commonly defective from having been taken with lenses of too wide an angle.

The English mails are carried on land by the South Eastern Railway Company, and across the Channel by the boats of the London, Chatham, and Dover Railway Company, in accordance with an understanding between the two companies. The French Government will not allow its mails to be carried under the English flag, hence some of the mail boats crossing between Dover and Calais are under the command of French captains, and manned by French crews, a fact of which the passengers travelling by them are not always aware. Some of the reputed French sailors on these boats cannot speak French, but were born in Dover, and can speak no language but English. These French boats, again, belong to the Chatham and Dover Railway Company, which lends them to the French Government for an annual payment rumoured to amount to £9,000 a year.

The largest passenger boat running between Dover and Calais is the *Calais-Douvres*, built in 1888; two other large ones are the *Empress*, built in 1887, and the *Victoria* built in 1886. Another large boat is the *Invicta*. Among the smaller passenger boats on this line are the *Petrel*, *Foam*, *Prince*, *France*, and *Wave*. The three large boats first mentioned are all built of Siemens' steel, and have compound engines; they run to Calais in about from fifteen to twenty minutes less time than the smaller boats, and at the cost of the great consumption of coal which is always necessary to get high speeds on the water; in fact, a gang of men is ceaselessly stoking all the way across.

The twin-ship, the well-known *Calais-Douvres* of times past, exists no longer; the new *Calais-Douvres* now running is not of such an experimental type, but is a steamship of a more normal description. As already stated, she is the largest boat on this service;

her length is 325 feet, breadth 70 feet, 1,000 tons burden, and steams, we are told, at from 19½ to 20 knots per hour, that is to say, about 23 miles per hour. Her upper deck is a shelter deck, which makes a fine promenade; there is also a broad promenade round the sheltered main deck. Deck cabins are numerous, and serve the purposes of the proprietors admirably, since the letting of them is all profit. The saloons for ladies and other passengers are of a splendid and comfortable description, with nothing tawdry in the fittings or ornamentation. Captain Frederick Dane, who commands the *Calais-Douvres*, is exceedingly proud of his fine ship. He says that amateur photographers abound among the passengers, especially among those coming from America, and occasionally, when on the bridge of the boat, he hears the remark coming from below, "Now we'll take a shot at the captain." He then promenades the bridge to render the self-appointed task less easy, but in so doing probably under-estimates the powers given by instantaneous shutters.

The *Empress* is 315 feet long, 67 feet broad, and 875 tons burden. The *Victoria* is 309 feet long, 64 feet broad, and of 800 tons burden. They are of the same type as the *Calais-Douvres* just described. They are all built for steaming into shallow harbours, like that of Calais. The *Calais-Douvres* draws 9 feet of water, the *Empress* 8½ feet, and the *Victoria* 8 feet 3 inches. On two or three days in each month, at low spring tides, these boats cannot pass over the sand-bar off the entrance to Calais Harbour, and the smaller passenger boats have to be run in their places. All the steamships in the Dover-Calais passenger service are paddle-boats.

At Dover, the incoming boats are usually met by three trains upon the Admiralty pier. One of these is the South Eastern train, to carry mails and passengers to Cannon Street; another is a Chatham and Dover train for Victoria; a third is a train of the same company for Holborn Viaduct. Most of the boat trains do not stop anywhere between Dover and London. Passengers, whether more or less sea-sick, can get tea and coffee directly they get on firm land, that is to say, on the Admiralty pier, Messrs. Spiers and Pond having fitted up a coffee stall on the pier in a bleak situation, chilly even in the summer; they might as well provide some kind of shelter, as in the offices on the pier of some of the officials alongside. Messrs. Spiers and Pond's coffee stall does not run upon wheels in orthodox fashion, but consists of a few planks; fried fish is not dispensed at this establishment. At Dover town Station the same firm has an excellent restaurant, and the moderate prices are in violent contrast to the excessive charges on the French side.

In certain states of the weather there are more facilities for obtaining good marine views from the decks of the Dover and Calais boats than can be obtained upon any other route. The Channel is at its narrowest there, and, moreover, is not much frequented on the shallower French side by shipping; hence, after vessels have been detained up Channel for some days by strong westerly winds, the sea off Dover becomes crowded with vessels. Last Sunday morning we counted more than a hundred ships in sight at one time from the deck of the Calais boat, and some of these sometimes passed under full sail close at hand; one of them had a windmill on deck, with the vanes rotating; the sunshine was bright and the clouds magnificent. In the broader parts of the Channel such photographic opportunities are less numerous.

As Calais is approached, the dark indigo colour of the sea begins to be broken by various areas of green and yellow water, and a line of surf is sometimes seen; the latter marks the position of one of the outer sand-beds, but not the one farther in, which sometimes prevents the passage of the larger boats. The differences in the colours of the sea are due to the character and amount of suspended particles in the water; the darker the sea, the more indigo-like or black it appears, the purer is the water; it is more free from suspended particles. Under these circumstances, such of the incident light as is not reflected at the surface, passes into the depths of the sea, and not being reflected abundantly to the eye of the spectator, the water looks dark. With a moderate proportion of suspended particles in the water the sea looks green, and with more particles still it looks yellow Professor Tyndall once illustrated the principle in his exquisitely clear way by attaching a dinner-plate to the end of a rope, then dropping the plate over the side of the ship into a dark indigo-looking sea. The plate looked bright green in the dark water, because it reflected to the eye green rays which otherwise would have penetrated to great depths. "Suppose this plate to be crushed into powder," he said in effect, "or into an infinite number of microscopically small white plates, each suspended white particle would still reflect green light to the eye; hence the green appearance sometimes presented by the sea."

With Calais we shall deal in the next article in this series.

PHOTOGRAPHY AT THE EXHIBITION OF THE MEDICAL CONGRESS.*

MEDICINE is one of the sciences which earliest adopted photography as an aid, and in few other sciences has our art achieved such triumphs as in this one. Whoever has examined the objects in certain departments of the recently closed Medical Exhibition in Berlin, cannot have escaped being impressed with the importance of photographic results in connection therewith.

The service rendered by photography to medicine is not confined to its application as a means of research; hygiene, diagnosis, statistics, pathology, and forensic medicine, are all indebted to it for the evidence which it brings to bear.

As it is difficult to classify the photographic contributions on view at this Exhibition, the description of them must partake, more or less, of a desultory character. Of cameras, and such mechanical aids to photography, there was a good and interesting display furnished by Stegeman, Schröder, Hezekiel, and others. Stegeman exhibited

* Translated for the PHOTOGRAPHIC NEWS from the *Photographisches Wochenblatt*.

amongst others, a very well-made bellows-camera, with a long base-board, to be used in combination with a microscopic objective, for the purpose of producing micro-photographs. Hezekiel showed a Loman camera and others specially adapted for medical purposes, particularly hand-cameras and flash apparatus, in the newest and most improved form. Dr. Hartnach and Görz had a large collection of photographic objectives. The latter showed optical glass, as used for photography, in large pieces and in the rough state, as well as an entire series of his new objectives. Dr. Hartnach exhibited here, for the first time, a selection of photographs exhibiting the capabilities of the lenses shown. As a step in advance, it is to be noted that the principle of the Iris diaphragm has been strictly carried out.

A very extended application of photography is found in the representation of typical forms of disease. Dr. Bein has cultivated this branch of photography at the University of Berlin with remarkable success. We find pictures of consumptives in all stages of the disease, and a similar collection of photographs illustrating asthma and various other maladies. In another place we meet with photographs enlarged from small originals to life-size of an old man in whom the action of particular muscles of the face has been called into play by electrical applications. The typical expression of pain, aversion, laughter, pleasure, astonishment, and fear, are clearly brought out. A very impressive series is that of photographs of the dying, mostly phthisis cases, in which the anguish of death is fearfully brought home to the spectator.

Particularly instructive for the surgeon must be the series of photographs in which the various phases of an operation are shown up to its successful completion. We thus follow the course of the amputation of a foot, and the manner in which the wound is closed; the curvature of a spine, and its improvement under orthopœdic treatment: the means employed with crooked legs; and many others of a like character.

Of a very large range are the performances of micro-photography. To the union of photography with the microscope medicine is indebted for some of its most successful progress. Drawings of microscopic objects, which are necessarily very imperfect and subjective in character, are now supplanted by photography. The study particularly of the bacteria organisms, which, though small, are of such destructive character to humanity, is enormously advanced by photography. Even where the eye of the seeker fails to reach, photography steps in and brings forth evidence of minute structure; the circumstance that we have the help of light, the wave-lengths of which are invisible, though still active upon the sensitive plate, coming to our aid. Pictures illustrating this department have been shown by Dr. Neuhaus. The sharpness and technical completeness of these photographs is wonderful.

Amongst the apparatus for micro-photography, the great camera of Dr. Zeiss, and the smaller one of Dr. Hartnach, should be particularly mentioned. The object aimed at in both cases is a fine and immovable focus, but it is brought about in very different ways. Very good apparatus of this kind is also shown by Klönne and Müller, and by Leitz. How far the task of resolving the finest structure has been achieved by modern apparatus may be illustrated by the fact that there is now no difficulty in resolving an object (*amphipleura pellucida*) which shows lines of 4,000 to 5,000 to the millimetre.

The experiments made in various quarters for bringing flash-light into the service of micro-photography are very noteworthy. Both in the original form of explosive powders, as prepared by Gaedicke and Miethe, and in that of blow-through light, as used by C. C. Schirm, the method finds application. Remarkably perfect results obtained in this way are shown by Dr. F. Röhmann, who has employed certain metallic salts for the purpose of colouring the flame.

(To be concluded.)

THE IMPERIAL AND ROYAL INSTITUTE FOR INSTRUCTION IN PHOTOGRAPHY AT VIENNA.

Assembly of the Students.

On the 12th, 13th, and 14th of September will take place the reception of students for the winter session of 1890-91 at the Royal and Imperial Institute for Instruction and Research in Photography and Reproduction Processes in Vienna; the course of instruction begins on September 15th. The duties of instruction are undertaken, and the processes gone through with the pupils, by the various practical professors in the studios, laboratories, and printing rooms of the Institution. Portrait and copying by the camera, wet and dry negative processes, orthochromatic photography, the preparation of emulsions, retouching of negatives and positives, printing processes, processes of printing direct from tracings, transparencies, enlarging, and micro-photography, are all gone through. Moreover, the photo-mechanical reproduction processes, collotype, photo-lithography, zinc etching, photo-zincotype, and other special photographic methods are demonstrated according to the measure of the requirements, and of the means at hand for executing the work.

The studios and printing rooms are open daily from eight in the morning till half-past three in the afternoon. The drawing studios—for freehand drawing, instruction in perspective, and mechanical drawing—are open daily from five till eight in the evening. There is instruction in the day-time for special artistic ends, such as making drawings for the purpose of having reproductions made therefrom, for more advanced pupils in drawing from the solid, in lighting, and in the study of colours.

The instruction includes photo-chemistry, photography, details of printing processes, retouching, chemistry, and physics, chemical manipulations (with practice in the laboratory), professional calculations, geometrical drawing, and the consideration of the question of protection of artistic and literary property.

For the use of the members of the classes, the Institute possesses a rich collection of apparatus and library of works pertaining to the art.

Professional photographers, artists, and teachers, who only require instruction in some particular photographic processes, are received as extra students.

Further particulars may be obtained at the office of the Institute, Dr. J. M. Eder, Chief Director, Westbahnstrasse No. 25, Vienna.

Messrs. Newton and Co. have just published a series of new lantern slides, consisting of pictures from Stanley's new book, "In Darkest Africa." Many of the pictures were copied from the original drawings on the wood-blocks before the latter were cut by the engraver; others were copied from the engravings as they appear in the book. Some negatives were taken in the course of the expedition itself, but rumour says that they were not of a first-rate description.

LIMITATIONS IN THE TREATMENT OF SUBJECTS BY FOCUS.

BY T. R. DALLMEYER.

Some Points of Comparison between Vision and Lens Images in Photography.

In this paper I propose not only to reply to the points raised by Mr. Burton on this subject, but also to some others that were recently brought forward by Mr. Dennis Taylor in the *Photographic Quarterly*. If I have misunderstood Mr. Burton, I have at any rate only spoken about what he has written, and endeavoured to put a fair interpretation upon it. Mr. Burton now confines himself to one aspect only of focus, viz., that one plane should be as sharp as any lens is physically capable of giving it, supporting this by the statement that it had been shown by Lord Rayleigh that the eye will define quite as perfectly as the best of lenses.* When comparison is made between what the eye can do and the definition to be assigned to a lens to become parallel with it, there are various considerations to be taken into account that must be weighed for a faithful representation of ordinary physical eyesight. As an optical instrument, Helmholz certainly has spoken of the eye in facetious terms, but I do not presume that Helmholz or any authority would detract from the beauty and value of the eye as it exists.

The late Sir John Herschel, speaking of the eye, has said:—"However anatomists may differ on points of structure, or physiologists dispute on modes of action, there is in what we do understand of the formation of the eye, so small and yet so infinitely superior to a production of human ingenuity, such thought, such care, such refinement, such advantage taken of the properties of natural agents used as mere instruments for accomplishing a given end, as forces upon us the conviction of a deliberate choice and premeditated design more strongly, perhaps, than any single contrivance to be found, whether in art or nature, and renders its study an object of the deepest interest." The scientific investigations on the construction of the human eye only help us to appreciate this most wonderful piece of mechanism, and if possible, from any of its defects as an optical instrument, value still more the enjoyment we derive from its marvellous powers as they exist. If, when we opened our eyes, we received a "sticking-plaister" brain-impression like the monotonous uniformity of impression given by a well stopped down lens on a sensitive plate—supposing such a state of things were suddenly to arrive to us—we should probably yearn again for the more defective construction that had doled out the beauties or incidents of the scene before it—the wherewithal for us to feast on, when and where we found enjoyment, by the combined use of our opticial and mental foci.

Mr. Burton's contention seems unsound, for the following reasons. First, in viewing any landscape or subject, the retina of the eye is more or less flooded with a diffused light; in the case of a camera with a well stopped-down lens there is comparatively no diffused light to interfere with the powerful discriminating focus that registers the image. Then, in viewing any subject, we have *binocular vision*. Binocular vision is, in one sense, of use only up to a certain distance, but is a very powerful means of discrimination for near planes. I believe I have normal vision, and I can distinctly see print using two eyes at a greater distance than is possible with one. I before mentioned that if a subject be photographed, then viewed at the same angle as is included in the photograph, near to the eye, with binocular vision, the discrimination seems to be very much greater, and even for one plane alone, as now contended for by Mr. Burton.

As a matter of opinion, I do not think that if photography is to be in accordance "with the contention that a picture should be a translation of the scene as seen by the normal human eye," that the best possible focus even for one plane should be quite as sharp as a lens can make it, but, of course, there may be occasions when it is necessary. Mr. Burton does not now, from his remarks, appear to maintain the position that every plane should be equally sharp. In Mr. Dennis Taylor's paper, at the outset he concurs with the quotation above given from Dr. Emerson, and then endeavours on optical grounds to refute the principles of focussing as carried out by the naturalistic school. It appears to me that the one optical principle that Mr. Dennis Taylor has enunciated, and certainly clearly explained, is not the only one to be considered. He says: "It is obviously out of the question to represent binocular effects upon a plane surface," and again. "It is evident that no out-of-focus effect produced by one lens can possibly resemble or stand duty for the important duplication effect, the result of binocular vision." Now the fact of binocular vision appears to me the greatest claim *on scientific grounds* that the naturalists have for their method of focussing. Of course binocular effects cannot be produced except through the stereoscope upon plane surfaces, but the "important duplication" can.

A simple experiment will show Mr. Dennis Taylor that this is easily attained by inserting a stop with two apertures in a lens, and separated by a convenient interval. Taking a lens of, say, 15 inches focus, or that of good normal eyesight, with two apertures of $\frac{1}{8}$ inch (the limit of size deduced by Mr. Dennis Taylor), separated by a distance of $2\frac{3}{8}$ inch, or about the distance between the eyes: this should register, on a photographic plate, what a "sticking-plaister" brain would receive. The effect of binocular vision so registered will show a distance for a given focus, beyond which the separation of double images is so slight that they may be said to coincide. Taking this as a displacement of $\frac{1}{100}$th of an inch at a distance of 15 inches, the distance after which there would be no detrimental interference from the duplication would be about 50 yards. Now the aperture for a lens with the ordinary stop, to accomplish the same end, would be *f* 6. It is remarkable that this is about the ratio of aperture to focus of the single lens of the eye. The duplicating effect for near planes thus obtained with a lens with a binocular stop is most disagreeable, as, although we do have a duplicating effect in the eyes, it is not so distinctly appreciated, no doubt one important reason being that we really see more distinctly with one eye than the other; and from experiment I have found that, by enlarging the $\frac{1}{8}$ inch aperture in the binocular stop till the apertures more than meet in the centre, some very interesting results are obtained when the apertures are made so large that the duplicating effect is not pronounced.

Again, in a paper that I contributed to the Camera Club, I mentioned that I had had the opportunity of consulting an artist, Mr. Davis Cooper, who had for many

* As a matter of fact, Lord Rayleigh has not said so, but in a discussion on the alleged superior vision of savages, he stated that "the margin for improvement in the vision of civilized men was not great," and in answer to my enquiry Lord Rayleigh says, "I have no doubt that a perfect lens of aperture and focus of the eye would give somewhat better definition than does the eye."

years lost the sight of one eye, and in his case, after careful and protracted trial, he was of opinion that there was muscular effort to focus for different planes within a distance of fifty yards. Dr. Emerson was the first to enunciate the distinctly appreciable time required to adjust the focus for different planes, and point out that it was *not instantaneous*.

Now as one single eye, for example, which is considered normal, can appreciate different conjugate points within this distance, and as also duplicating effect with both eyes ceases to exist appreciably beyond the same distance, it appears to me that, for a lens of the focus of normal human vision, say 15 inches, one should employ a stop *f*/6 to be on a parallel, or the nearest approach to a parallel with that of normal human vision. The round stop, as it exists, takes away any disagreeable duplicating effect in reproducing a photograph of any scene (as seen), and at the same time maintains a correct ratio as regards its relation of aperture to focus; *f*/6 for a lens of 15 inches focus. I repeat that binocular vision appears to me to be one of the most powerful arguments that the naturalists have in representing on a plane surface the chief object of interest with the most pronounced degree of definition, and allowing the remaining portions of that picture to be subservient to that one plane.

I have not had very much time to investigate the use of the binocular stop, but it appears that if a separation of $2\frac{3}{8}$ inches at a distance of 15 inches corresponds to normal human vision, it will be easy to find experimentally the correct separation, or, if a round stop be used, the correct aperture (theoretically, of course, a constant), for different foci of lenses, be they longer or shorter. Artists alone must be the judges. I should much like to see the effect of a picture taken with a 6-inch focal length of lens, with a binocular stop showing pronounced duplication, and this reproduced upon a screen by the lantern with the same lens and stop. Duplication, of course, will cease in the image, and it is possible that a more stereoscopic effect might be thus attained. I very much appreciate the direction of Mr. Dennis Taylor's work, and were it not for binocular vision, the $\frac{1}{8}$ inch stop that he deduces as that for every lens would be correct on optical grounds alone, but the mere fact of binocular vision, of course, upsets this; and I think it also would have been well to take into consideration, in the first place, what the eye can do as an instrument, and then assigning a sight stop to photographic lenses to be on a parallel with it, instead of only taking the measurement of the iris and the focus of the crystalline lens, as though it were a perfect lens.

As far as I understand, the object of pictorial art, in the matter of drawing, is to render a truthful impression of what is *seen*, and nothing more. The *sharp* throughout photograph is a truthful record of *what is* from the one point of sight of the lens, and to appreciate it as a picture you must find a picture in it. It is the memory and record of all the scene in its proper relation as regards *mathematical angular measurement*, and not of the picture that can be recalled by the contemplation of any portion of that scene. If a scene is of uniform interest, record it as such, and you will have done as much as lies in your power to convey to the one viewing the photograph the pleasurable sensations the scene had for you. I still contend that artificial means must be used in connection with the eye to make it see any point as clearly as a well stopped-down photographic lens will represent it. It is evident on the above reasoning that pinhole photographs must be failures, artistically, unless the nearest plane included be distant fifty yards; of the *quality* of definition artists must judge.

MODERN DEVELOPMENTS OF PHOTOGRAPHY.

A paragraph which we published a fortnight ago led to the following expressions of opinion in a leading article in the *Daily Telegraph* last Friday:—

From the mouth of his recognised organ comes the wail of the photographer, and his plaint is to the effect that there is a distinct falling-off in the demand for photographs of celebrities. No longer, it seems, does the gilded youth of the day decorate his mantel-piece with the sun-pictures that succeeded the old engravings of "Pets of the Ballet." If he sticks up photographs at all, they are personal gifts with autograph inscriptions, and his old habit of investing in "cabinets" of popularities has been abruptly dropped. In vain is the reigning beauty of the hour set in a shop window to entice him to purchase her, either in the pose of languid laziness when swinging in a hammock, pouring out tea, investigating her own personal charms in a hand-glass, or, in still more daring and original mood, focussed in the very act of attempting to resuscitate a stuffed canary, or swallow an enormous muff in the middle of a snow storm. Eminent photographic firms no longer, we are told, look upon the photo-mania of a few years ago as a source of income. Well-known shops, "for years useful to artists in want of photographs of celebrities," are closed, and no man is bold enough to adventure re-opening. The peripatetic vendors of like wares have disappeared from the public streets, or filled their carts and barrows with more saleable merchandise, and, according to the same trade authority, the Automatic Photographic Supply Company has discovered that the fascination once exercised by likenesses of ladies and gentlemen of the dramatic profession has sensibly waned, even though these gifted personages were to be procured, like everything else nowadays, by dropping a penny in the slot. Amongst learned and scholarly circles there is still a demand for bishops, men of letters, and "advanced thinkers" of various schools. Poets and artists and novelists are asked for and invested in, and there is still extant a fondly loyal class delighting in the possession of photographs of all "Royalties" of all countries, at all ages, and in all positions. It must also be admitted that the "family album" is still a cherished institution, and that usually dreary volume is highly useful as a record of the fitful changes of fashion, a study of the rise and fall of crinoline, and chignons, and similar eccentricities as extinct as the dodo. The rage for the purchase of celebrities or "notorieties," however, is stated to be exhausted. What has led to this remarkable change in public humour, and whence comes the disappearance of a once-popular whim? This is a question which the authorised organ of the craft is powerless to answer, contenting itself with a regretful record of the facts. A little investigation may possibly furnish some clue to the mystery.

Perhaps the secret lies in the fact that, while the purchase of public photographs issuing from well-known ateliers has sensibly decreased, the practice of the art of photography has spread enormously among the ranks of the amateurs. Really beautiful, sympathetic, and serious work is shown year after year in the photographic exhibitions; the

mysterious varieties of the various "processes" are being gradually mastered by the amateur apprentices; and the cult has been brought to such perfection that high-class photography may in truth be said to have captured Phœbus Apollo, and made an artist of the sun-god. The serious artist-photographer, then, would scorn to buy a picture not of his own producing, and it is likely that a similar spirit inspires his more comical brother, who has taken up the merry pastime of playing with one of the various amusing forms of "detective"—or, as they are often very properly termed, "demon" cameras. These ingenious "snap" detectors—remorseless recorders of a chance attitude, possibly inartistic, nay more, possibly compromising—are concealed in despatch or cigar boxes, peep out with enquiring eye from the back of a harmless, neatly-bound book, or can even hide their inquisitive eyes in the most innocent-looking of brown-paper parcels. With a couple of dozen "dry plates," a combination of a string and a shutter, and this apparently guileless instrument in his possession, the owner has only to learn the knack of holding it steadily and firmly against the body, and he can literally "shoot his friends flying," when they never dream of pose or smile. The flight of birds, the movement of a horse and its rider in the very act of topping a hurdle, the rush of a racing yacht through the foam—they have even gone so far as to be able to snatch the changing shapes taken by a charge of small-shot in mid-air—are all picturable by the new race of "Peeping Toms." The pictures are wonderfully brilliant and sharp, and the detective camera fairly takes rank with Edison's phonograph as part of that new movement which may be termed the ceaseless surveillance of science. How Fox Talbot and Daguerre, and others, who almost contemporaneously gave to the world the secret of producing a photographic image by the action of light upon the sensitive salts of silver, would have wondered could this "fin de siècle" result of their experiments have been prophetically revealed to them! Their advanced disciples are now numbered by millions, and it is, no doubt, largely to the spread of amateur photography, especially of this humorous though not altogether comforting detective character, that is to be attributed the alleged falling-off of the demand for the works of the professionals.

Of course, no one likes the idea of being caught, fixed, developed, and mounted, when unprepared. It is not given to all men and women to be habitually graceful, and even the most elegant youth, whose permanent public pose is that described by lady novelists as suggesting "a young Greek god," may sometimes relapse from his habitual Hellenism, and, what is more to the point, be caught in the act. It is hard, very hard, to evade the all-searching eye of this remorseless inquisitor. That astute convict, "Henry Fergusson," as told by our Paris Correspondent the other day, in spite of the fact that he possessed "finely-cut features" and had "hair falling in ringlets over his shoulders," displayed a resolute antagonism to be photographed. He made grimaces at the lurking camera, and wriggled out of focus, despite all the efforts of the prison authorities of Rennes. He may have had some rooted personal objection to having his "finely-cut features" sent to all the police albums of diverse countries; for many convicts entertain a singular prejudice against this artistic custom. It was only after he had spoiled many negatives, and successfully escaped all recording recognition a dozen times, that he was "snapped" when in the presence of the Judge and jury of the Assize Court by a concealed camera, and in this unsuspicious moment handed down his features and his ringlets to posterity and the French police. During the forthcoming decade of his enforced seclusion from society, owing to the lamentable fact that he had contracted a habit of collecting jewellery not legally his own, he will have leisure wherein to reflect on this irritating example of the surveillance of Science.

"Mr. Fergusson," of Rennes, however, is by no means the only objector to the "snap" system, for complaints on the subject are to hand from erudite and scholastic circles. At a certain large public school it is one of the canons of chastisement that when a form-master is under the painful necessity of caning a truculent or perversely stupid boy, the punishment must be so inflicted that the cane is raised no higher than the master's own shoulder. This benevolent and merciful rule was, it appears, habitually neglected by one of the form-masters, whose style was of the lofty-brandishing order. Various chastised culprits from time to time made protest against this literally high-handed proceeding. They requested that the regulation horizontal, and not the perpendicular movement, should be rigidly adhered to, and protested as strongly as did their cricketing forefathers, before the rules were revised, against the "over-hand delivery." The castigator stoutly denied the accusation, and the situation became very involved indeed, until one of the youthful offenders bethought him and bought a detective camera. At the very moment of punishment, when naturally, as the correspondent puts it, "the master's attention was otherwise occupied," a flash on a dry plate exhibited beyond all possibility of doubt the cane elevated above the regulation point. The fatal film was shown to the head-master, who, with impartial Spartan severity, rebuked the transgressing under-master on the evidence of the photograph, and at the same time gave the audacious young photographer four hundred lines of a recognised classical author to write out for "playing in class." These instructive stories point out some of the possible terrors of the new photography, but to continuously upright and properly-behaved people there should be no ground of apprehension at all. "So act," says Kant, "that the motive which influences you shall be fit for law universal;" and, coming from the region of pure ethics to more sensuous æsthetics, it might be suggested as a parallel maxim, "Always conduct yourself in such a picturesque and graceful fashion that you may boldly defy the doings of the demon camera, and stand in no fear of a random snap-shot."

The uses of celluloid seem to be increasing almost daily, and particularly in connection with photography and kindred arts; it is now being used considerably as the basis of photographic reproductions by the photo-mechanical processes, and is peculiarly adapted to such work, owing to the ease with which it lends itself to retouching, and artist work either with brush pencil, or pen. Its employment in this field will doubtless expand rapidly and permanently.

Dr. R. Krugner writes to *Anthony's Bulletin*:—"It is very well known to me that eikonogen has the displeasing quality of turning sometimes to a dark colour; but this is of no importance against the other excellent qualities of the product, if the discolouring takes place only on the surface of the crystals, and if the interior of them rests unaltered, which is the case generally. By testing, you will find the above confirmed. It is not known with certainty by what the discolouring is caused, but you can be assured that the best is being done to prevent it."

PHOTOGRAPHY: THE SCIENCE AND THE ART.

We often hear photography spoken of as the art-science, a combination of terms which seems somewhat contradictory, but which is really most comprehensive and accurate. Science has been defined as "knowledge reduced to a system," and when examined from this standpoint, both in its details of operation and in the methods of its application, photography may fairly claim to be one of the most exact branches of science. It is, indeed, not without its experimental side, in common with all branches of science, but in the present acceptation of the term, the camera is as much a scientific instrument as the engineer's transit or level, and for scientific purposes its uses may be acquired as methodically.

The application of the camera and its work to scientific pursuits has, however, not generally been regarded altogether as legitimate as some other instruments, and for a rather curious reason, namely, that it is rather an artistic than a scientific instrument; while, at the same time, the artist is sometimes disposed to give the camera the cold shoulder because, forsooth, it is a scientific instrument! and so, while claiming to be an art-science, photography flits midway between the two camps, like the bat in the fable, and is not fully accepted by either side.

Now, photography is really a science, and is also as thoroughly an art as is any other division of that much-abused term; but it is not both at the same time, and, without reopening an old discussion or stirring up old antagonisms, it may be worth while to examine somewhat the difference between the scientific and artistic applications of photography.

When the discoveries of Daguerre, and Niepce, and Talbot first made photography practicable, the immediate thought of everyone was of its application to portraiture: and even to-day, if one speaks of a photograph, without any further definition, it is generally understood to mean a portrait. Landscape photography, before the introduction of modern dry plates, was so little followed as to be of minor importance, and with the exception of some professional work in architectural photography, the artistic side of photography was mainly limited to portraiture.

Since the advent of the amateur into photography, however, we hear much more about photography as an art, and the ease with which the operative details of manipulation are mastered has made it possible for men of cultivated artistic tastes to exercise talents which might otherwise have remained purely critical. The result has been the development of what may properly be termed a "school" of artistic landscape and group photography, consisting of a number of earnest men of true artistic taste, whose time and opportunity have not permitted to acquire the technical skill with the brush, or crayon, or etching needle which, in former days, would have been necessary to make their talent evident, but who can, with the aid of the camera, show their ability, and gratify their own artistic sense in a manner otherwise unattainable.

Dr. Emerson, to name but one, has amply demonstrated by his published works how fully comparable the work of the camera may be made to the work of the needle and acid; and there are not wanting to-day those who openly express their preference for photograph to etching. The details of the latter process are quite as mechanical as those of the former, and the absence of colour is chargeable to both alike, and to what extent the public opinion upon the subject is due to the influence of unreasoning fashion, the reader can judge.

The artist photographer does not use his smallest stop for the purpose of obtaining the painful microscopic sharpness of definition which the mechanical taste may deem essential; he does not need to be taught any cast-iron rules about the direction of the light, or the introduction of the inevitable foreground stump. When his negative is made, he does not improve (?) it by printing the sky full of clouds, whose lighting gives the lie to every shadow in the picture. Indeed, his work is as marked by what he does *not* do as it is by what he does, and if he succeeds at all in any degree, he succeeds in leaving the impress of his own taste upon all his work.

Turning now to the use of photography as a science, it will be seen how different and yet how legitimate its claim to the title may be made.

Probably the use of the camera for astronomical purposes is one which would first suggest itself as a scientific application; but, as a matter of fact, stellar photography—while most valuable and interesting—can scarcely lay claim to the highest place under this head. The modern science of photogrammetry, using as it does the image on the plate in connection with measured horizontal and vertical angles, the whole to be combined with a similar record made from another standpoint to form an accurately plotted survey, is a far better example of the use of photography as a science. So, too, the boundless field of photo-micrography, and the use of the camera as a record for scientific experiments whose truth is beyond impeachment—these need only to be mentioned to be recognized as scientific uses totally distinct from the artistic use of photography.

The distinction between the two terms can readily be kept in mind, and if the artist would only remember that the camera belongs to him as an instrument of his art as much as do his brushes and his pencil, and if the engineer would also recall the fact that the same pencil which he uses for his accurately drawn diagrams may, in the hands of the artist, produce the sketch of a masterpiece, there would be less discussion about the meaning of art-science.—H. H. S., in *The American Journal of Photography.*

Photographers and the Phonograph.—Photographers consider it necessary in these days of competition to have special attractions in their parlours, and I hear of one leader in the field of photographic art who has a phonograph to amuse his customers while they are waiting for sittings. It is Falk, and as he numbers many prominent actors and singers among his patrons, the *repertoire* of his phonograph contains some great novelties. Patti and Tamagno sang into it. Edwin Booth recited a portion of Hamlet's soliloquy, which it gravely repeats, and Col. Bob Ingersoll has filled it up with some remarks about brimstone which make one feel hot and uncomfortable.—*New York Press.*

A Troublesome Customer.—To take a man's photograph against his will, says the *Daily News*, seems as difficult an operation as the proverbial taking a horse to the water and making him drink. So the French authorities have found at Alençon in their attempt to secure, according to law, a permanent memento of a prisoner who is now undergoing ten years' imprisonment for numerous robberies. It was in vain that he was brought in sight of the photographic camera; it was in vain that the official photographer cunningly hid under his arm a portable apparatus capable of taking an instantaneous likeness. The instant the dread engine made its appearance, the prisoner made such frightful grimaces that his own mother, as the popular expression has it, would not have known him.

Notes.

Lord Salisbury deserves the thanks of photographers for the vigorous utterances he made some time ago about the "almost inconceivable stupidity" of an English Custom House officer who interfered in a vexatious manner with the exposed plates of a returning tourist. The dynamite scare is not yet over at our seaport towns; every article of baggage has still to be opened for inspection, but the officers do not interfere to an unnecessary extent with photographic apparatus and plates. At the English frontier there is more delay and examination in passing the revenue inspection than anywhere else in civilised Europe. Chiasso and some few other places on the Swiss-Italian frontier are bad in this respect, but the inspection is tempered to passengers with through tickets who have come long distances. Smuggling into Italy from Switzerland flourishes on the southern border of Canton Ticino; the birds of the air, the fishes of the river, the winds of heaven, and the handkerchief-tied-up dinners of the labourers, all vie with each other in pouring contraband goods into Italy. The Italian Government has often complained to the Swiss Government about this, and the latter has replied, in the politest of terms, to the effect that it is not its business to provide revenue officials to protect Italian interests. The Italian Government should put such moderate imposts upon foreign goods as to make petty smuggling by individuals unremunerative.

Dr. Janssen has left, or is about to leave, the Observatory at Meudon, to make the ascent of Mont Blanc in a novel manner and for a special purpose. His object is to make observations at a high altitude in relation to certain problems connected with the solar spectrum, for the dirt floating in the lower strata of the atmosphere cuts off some of the rays of the sun which would otherwise reach us. Because of his state of health Dr. Janssen will not make the ascent on foot, but will be carried in a kind of specially designed slung hammock to the top; fifteen porters will do the carrying work. Dr. Janssen intends to spend several days at the Bossons chalet, 4,450 mètres above sea-level, where he will have a small observatory fitted with meteorological instruments.

In relation to spectroscopic observations at high altitudes, Captain Abney one evening told a good story in a Royal Institution lecture, and it was somewhat to the following effect. He was doing some spectroscopic work on the Riffel, when a curious Yankee wished to know what he was about, and Captain Abney told him about the problem of the presence of hydrocarbon vapour—a sort of alcohol—between the earth and the sun. That American returned to the hotel, and reported that there was a lunatic up on the mountain, who had told him that soda had been found in the sun, and that now he—the lunatic—was searching for brandy in the realms of space.

The prospectus of the fourth Annual International Exhibition of the Photographic Society of India is in circulation. The Exhibition will be held in Calcutta during December. Five gold, fifteen silver, and fifteen bronze medals are offered for competition, of which one gold, five silver, and five bronze are offered to the amateurs of the world; one gold, two silver, and three bronze to amateurs of India and Burmah; and one gold, two silver, and two bronze to amateur members of the Photographic Society of India. In addition to the above, a special medal will be given for the best photograph in the Exhibition. Copies of the prospectus and full particulars can be had from Mr. J. S. Gladstone, Woolton Vale, Liverpool.

Strolling the other day through a large cemetery in London, we noticed that in several instances photography had been utilized for preserving a memorial of the dear departed. In many of the gravestones there was an aperture cut the entrance to which was sealed by a plate of glass, and inside the little casket thus formed was a vase of flowers, and in some cases a photograph. The effect was pathetic, especially in the case of children; but it was sad to see how often the fugitive silver print had become almost obliterated, most probably this being hastened by the damp surroundings of the picture. This custom of ornamenting the shrines of the dead with the portraits of those who have gone is of course not new, as every visitor to the Egyptian Room at the British Museum can ascertain for himself. The paintings on the mummy cases there look as fresh as the day they were executed so many centuries ago. But the colours used—chiefly earths of a stable character—are far more permanent than the metallic deposit laid on paper by light.

But there is at least one process which would suffer no decay by exposure to the atmosphere, and if this were once understood by the public, it would give a great impetus to the practice of this particular branch of photography. We allude, of course, to the ceramic method, by which the image is burnt-in to its support. Such photographs can be made either upon porcelain or enamelled copper, and the latter material would be preferable for churchyard monuments. A well executed burnt-in photograph has no rival, for while it has all the best qualities of a silver print, it is as imperishable as anything on this globe can be, and its utter absence of all texture gives it a depth which no other printing method can boast.

What is called post-mortem photography must be always more or less unpleasant, and ought to be well paid for. The most repugnant task in post-mortems is without question that which relates to the photographing of corpses which are found from time to time floating in the river Thames. A journalistic friend has just related the result of a casual interview with one of the Thames police, and the officer in charge of the mortuary of a riverside parish. It appears that these

bodies, when not identified, are always photographed. There is, however, no accredited photographer attached to the police force, and an outside photographer is always engaged. The sum paid for photographing these bodies in all stages of decomposition is, we are informed, £2. Not an extravagantly liberal sum, considering that a copy has to be sent to the head-quarters of each division of the police throughout the metropolis. But, no doubt, the photographer makes his own terms; if he is satisfied, we do not know that anybody has a right to say a word.

Her Majesty the Queen, as is well known, is a great lover of photographs, and every part of her various palaces has formed at some time or other subjects for the camera. But the Queen is also a collector of portraits of those who have distinguished themselves in her service, from the highest in command to the humblest soldier in the ranks. Many of these portraits are burnt-in photographs upon metal, and one worker in London was at one time constantly in receipt of commissions to produce them, very often from faded silver prints. So that it will be seen that Her Majesty has a little national portrait gallery all to herself, and one in which the pictures are warranted permanent.

This thought brings us to a subject which has often before been broached, but which, like the farmer at the county dinner who drank claret in mistake for port, seems to get "no further." It is quite time that we had a national photographic portrait gallery, and it might be made an adjunct of the gallery already in existence, which is presently to find a new home. The photographic section need not take up much room, for the portraits would be in the form of miniatures, and a large number would cover small wall space. When possible, an oil painting should have hung near it the photograph of the original, so that future critics may be able to compare the two. We have thus shown that in many ways there will come a demand for ceramic pictures, and those of an enterprising cast of mind will do well to turn their attention towards the subject.

The question of the necessity of swimming is very much to the front just now; in fact, it always is in the summer months. To those who can swim nothing is easier than swimming; to those who cannot, and make futile efforts to acquire the art, nothing is more difficult. A swimming class which was established recently in South London for teaching swimming on land, and which met with some success, suggests that the various movements might be made tolerably plain by means of a series of photographs. To photograph a person swimming in the water is impossible for practical purposes. The distortions would be an obstacle; but the South London plan was to turn a piano stool to account as a substitute for water. It is clear that, so long as the stool is fastened securely to the ground, the motions necessary for swimming could be well displayed, and if so, the various movements could be photographed. We are not going to say that the resultant pictures would not be open to ridicule as pictures, but that is not our affair.

It is reported that the district through which the Manchester ship-canal finds its way is about to be photographed on a most extensive scale. Materials for a lecture on this gigantic engineering work have been collected, and, as a lecture now-a-days is nothing unless it is illustrated by an optical lantern, an enterprising photographer has obtained special facilities for photographing every spot and locality, including notable incidents and features in the work of constructing the water-way. It appears that no fewer than two thousand negatives have been already taken, and as many more are likely to be added to the store before all the points of interest are exhausted. It is rather curious that a perfectly new work of this kind should receive so much attention, when the river Thames, which is full of lively interest from its source to its mouth, should have been comparatively neglected. The Thames has been photographed in spasmodic fashion, but nothing like a systematic series of photographs exists. The work surely should be worth undertaking.

One of the oddest uses to which a photograph can be put is to eat it! Yet a singular fact of this kind is recorded by the author of an interesting book just published giving an account of the French nunneries. As a teacher of gymnastics, which the Government insisted should be introduced into the religious establishments to improve the health and physique of the inmates, she had an opportunity of seeing the inner life of the nunneries, and graphically describes the morbid condition of mind which discipline and monotony induce. "Many," she says, "were ailing, and to cure themselves put very small photographs of the heart of Jesus into the soup and swallowed them!" Apart from the extraordinary purpose for which these photographs were used, the fact that such photographs were in existence is a curious revelation of what may be called one of the bye-ways of photography. One is tempted to enquire whether any other religious symbols are photographed, and the photographs sold to such as derive comfort from gazing upon them.

Photographs are more often the cause of quarrels than is generally suspected. The latest example is that of a lady who was lately charged at the North London police court with assaulting a gentleman by striking him in the face with a glass. The whole thing arose out of being photographed. The attitude the lady assumed when the photograph was taken appears not to have been pleasing to the gentleman, and it seems to have rankled in his mind until night, when his remonstrances seem to have taken so severe a shape that the lady flew at him, so the prosecutor asserted, and bit his wrist. This is sad, and one would like to know what was the precise attitude which excited the anger of the gentleman, just as a warning to other people.

HOW THEY WERE PHOTOGRAPHED.

THEY came in late in the afternoon, all talking at once.

"We want our tintypes taken."

"Yes. Altogether?"

"In a group."

"Any particular style you'd like?"

"Oh, we want something picturesque. Yes, we want it artistic—an outdoor scene, you know."

The photographer quickly whee's up a mountain view background, waltzes a wooden-looking "rock" into the foreground, props up a rustic fence at one side, and throws down a shaggy, grass-suggesting mat before it. While he is composing this medley from the inexhaustible beauties of nature, the girls discourse on the subject in hand.

"Belle, you sit on the rock and I will stand beside you; Grace can lean on the fence, and May, you sit on the floor. We ought to have a book to be looking at. Ah, here's an album; that will do. Dora, which side of my face would be the best to have taken?"

"The outside," said Dora, promptly.

"I wish we had a parasol," says Grace.

"Be quick as you can," interrupts the photographer, realizing how precious is every moment of the fast-fading light. Dora bestows upon him a look which plainly says "with intent to annihilate."

"We pay you by the job, not by the hour. Do not presume to hurry us."

At last they locate themselves according to the dictates of their own sweet and wayward fancies.

"Ah, my," exclaimed Belle from the rock, "what an awfully uncomfortable thing this is to sit on"

"Put your hand on my shoulder, Grace."

Finally all seems in readiness, when, just as the photographer is about to remove the cap to expose the plate, May suddenly exclaims from the floor:

"Hold on a minute, Grace, you ought not to be standing, you are too tall. Change places with me."

Then ensues a general scrambling and rearranging, Belle improving the opportunity to try for a softer spot on the rock.

"Am I looking at the right place?" May anxiously asks of the photographer, as if the sun would certainly fail to do its desired work if her head was not turned at just the most becoming angle.

"Yes," replies the much harassed personage addressed, heroically choking back unholy utterances. "Sit perfectly still now."

He removes the cap, and a brief and blessed silence ensues. When he replaces the cap for a moment the chorus breaks out.

"Oh, my goodness—dear me—I never—why, I was just——"

"Keep just as you are," says the photographer, authoritatively, unexpectedly removing the cap again, and thus effectively shutting off the threatened deluge of remarks.

The poor light necessarily made the exposure unusually long, and when at last it is over, a volley of deep and revengeful groans comes from the girls as the photographer disappears with his plate.

Then their tongues are loosed.

"My! I feel all tied up in a bowknot."

"Goodness! but I'm tired standing so long."

"I never knew any one to be so long taking a tintype."

"Oh, I feel as if I had just had a tooth pulled—so thankful it is over."

"Oh, see this picture of some girls in a boat. Why didn't he say he had a boat?"

"I don't think he is very agreeable, anyway. All he thinks of is to get it over with."

"Oh, here he comes with the pictures."

Now they gather around the man with the pictures, all talking excitedly.

"Oh, oh, just look at me."

"Just see the way my eyes look."

"My head is held too high, and I asked you"—

"Oh, see how my dress looks," &c., &c., until at last they relinquish the artistic treasures long enough to have them put in envelopes. Then they pay for them and go out, leaving the long-suffering photographer free to relieve his overwrought nerves in any form of speech he thinks will be most soothing to his feelings and expressive of his sentiments.—*Boston Herald.*

A NEW SOCIAL FANCY.

ONE of the latest fads of social swelldom is the "Trousseau Album"; and although it has been mercilessly ridiculed in various quarters, we think the idea will increase in favour, and that it has come to stay. An album of this kind, even if not as extravagantly gotten up as the one here described, will without doubt always be an object of interest and curiosity, the more so as the years elapse. To a family in which it descends as an heirloom its value cannot be measured by money; while to the student of history and social philosophy a work of this kind—a century hence—would prove a perfect storehouse of information.

To properly arrange an album of this kind is not an easy task, as it requires not only good judgment on the part of the photographer, but of the modiste and binder as well, to which must be added a liberal outlay of money.

The specimen which came under the notice of the writer was a perfect specimen of its kind. Sufficient funds had fortunately been left the family, after securing the titled foreigner as a husband for their daughter, that they were free to indulge in this whim of the bride. The album was handsomely bound in Turkey morocco, and fastened with gilt clasps. On the corner was emblazoned a gorgeous crest and coat-of-arms in gold, silver, and bronze. The inside of the cover was lined with heavy watered silk, as was the fly-leaf, which protected the illuminated title pages. Then followed on opposite pages a portrait of the bride and her foreign consort. On the next left-hand page was a full-length photograph of the bride in her wedding dress, veil, orange blossoms and all, just as she had stood before the altar. Opposite, on the right-hand page, a dress similar to the photograph was constructed in miniature of the identical fabrics, silks, satins, and laces, as was the original; even the garniture of orange blossoms being painted on the model. This was protected by a deep hinged matt, made of the finest pebble board, with gilt bevelled edge. The next picture represented the bride in her tailor-made travelling dress, which was worn on the wedding tour immediately after the ceremony. On the opposite page we again had a miniature model of the original fabric, showing the colours and materials, which could not be reproduced by the camera, and so on through the whole category. Evening dresses, street costumes, house robes, followed one after the other, through the whole list of trousseau, the pose of the bride being varied in each picture so as to show off the dress and its fair wearer to the best advantage, while on the opposite side was to be seen the exact model of the identical fabric, always, of course, protected by the deep matt. The whole album did credit to the different artists who were engaged on it.—*American Journal of Photography.*

SUBTERRANEAN PHOTOGRAPHY.—Mr. Langlois has constructed an apparatus for subterranean photography, in cases where the only means of communication to underground localities is a narrow shaft, and the instrument must be manipulated from the surface. His invention consists of a *camera obscura* of small size, the plate being about two inches square, and the focus of the lens being of comparatively short range. The camera, mounted in a metallic case or tube, open on one side, can be lowered by means of a cord or small chain attached to the tube. The camera is pivoted within the tube, at its upper end, so that it can be kept at an angle by means of a cord or small chain fastened to the lower end of the camera. Above and below the camera are placed rows of incandescent lamps. When the apparatus is lowered, and the camera made to incline outward from the case, the current is turned on and the plate exposed. The photographs thus obtained are said to be excellent.—*Mechanical World.*

Literary Notices.

The Evolution of Photography. By John Werge. (*London: Piper and Carter*, 1890.)

This book consists of 139 pages devoted to the history of photography chronologically arranged, followed by 173 pages of articles which, at different times, Mr. Werge has contributed to photographic periodical literature.

As regards the first part of this book, it is interesting because it deals with subjects with which Mr. Werge, as a member of the photographic fraternity of the old school, was, to a large extent, personally conversant. He tells of men and events which played their part in the photographic world before the new race of photographers of the gelatino-bromide dry plate period came into existence. He has also been careful to collect and publish the portraits of many pioneers of photography, and sometimes took special pains to achieve this result. For instance, he obtained the likeness of Josiah Wedgwood from Mr. Godfrey Wedgwood, photographed from a plaster cast taken after death, and the portrait of Nicephore Niepce from the Mayor of Chalons-sur-Soane. Sir John Herschel's portrait was obtained by him from Mr. H. H. Cameron, and he took pains to specially obtain a few others. The following is the complete list of those given in the book: Josiah Wedgwood, Nicephore Niepce, the Rev. J. B. Reade, Henry Fox Talbot, Sir John Herschel, L. J. M. Daguerre, J. F. Goddard, F. S. Archer, Dr. R. L. Maddox, and Richard Kennett. We should have liked to have seen those of Thomas Sutton and Major Russell in the list. The portraits have been well reproduced by the collotype process by the Autotype Company; the latter were about the earliest commercial pioneers of that process in this country.

The work consists largely of personal reminiscences, and is written in easy narrative style, which makes it all the more interesting; and the fact of its being arranged in chronological order renders it easier for the reader of the present to follow the march of discovery in the past. Mr. Jerome Harrison has written a little book on photography, in which historical events are given in chronological order, so Mr. Werge does not stand so much alone in this arrangement as he seems to think, judging by some remarks in the preface.

More might have been said by Mr. Werge about the collodio-bromide emulsion process of Messrs. Sayce and Bolton than the three lines given to it on page 135, and might have been done without taking notice of recent disputes, but summarising only the original utterances of 1864. More also should have been said than the three lines given about Gaudin's position in relation to the origination of gelatine negative processes.

The facts are, that on the 15th of April, 1861, M. Gaudin published an article in the journal *La Lumière*, of Paris, in which he set forth in minute detail, and giving the proportions, how he prepared a gelatine emulsion containing *washed iodide* of silver. With this emulsion glass plates were coated, and the emulsion made to adhere thereto by means of an albumen substratum. These plates were exposed in the camera, and developed by means of a solution of tannin to which a few drops of solution of nitrate of silver had been added.

More than ten years later, Dr. Maddox first published, in *The British Journal of Photography* of September 8th, 1871, how he made an *unwashed bromide* of silver gelatine emulsion, which he spread upon glass and upon paper; then printed images thereupon from negatives, and developed with a solution of pyrogallol containing a trace of nitrate of silver. He put it forth as a positive printing process, and said nothing in the article about its being of any use for negatives.

Between the above dates, and in the journal last mentioned, another experimenter published on the 17th of January, 1868, how he coated a glass plate with a gelatino-bromide of silver *unwashed* emulsion, dried and exposed it, then brought out the image with an alkaline developer. He said:—"I wanted to have a solution which would give a good dry plate by simply coating a sheet of glass with it, and allowing it to dry on the levelling stand, thereby abolishing baths, washings, and the use of collodion in the process." This was put forth as a gelatino-bromide negative process, and one to be used with alkaline development, and was published three years before Dr. Maddox printed his emulsion process for positives.

When we have a school of historical criticism in photography composed of men whose duty it will be to see to the accuracy of historical utterances, their chief attention will have to be given to the original text of the three articles just mentioned, when investigating the facts about the origin of gelatine negative processes. When that time comes, we shall hear much more about the part taken by M. Gaudin in the origination of those processes than we do at present, or than is given in Mr. Werge's book.

The following narrative of the manner in which modern gelatine plates gradually came into commercial use will serve to illustrate Mr. Werge's style of writing, and of describing circumstances of which he was cognisant:—

In 1873, Mr. J. Burgess, of Peckham, London, advertised his gelatino-bromide emulsion, but as it would not keep in consequence of decomposition setting in speedily, it was not commercial, and therefore unsuccessful. It evidently required the addition of some preservative or antiseptic to keep it in a workable condition, and Mr. J. Traill Taylor, editor of the *British Journal of Photography*, made some experiments in that direction by adding various essential oils; but Mr. Gray—afterwards the well-known dry-plate maker—was most successful in preserving the gelatine emulsion from decomposition by the addition of a little oil of peppermint; but it was not the emulsion form of gelatino-bromide of silver that was destined to secure its universal adoption and success.

At a meeting of the South London Photographic Society, held in the large room of the Society of Arts, John Street, Adelphi, Mr. Burgess endeavoured to account for his emulsion decomposing, but he did not suggest a remedy, so the process ceased to attract further attention. Mr. Kennett was present, and it was probably Mr. Burgess's failure with emulsion that induced him to make his experiments with a sensitive pellicle. Be that as it may, Mr. Kennett did succeed in making a workable gelatino-bromide pellicle, and obtained a patent for it on the 20th of November, 1873. I procured some, and tried it at once. It gave excellent results, but preparing the plates was a messy and sticky operation, which I feared would be prejudicial to its usefulness and success. This I reported to Mr. Kennett immediately, and found that his own experience corroborated mine, for he had already received numerous complaints of this objection, while others failed through misapprehension of his instruction; and very comical were some of these misinterpretations. One attempted to coat the plates with the *end* of the stirring-rod, while another set them to drain in a rack, and those that did succeed in coating the plates properly invariably spoiled them by over-exposure or in development. He was overwhelmed with correspondence and visitors, and, to lessen his troubles, I strongly advised him to prepare the plates himself, and sell them in that form ready for use. He took my

advice, and in March, 1874, issued his first batch of gelatino-bromide dry-plates; but even that did not remove his vexation of spirit, nor lessen his troublesome correspondence. Most of his clients were sceptical, and exposed the plates too long, or worked under wet-plate conditions in their dark rooms, and fog and failure were the natural consequences. Most, if not all, of his clients at that time were amateurs, and it was not until years after that professional photographers adopted the dry and abandoned the wet process; in fact, it is doubtful if the profession ever tried Mr. Kennett's dry plates at all, for it was not until Mr. J. W. Swan and Messrs. Wratten and Wainwright issued their dry plates that I could induce any professional photographer to give these new plates a trial, and I have a very vivid recollection of the scepticism and conservatism exhibited by the most eminent photographers on the first introduction of gelatino-bromide plates.

For example, when I called upon Messrs. Elliott and Fry to introduce to their notice these rapid plates, I saw Mr. Fry, and told him how rapid they were. He was incredulous, and smilingly informed me that I was an enthusiast. It was a dull November morning, 1878, and I challenged him, not to fight, but to give me an opportunity of producing as good a picture in quarter the time they were giving in the studio, no matter what that time was. This rather astonished him, and he invited me up to the studio to prove my statement. I ascertained that they were giving *ninety* seconds—a minute and a-half!—on a wet collodion plate, 10 by 8. I knew their size, and had it with me, as well as the developer. Mr. Fry stood and told the operator, Mr. Benares, to take the time from me. Looking at the quality of the light, I gave *twenty* seconds, but Mr. Benares was disposed to be incredulous also, and after counting twenty, went on with "one for the plate, and one more for Mr. Werge," but I told him to stop, or I would have nothing more to do with the business. The plate had twenty-two or three seconds' exposure, and when I developed in their dark room, it was just those two or three seconds over-exposed. Nevertheless, Mr. Fry brought me a print from that negative in a few days, and acknowledged that it was one of the finest negatives he had ever seen. They were convinced, and adopted the new dry plates immediately. But it was not so with all, for many of the most prominent photographers would not at first have anything to do with gelatine plates, and remained quite satisfied with collodion; but the time came when they were glad to change their opinion, and give up the wet for the dry plates; but it was a long time, for Mr. Kennett introduced his dry plates in 1874, and it was not until 1879 and 1880 that professional photographers had adopted and taken kindly to gelatine plates generally.

With amateurs it was very different, and many of their exhibits in the various exhibitions were from gelatine negatives obtained upon plates prepared by themselves, or commercial makers. In the London Photographic Society's exhibition of 1874, and following, several prints from gelatine negatives were exhibited, and in 1879 they were pretty general. Among the many exhibited that year was Mr. Gale's swallow-picture, which created at the time a great deal of interest and controversy, and Mr. Gale was invited over and over again to acknowledge whether the appearance of the bird was the result of skill, accident, or "trickery"; but I don't think that he ever gratified anyone's curiosity on the subject. I can, however, state very confidently that he was innocent of any "trickery" in introducing the bird by double printing, for the late Mr. Dudley Radcliffe told me at the time that he (Mr. Radcliffe) not only prepared the plate, but developed the negative, and was surprised to see the bird there. This may have been the reason why Mr. Gale was so reticent on the subject; but I am anticipating, and must go back to preserve my plan of chronological progression.

RATHGEBER FUR ANFANGER IM PHOTOGRAPHIREN UND BEHELF FUR VORGESCHRITTENE. Von Lieut. Ludwig David. (*Halle a. S.: Wilhelm Knapp.*)

THIS is a modest little book written in a concise and popular style for beginners. It is divided into two parts, the first treating of the negative, and the second of the positive process; the whole is illustrated by eighty-six engravings. As frontispieces are representations from a photographic negative and positive respectively of the same picture. At the end of the book samples are given of photographic labels for the various materials used by the photographer.

PHOTO-CHEMICAL INVESTIGATIONS.*

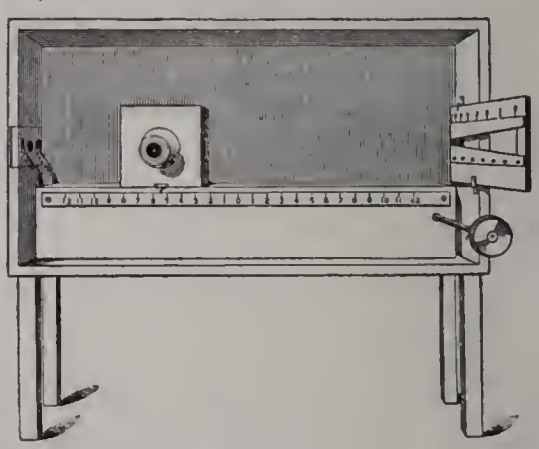
BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

II.—INSTRUMENT FOR MEASURING DENSITIES.

WE proceed to describe the instrument for measuring the density of the deposit. It is based on the relation existing between density and opacity. We measure the opacity of the plate, and, in order to avoid calculations and references to tables of logarithms, the scale of the instrument is so arranged as to read the logarithm of the opacity, which is the density. The reason why we prefer to have the results expressed as density is because the density is a measure of the amount of silver deposited, or of the chemical work done by the light.

The instrument pictured in Figs. 1 and 2 consists essentially of a small Bunsen photometer similar to those

FIG. 1.



used for testing the illuminating power of gas. The paper disc with its grease spot is placed in a small cubical

FIG. 2.

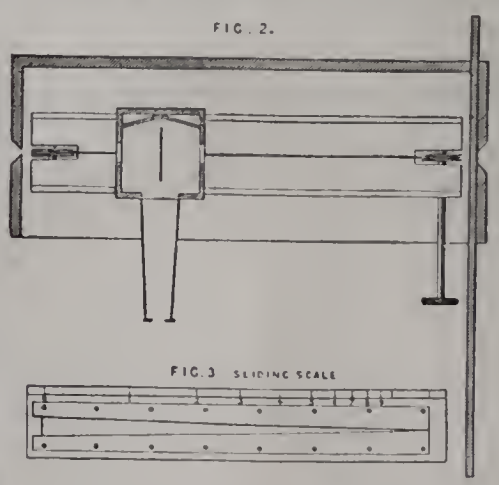


FIG. 3 SLIDING SCALE

chamber. The chamber carries an eye-piece, through which an image of each side of the disc can be viewed in two small mirrors, and so compared. The chamber can be made to slide in a straight line on a support by turning

* Continued from page 599.

a key connected to one of two pulleys, over which passes an endless cord attached to the chamber. This arrangement is placed within a larger box, the ends of which have apertures through which light is admitted from two powerful petroleum lamps. Corresponding exactly with these apertures, similar apertures are bored into the sides of the small chamber, which admit the light to either side of the Bunsen disc. The dimensions we have adopted are, for the larger box, 12 in. long, 6 in. high, and 4 in. deep. The small chamber is a cube measuring 2 in. insied. We find it neeessary to blaeken everything within the box except the seales, and it is also important to exelude all extraneous light by means of a sereen. The heat of the lamps, also, very soon injures the woodwork unless it is covered with asbestos eardboard and sheet metal.

The aperture on the left-hand end of the large box we reduce to about ¼-inch diameter by a diaphragm. At this end is placed the plate to be measured, held in position by springs. The hole at the right-hand end of the box is redueed by a reetangular diaphragm, ¼-inch wide and ½-inch long, the length being vertieal. This diaphragm can be reduced in length by moving a taper diaphragm past it.

The instrument is provided with two scales, one fixed, the other movable, the use and construction of which we will now explain. The fixed scale indicates the position of the disc ehamber, and is constructed as follows:—

Suppose that the lamp on the left-hand side gives light of the intensity T_1, and that on the right-hand side light of intensity T_2, and that both lamps are equidistant from the centre of the instrument, and that this distanee is l.

Then, when the dise ehamber has been moved to a distanee x from the centre of the instrument, so that—

$$(1) \qquad \frac{T_1}{(l-x)^2} = \frac{T_2}{(l+x)^2} \text{ or } \frac{T_1}{T_2} = \left(\frac{l-x}{l+x}\right)^2$$

the two images of the dise will be alike. If a plate is now inserted which reduces the light from the intensity T_1 to intensity i, then the dise ehamber will have to be moved to another plaee nearer to the plate before the two images of the dise are alike again. Supposing the distance of the dise from the centre of the instrument is now y, then—

$$(2) \qquad \frac{i}{(l-y)^2} = \frac{T_2}{(l+y)^2} \text{ or } \frac{T_2}{i} = \frac{(l+y)^2}{(l-y)^2}.$$

By multiplying the two equations we find the fraction which measures the opacity—

$$\frac{T_1}{i} = \left(\frac{l-x}{l+x}\right)^2 \left(\frac{l+y}{l-y}\right)^2.$$

Taking logarithms on both sides, we have, since log. $\frac{T_1}{i}$ is the density D of the plate,

$$D = \log. \left(\frac{l+y}{l-y}\right)^2 - \log. \left(\frac{l+x}{l-x}\right)^2.$$

If, therefore, at the distanees x and y we write on the scale the values of log. $\left(\frac{l+x}{l-x}\right)^2$ and log. $\left(\frac{l+y}{l-y}\right)^2$, we can simply read off these logarithms, subtract one from the other, and the result is the density of the plate. For general convenienee, we use vulgar and not hyperbolie logarithms. In order to avoid all errors arising from the distance of the lamps, we make the apertures in the box small compared with the luminous portion of the flame of the lamps; it can be shown that in that case the distanee l must be measured between the centre of the instrument and the diaphragm.

The following table gives the relative distances of the various points of the scale from the centre of the instrument, at which the logarithms of $\left(\frac{l+x}{l-x}\right)^2$ have the values 0·1, 0·2, 0·3, &c., l being half the distance between the diaphragms.

Table I.—Fixed Scale of Instrument.

Log. $\left(\frac{l+x}{l-x}\right)^2$	Distance from Centre of Instrument.	Log. $\left(\frac{l+x}{l-x}\right)^2$	Distance from Centre of Instrument.
0·000	$l \times 0{\cdot}000$	0·900	$l \times 0{\cdot}476$
0·100	$l \times 0{\cdot}057$	1·000	$l \times 0{\cdot}519$
0·200	$l \times 0{\cdot}111$	1·100	$l \times 0{\cdot}560$
0·300	$l \times 0{\cdot}171$	1·200	$l \times 0{\cdot}599$
0·400	$l \times 0{\cdot}226$	1·300	$l \times 0{\cdot}634$
0·500	$l \times 0{\cdot}280$	1·400	$l \times 0{\cdot}667$
0·600	$l \times 0{\cdot}332$	1·500	$l \times 0{\cdot}698$
0·700	$l \times 0{\cdot}382$	1·600	$l \times 0{\cdot}726$
0·800	$l \times 0{\cdot}430$	1·700	$l \times 0{\cdot}752$

Suppose, as in our ease, the box were 12 in. long between the diaphragms, then l is 6 in. The eentre of the instrument is marked with zero, and we find from the table that 0·500 must be plaeed at $6 \times 0{\cdot}280$ in. from the centre on both sides of the eentre. Similarly, other points of the scale are found by means of the table. The scale on both sides of zero is symmetrical. The distances between the points so found are subdivided into equal parts. This is not absolutely neeessary, but it is convenient.

The movable seale (see Fig. 3) is attaehed to the upper edge of the taper diaphragm, which is used for reducing the amount of light admitted through the reetangular opening. This taper diaphragm is made of sheet metal about 12 in. long and 2 in. wide, out of which is eut a triangular opening about 10½ in. in length from base to apex, the width of the base being ½ in. It is essential that the sides of this triangle be absolutely straight lines. The scale attached to this taper diaphragm is constructed as follows: From the apex we measure 10 ins. exactly towards the base; this gives the zero point of the scale. The other points of the scale are marked so as to read directly the densities. At any distance x from the apex the area of the opening, and with it the intensity of the light, will be reduced as 10 : x, and the vulgar logarithm of the fraction $\frac{10}{x}$ is the corresponding density with whieh the seale is marked. For convenienee we append table showing the distances from the apex at which the figures 0·1, 0·2, 0·3, &e., are to be placed:—

Table II.—Movable Scale.

Value of Log. $\frac{10}{x}$.	Distance from Apex.	Value of Log. $\frac{10}{x}$.	Distance from Apex.
	Inches.		Inches.
·00	10	0·50	3·16
·05	8·91	0·60	2·51
·10	7·94	0·70	2·00
·20	6·31	0·80	1·58
·30	5·01	0·90	1·28
·40	4·00	1·00	1·00

Intermediate points are obtained by subdivision into equal parts.

An index is fixed to the inside of the box over the centre of the rectangular diaphragm, pointing to the num-

ber to be read. The figures 1 and 2 will help to make this description clearer.

Two examples will show how the instrument is used.

1. When measuring a small density we move the sliding scale to zero, and the disc chamber to such a position that the images of the Bunsen disc are alike. We then insert the plate to be measured, and, without altering the position of the disc chamber, slide the movable scale until equality is restored. The density will then be indicated by the fixed index on the diaphragm scale.

2. In the case of a high density we place the sliding scale to 0, and by placing a piece of opal glass outside the box, between it and the lamp, we reduce the light on the right-hand side until the disc chamber requires to be moved almost up to the right-hand end of the box in order to secure equality of the images. If necessary, we move the lamp further away. When equality is thus secured, we read the number below the index of the disc chamber on the fixed scale. We then insert the plate to be measured, and move the disc chamber to the left until equality is again restored. If that cannot be done by the movement of the disc chamber alone, it can be obtained by using the movable scale in addition.

Suppose the index stood at 1·100 on the right, and afterwards at 1·55 on the left of zero, then the density would be $1{\cdot}100 + 1{\cdot}55 = 2{\cdot}65$.

If the index stood at 1·10 to the right and afterwards at 1·7 to the left, and equality could then only be restored by using the movable scale as well, and its index pointed to ·75, then the density would be $1{\cdot}10 + 1{\cdot}7 + 0{\cdot}75 = 3{\cdot}55$. Higher numbers than 3·55 do not occur in ordinary negatives. A plate, the density of which is 3·55, only transmits $_3{}^1{}_{4\,5}$th part of the light it receives.

The general rule for finding the density is: Consider the numbers to the right of zero as negative numbers, those to the left as positive. Subtract the first reading from the second; the result is the density. If the movable scale be used as well, the amount it indicates must be added.

With this instrument we have obtained fairly accurate results. Analyses of mixtures of Indian ink and water, indigo solution and water, and of many other substances have been made by it. The following analyses are given to show the capabilities of the instrument:—

1. Experiment with Indian ink.—An Indian ink solution was mixed with water in known proportions, and the density of one solution being known, that of the others was calculated. The following table shows the observed and calculated densities. The calculated density is simply proportioual to the amount of Indian ink employed

Table III.—Experiment with Indian Ink.

Indian Ink employed to 100 c.c. of Water.	Density calculated.	Density found.	c.c. of Indian Ink found.
c.c.			
5	·240	·240	5·00
10	·480	·500	10·42
15	·720	·750	15·62
20	·960	·950	19·80
25	1·200	1·245	25·90
30	1·440	1·440	30·0
35	1·680	1·665	34·7
40	1·920	1·885	39·3

The greatest error made does not reach 4 per cent. of the total amount, and even better results can be obtained if more than one reading be taken. But this accuracy is quite sufficient for photographic purposes, where, from other causes, still greater errors are liable to arise, as will presently be shown.

Sometimes, when using the instrument for analysing solutions of coloured salts, a peculiar difficulty arises from the different colours of the two images of the Bunsen disc. This is easily overcome by viewing the disc through appropriately coloured glass, red, green, and blue glasses being the most useful. The following experiment with indigo solution is representative of one of the most difficult, since dark blue glass was used to view the disc.

Table IV.—Indigo Solution.

Indigo Solution Employed.	Indigo found.	Density calculated.	Density found.
c.c.	c.c.		
100	96·0	1·554	1·487
50	50·6	·777	·787
25	24·1	·388	·375
10	10·0	·155	·155

It will be seen again that the results are only accurate within five per cent. of their value.

With regard to the lamps, they should be powerful petroleum lamps with duplex burners. The flames should be in planes at right angles to the axis of the instrument. Very erroneous results are obtained if Argand burners are used. The lamps should be placed close to the diaphragms, and it is advisable to provide a small stage outside the diaphragm, to hold coloured glasses when a substance requires investigation in light of a particular colour. Captain Abney has also devised an instrument for measuring transparencies. His instrument consists of a Rumford shadow photometer as indicator, and of a revolving sector, which can be closed or opened whilst revolving, as a measure of the transparency. Apart from the fact that a Bunsen disc is more sensitive than the shadows, there is a fallacy in the assumption that the amount of light which passes through a revolving sector is proportional to the angle to which the sector is opened. Experiments made for the purpose show that the amount of light passing through a revolving sector is more correctly represented by a formula—

$$T_x = T\,\frac{\phi}{360} + C,$$

where T_x is the light transmitted by the sector, T the intensity falling upon the sector, ϕ the angle of opening, and C a constant, which depends upon the relative position of the lamp, the sector, and the screen, and is, in fact, due to the semi-shadow on both edges of the sector openings. The error caused by this constant is small with plates of low density, but it rises to over 100 per cent. with plates of high densities, which renders the results utterly untrustworthy.

We have thought it necessary to give this lengthy description of our instrument, since we consider it a very important one; it is for photographic experiments as indispensable as the balance is in analysis. The instrument is capable of other applications; its indications can always be translated into weights by simply multiplying them with a factor. It is, therefore, capable of applications in analysis.

(*To be continued.*)

ROYAL CORNWALL POLYTECHNIC SOCIETY.

The following is the list of awards in the Photographic department:—

Professional.—1st Silver Medal—L. Sawyer, R. H. Lord, W. W. Winter; 2nd Silver—W. J. Byrne; 1st Bronze—T. Protheroe, T. G. Whaite, H. W. Reeves, R. Keene, T. Whalley, R. W. Robinson.

Amateur.—1st Bronze Medal—W. W. Fry, A. G. Tagliferro, Rev. H. B. Hare, A. K. Dresser, J. W. Charlesworth, H. D. Arnott.

Honourable Mention—R. W. Robinson, York and Sons; S. W. Bhedwar.

RULES OF LIGHTING.

BY H. EDWARDS FICKEN.

Hard and fast rules, formulated but from one point of view, will inevitably produce hard and fast effects; nor will isolated passages from the writings of the old masters, bearing but upon the production of *certain* effects in *certain* directions, prove anything else.

In the review of "The Lighting in Photographic Studios," given in a recent number of the *Photographic Times* (No. 448, p. 184), occurs the following paragraph, taken from the first chapter of the book: "The illumination of the face being the main object in portraiture, every other light should be subordinate to it, and no light should surpass or equal it in brightness."

There is not an artist who would not, on purely artistic grounds, take strong exception to this hard and fast statement set down as a rule. It is simply mischievous, and altogether bad and misleading. There is not an artist who has ever painted a portrait who would not laugh at it. The reference to artists is only made as the chapter quoted, and from which the above paragraph is taken, constantly refers to artists and their work.

All artists hold the colour of the flesh as a distinct tone—distinctly lower than the greatest lights in their paintings. A knowledge of the works of our best modern portrait painters—and modern work is only suggested as the more accessible for study—will prove this without question.

Take Alma Tadema, Herkomer, Sargent, Chase, Beckwith, and others as well known, and you will find their backgrounds, their accessories, their details of costume, painted in higher and more brilliant tones than the flesh, and their work is the work of master hands, and founded upon the truest insight into nature, and the truest study of art.

The face is never the highest light in nature, and to portray it so in photography is to portray a photographic untruth. It is the restless striving to produce too much lighting, too much shading, too much modelling, that mars the usual photograph of the face, and irritates the artistic judgment.

No better illustration of the highest results artistically to be obtained in photographic portraiture could be given, in its combination of the brush and the camera, than two photographs taken some two or three years ago by Mr. Kurtz from the original paintings—one of a young Vanderbilt, painted by Cabanel, and the other by Mr. Walters, of Baltimore, painted by Bonnat. The paintings were masterpieces, and the photographs of them, taken on orthochromatic plates, were photographic masterpieces, the schemes of colour being perfectly preserved. Each photograph seemed to be from life—in this lies the moral—and no better tribute could be paid the painter.

In the case of the young Vanderbilt, the background and the accessories—the costume was that of a young cavalier—were all in a *lighter* key than the flesh tones. In Mr. Walters' portrait the dress was the modern frock-coat, but the colour showing above and the cuffs over the wrists were *white*, the flesh tones being quite intermediate.

There was but little attempt at "modelling" in the face of the boy, yet it was full of expression. In the man's portrait the face was full of deep shadow, and the white hair and shaggy eyebrows quite subordinate to other and higher lights.

Both pictures—and the photographs alone are referred to—were notable in all ways, and especially for study and example—for the study and example that will do more a thousand times for the student than hard and fast rules that are as jingling emptinesses in the presence of nature.

If photography seeks to follow in the footsteps of art, it should free itself from the limitations of lighting in portraiture imposed by the narrow confines of skylights and reflecting screens. Were more study given to simplicity in lighting, the more successful would be the average portrait. This is exactly the study of the painter—*simplicity* in his methods.

Why does the amateur often beat the professional? Because he is backed with more artistic judgment, and, freed from the conventions of the skylight, works with the greater simplicity. What has made the artistic success of the Messrs. Cox? Nothing but this. What has led Sarony nowadays to discard backgrounds and bric-a-brac altogether?

Mr. Duchochois quotes Da Vinci in relation to light and shade: but what value has the reference in the light of modern methods, and the wider, sounder, and better equipped knowledge of art to-day? Every picture gallery, every collection of connoiseurs, contains masterpieces of genre painting without a single cast shadow. The very narrowness of education, of vision, of surroundings of the old masters, effected by the confines of their times, produced their hard and fast effects under the hard and fast rules of circumscribed and purely conventional schools. Some did rise above their fellows and their time in occasional greater freedom from conventional method, and these to-day remain cherished—cherished as "old masters," but no longer held up to the student for more than study of generally what to avoid.

The student of to-day must study the modern master, working in his greater knowledge of perspective and the laws of atmospheric condition governing it, as he works with his brighter palette, with its modern extended range of colour, working in his greater insight of nature's moods and harmonies in his drawing upon nature itself for his inspiration.—*Photographic Times.*

The *Wiener Allgemeine Zeitung* (weekly), of which several sample copies are forwarded, has opened a photographic column. Several articles on "Amateur Photography" have appeared over the signature "E.K.," followed in some cases by answers to correspondents and brief notices of books.

Our Egg Supply.—In a return which has been published, it is stated that our egg imports increased from 123 millions in 1853 to 757 millions in 1881. The imports were 1,090,089,240 eggs, valued at £3,085,681, in 1887; 1,126,792,680 eggs, worth £3,083,167, in 1888; and 1,129,796,680 eggs, valued at £3,122,813, in 1889.

Specifications Published.

15,451. *October 2nd*, 1889.—"Preventing Second Exposures." GEORGE RENWICK, 20, Station Street, Burton-on-Trent, Staffordshire, Photographer.

This invention consists of the herein described improvements in connection with photographic dark slides, by which the operator can tell whether the plate has been exposed or not, and which will prevent the dark slide shutter being accidentally withdrawn to expose the plate a second time.

For the purposes of my invention, I provide a lever-catch which is pivoted near one end to a base plate fixed to the dark slide frame near the open end of the rabbet in which the shutter fits. A suitable spring acts upon this lever-catch, and forces its free end towards the shutter, so that it will engage with a projection on the shutter, and thus lock the shutter in its closed position. This projection may be the end of the tongue on the shutter which fits in the rabbet. Fixed to the shutter adjacent to the free end of the lever-catch is a peg or hook, and on the said lever-catch, and preferably at or near the free end thereof, is a projection corresponding with the said pin or hook.

The parts above described operate as follows: When an unexposed plate is in the dark slide frame the operator, just before closing the shutter, pushes the lever-catch sideways, so that when the slide is pushed home, the pin or hook on the shutter will come into contact with the said projection on the lever, and prevent the lever engaging with the shutter, thus leaving the shutter free to be withdrawn to expose the plate. On withdrawing the shutter to expose the plate, the said pin, or hook, on the shutter, being withdrawn from the projection on the lever, allows the lever to spring against the shutter, so that when the plate has been exposed, and the shutter again pushed home, the said projection on the lever will be free of the pin or hook on the shutter, and the lever-catch will engage with and lock the shutter. As the shutter cannot be withdrawn without the operator first pushing the lever-catch sideways to unlock it from the shutter, the operator knows that the plate has been exposed, and its accidental exposure a second time is thus prevented.

15,530. *October 3rd*, 1889.—"Camera Stands." ROBERT WILLIAM BOYD, Fairbank, Caterham, Surrey, Merchant; HENRY SUTTON NOBLETT, Ashton Place, Cork, Ireland, Gentleman; FRANK THOMAS CANTLE, 4, Shepherd's Bush Road, Shepherd's Bush, London, Electrician.

Our invention relates to the portable class of camera stands, and is constructed so that while having the advantages of the ordinary stand, it can be closed up into the form of a walking-stick, or staff, and is fitted with special arrangements for facilitating the movement of the camera, also for keeping the stand rigid, and for raising or lowering; and to carry out our invention, we make the legs of the staud preferably of a shape so that in section they would (if three legs are used) be each one-third of a circle, or (if four legs are used) one-fourth of a circle, so that when closed they appear as one stick; the bottom ends of these legs are provided with spikes to prevent slipping when in use; on the upper part of the fitting of these spikes is a part of a screw thread, which forms a complete thread when the three, or four, are closed together, and a ferrule is provided to screw over the spikes on to this screw, which protects them, and also keeps the lower ends together when the stand is being carried: a bayonet or other suitable joint may be used in place of this screw. The upper part of each leg is hinged to a top fitting which carries a screw socket into which a ball is fitted, which ball has a screw projection to screw into a plate, or other fitting, on the bottom of the camera; the screw socket is made for this ball to fit into loosely and screw down over the ball to fix it in any desired position, thus forming an ordinary ball-and-socket joint.

The periphery of the top fitting is provided with a screw, and a hollow knob is provided to fit over the ball-and-socket joint, and screw to this screw, thus forming, when closed, and with bottom ferrule attached, a walking-stick; or, instead of a knob, a crooked or other suitable shaped handle may be used to screw on in a similar manner, or a bayonet joint may be used instead of a screw. This stand may be made the length of an ordinary walking-stick, or, if desired longer, can be made of any suitable length and form a staff. If the stand is required to be adjustable in height, we construct the legs so that when closed there is a hollow space down the centre, and in this centre space we fit a tube connected to the top fitting; in this case the ball-and-socket is attached to a rod which is made to slide down through the top fitting into this centre tube, and this rod may be raised to any desired height and fixed in position by a set screw or other suitable means.

To make the stand more rigid we attach ribs to the inner side of each of the legs, and these ribs are fastened to a collar running on the central tube; one or more of these sets of ribs may be used; preferably two sets are used, one set at or near the bottom to keep the legs extended, and one set at or near the centre, made somewhat shorter than the actual distance between the centre tube and the legs, so that they will spring the legs slightly in, and thus prevent all vibration. Various modifications may be made, and any suitable materials may be used, always preserving the essential features of our invention, which are a portable camera stand, made and fitted with the supplementary parts, as herein described.

3,736. *March 10th*, 1890.—"Stand for Use in Enlarging." JAMES CHAPMAN SHENSTONE, 13, High Street, Colchester, Essex, Chemist and Druggist.

The material used from preference is white pine wood. It consists of a rectangular platform on which to stand the lamp, the height of which can be made such as to bring the lamp to a convenient height, and with a base for a camera adjusted to the front and on the top of and square with the platform, by studs or suitable screws. This base can be made of such a size and height to bring the camera into a convenient position. A horizontal slot in front and back of the platform receives a flat rod of wood of sufficient length gauged to move steadily through the slots of the platform, and always parallel to the axis of the camera. At the distance end of the rod is fixed a bracket to hold a board or picture at right angles to the rod, and parallel to the end of the camera base and platform.

This bracket may be hinged, so that it can be laid flat upon the rod for convenience in putting away when not in use, and can readily be raised and fixed into its proper position by a thumbscrew at the back. The top surface of the rod has a shallow slot along its centre, in which is a scale in feet, and inches, and centimetres, whereby to note the focal distance for facility and accuracy in taking duplicate copies or enlargements.

THE Berlin *Photo-Nachrichten* grows enthusiastic over a beautiful zinc etching by Mr. Kurtz, recently published. It says: "It shows a wonderful clearness and fineness of light, and has an entirely individual quality. This is the process of the future for illustration."

Correspondence.

HACKNEY PHOTOGRAPHIC SOCIETY.

Sir,—Below is our programme for September, 1890:—6th—Excursion to Broxbourne (train leaves Liverpool Street at 2.15); 11th—"'Silver' and 'Obernetter' Toning," Messrs. H. J. Beasley and A. Barker; 25th—"Shutters," Mr. W. L. Barker.

The Council has decided to withdraw Class F, and the Championship award will be made to the best picture in the Exhibition, without any special fee or classification.

W. Fenton Jones, *Hon. Sec.*

12, *King Edward Road, Hackney, London, N.E.*

THE CAMERA CLUB AND TRADING IN PHOTOGRAPHY.

Sir,—Having only just returned from a short visit to the Continent, it was but to-day that I read the last two numbers of the Photographic News. In each number there is an "editorial" criticising an action of the Camera Club. As mine is the firm referred to, it may make matters a little clearer if you will allow me to state the following.

About eighteen months ago, hearing that the Club was to have new premises with a shop on the ground floor, I wrote to Mr. George Davison, asking him for the first refusal of the lease of the shop, as I thought about taking a West-End branch. Our business has now grown so rapidly and extensively, that we find additional premises necessary, and even imperative. We are taking them on a seven, fourteen, or twenty-one years' lease, the seven to be terminable at our option only, and not that of the Club.

As to your remark about rent, it probably may be excessive, but that is, of course, a matter entirely for our own consideration. There is no occasion for us to be in any way dissatisfied with the treatment of the Camera Club, and we neither ask for nor expect trade at their hands merely because we are their tenants, but fully hope that by catering in our usual prompt and general business-like manner, to deserve not only the patronage of the Club's members, but of the photographic public generally.

Pro Adams & Co.

81, *Aldersgate Street, London, E.C.* Arthur L. Adams.

SPHERICAL ABERRATION AND TREATMENT OF SUBJECTS BY FOCUS.

Sir,—I did not ask Mr. Debenham to criticise my style of writing. Mr. Burton and I correspond privately, and if we disagree on any subject, we agree to be perfectly free to use expressions which we consider honest. Mr. Burton has *said* that I have been wrong, and I have *proved* him to be wrong.

As Mr. Debenham does not *yet* seem to understand this subject, I will ask you, Sir, to allow me to reproduce the diagram by Grubb that you have reproduced before, and another one which I shall furnish you with, *correctly disposed*, in order that, placing the two together, I may repeat distinctly and concisely the advantages that exist by the introduction of spherical aberration as regards improvement in out-of-focus planes.

Th. R. Dallmeyer.

25, *Newman Street, London, W., 26th August*, 1890.

The Photographic Club.—Subject for discussion on Wednesday, September 3rd, "Supplementary Exposure;" September 10th, "On Modifying Lenses."

Chained Up.—A photographic newspaper printed in Coventry, a few days ago said about our criticisms on the wisdom of having a photographic shop on the Camera Club premises:—"The Photographic News has found a mare's nest, and built up a couple of two-column articles upon it." As the said journal publicly parades the names of leading members of the Camera Club every week as its chief writers, it is unlikely to give offence to its chief patrons by ever criticising the Camera Club adversely, and may be assumed to object to any free discussion as to whether anything is strongly under the thumbs of members of the Club.

Proceedings of Societies.

Photographic Society of Great Britain.

At the technical meeting of this Society held on Tuesday evening last, the 26th inst., Mr. W. England occupied the chair.

A set of photographs of microscopic sections of marl-stone and of chalk-bearing foraminifera was shown by Mr. T. E. Freshwater. He had preferred to use a low power on account of the field then being flatter, and obtained size by a long extension of the camera. The magnification was about 250 diameters.

Some prints sent by Mr. O. Schölzig to illustrate the advantage of printing through green glass were submitted to the meeting, and a letter accompanying them was read by the Chairman. In the letter it was stated that prints made in this manner readily toned to a good black colour, and that thus they were a perfect substitute for the expensive and troublesome platinum process.

Mr. W. E. Debenham said these prints might and did resemble platinum prints in colour, and so might matt-surface prints without green glass, but that to be a perfect substitute for platinum they should be equally permanent. The effect of printing under green glass he had found was to cause toning to take place much more quickly, and thus black prints were easily obtained. It also lessened the contrasts, and so was useful for printing such negatives as, in the ordinary way, were so dense as to lose in printing the details in the high lights and deep shadows. With negatives wanting in contrast it had consequently proved injurious. As ready-sensitised paper was generally more difficult to tone than that prepared at home, the facility of getting a black tone when using green glass was an advantage of more consequence than with home-sensitised paper.

Mr. Scamell had found that the ready-sensitised paper did not tone with at all the same facility as that prepared at home.

A print on gelatino-chloride paper sent by a Dutch firm was submitted to the members.

A number of views of the cyclists' camp, and some taken at a recent photographic outing, were shown by Mr. Chang.

It was announced that the next technical meeting of the Society would be held on the 30th of September, the fifth Tuesday of the month instead of the fourth Tuesday, as is customary.

London and Provincial Photographic Association.

August 21st.—Mr. A. Haddon in the chair.

A question was asked if any advantage was gained by using an old toning bath in preference to a new one?

Mr. W. E. Debenham said that he always used an old bath; he believed it worked better.

Several members thought that an old toning bath had no advantage whatever, and that after a time its composition could only be a matter of speculation.

The subject for discussion was "Cloud Negatives." This was opened by Mr. J. S. Teape, who said that he used slow landscape plates, the lens being well stopped down. In developing, he recommended using a full proportion of bromide and very little alkali. Clouds could be printed artificially by applying colour to the back of a thin, or reducing parts of the sky of a dense, negative, or holding the negative over the smoke from a lamp. Mr. Teape exhibited a variety of prints and negatives of clouds.

Mr. T. E. Freshwater found a difficulty in getting sufficient contrast between a blue sky and white clouds.

The Chairman suggested reflecting the clouds at an angle on a piece of plain glass.

The Hon. Secretary said that excellent results in cloud pictures could be obtained with isochromatic plates; he had used these plates with very great advantage.

Mr. Atkins thought that Nicol's prism might be found useful in photographing clouds.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.

THE last half-day excursion took place on Saturday last to Lichfield, under the leadership of Mr. A. J. Leeson. The light of the afternoon was excellent for photography, and considerably over one hundred negatives were taken by the party, which was the largest this season. The cathedral—interior and exterior—made some charming architectural pictures, while St. Chad's church, and some old picturesque cottages near the reservoirs, together with a very fine rainbow, which about a dozen members attempted to take, gave sufficient employment till the shades of night came on.

THE BATH PHOTOGRAPHIC SOCIETY.

LAST Thursday's outing of the members was well attended, notwithstanding the threatening aspect of the sky. The excursion party left the city in a brake, taking the Wells Road, through picturesque Midford, to Norton St. Philip. Upon arrival at Norton nearly a score of cameras was quickly ranged in line for views of the quaint "Old George Inn," an ancient hostelry said to have sheltered Charles one night and Cromwell the next when on the war path. Having visited the church and exposed plates on the village surroundings, a start was made for Bradford-on-Avon, a cloth manufacturing town of some 7,000 inhabitants. Farleigh Castle was passed upon the road. The "Swan Hotel," Bradford, was reached in due course, and a move at once made for the Duke's or Kingston House, a splendid mansion erected in the 17th century for the Duke of Kingston. Mr. Fred Shum, F.S.A., in a paper read before the Archæological Society, describes the style of the buildings as transitional, between the old Tudor and Palladian. The front, facing south, is divided into two stories, with atties in the gables. The windows are in beautiful proportion with the stone mullions, and at first sight appear to cover the whole front. The present owner received the party, and gave every facility to photograph within and without his premises.

At Belcombe Brook the party and some other subjects were photographed; but owing to the approaching twilight no work was attempted within these picturesque grounds.

WHY A SITTER COULDN'T LOOK PLEASANT.—"A man trips over his own cleverness now and then," said Max Platz in the *Chicago Mail*. "You know that when people are sitting for pictures they are given an object to keep their eyes fixed on, don't you; that this object is usually a photograph fixed in a clasp at the top of a stick, which may be raised or lowered to suit the case. Usually there are two photographs back to back—one the picture of a gentleman and the other the likeness of a lady; if the sitter is a gentleman he is given the *charmante dame* to rest his eyes on; if a lady, the gentleman's photograph is turned to meet her gaze. The other day a charming young society lady was sitting for a picture. I had her all posed and told her to look at the object indicated and look pleasant; she complied by looking savage enough to fight a dog. I didn't say anything. Its no use, you know. Besides, the plate was spoiled; so I slipped in another and gave her a slightly different attitude, and ventured a bit of time-tried and fire-tested wit in order to make her look sweet as I called her attention to the object picture and pulled the string. Same as before—a scowl that nearly broke the plate. Once more, and a funny story thrown in. No good. Still another, with a neat bit of flattery at the critical moment. Worse and worse! Four plates spoiled. Finally I said: 'Had a death in the family?' 'No,' she said. 'Lost a pet dog?' 'No.' 'Had a quarrel with anybody?' 'No.' 'Well, then, please look pleasant,' and I drew her gaze to the aforesaid picture. 'Must I look at that?' she asked. I told her she must. 'And look pleasant?' she enquired. 'Yes,' I said. 'I can't,' she remarked quietly but firmly. I looked at the photograph to which I had been directing her gaze. It was a picture of myself. The joke was on me."

W. D.—The matter you write about in *ex parte* form is more within the functions of the law or police to take up than it is within the functions of a newspaper, especially as we know neither of the parties to the case.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

FERRIC OXIDE.—*Photography in Natural Colours.* There is literally nothing new since the Editor reviewed the present state of our knowledge on this subject in an article of fourteen pages in the YEAR-BOOK.

ARISTOTYPE.—*Difficulty in Toning.* We share your opinion, having lately been troubled in the same way. One sample of gelatino-chloride paper refused to tone either in the borax and gold, sulphocyanide, or compound hypo bath. Although Dr. Liesegang's name is marked on the packet, there is no guarantee that it was actually made by him. The finished prints were all of a foxy yellow tint, and nothing would change them to a more agreeable colour. The film is always tender, and becomes especially so after long soaking.

W. L. B.—*Isochromatic Plates.* It is hardly worth while attempting to prepare them for yourself, for the colouring matter, whether azaline or erythrosine, ought to be put into the emulsion. Mr. Pringle has, however, succeeded by bathing the plates, and all authorities agree in advocating the very sparing use of colour, so as not to injure the sensitiveness.

X. Y. Z.—*Ruling Prices.* We can hardly advise you on this point, so much depending on the locality and other circumstances. Offer a good thing, and the public will pay for it. Remember, it is easier to reduce than to raise your scale of prices.

S. P.—*Collotype.* Dr. Gunther sends the following information:—1. "Thick *gelatine*" (page 608, line 28 from bottom) is misprinted; it should be printed "thick *glycerine*." 2. By the "*short damping process*" is understood the treatment of the printing plate with the etching fluid *just before fixing it to the press.* After printing under the negative in the printing frame the plate is, of course, *thoroughly* washed in the usual manner to remove the excess of bichromate. The method of damping or etching described on page 608 serves more especially in cases where a collotype plate has to be prepared from a rather *over-exposed* and *dense* negative, where the impression would turn out too hard in printing if the plate were damped sufficiently. In the case of a normal negative the plate may be damped for half-an-hour.

C. N. W.—*Travellers' Damage.* One of the railway companies may be responsible; but there will be a difficulty in proving your case when two lines have been traversed, and a short sea-trip forms part of the journey.

L. T.—*Instantaneous Shutter.* Choose the first-named, for it is actuated by a steel spring, which is less likely to get out of order than the elastic band arrangement of constantly varying tension used in the latter.

F. C. S.—*Nickel as an Illuminant.* One of the most astounding discoveries in modern chemical science has just been announced by Messrs. Mond, Langer, and Quincke. It is the formation of a *volatile* compound of nickel with carbon monoxide, $Ni(CO)_4$, the vapour of which burns with a "highly luminous flame," that may some day find application as a photographic illuminant. A porous quality of metallic nickel is first prepared by passing hydrogen over oxide of nickel heated to 400° C.; a slow current of carbonic oxide gas, CO, is then substituted for the hydrogen, and when the temperature cools to about 100° C., or lower, the new body is formed, and passes forward diffused in the excess of the before-mentioned gas, communicating to it the property of burning at a Bunsen jet with great brilliancy. Such a flame, being free from the disadvantages of the chloroehromic light in regard to the absence of acid fumes, may be expected to lend itself to many practical applications, and, amongst them, to serve the purpose already indicated. It likewise reduces an ammoniacal solution of chloride of silver to the metallic state. For further details, see the current number of the *Chemical News.*

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1670.—*September* 5, 1890.

CONTENTS.

IN THE SUN'S EYE.

MOST of the photographic instruction books—and they are happily numerous—in giving the tyro directions by which he can select the best point of view for his first attempts, strenuously urge him to so place his camera that the sun is either at one side or behind the instrument; and they are certainly right, for were the beginner to face Father Sol he would speedily get launched into all kinds of difficulties, from which he would not know how to deliver himself. But with the practised hand it is different, and some of the most beautiful natural effects can be secured by the man who is bold enough to aim his lens "in the sun's eye." This phrase is allowable, we think; and in the same sense in which a mariner speaks of "the wind's eye," we may write of the sun. Anyway, we mean by the term pointing the camera more or less directly towards the sun, so that shadows are cast toward the camera.

Some of the old workers were certainly fond of this method of treating a view. One we may name in particular, whose pictures made a very great sensation some forty years ago. They were mostly seascapes, and consisted chiefly of broad effects of light and shade, and were the nearest approach to instantaneous work before the days of gelatine. A few of these photographs by Breeze are still extant, and they represent good work, considering the difficulties inherent to the old processes. They are, besides, excellent examples of cleverly combined negatives, some of the views being due to patient building up of three or four pictures. Another worker who delighted in looking into the sun's eye was Colonel Stuart Wortley, who produced some excellent seascapes of large size, and who generally, after the manner of Breeze, secured an effect of sunlit ripples and illuminated sky, which were wonderfully effective.

It is, indeed, impossible to secure certain effects unless the camera is placed so that its lens points towards the sun, and there is no reason why this position should not be adopted if sufficient precautions are taken to prevent the sun's rays actually entering the hood of the lens. Old stagers know well how to secure this end, and will carry with them a short funnel lined with black velvet, or a piece of card to project above the camera, which, with the focussing cloth adjusted round it to make a kind of hood, answers every purpose. As a makeshift, the hat is sometimes used as a lens shade, but here there is always a risk of part of the obstruction intruding into the picture, for at the supreme moment of timing the exposure one is apt to let the hat down a little too low, and the picture is probably spoilt.

Taking the precaution named, pictures may be taken in the direction of the sun without any great difficulty, and sometimes with very great advantage. Of marine pictures this is especially true, for it is obvious that those lovely reflections which sparkle in the sea like diamonds cannot be reproduced under any other conditions. The same remark is true of the lovely line of light that touches every ripple as its curve is bent towards the sky. But it is, perhaps, in broad effects of sea and sky that the advantage of aiming towards the sun becomes most apparent. Suppose, for instance, that one is standing upon the Admiralty Pier at Dover, a position from which the grandest effects are obtainable. It is afternoon, and the sun is sinking towards Shakespeare's Cliff, and rendering every wave, as it dashes towards the pier, semi-transparent. There is a sky which is just cloudy enough to cast lights and shadows alternately upon the sea, and we take advantage of a temporary eclipse of the sun by one of these clouds to focus a general view of cliff and sky. There is a steamer at anchor about half a mile away, and one or two black buoys which usefully break the surface of the water. The wind is bringing the clouds directly towards the camera, and they seem one after the other to lift themselves up above the sun like so many curtains, to let its light flood the sea below. Such a flood of light is now creeping towards us, and is gradually changing the waves into molten silver. The light has crept to the big cliff, and is slowly approaching us. Now it has got as far as the steamer; in another

moment it will be at the pier; but before it has time to come upon us, we squeeze the pneumatic ball, and the picture is taken. And then comes the sun over everything, lighting up pier and shipping with its genial rays. An amateur photographer passes, and, glancing at our camera, from which we are removing the dark slide, gives a contemptuous laugh, and says to his friend, "No good taking a view in that blaze of light." But the picture which we secured was a gem, after all, for it secured a lovely effect, and one which may not readily occur again.

One more instance where working "in the sun's eye" brought its reward occurs to us, and this time it was not a sea view. We were in a harvest field, about six o'clock on a July evening, and the sun was, of course, both low and feeble in actinic power. A picturesque gate was before us, and beyond this a deeply rutted path led to meadows bounded by trees. These trees were in a mist of yellow light, and every ridge in the ground was lighted up almost as if it had been a ripple on water. A labourer with tools slung on his back came through the gate, and we begged him to pause there for one moment while we took a picture. This was most successful, and the shadows of the five-barred gate striking downwards in irregular ribbons tell the observer that it was taken "in the sun's eye."

TOURIST PHOTOGRAPHERS AND THE CHANNEL PASSAGES.

IV.

CALAIS, from the sea, is absolutely uninteresting from a photographic point of view: at first sight a few spires and factory chimnies are seen rising apparently from the water, but as the steamboat draws nearer, a low sandy beach comes into sight. The town is on a flat area of land, but to the west and stretching away to Cape Grisnez are hills and seaside cliffs; some three or four miles west of Calais, on the top of one of the cliffs, may be seen the buildings connected with the Channel Tunnel works, now at a standstill. Some years ago we descended from these works into so much as has been made of the tunnel on the French side; more water gets into the tunnel there than on the English side. Cape Grisnez is the nearest point of France to England, and at different times the project has been mooted and abandoned of constructing a harbour there. In the first place, only three or four miles of sea voyage would be saved; in the second, the sea deepens rapidly there under the cliffs, and has a bottom composed of broken rocks, so that the expense of making a good harbour there would be immense; in the third place, there is no town near, and in the fourth place, a considerable length of railway would have to be made to join the existing line near Boulogne.

Although an exceptional case has been published to the contrary, no objection is likely to be made to anyone taking photographs at and about the marine railway station at Calais, provided that subjects are selected in full view from thronged public thoroughfares; at the worst, the photographer might but be told to pack up his apparatus and walk. If, however, he selected an unusual point of view, and then tried to take the exterior or the interior of some of the forts, he would in all probability be locked up. There are five detectives in plain clothes constantly on duty at the marine railway station at Calais, and they are chiefly on the look-out for political offenders, for whose apprehension they have a considerable stock of warrants on the premises. Sometimes they witness the arrival of one for whose apprehension they have no warrant; from that moment he is watched, and a telegram about his landing is sent to Paris; when he reaches there, he has plenty of unseen friends who are able thenceforth to give a full account of his movements.

Within the last eight or ten years immense improvements have been made in the port of Calais, so that its aspect is greatly changed. Neither the French Government nor Calais cares much for the little trade brought by steamboat passengers, who almost invariably pass through without stopping in the town. The chief idea is to divert some of the trade of the great city of Antwerp by saving ships a voyage farther up the Channel, thus obtaining extra goods traffic for French railways and canals. Perhaps, also, it is thought that the new harbour may be of use in times of war. Some of the larger harbour-improvement works at Calais are not seen by passengers passing close to them; for instance, if they mount the low bank behind the railway station, they will find themselves on the edge of an immense artificial reservoir, or rather lake, not yet in use, but intended to take in water as the tide rises; at low water the sluices will be opened, and the outflow of this great body of water is expected to sweep a deep passage through the sand-bank off the mouth of the harbour. Should it do so, a gale of two or three days from the north-east will pile up the sand again, just as it now undoes the work effected by the dredging boats. Calais can never be a first-rate harbour until a sea-wall is run out to the north-east to prevent the sand getting back again. The old picturesque fortifications of Calais have been pulled down, with the exception of two or three of the towers and gateways, and these are well worth photographing. A great desire existed not to destroy the ancient fortifications, but they covered an extensive area of ground of high commercial value for utilitarian purposes. New fortifications, about six miles long, have been constructed all round Calais and its suburb of St. Pierre; the latter is larger than Calais itself, and is one of the great seats of the lace industry of France. One of the chief lace manufacturers there is M. Darquier, President of the Calais Chamber of Commerce; he is also the Consul of several foreign nations, and is highly popular in the town. Calais altogether is a great place, and not a kind of dirty little fishing village, as ordinarily described in guide books, and as believed by most tourists, for they can see little of St. Pierre as they pass through in the

train. Still, it is not an attractive place to a stranger, and may, perhaps, hereafter improve in its general appearance and in its average quality of hotel accommodation. There are few photographers in it; one of them, M. Landouzy, of the Grand Rue, St. Pierre, is always sent for by the authorities when any photographing of parts of the new harbour works is required; he is, therefore, the best man to go to for pictures thereof.

The new and fine Central railway station at Calais was opened a year ago; at the present time men are glazing the roof. The old railway station, so well known to many of the readers of these pages, is now used as a goods station only; it is in a deplorable condition; all its glory has departed. Its roof is falling in, and grass is growing freely between the rails outside the building. The place, nevertheless, in its main features is as of yore, and is worth photographing for the sake of old acquaintance. The old harbour adjoining is now used for cargo vessels and petroleum vessels, but not for passenger traffic.

When the new harbour works were in full progress, we went over them with Mr. Vertillard, their chief engineer, who narrated an interesting scientific fact discovered during their construction. Piles, in vast numbers, had to be driven into the sand, but, shoe them with iron or shoe them with steel, all efforts were in vain; their ends would get blunted like carrots, but no power could drive them into dry sand. Some genius, whose name we forget, made an arrangement whereby water was caused to constantly trickle down each pile, so as to wet the sand immediately under the shoe; the piles could then be driven with ease. Mr. Vertillard was then a comparatively young man to be entrusted with the command of such a great undertaking, but his abilities were equal to the task; he is now chief engineer to the whole district, and resides at Boulogne.

Recent statistics issued by the French Government show that the passenger traffic of Calais is steadily increasing, and that of Boulogne decreasing. A tax of eightpence is imposed upon every passenger who enters or leaves Calais harbour; the amount is included in the cost of the railway ticket. Nothing of this kind is done in Belgium ports, and in Belgium the ordinary railway fares are much lower than in France for equal distances. At the buffet and hotel in the new station on the Calais pier the charges are among the highest in Europe.

Murray says of Calais:—"An English traveller of the time of James I. described it as 'a beggarly, extorting town; monstrous dear and sluttish,'" and adds that, "in the opinion of many, this description will hold good at the present time." Prices are somewhat high in town, partly because of the heavy octroi duties.

Among the historical architectural subjects worth photographing in Calais is what is known as "Hogarth's Gate," built by Cardinal Richelieu in 1635; the Hotel de Guise, once the Guildhall, and in which Henry VIII. occasionally lodged. There are also several ecclesiastical and civil buildings of historical interest in and near the Place d'Armes, the chief square in Calais.

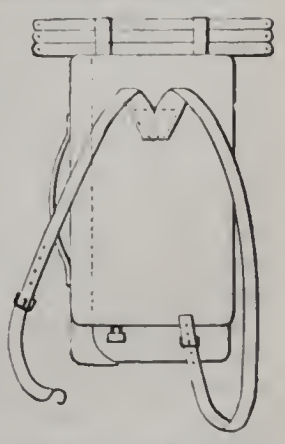
HOW TO CARRY THE CAMERA.

BY CAPT. ABNEY, C.B., D.C.L., F.R.S.

It has struck me that it would be well to place on record some experience that I have gained regarding the carrying of photographic apparatus in mountain expeditions, and this, perhaps, is best done now whilst I have in my mind a recent Alpine tour over high level passes from Chamounix to Zermatt. In the first place, it may be mentioned that when one cuts off from the base of communication (one's portmanteau) for four or five days, it is a necessity that the baggage taken should be as light as possible, and also—which is equally important—as convenient to carry as possible. We may leave the question of personal baggage, merely remarking that an Alpine sack will contain sufficient garments for changing for two persons, together with a spare box of plates or a few dozen films, and that a porter can readily carry the lot, together with a small provision sack.

How to carry a camera is another important point, however. It may be premised that if a 12 by 10 camera has to be taken, it will be found almost essential to have an extra porter for the case containing the slides and extra plates, leaving the guide to carry the camera itself and the legs. The tourist, however, generally confines himself to a 7½ by 5, or a half-plate camera, and it is to such sizes that the following remarks apply. My own tourist camera, of the first-named size, is contained in a leather case 18 inches by 11 inches by 5 inches. In this case is a camera by Meagher, made specially light, and, being of his usual excellent workmanship, has stood four seasons' rough usage without harm. It expands to a focus of 26 or 27 inches, and occupies just half the leather case, five slides of very light construction occupying the other half. It weighs about 12 lbs. when full.

To carry this I have had knapsack straps attached. The accompanying figure will give an idea of the way the straps are attached. It will be seen that the usual handle to what may be called the lid of the case remains. Each strap can be shortened at pleasure by means of buckles, so as to fit the height or back of any porter. The weight by this arrangement is distributed properly, and was carried by my guide for several days without the slightest inconvenience; in fact, he said it was a pleasure to carry it. I suppose the pleasure consisted in carrying it rather than the heavier provision sack. The legs are packed at the top, as shown, with two straps. I have myself carried this camera, as arranged, many hours, and found it much easier than when using the ordinary sling straps. A relation of mine has also been travelling with the same sized camera, but divided his camera from the slides, having knapsack straps put on each. The same guide carried this camera alone up the "Nord end" of Monte Rosa, and when he returned, declared that he preferred my camera, though heavier, as it fitted so much better into his back. To those who mean to travel with a



camera, I recommend the arrangement indicated, as it can be readily fitted to any camera case, and cost me five francs to have attached at Chamounix. It may be thought that a sling answers all purposes, and this I believed until I was persuaded to try the knapsack arrangement. The late Mr. Donkin carried his own camera, and always used knapsack straps, but I cannot recollect the form of his camera case. Suffice it to say, any case, in climbing rocks, which is not attached tightly to the body, is a source of annoyance, if not of danger.

THE PROGRESS OF THE PHOTO-MECHANICAL PRINTING PROCESSES.

BY HERMANN E. GUNTHER.

V.—PHOTO-ENGRAVING.

THE improvements made within the last few years in photo-engraving—or phototype, autotype, and heliotype, as the same process is termed in Germany—are striking. We have scarcely any illustrated journal of importance without photo-typographic illustrations, and most of them are so good as to stand comparison, artistically, with the best woodcuts. In the reproduction of paintings or drawings, the photo-engraving processes are especially of the highest capability, provided that the printer of the blocks possesses the same skill and experience as the photo-engraver.

The head-quarters of photo-engraving in this country are Munich and Vienna, each of which has worked out its own method. The production of the negatives for subjects in half-tone is identical in both methods. A transparent screen plate is placed in front of the collodion plate inside the camera, at a distance of about 1-52nd to 1-13th inch of it, according to the degree of contrast exhibited by the subject to be reproduced. The two methods differ materially, however, as regards the production of contrast or degradation of the tones, which forms one of the most important operations of the whole process. I am indebted to Mr. Joh. Kloth, a very skilled photo-engraver, for some information about this part of the two above-mentioned methods.

According to the Munich method, the degradation is produced solely on the zinc plate. The shadows of the already roughly-etched zinc block are covered with varnish, the outlines are drawn in, and then etched in a weak acid bath. This covering and re-etching proceed over all the degradations of tone, until the points in the highest lights have acquired the utmost fineness. The nitric acid is used in the proportion of about 1 : 70, and the duration of the etching process varies from ½ to 2½ minutes, according to the degree of contrast desired. This can only be ascertained by experience.

In the Vienna method, the endeavour is to obtain the degradation directly on the photographic negative, which is attained by employing the finest possible screen plate, by a suitable arrangement of the subject, and by retouching the negative. On the production of a suitable screen depends very much of the success, this being, at the same time, undoubtedly the most difficult part of the entire process. The screen may be either ruled directly on glass, or a reduced photograph may be taken from a ruled plate. Care should be taken that the lines of the ruled sheet are as fine as possible, because otherwise the shadows, which are to be broken up in dots or stipple by these lines, will turn out much too light. These dots should not be too small, since the stronger light in the lighter portions of the image will cause the dots in these portions to be soon blocked up. With regard to the size of the dots, it may be mentioned that, according to the Munich method, 104 to 130 lines go to the inch, whilst the Vienna method requires 150 to 180 lines to the inch. Now, since the lines breaking up the shadows into dots or stipple should be equally fine in both methods, it follows that in the Munich method the intervals must be much larger than in the Vienna method. This is proved by the fact that these larger dots must bear a prolonged action of the etching fluid, until it is possible to produce all the degradation desired; nor should any of the dots be wanting in the highest lights. The proportions of the intervals to the line are with the Munich method about as 2½ to 1, whereas the Vienna method should be as nearly as possible 1 to 1. The Munich method is undoubtedly to be preferred, for the less the number of the dots within the corresponding space, the larger they will be, and the lighter the ground will appear on which the few dots are standing, if they are etched back to the utmost fineness. Besides, the larger dots yield darker shadows, because they present fewer interruptions. This latter quality is important, since it enables the photo-engraver to produce all the required half-tones, even the softest ones, by etching.

The etching process for transfers on zinc has been fully described by Mr. F. G. Albert in Professor Eder's Year-Book. The method is both original and simple, and gives good results, for which reason it has been adopted by several large establishments. The main points of this method may be here reproduced.

After the impression has been transferred to the zinc plate, it is dusted with asphalt (10 parts of Syrian asphalt, 1 part of yellow wax, melted together, and, after cooling, rubbed down to finest powder). The excessive powder is then removed by means of a pad of cotton-wool, and the plate warmed over a spirit flame, until the asphalt of the transfer has acquired a dark colour. While the plate is still warm, the edges and the back of it are coated with spirit varnish, and, after drying, the plate is placed in a dish containing 2,000 c.c. of water and 25 grammes of nitric acid. In this solution the plate is rocked for five minutes, when the dark deposit which has formed on the surface is removed with a moist sponge. To render the transfer resistant to the etching process, the plate is covered with the following ink:—

Chalk ink, No. II., for lithography ...	10 grammes
Yellow wax	10 ,,
Venetian turpentine	15 ,,
Beef-tallow	5 ,,

The mixture is melted, and, after cooling, 40 grammes of chalk ink No. II. are rubbed in, because the latter is difficult to melt. A small portion of this ink—more or less, according to the fineness of the image—is placed, by means of a palette-knife, on a lithographic leather roller of middle-fine grain, distributing it evenly upon the slab by rolling vigorously upon it with the roller.

A NEW SPECIES OF IVORY.—Celluloid has taken an important place in photography, and now we have a new kind of ivory, just patented, and which may prove useful in making positive prints, as it very greatly resembles real ivory. This composition is made by mixing pulverised or granulated ivory (waste), 8 parts; fish glue, 20 parts; French chalk, 5 parts; water, 40 parts; brandy, 2 parts; cotton, 2 parts (by weight). These substances are mixed, heated over a water bath until the boiling point, shaken up mechanically for about ten hours, kneaded, and then rolled.—*Revue Photographique.*

THE CARTE-DE-VISITE.

BY JAMES MEW.

The expression carte-de-visite has become synonymous in the public mind with a photographic portrait of a particular size and shape, but a little reflection about the meaning of this compound term will show that this could hardly have been its original signification. Nor was it. The carte-de-visite, which we have of course borrowed from the French, referred, in that language, primarily to the oblong piece of polished or glazed card or paste-board which is commonly given on ceremonial occasions to the servant of our friend when we make our so-called "call"—that visit of professed solicitude rendered compulsory by the fashionable code—and find, often with heart-felt but concealed satisfaction, that our friend is, in the stereotyped though too often false formula of the day, "not at home." On such an occasion as this, before the carte-de-visite was known, the visitor of the olden time would anxiously seek after pen and ink, or pencil and paper, and, having written his name, go away with a happy sense of repose like that of Longfellow's village blacksmith, and a sweet consciousness of something accomplished, and of a duty done.

But many times, surely, in those old days the pencil was not to be found, the ink turbid and scanty, the pen resembling a meat skewer, and the paper, by too constant manipulation, covered with an adipose film. Under these circumstances, doubtless, the carte-de-visite was born. From the brain of some visitor labouring with a rigid pen smeared with viscous ink to inscribe his name upon greasy paper, sprang forth like a second Minerva the neat, oblong little card with the name already written or printed thereon; the little card destined to play afterwards so important a part in those morning "calls," which, says an atrabilious cynic, are made by persons privileged by a charter of society to wander about from house to house, obstructing the acquisition by others of that knowledge which they are themselves unable to impart and unsolicitous to attain—people who, having nothing to do, and no business of their own, hinder the business of their acquaintances; people who, having nothing to say, insist on sitting out the full twenty minutes—the present period of the morning call—to say it, in company of those unhappy ones who by some evil fate have become their friends.

The carte-de-visite, when it meant only "the visiting-card," in process of time fell under the edicts of fashion. It was large with the name small, or it was small with the name large. It presented the appearance of watered silk, or of porcelain; it was of various colours. It was adorned, as some of the cards of our advertising tradesmen are adorned at this present, with many varieties of ornamentation. In the land of its birth, the carte-de-visite, in the days of Napoleon, bore the name of its proprietor, overshadowed by the majesty of the outstretched wings of the Imperial eagle. In the days of the Restoration, that same name reposed on a fair field, diapered with *fleurs de lis*. This was the artistic carte-de-visite. The autographic carte-de-visite succeeded it, bearing the facsimile of its owner's signature; and this, perhaps, is the nearest approach made by the carte-de-visite, as it was originally understood, to the carte-de-visite in its present popular signification. From the likeness of the handwriting of the name arose the likeness of the features of the face, and so it has come to pass that we now find "carte-de-visite" admitted into our English dictionaries, and defined with an exclusively photographic meaning, as a "small likeness gummed on a card," a statement barbaric in its plainness, but substantially correct, though some doubt may be entertained about what succeeds, "so called from photographs of very small size, having been originally used as visiting-cards." How far this latter part of the dictionary definition may be consistent with fact there is little evidence to show. One witness, however, has already appeared in favour of it in an old number of the Photographic News, for Feb. 24th, 1865. In this it is to be found that a certain Mr. Skaife had recently favoured this journal with a specimen of a visiting-card portrait—our present carte-de-visite—of a date many years earlier than the actual advent of the present photographic fashion. It is a card containing a wood engraving of a full-length figure, slightly grotesque in design, of Dr. Parland, who left it as a visiting-card at Mr. Skaife's residence, Vanburgh House, in 1851.

There is generally a difficulty about exact verification of dates. We are assured that cartes-de-visite were popular in Paris three years at least before they were introduced into London, and it is clear that Disdéri, on his own testimony ("L'Art de la Photographie," p. 146), was the first to take out a patent for photographic cartes-de-visite in 1854. "*On sait quelle popularité je lui ai rendue*," says this author; "the world is well aware how I helped to bring photography into sudden popularity by my invention of the carte-de-visite." People who were tired and sick of portraits more or less ugly and deformed, obtained by the use of instruments impotent to preserve on a large scale the harmony of human proportions, received with enthusiasm these very little images, in which their friends were seen at full-length, in their ordinary attitudes, and designed with an accuracy which charmed the eye of those least experienced in the subject of art. The carte-de-visite was calculated to spread abroad in profusion visions of artistic beauty. This, at least, is the idea of its author, an idea which subsequent experience may have slightly modified. Another advantage claimed by Disdéri for his invention is that it enabled people to make collections of portraits of public celebrities—to form, in short, a popular gallery of delight, for the gratification of that curiosity which has been called idle, but is, according to Dr. Johnson, a leading feature in the intellectual dignity of mankind.

In an early period of its existence the carte-de-visite met with some hard words from a journal of the time known as the *Reader*. This periodical, speaking of card pictures, as they were then called, says, "These photographic likenesses bring out all that is most vulgar and pretentious in our age, officers and civilians attitudinizing in their respective uniforms, and—worse still—clergymen with the Bible in their hands in their preaching attitudes (fancy St. Paul posing himself for a photograph in the attitude in which he addressed the Athenians); ladies in moire antique and babies in long clothes—all bidding for public notice." It is a severe sentence, but the *Reader*—perhaps a disappointed photographer—was doubtless very wroth. It is easy to understand a man objecting—as, for example, Dr. Pusey is said to have objected—to have his portrait taken, but why any clergyman with or without the Bible in his hands, or why even St. Paul himself should not have been photographed, if a camera had been handy, we are unable to conceive. On the contrary, the carte-de-visite of that Saint as he appeared addressing the Athenians, or any other congregation, might be not

only a satisfaction to the sincere Christian, but also of no little adminicular service in the support of religious faith.

But the *Reader* will have none of it. "There may be," it continues, "and we believe there is, an amiable motive at the bottom of it all." Would that the ghost of the *Reader* might be called up to explain this sibylline sentence, "the amiable motive," and "the bottom of it all." "But surely the great majority of these good people might forbid the public exhibition of their beauty or ugliness, especially when there is no human thought or faculty present in the production of their portraits"—another mystic period—"the presence of which alone justifies the portrait painter in the exhibition of his work, and redeems it from impertinence."

The *Reader*, who would surely have fallen into a fit if he had walked through any one of our principal thoroughfares in the present day, adds that the exhibition of the photographic likenesses of "public characters" in shop windows is perhaps one of the penalties imposed upon them, but "ordinary individuals" are not called upon to exhibit their portraits in a photographic exhibition unless there is really some remarkable improvement in the process by which they are gibbeted for public display. It seems never to have occurred to the indignant mind of the *Reader*, that by what was at the worst a little harmless vanity, a large number of tradesmen were enabled to provide meat, clothes, and fire for themselves and for their families, and that it would not be always easy to draw a line of distinction between the "ordinary individual" and the "public character."

The famous lexicographer, in his "Life of Pope," describes the careful ingenuity of that poet to bring about the publication of his letters, which he desired to enhance his popularity, without his own apparent consent.

The story of Curll, the bookseller, and the visit paid to him one evening by the man in a clergyman's gown but with a lawyer's hand, is generally known. Had Pope lived in these modern days, he needed not to have taken so much pains to attain his end; he might have fed his vanity in a way far more effectual than by the publication of his letters. The carte-de-visite would have provided him as it now provides—who shall say how many—prize-fighting pugilists, music hall singers, parsons, actresses, titled ladies, lawyers, physicians, fasting men, military men, strong men, and infant phenomena, musical or otherwise, with a refined advertisement easily obtainable, and at the public expense.

(To be continued.)

Boletin do Gremio Portuguez is the name of a new amateur magazine published at Lisbon.

DEVELOPING TRANSPARENCIES.—Captain Pizzighelli gives the following formula of a developer for transparencies:—A. Dissolve 39 grammes of citric acid in 135 c.c. of water, and neutralise with aqueous ammonia. Should too much ammonia be used, it must be removed with the aid of heat. Then add 26 grammes of citric acid, and the solution is diluted so as to make 270 c.c. B. Solution of ferrous sulphate, 1 : 3, slightly acidified with sulphuric acid to prevent its oxidation. C. Solution of chloride of sodium, 1 : 30. To develop take—A, 10 parts; B, 5 parts; C, 1 part. Chloride of sodium is a powerful restrainer, and should be used with care. Sulphate of iron, in a larger proportion than that indicated, retards development. By diluting the developer, we obtain prints that are soft and of less intensity. Gallic acid acts as an accelerator. It produces sepia tones; to the above solution we may add two and a half parts of a solution of gallic acid at one per cent. By this process we are certain to produce excellent transparencies.—*Revue Photographique.*

THE USE AND ABUSE OF HAND-CAMERAS.*

BY R. P. DRAGE.

IN opening this discussion, I should like to say that I had no idea, when suggesting the subject, that I should have to open it, but I fancy Mr. Cowan, who proposed that I should, was bearing in mind some jocular remarks made by myself on the occasion of our last outing on the subject of hand-cameras, or luncheon-boxes, as I called them. I believe on that day about half of our number carried hand-cameras. Well, there are some of our members who can take out a hand-camera and a dozen plates, and can bring home twelve pictures. They are men whose names, we may say, are as household words in photography, and they deserve every credit for the labour and time expended in perfecting their experience and apparatus; and there are many more workers like them throughout the country, men who have thoroughly mastered the two great factors, as I take it, in this matter, which are, judging distance, and development; but these, we find, form a very small percentage of hand-camera users. What do the dealers say? "People are buying these hand-cameras extensively; they treat photography as a toy." One hears on every side, "Quite easy, you know; you push the button and the thing is done!"

These new recruits of ours consequently take out their dozen plates and fire away regardless of lighting and subject: sometimes they get one fair negative out of a dozen exposures, and that result is about the proportion for their first gross or two of plates. Naturally they get discouraged, and a large majority of them turn the thing up in disgust. As an example, at Bettws-y-Coed lately I met a young American lady who was going about there snapping at all those beautiful scenes with a kodak. In conversation with her I ventured to hint at her probable non-success, but I was completely silenced by her answer that the dealer in New York, just before she sailed, told her it would take anything. I also met a gentleman in the same locality carying a very neat, morocco-covered detective: he was just going to take the Miner's Bridge with it, he told me. Many other instances of the "abuse" side might be noticed; there is the playful habit some gentlemen have of taking their fellow photographers in all sorts of grotesque attitudes.

Taking a view at St. Albans on our last Bank Holiday outing, and trying to arrange a group of children in the foreground, I was mercilessly snapped at by three hand-camera men. I show results of two; I have not seen the others yet, but they will, no doubt, be shown on the screen in due time.

In conclusion, I should like to appeal to all who follow this interesting art not to allow themselves to be led away by this fashionable craze; it is all very well to grumble about carrying the tripod, but let us think what will be the future of landscape photography if we allow such a thing as a little extra weight to carry to count as a factor in our picture seeking.

It is granted that hand-cameras are indespensable for such as street views, or on the beach, or on shipboard, but they are decidedly out of place for use as picture producers. Therefore let us oppose all attempts to popularise the use of hand-cameras at our photographic outings, the high standard of pictorial excellence to which landscape photography has attained being in great danger of reduction by the use and abuse of hand-cameras.

* Read before the London and Provincial Photographic Association.

UNVEILING THE AMERICAN DAGUERRE MEMORIAL.

On Friday, August 15th, the ceremonies connected with the unveiling of the monument to Daguerre took place in the National Museum at Washington. During the recess at the close of the Photographic Convention, the workmen at the Museum were busy draping the memorial of Daguerre, which was placed in a niche in the rotunda. From the balcony above the statue were hung two great flags, side by side, the stars and stripes and the tricolor of France making a graceful and effective screen to hide the bronze figures until the time arrived for unveiling.

At the south end of the rotunda a platform was erected, on which were a number of seats to accommodate prominent personages. Gradually the crowd which had separated after the adjournment of the morning session began to gather again, and before 2.40 p.m. there was a fair number of people in the Museum.

A few minutes before the appointed time Mr. Secretary Noble made his appearance, and was at once escorted to the platform, where he held an informal reception ; many of the officers and prominent members of the Photographic Association of America were introduced to him, as was also Mr. Hartley, the sculptor of the memorial.

Mr. H. McMichael, of Buffalo, the Chairman, delivered the opening address. Among other things, he said :—"Although it may seem extravagant appreciation of the man to whose memory we offer to-day lasting and substantial tribute, I trust I do not misrepresent the voice of this Association when I say it is one of the most significant events that has ever happened in this American capital. Inspired by the thought that this body, as only an inconsiderable fraction of the thousands now engaged in various phases of the photographic art all over the globe, might erect in suitable form an enduring monument to the founder of our craft and our profession, this Association has ordered the work to be executed. The statue is in conception entirely out of the commonplace or conventional. It presents a simplicity in keeping with the camera, which, while one of the three greatest inventions of modern times, is also the most universal over the earth by the very reason of its primitive character and processes of manipulation. Travellers all over the world carry with them the instrument that brings home such enduring memorials of their experiences. The camera has been the headlight of science. It has explored the moon and the planetary system. To the newspaper, the courts, and the surgeon, it has become a useful assistant. If humankind be here considered, may I not ask is this not better than steam by land or sea, electricity or dynamite projectiles? We can all appreciate the story this memorial tells. The figure of Fame in reverential pose places the laurel wreath about the head of Daguerre, and it extends around the earth, thus typifying the universal blessings combined by the great Frenchman, and the pedestal is a granite Atlas on which, we may believe, this artistic and eloquent composition will rest for ages yet to come."

Mr. Noble, the American Secretary of State for the Home Department, responded in an eloquent tribute to the great French inventor, whose genius is to be commemorated by the monument, opening his address as follows :—

"Fame enwreathes the globe with the glory of Daguerre. His name might be properly inscribed upon the figure of the sun. With its divine light his name will evermore be associated ; with its brightness his genius will be illumined for all time. The earth and the firmament show forth the handiwork of the great Creator, but their most hidden forms have been, and are yet to be developed by that art, the secret of which God gave Daguerre."

The speaker did not overlook the claims of Scheele, Wedgwood, Seebeck, Talbot, and Daguerre's associate and compeer, Niepce, yet, he said, the practical invention was the result of months of toil in the laboratory of Chalons of the one whose name was being honoured. Daguerre not only found the secret, but he gave it to mankind. He added :—

"It is most appropriate to have placed in the capital of our Republic to-day a monument of one who commenced his career as an artist, in very truth, at the foot of the ladder ; who obtained means for testing his already conceived invention by exhibiting the first fruits of his search—the diorama—and amid the most marked characteristics of whose genius was an unfailing reliance on his own industry. In our country the lesson cannot be too frequently taught, that for intelligence and industry the way to success and distinction is ever open. The Republic knows no class, and even as the sunlight enveloping the globe vivifies and beautifies all that seeks its light, so does liberty embrace, sustain, and reward the souls of all that aspire and work. The American Association of Photographers may proudly place at our National capital the statue of this founder of the art it cherishes, whose life and success illustrated anew the dignity of labour."

It might, he remarked, be said by some that if Daguerre had never lived, photography would have existed. His answer to this was that many sailed, but Columbus discovered. The country was his who first erected his standard, and invited all people to its shores. He illustrated this point with a pathetic story of a youth who, having discovered what Daguerre afterwards utilised, was refused assistance, and he and his secret were lost sight of for ever. Daguerre both discovered and made known.

From the first experiments of the great Frenchman, Mr. Noble followed the progress of photography to the present time, enumerating some of the blessings it had been to mankind.

"To-day," he said, "the movements of the fleetest horse are caught as if he were suspended in the air. Wheels of the swiftest locomotive are so instantly impressed that the spokes in the driving wheels of a forty-mile train appear the same as if at rest. The bird in its flight is pictured with the shots that are rushing to overtake it. The lightning's flash is caught, and the dropping rain presented with it and by its light. The telescope has indeed revealed many secrets of the sky, but with the mightiest telescope that man has ever made there is not presented to the human eye worlds that through it are depicted upon the plate of the photograph, and thus, and thus only, transmitted to human intelligence."

He next spoke of composite photographs, and the results which had been obtained in composite pictures of Washington.

May not this suggest, said he, to devout minds even a higher conception that, were all the features of all the human faces that God has made portrayed and successfully combined upon the photograph, we might have therefrom produced the true features of the Saviour, the perfect flower of all humanity!

After paying a high compliment to Mr. J. Scott Hartley, the designer of the monument, the Secretary closed as follows:—

"Americans have not been unfaithful stewards of the talent entrusted them by France. The improvement to its present wonderful stage of advancement, and the enhancement of the commercial value of photography, has been in great part the result of the activity of our native inventors. They have improved the camera, the shutters, and especially the sensitive films or surfaces.

"As the Secretary of that Department of which the Patent Office is the most valuable and advancing portion, I thought it but my duty, however feebly, to meet you and to aid you; you are bees of this hive, and your king will be he who does most for the art of Daguerre.

"But, gentlemen, your art, that in some sense may be deemed to have rivalled nature's own lenses, cameras, and tablets, cannot hope to reach, as some have vainly thought, to the spiritual world, the realm of spirit. You may depict the homestead, but the happy memories of childhood, the affection of parents, the hopes of youth, the aspirations of manhood, the belief in God, and the fraternity of man, are printed on the mind by the Great Photographer of the soul, that when the stars shall fade away, the sun himself grow dim with age, and nature sinks in years, shall flourish in immortal youth, unhurt amidst the war of elements, the wreck of matter, and crush of worlds.

"May we all take care not only of success on earth, but that the form we are imprinting on the great hereafter will unite these with the great souls who have deserved their highest reward by living for the good of man."

Literary Notices.

BURTON'S MODERN PHOTOGRAPHY, comprising Practical Instructions in Working Gelatine Dry Plates, Printing, &c. By W. K. Burton, C.E. (*London, Piper and Carter, 5, Furnival Street, E. C.*)

THIS is the ninth and greatly enlarged edition of a deservedly popular work. It is only about three years since the book was last revised, but during that time there have been so many advances in photography, that the author has found necessary a complete revision of the work, the re-writing of a great part of it, and the addition of several new chapters. These have reference chiefly to the matters of development, orthochromatic plates, and printing processes. An excellent feature in the present edition of the book is the introduction in foot-notes of the French decimal equivalents for English weights and measures. On this subject Mr. Burton says:—

The system known as "Apothecaries' weight" has been adopted throughout this book, because it is that most generally used for practical chemical and photographic work in this country. But it is unnecessary to say that the French decimal system is vastly superior; but, in the case of all formulæ, a corresponding formula in French decimal measures and weights is given in a foot-note in the present edition. It has not been attempted to make these correspond exactly with the English weights and measures. It would involve very odd figures, and often many decimals, to do so; and, as photographic formulæ are generally very elastic, it is considered that it will be of more convenience in practice to give formulæ that are practically correct, and that are in round figures, than to exactly reproduce the proportions given in the English formulæ.

Mr. Burton, some months ago, made a long experimental research into the merits of eikonogen as a developer, and the conclusions at which he has arrived are thus briefly summarised in the book now under notice:—

This developer was introduced in 1889, and immediately produced a great sensation. It was claimed for it that it would permit of good negatives with a much shorter exposure than was possible with any other developer, that it gave a better colour of negative, and that it did not stain the hands or anything else. In my experience it allows of a *very little* shorter exposure than other developers, and certainly gives a good colour of negative, though not, I think, better than that given by hydroquinone. It is certainly, when mixed with sulphite of soda, an extremely clean developer, with apparently no tendency at all to stain.

The substance is used in the same way as pyro, but two or three things must be closely observed. In the first place, it is necessary to use much more eikonogen than would be necessary in the case of pyro. In the second place, only carbonates can be used as alkalies, as caustic alkalies produce colour fog; and, in the third place, if a restrainer is needed, it must not be bromide of ammonium, but either bromide of potassium or bromide of sodium.

He expresses the opinion that pyrogallol is still the best all-round developer we possess.

The following paragraph from the pens of Mr. A. Pringle and himself, about a simple method of orthochromatising plates, may be of interest:—

Of all the processes tried by the writers, none seems to them more satisfactory—certainly none is more simple—than that last suggested by Mr. Ives, of Philadelphia. It may be stated thus:—In four ounces of absolute alcohol dissolve one grain of erythrosine or cyanine. Soak the gelatine bromide plate in this for a minute. Allow to dry. Wash for a short time in running water. Dry, and use. No alkali used. The plates keep well. The cyanine renders the plates so very sensitive, even to red rays, that these operations as well as development must be conducted practically in darkness. The erythrosine formula has proved in our hands eminently satisfactory, the cyanine no less so, but the precautions necessary with it apt to be irksome.

The first edition of this book was published in 1882, and may be remembered by many by its first title, "Burton's A B C of Photography." The latest edition has an index, which shows the advance that has been since made.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.—Subject, Sept. 11th, "Carbon Printing," opened by Mr. W. E. Debenham; Sept. 18th, "Is there any Advantage in the Use of a Large Object Glass in an Optical Lantern?" Mr. Freshwater; Sept. 20th, last outing for the season, Hampstead—tea, "Bull and Bush," 6.30.

AN OPEN AIR LANTERN ENTERTAINMENT.—An open air lantern entertainment calls for management of a different nature compared to that in a hall. However, Mr. E. H. Stevenson, of Norwich, proved himself quite equal to undertaking such a task, and on August 14th gave an exhibition to an audience of five thousand persons in the dell of the picturesque ground of Mr. H. Trevor, of Norwich.—*Magic Lantern Journal.*

NOVEL CARD FRAMES.—Messrs. Marion and Co. have just issued some novel card frames inscribed with rich designs and mottoes appropriate for Christmas and other seasons. A photograph, a drawing, or a water colour picture may be slipped into the front of these frames, and so become an elegant Christmas present. Each card mount, or frame, has a strut back; thus it serves the entire purpose of a frame; it is made of fine cardboard, and is much cheaper than the ordinary plush or leather frame. Messrs. Marion and Co. say that photographers will find them suitable for the display of their photographs in the shop window or reception room, as well as for sale. They have sent us some specimens, and we think these card frames likely to become highly popular.

EIKONOGEN.

Our readers will remember that the earlier samples of eikonogen that reached us varied considerably in appearance, solubility, and developing power, and, if we may judge from correspondence, both private and published, the variation still continues, although to a limited extent. But the statements of such correspondents—and, indeed, of a considerable number of hard-working, earnest, observing photographers as well—must be taken *cum grano salis*, large allowance being made for the influence of individuality, and the tendency to overlook the influence of what may seem trifling causes of interference to the untrained observer.

In view of the large amount of space that has been given by the various periodicals to eikonogen formulæ, and discussion thereon, we can almost sympathise with one student of photographic literature when he writes that "the eikonogen hobby has been ridden to death," while, at the same time, we are anxious to be helpful to many others who write somewhat to this effect: "What about eikonogen? Do you like it as well now as you did when you last wrote about it, and do you still recommend the formula as given on page 217 of last volume?" To those we reply that we still like eikonogen; like it, in fact, better than we did then, just as we do every thing and all good people the better we become acquainted with them. We like it because of its cleanness, its non-liability to stain the negative, its good keeping qualities, its persistent developing power, and its apparently equal suitability for various kinds of work; employing it, as we do, indiscriminately on gelatino-bromide plates, lantern slides, bromide paper, transparent film, and positive celluloid. And last, but not least, we like it because of its greater economy; as, although a six-grain solution costs more to begin with than the average three-grain solution of pyrogallol, the latter will be practically exhausted or discoloured beyond further use by the development of a single negative, while the former will be clear and able for more work after having developed six.

Eikonogen, as found in the market at present, in a decidedly crystalline form and of a light yellowish colour, is more uniform than when we last wrote on the subject; and recent experiments with various samples show that in the presence of twice its weight of sodium sulphite it is soluble to the extent of nearly, but not quite, twenty grains to the ounce of water. Taking this as datum, and believing in formulæ that demand the smallest amount of calculation or measuring out, we adopt in our own practice, and recommend the following:—

A.

Eikonogen	...	...	1 ounce avoirdupois
Sodium sulphite	...	...	2 ounces ,,
Water ...	...	...	... 22 ,, fluid.

Dissolve the sulphite in the water, warm it if in a hurry, and add the eikonogen, shaking till dissolved.

B.

Sodium carbonate	...	...	2 ounces avoirdupois
Water ...	...	...	... 22 ,, fluid.

Dissolve.

For the development of ordinary plates that have got something like a fair exposure, one ounce each of A, B, and water will make a developing solution that leaves nothing to be desired, giving perfect detail and full density within a reasonable time, while the deposit is of such a nature as not to lose much in the fixing solution.

We have experimented with both potassium carbonate and the caustic potass and soda salts, but do not like either of them. The former possesses no advantage over the soda, and the latter, while they seem to increase the action of the eikonogen, are fatal to the keeping qualities of the solution after having been once employed, it becoming dark and muddy in a very short time. That the keeping qualities of solutions of eikonogen with sodium carbonate, after use, are greater than is generally understood, may be known by the fact that we have to-day developed a technically excellent negative with a solution that has been used over and over again, and some part of which was made in November last.—*The Beacon.*

PRIZES AWARDED AT THE AMERICAN PHOTOGRAPHIC CONVENTION.

Just before the close of the American Convention, when it was announced that the grand prize committee was ready to report, there was a rush for the hall from the corridors and adjacent rooms. The report awarded the grand prize trophy to Mr. George H. Hastings, of Boston, and the Convention approved the decision by applause. The grand prize was offered for the three best photographs illustrating Tennyson's "Enoch Arden." The trophy is in bronze and gold, and represents three figures running a close foot-race. It is a work of high art, designed and manufactured in Paris.

The other committees on awards reported as follows:—

Class A—A beautiful silver plaque, mounted in plush, representing "Victory," for the best exhibit of genre photographs. Awarded to S. L. Stein, of Milwaukee.

Class B.—One gold, one silver, and one bronze medal for the best collection of portrait photographs. Awarded to Dana, of New York, first; J. Lundy, of Cincinnati, second; and P. O. Scott, of Chicago, third.

Class D—Heimberger and Son, New York, gold medal; Miss C. E. Sears, of Boston, silver medal, and Zybrack, Niagara Falls, bronze medal for landscape photographs; Allen and Rowell, Boston, silver medal, for marine views; E. W. Lincoln, silver medal, and George Hastings, bronze medal, for best collection of architectural views.

Class E—F. T. Clarke, silver medal, and C. P. Wilcox, bronze medal, for best retouching.

Class F—W. G. Kimball, silver medal, and Rothengatter and Dillon, bronze medal, for plain enlarged photographs.

Class G—C. H. Codman, medal for best invention for photographers produced during last year; an improved camera-stand.

Class H—Lafayette, of Dublin, and J. Hannah, of New Zealand, for best foreign displays.

In the private awards Mr. Motes, of Atlanta Ga., captured the Anthony prize of $100 for best plain enlargement, and Mr. A. A. Knox, of New York, $50 for the best worked enlargements. Mr. C. E. Vredenburgh, of Elizabeth, N. J., took the $50 prize offered by the manufacturers for the best work with "climax" films. The air-brush prizes were won by Mr. P. Fleming, for best water-colour painting, and Mr. C. G. Waldeck, of St. Louis, for a black and white portrait. The Knorr Manufacturing Company's prize of $100 for the best print on "diamond" albumen paper was awarded to Rose, of Providence.

The Convention then adjourned *sine die*.

Texas Siftings says that there is something at the seaside this season worse than sharks. It is the amateur photographer, with his tripod and camera.

Notes.

To illustrate the danger which may attend the use of certain explosive powders containing magnesium, the *Moniteur* recommends the mixing of a few grains of magnesium powder with a few grains of permanganate of potash, then to place a fifth of a gramme of the mixture upon a piece of white iron, and to moisten it with a single drop of glycerine. A blow will cause the mixture to explode with terrific violence. A mixture of magnesium powder with powdered chlorate of potash is equally dangerous, especially if some organic matter be also present; such a mixture is far more violent in combustion than gunpowder, and is liable to go off from accidental causes, such as friction. The only safe way of using such explosive powders is to keep the ingredients in separate bottles, and then to mix a few grains in all, when an explosive magnesium compound is required for use. The mixing is best done with the feather end of a quill pen. Not a few fatal accidents have occurred from the explosion at unexpected times of mixtures of chlorate of potash with foreign matter. By itself the salt is harmless enough.

Last year the price of standard silver averaged rather more than three shillings and sixpence an ounce; at the present time its price is four shillings and sixpence an ounce. To what extent this great rise in price may be due to combination by individuals, or to prevalent public opinion that the value of silver must go up, is not publicly known. The American Treasury is purchasing silver at the rate of two million ounces per month more than it did a month ago, but that by itself does not account for the large increase in the price of the metal.

From the *Evening Standard* we glean some particulars about the ascent of Mont Blanc by Dr. Janssen, to make spectroscopic observations at a height of 4,050 metres above the level of the sea, and only 400 metres below the summit of the mountain. He was drawn up in a sledge by fifteen men, because of his state of health and his advanced age. It is said that "his observations with the spectroscope have demonstrated that the sun's atmosphere certainly does not contain oxygen in the state in which that gas is found in the terrestrial atmosphere." From another source we learn that Captain Abney was in the Mont Blanc district at the time, therefore it is probable that he knows something of the scientific results obtained by Dr. Janssen. The journal already mentioned says: "After an excursion to the Bosson, M. Janssen returned to the Grands Mulets, and on Sunday last reached Chamounix, where Madame and Mdlle. Janssen were anxiously awaiting his return. They had followed his perilous journey from a distance by means of powerful telescopes. His ascent of the Bosson took place on Friday. It appears the snow was in such a dangerous condition that the guides advised M. Janssen to get out of the sledge and walk. The learned astronomer attempted to complete the ascent on foot, but fell exhausted after taking a few steps."

Recently we were considering in these pages to what extent two tenants upon the same premises may be independent of each other. There is a limit to such freedom on both sides, as instanced in a case which last week attracted the attention of the Parisians. A lodger hired an apartment, and it was agreed that if ever he cooked onion soup therein he must quit; he, however, looked upon this as a joke, and a few days later had some onion soup cooked in the room. The landlord went upstairs, livid with rage, and the tenant had to go. Had there been a photographic society armed with scientific appliances at the top of the premises, it would have been in a position to send a steady flood of carbonic acid gas down the chimney, to quench the fire and close the glottis of the soup-cooking tenant. Sitting on the chimney-pot would do.

Old persons—some of them at least—are fond of talking of the good old times, and deploring the degeneration of the present age. In the main we cannot agree with them, for the advance of knowledge has been of benefit to all. But if they were to limit their remarks, and say that there was more fun going a couple of generations ago than there is now, we should be inclined to corroborate them. This is a matter-of-fact age, and the appearance of the steam engine and various other more modern devices for turning the world into a big machine has had the effect of driving away much of the genial frolic and jollity of past times. Photography has had its share in the business, and has stopped a great deal of rough fun of old type. It is difficult, for instance, for any merry fellow to take it into his head to personate any well-known character, for the simple reason that, by means of his widely-published photographs, the celebrity is well known to sight as well as to fame.

But it would seem that this does not hold good in Canada, or it may be that photographs of H.R.H. Prince George of Wales have not reached that far-off dominion. One more reason we hesitate to suggest is that the photographs which do go there may not be like the original. Whatever be the cause, it is certain that the good people of Canada were not familiar with the personal appearance of the prince, otherwise those frolicsome midshipmen would not have succeeded so well in palming off one of their number as the Queen's grandson. Although this conduct is highly reprehensible, and the young jokers are to be court-martialled for "conduct unbefitting English officers," we cannot help feeling a tickled satisfaction at the thought that there is yet some little fun abroad in the British Navy. We trust that the officers who constitute the court-martial will prepare themselves for their serious duties by reading beforehand a chapter out of Captain Marryatt, unless, indeed, after all, the affair turns out to be a clever hoax.

Of late years there have been many attempts to revive interest in that moribund instrument, the stereoscope; and, seeing that there are so many amateur photographers who are always anxious to take up a new line of work, the revival is sure to come about sooner or later. The other day we lighted upon an itinerant peep-show man at a certain seaside resort, and, remembering those wonderful shows of our childhood, with their impossible battles and burning mountains, we invested a penny, and had a peep. Imagine our disgust at finding that the pictures, instead of rivalling the modern impressionist school in their vagueness, and thus allowing you to "pay your money and take your choice" as to interpretation, were only stereoscopic views. The entire exhibition was called a "Stereorama," which is, perhaps, Latin for peep-show; and its basis was a perambulator, with a superstruction formed out of an egg-box, with holes in it through which the spectators peeped. In the interior was a paraffin lamp, which necessitated a long chimney reaching to the outside. The chimney seemed to be a great attraction to the uninitiated, who evidently regarded it as part of "the works."

At the same seaside place we came upon another application of photography in the shape of various knicknacks ornamented with small pictures of the lions of the neighbourhood—the pier, the parade, the High Street, and so on. We must presume that these mementoes of the place are purchased by somebody, or they would not be produced; but imagine the horrors of a house completely furnished with pictured memorials of this kind—glove-boxes, cotton-boxes, paper-knives, egg-boilers, egg-cups, table-napkin rings, and every other household machine capable of decoration. The vendor of the articles told us that the pictures were produced in the place and sent over to Germany, where they were affixed to the aforesaid wooden articles and varnished. Seeing that a well-made napkin-ring, after this division of labour, was sold for threepence, it is evident that the photographer is not amassing a fortune by his work.

Perhaps, taking one thing with another, it is not altogether pleasant to be a celebrity. You are not only pestered with circulars from all sorts and conditions of men, from the philanthropist down to the purveyor of coals, but you are also worried to sit for your photograph. Prince Bismarck seems to be a martyr to this kind of thing, and in a conversation with a friend he said lately that the photographers gave him no peace. This is very sad, but there is a remedy, so far as Bismarck is concerned. Some three or four years ago, a man very much like Bismarck used to sit constantly for the photographs of the German statesman. The result of this enterprise was that the counterfeit Bismarck eventually found himself imprisoned. The real Bismarck at that time did not see the necessity for a "double." What he should do now would be to find out the whereabouts of this individual, and engage him to go to the studios of the photographers who are so pertinacious. The difficulty, it is obvious, would be overcome. The photographers would be perfectly satisfied, and Bismarck would be left in peace.

What becomes of the yolks of the eggs used by the manufacturers of albumenised paper is almost as profound a mystery as what becomes of the dead donkeys. We believe that most of the manufacturers in the neighbourhood of London get rid of all they can to the confectioners, but that there is still a surplus difficult to dispose of. According to a statement in a contemporary, this difficulty ought no longer to exist, as it is said that egg-yolks are used extensively by soap makers and dyers, and that only recently hogsheads of yolks of eggs have arrived from a portion of the Russian Empire on the borders of Bessarabia. Here, it is said, are millions of hens, and that only recently has a cheap mode of carriage from this remote quarter of Europe been established. The same authority says that the "dearness and scarcity of egg-yolks have retarded the advent of many a new colour, and rendered the refined qualities of soaps almost unattainable to anybody but the aristocracy." It would be interesting to have some more information on this point, as the makers of albumenised paper would be glad to hear of a source of unlimited demand.

We understand that the American railway companies are making practical use of the automatic photographic machine. In America they have a system of what they call a "mileage ticket," which, we presume, corresponds to the season ticket of the English railway passenger. It would appear that it is a common practice for the mileage ticket to be passed round the family, so that the regulations in issuing the said ticket must be rather lax. It is now arranged that the person who takes out a season ticket must have his photograph taken by the automatic machine which is kept in the superintendent's office, and his likeness is pasted on the season ticket, so that the use is confined to its proper owner. This is about the best thing we have heard hitherto concerning the automatic photographic machine.

The conditions attached to the gift to the Harvard College Observatory of six thousand dollars, offered by Miss C. W. Bruce in aid of astronomical research, have been published. In the hope of making it the greatest benefit to science, the entire sum will be divided, and, in general, the amount devoted to a single subject will not exceed five hundred dollars. Precedence will be given to institutions and individuals whose work is already known through their publications, also to those cases which cannot otherwise be provided for, or where additional sums can be secured if a part of the cost is furnished. Applications are invited from astronomers of all countries, and should be made before October 1st, 1890, giving complete information regarding the desired objects.

SHORT FOCUS AND WIDE-ANGLE LENSES.

BY MAJOR ST. GEORGE GORE, R.E.

THIS subject is a well-worn one, and much has been said and written on it. In view, however, of the large accessions to the ranks of amateur photographers which are daily taking place, I have ventured to write this article.

There are two points of view from which the subject may be treated, which, although closely connected, are not identical; these are the length of focus of the lens with which a view is taken, and the width of angle of view included in it. For one and the same sized plate, these are, broadly speaking, inversely proportional, but it does not follow that a short-focus lens is of necessity a wide-angle lens; a 6-inch focus lens on a quarter-plate gives the same angle of view as a 12-inch focus lens on a whole plate.

The picture produced by a non-distorting lens of any given focal length is the same as that which would be formed by holding up a sheet of glass of the same size as the sensitive plate at a distance from the eye equal to the focal length of the lens, and tracing on it the outline and detail of the view in question as seen through it.

Now clearly, a picture drawn under these circumstances, if it is to represent the view as seen from that particular standpoint, would always have to be viewed from a distance equal to that at which it was held from the eye when drawn. Similarly the photograph, in order to give a true idea of the view represented, should be held at a distance from the eye equal to the focal length of the lens which produced the photograph.

Now the human eye, though no doubt an excellent optical instrument, is unfortunately not fitted with a rack and pinion to the retina, and has only a limited power of adjustment for focussing very near objects. In the case of a normal vision, if a medium size photograph, say a whole-plate print, is looked at, so as to study its detail, it will be held at from 9 to 10 inches from the eye, while if being looked at as a whole—being viewed as a picture—the natural position to hold it will be about twenty inches from the eye. It follows then that, if an effect is required which will appear true to nature, a whole-plate photograph should be taken, if possible with a lens of very much longer focal length than is usually the case, a length of 18 to 20 inches being very suitable. Were it taken with a short-focus lens, and then held at the natural distance of some 18 or 20 inches, the result would be that the perspective would appear false, and the relative proportions of objects in the foreground greatly exaggerated as compared with the distance. No hard-and-fast rule can be laid down on the subject, nor would it be advisable to do so if it could. The size of the picture influences the matter considerably; thus, in the case of a smaller picture, say a quarter-plate, it is not necessary to hold the print nearly so far from the eye in order to study its appearance as a whole, and, consequently, a proportionately shorter lens may be used, the converse being the case with photographs larger than whole-plate size.

There is another side to the question, which is far more important in its effect for good or evil than the errors induced by looking at a photograph at a distance different to the focal length of the lens it is taken with; I refer to the width of angle of view included in the picture.

Many abler pens than mine have written on this subject, your own included, Mr. Editor; but, judging from a large number of photographs one sees which sin greatly in respect of attempting to include too much, I am afraid that the lesson has not been taken to heart as generally as it should be.

The angle included in a picture may be measured, as I dare say everyone knows, by drawing a line equal in length to the longest dimension of the plate, and from its centre erecting a perpendicular equal in length to the equivalent focus of the lens. If, now, lines are drawn from the extremity of this perpendicular to the ends of the line representing the length of the plate, they will include the angle of view for that particular lens and plate.

Opticians have much to answer for in the abuse of lenses. It has become the custom with many of them to class their lenses as "half-plate," "whole-plate," and so on, without giving any information as to their focal length, and the young photographer, buying, say, a half-plate camera, naturally buys a "half-plate" lens, assuming, of course, that it is the best lens to use on that plate.

Even in the case of celebrated opticians, who, of course, advertise all particulars of their lenses, if we take, say, Dallmeyer's R. R. lens for 8½ by 6½, we find its equivalent focus to be 11 inches; this will give an angle on that sized plate rather over 42°. If, now, we turn to his wide-angle rectilinear lens, for whole-plates its equivalent focus is 5¼ inches, which gives an angle on that plate of 78°.

When we look at views in nature, the eye sees clearly only the exact point looked at, but it, at the same time, takes in generally other objects covering an angle of, perhaps, 20° to 30°. Anything beyond that angle forms no part of that picture or view as presented to our minds.

Artists, when drawing from nature, rarely include an angle of more than 20° to 30° in their picture, or, if they particularly wish to include a wider angle, they possess the power, denied to the photographer, of putting matters right by apparently narrowing the angle, which is easily done by keeping down the dimensions of objects in the foreground, and increasing the vertical dimensions of distant objects in proportion to their horizontal dimensions.

The photographer, however, seeing a pretty view, is apt to strive to get as much of it as he can on his plate. He puts on, say, a 7-inch focus lens on to his whole-plate camera so as to be sure to get the view all in, and takes his photograph, including in this case an angle of 62°.

He prints his photograph, which very probably is technically all that can be desired, and shows it complacently to his friend. The latter holds it naturally some 18 inches from his eye—where the scene which embraced 62° in nature now only subtends an angle of 26°—and wonders (though if he is wise he does not say so) what has happened to the perspective of the house in the foreground, and why it seems as if it was trying to tumble on its back, and why the distance is so minute as to be scarcely visible. If he is so bold as to criticise the picture, the author will possibly tell him that it *must* be correct in perspective, as photographs must be true.

The truth is that, as mentioned previously, the perspective of a photograph, as seen by the person looking at it, is *never* true unless the photograph is viewed from a distance equal to the focal length of the lens producing it.

Who is there that has tried photographing the snowy ranges as seen from our various hill stations, who has not been disappointed at the insignificance of the snows in the result?

Let such give up the idea of taking in a panoramic view of 50° or 60°, and use a lens of 18 or 20 inches

focal length, if their cameras will take it, on such a sized plate as will not include more than 20° or 25° of view. They will have to choose their view more carefully as it includes so little, but the result will be worth having, and the mountains will look like mountains.

As example is always better than theory, I send two photographs of the Ochterlony Monument. One was taken with a lens of $6\frac{3}{4}$ inches focus, the other with a lens of 19 inches focal length. In the former I have especially abstained from exaggerating the ease against wide-angle lenses, for I chose a point from which the monument subtended an angle from summit to base of only 28°. I might easily have gone nearer, and made the caricature much more gross by increasing the angle subtended to 40 or 50°. Notice in it how much the underside of the gallery round the summit is visible. The eye refuses to believe it is called upon to take in such a wide angle, and consequently the perspective of the tower appears false, and the mind accounts for the result by imagining the tower to be tumbling or bent away from the observer.

Then, again, look at the relative proportions of the monument and the lofty houses behind on the esplanade; the result is utterly ridiculous.

Now turn to the long-focus picture; the tower is straight, the houses behind appear to have assumed their true proportion, and the eye accepts it as a true picture.

There are occasions, of course, when the use of wide-angle lenses is quite legitimate: such are when it is essential to take the photograph of a particular object, and where the point of view is absolutely restricted to a position very near compared to the dimensions of the object. This is frequently the case with interiors, and sometimes, though rarely, with exterior views. There is nothing for it then but to use the wide-angle; but recollect that the result will certainly not be a thing of beauty.—*The Journal of the Photographic Society of India.*

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

III.—DEVELOPMENT.

THERE is a generally accepted belief among photographers that a great amount of control can be exercised in development over the density and the general gradations of a negative, and in this respect alkaline pyrogallol enjoys a special reputation On this account we have chosen this developer for the following series of experiments, except where otherwise stated. These experiments conclusively show that the only control the photographer has over development lies in securing a greater or less density of image (the former often only at the expense of fog), and that he has no control whatever over the gradations of the negative.

The plan we have adopted in carrying out these experiments is to subject *pieces of one and the same plate* to the varying conditions the influence of which, on the density or the gradation, is the subject of our investigation. A precaution we have always taken, except in our earliest experiments, is never to develop a piece of a plate which has been exposed to the light without simultaneously submitting to the same developer a piece of the same plate which has *not* been exposed, and which we term the "fog strip." The object of this precaution is to ascertain exactly how much of the resulting density is due to the action of the light, and how much is due to incidental fog, including therein fog inherent in the plate, or caused by injudicious development, and also the density due to glass and gelatine.

In the following series of experiments, made to ascertain the influence of time, of development, and composition of the developer on the density, we covered up one half of a plate and exposed the other half to a standard light, as will be presently more fully explained. After exposure, we cut up the plate in such a way that each piece includes a portion of the unexposed and a portion of the exposed plate. Each strip is then developed, such modification in time of development or composition of developer being made as forms the subject of the investigation. The resulting densities are then measured after fixing, washing, and drying.

Time of Development.

Experiment 1.—Plate: "Wratten Ord." Exposure. ?

Developer, 100 c.c. contain { 0·085 g. NH_3. / 0·400 pyrogallol. / 0·250 NH_4Br.

Results.

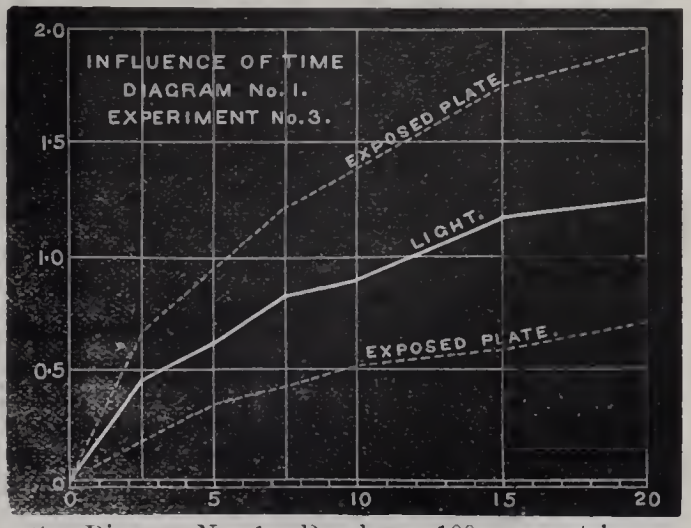
Time of development....Minutes	2·5	5·0	7·5	10·0	12·5	15·0
Densities produced	·183	·543	·793	1·160	1·10	1·17
Percentage.....	15·6	46·0	67·8	99·1	94·0	100·0

Experiment 2.—Plate: "Wratten Ord," Exposure = 60 C.M.S.

Developer, 100 c.c. contain { 0·162 NH_3. / 0·342 Pyro.* / 0·228 NH_4Br.

Time of development Minutes..	1·25	2·5	5	10	15
Density exposed plate...	·775	1·175	1·725	2·275	2·475
Density unexposed plate	·155	·270	·510	·590	·790
Density due to light....	·620	·905	1·215	1·685	1·685
Percentage developed...	36·8	53·7	72·1	100	100

Experiment 3.—Plate: "Wratten Ord." Exposure = 20 C.M.S.



See Diagram No. 1. Developer, 100 c.c. contain:—
0·162 NH_3.
0·342 Pyro.
0·228 NH_4Br.

* Continued from page 676.

* Sulpho-pyrogallol equivalent to pyro.

Time of development. Minutes	2·5	5	7·5	10	15	20
Density exposed plate	·670	·965	1·245	1·420	1·755	1·945
Density unexposed plate ...	·200	·345	·415	·505	·575	·710
Density due to light	·470	·620	·830	·915	1·180	1·235
Pecentage developed	38·0	50·2	67·2	74·1	95·5	100

These experiments show that the total density grows with the time of development, but that the density due to light reaches a limit in about fifteen minutes. The continued growth of the total density is due to the action of the developer upon the bromide of silver which had not been affected by the light.

Variation of Pyrogallol.

Density due to light ...	·415	·615	·870	1·085	1·015	·935

From these results we gather that an excess of pyrogallol beyond a certain limit tends to retard development and the production of density. This limit appears to be the equivalent of pyrogallol necessary to convert the ammonia into tribasic pyrogallate, $C_6H_3(ONH_4)_3$.

A similar experiment is here given, made with "sulphopyrogallol" compound, with sodium sulphite and citric acid. It will be evident that the presence of the acid, by neutralising the ammonia, is responsible for the much more marked falling off in density.

The general result of these experiments is that the addition of ammonia, up to a certain extent, increases the density in a given time, but that the amount of ammonia which can be added without giving rise to fog, and without simultaneously adding bromide, is very limited; the so-called accelerating action of ammonia being due almost entirely to its solvent action on bromide of silver, which, if the ammonia is increased sufficiently, results in greatly diminishing the density.

The following table shows the solubility of silver bromide in very dilute ammonia, such as is used for development of plates:—

100 c.c. of dilute ammonia containing:—

1·105 grms. NH_3	dissolve	0·0376 AgBr
·555 ,,	,,	0·0206 ,,
·162 ,,	,,	0·0100 ,,
·0897 ,,	,,	0·0052 ,,

The last two solutions represent the extreme concentrations usually employed by photographers for development.

If, to any of these solutions of silver bromide in ammonia, bromide of ammonium be added, an immediate precipitate of bromide of silver is the result. The so-called accelerating action of ammonia, and the retarding action of ammonium bromide, are probably due entirely to this solvent action of the one, and the anti-solvent action of the other of these two reagents. The rapid production of fog when ammonia is increased is due to the fact that when pyrogallol solution is added to an ammoniacal solution of bromide of silver, the silver in solution is precipitated immediately in the metallic state.

(To be continued).

The Photographic Club.—The subject for discussion on Sept 10th will be "Modifying Lenses"; Sept. 17th, "Extemporised Modifications of Photographic Cameras."

The Annual Exhibition of the Photographic Society of Great Britain is to be held in the gallery of the Royal Society of Painters in Water-Colours, and will be opened by a conversazione on Saturday evening, September 27th; it will remain open until the 12th of November.

Messrs. York and Son forward their twenty-first annual supplemental catalogue of optical lantern slides and lecture sets. In issuing it they call special attention to the fact that they have been compelled to adopt a trade mark by which their productions can be recognised. The selection of new subjects includes several of aborbing interest at the present time.

War Maps.—We learnt lately of a new use for photography. The War Office authorities make reduced transparencies from their large maps, and these are supplied to the officers in charge of expeditions, and, by the aid of a small magnifying glass, these miniature pocket maps give all the detail of a large scale map on linen, which in wet or windy weather it would be impossible to use, even if it were so easy to carry.—*Scraps.*

Washing the Faces of Sitters.—The *Magic Lantern Journal* says:—"This reminds me that if sitters were to wash their faces immediately previously to having a large (head) photograph taken, there would be less work for retouchers, and a better photograph would result. An interesting comparison is that of a large head photographed immediately after sponging the face, and another taken an hour or two afterwards. The marks in the face in the latter case will appear hard compared with those in the first, for it is surprising how a lens can detect foreign matter in crevices; but for a photographer to ask his clients to wash their faces is, indeed, a difficult matter, and great delicacy would have to be displayed; but perhaps two labelled prints showing the difference would answer best, if they were hung in a prominent position in a studio dressing-room." In this matter, perhaps, something depends upon the class of sitters to be operated upon.

THE ABOLITION OF LONDON SMOKE.*

II.—*The Proposed Remedy and its Advantages.*

I shall now lay before you in broad and general lines a practical remedy which, I trust, will receive careful consideration from those whose public duty it is to be interested in this momentous question; but, before doing this, I think it will be clearer to say in this place that the progress of electric lighting cannot make much difference to the plan. For lighting purposes, no doubt, the advantages of electric light as to brilliancy, penetrating power, and cleanliness are so manifest that its use ultimately must prevail irrespective of cost, provided that it can be manipulated with less danger and trouble than it appears to be at present.

I propose that gas should be made at the coal fields, that it should be manufactured as close to the pit's mouth as convenient, that it should be conveyed from the gas works, situated in the country, up to the metropolis in suitable mains, that it should be stored in gas holders as at present, and that it should be solely utilised for heating and lighting the metropolis, together with providing all the motive power required for driving engines and machinery. By this it will be possible to obtain the extinction of all the deadly fog of London, and of all the waste already alluded to.

That this plan is not unscientific or impossible is, I think, shown by the fact that Dr. Siemens proposed in 1863 to establish separate mains in Birmingham for the distribution of heating gas, to be applied for motive purposes to small boilers and the furnaces of the small factories, and for domestic uses. At the present time, when gas engines are more commonly used, this heating gas can be used with greater advantage and economy in supplying the motive power for electric lighting purposes and other schemes which are constantly coming into operation. Siemens intended that the gas should be manufactured in the coal pit itself. His favourite suggestion was a plan which consisted in placing gas producers at the bottom of the coal mines themselves, so that, instead of raising the coal to the surface, the combustible gases ascending from the depth of the mine would acquire, by virtue of their low specific gravity, such an onward pressure that they could be conducted long distances in tubes, saving thus the cost of raising and transporting the solid fuel.

The present plan is distinguished from that of Siemens by the fact that the gas works would be placed in close proximity to convenient coal stores in suitable coal fields, and not in the pit itself. The latter method would have so many obvious disadvantages that it is unnecessary to explain why it could not be adopted.

In the gas works situated on the coal fields, in close proximity to the beds of coal, we should have one enormous advantage over the present system of works in London itself. We would dispense with the enormous amount of unsightliness, unhealthiness, and waste of available area which now occur owing to their present position and construction. The conditions which affect the quality and character of the gas would also be greatly improved. The coal used would not be exposed, as at present, to a long continuation of atmospheric changes, but could be used without much delay after being brought out of the pit. The coal at the time of its distillation would be dry and not exposed to wet, and the waste in transit would be avoided.

The production of illuminating gas from coal is a simple process, and may be considered as the rearrangement of the elementary constituents of the coal under the influence of heat. It is well known that nearly the whole ingredients of coal can be so converted. It is also well known that coal can be converted into two kinds of gases which can be easily separated, and the lower forms or qualities may well be utilised as heating gas or gas fuel, whilst the more brilliant illuminating gas can be used for the ordinary purposes of lighting. The ordinary retorts can be used for the production of both heating and lighting gas; for, during half an hour after coal gas has begun to be given off, the gas is only fit for heating purposes, whereas afterwards, for about two hours, the illuminating gas

* Continued from page 667.

comes off, and then, when further heat is applied and continued, a very large volume of gas of low illumiuating power, but of efficient heating qualities, is extracted. Under the present system this heating gas is left in the coke, or, perhaps, sent off late at night to drowsy customers who are unable to perceive or account for the differeuce in the brilliancy and quality of the light supplied to them. Both kinds of gases can be made more suitable for their distinct purposes by this division, for the illuminating gas is made richer in light-giving properties, and heating gas could, under all circumstances, be burnt without the production of soot and smoke. There is but a small proportion of the total quantity of illuminants in coal gas to the bulk of the materials dealt with, and the public could, if necessary, well afford to pay a slightly advanced price for a gas of greatly increased illuminating power, provided that heating gas at a reduced and ecouomical rate were supplied to them.

There are many inducements to the employment of gas as fuel. There is no fear of gas engiues being stopped owing to lack of water ; there is the absence of danger from boiler explosions ; no stoking is required, and the ease with which gaseous fuel can be regulated, the comparative readiness with which cleauliness can be maintained, together with its high heating power, mark out its pre-eminent advantages as a motive power in iudustrial operatious. Costly canuel gas, with its brilliaut illuminating power, is no better suited for a gas engine or for gas fires than common gas ; and, for heating purposes, a much greater yield of gas might be obtained which in burning would evolve more heat than is sought for in making illuminating gas. Having thus stated the advisability and necessity of dividing the gases, it will be seen that it will be necessary to provide two distinct sets of mains to convey the heating gas and the lightiug gas to London from the spot which would be chosen for the establishment and coustruction of the central gas works and manufactury, and I propose to refer somewhat briefly here to the question of the mains which would be required.

The leugth of mains from the coal field gas works would necessarily be 100 miles at least, and the present system of gas mains would have to be re-duplicated in order to convey the heatiug gas. If any objection is raised as to the impossibility of driviug gas through this length of main, I can point out that the various gas companies which supply the metropolitan area alone have 4,000 miles of mains, which they are constantly working. For my own part, I do not see why it would be more difficult to work the mains from the coal fields by pressure than it is at present to supply London through this enormous extent of main. Gas pipes laid through arable land, *if it is found desirable to lay them underground*, are uot harmful to the land itself, but rather do a certain amount of good, as they assist in draining the country. If the joints are made perfect, and well puddled round with clay, they will effectually prevent any possible escape of gas.

Illuminating gas suffers, to a trifling extent, by being carried long distances by the deposit of napthalene in cold weather in the pipes ; but this is again remedied in warm weather by the volatilisation of the napthalene at the higher temperature. This objection would also be reduced if we obtained a richer lighting gas by the separation of the gases. Naphthalene is a valuable product, which might, if circumstances required, be used on the same principle as the albo-carbon lights, for enriching gas near the place of consumption, or for converting the heating gas into illuminating gas. The importation of gas in main pipes in this manner would be far more economical, more cleanly, more conveuient, and more expeditious than in the present modes of conveying coal to the metropolis. If it be objected that an enormous amount of capital would be wanted to invest in the layiug down of these mains, one can only point to the capital which is sunk in rolling stock in railway labour, and in local means of the transit of coal, to show how it can be obtained.

A wonderful revolution has taken place in America and the Caspian in the transportation of petroleum through the use of what are called "pipe lines." The cost in this country of petroleum has been reduced about one-half through the introduction of this cheap means of transit from the oil wells to the coast. The first experiments of these were unsuccessful ; and the enterprise met with the most determined opposition from persons who supposed their interests would be invaded by the use of these pipe lines. At the present time, the pipe lines not only form a complete network throughout the American oil regions, but there are trunk lines which extend from the oil regions to the large cities, such as Pittsburgh, Cleveland, Buffalo, New York. These trunk lines transport the oil of large areas to those cities under a high pressure, delivering thousands of barrels daily. They are laid for miles through the forest-covered hills and valleys of northern Pennsylvania and southern New York ; across hills and rivers ; on the surface of the ground, or only slightly covered. These main lines are 6in. pipes, tested to a pressure of 2,000lbs. to the square inch, and joined with couplings into which the lengths of pipe are screwed as are ordinary gas or water pipes. The problems in hydraulics presented in the construction and management of pipe lines, particularly those lines that may be denominated trunk lines out of the oil regions, are many and intricate, and required great courage on the part of those who projected the first line to meet and surmount them. These men had only the quite different problems and experience met in laying pipes for water to guide them. These problems dealt with a homogeneous fluid, flowing through pipes laid permanently on curves of large diameter, flowing slowly under a low pressure, and delivered slowly. This water pressure seldom exceeded from 40 to 50lbs. per square inch. The "pipe line" problems dealt with a fluid varying in density with the temperature, flowing easily in the hot summers, and with difficulty in the severe winters of the country, through pipes of small diameter, laid hurriedly, and frequently changed ; often on sharp curves, or at right angles, for rapid movement and delivery ; and at high pressures, to compensate in part for the friction due to long distances, rapid transmission, and small diameter of pipe, as well as at much greater elevations than are found in water mains. The pumps which are used to keep up the necessary pressure are very powerful machines, forcing the oil rapidly through great distances and in vast quantities, not only over the hills that are encountered in the course of the line, but against the friction of the pipe conveying the oil—an element in the problem of vast importance, when it is remembered that the friction increases enormously as the flow of the oil is increased in rapidity. I need hardly point out here that, in the case of the conveyance of gas, even for long distances, the friction will be incomparably smaller than in the case of driving oil through pipe lines ; and any pressure which may be required will be produced by means of far less forcible pumps than those now in use in America for similar purposes.

It is impossible to compute or estimate accurately the vast length of the pipe lines and their connections, but it is safe to say that there are thousands and thousands of miles of pipes in use in America. These lines run everywhere, through the streets of towns, across fields and dooryards, under and over and beside roads, terminating at pumping stations, at racks, or in storage tanks. In 1879, 2,286 miles were controlled by pipe lines, 18,000,000 barrels of oil were conveyed through them, and about 250,000,000 of gallons were distributed to the manufactories in one year.

(To be continued.)

EIKONOGEN AND QUINOL DEVELOPER.—Here is the formula given by Mr. Rossignol for this developer. In 1,000 grammes of water dissolve 100 grammes of sulphite of soda, add 15 grammes of eikonogen, then 5 grammes of quinol, and finally, 50 grammes of carbonate of potash. It is better to place the carbonate in a separate bottle, and to mix, in the required proportion, at the time of using.—*Moniteur.*

ALUMINIUM MOUNTS IN AMERICA.—Many lens manufacturers are now using pure aluminium for mounting all their optical instruments. This will diminish the weight, nor can such instruments corrode. We believe it is dearer to use than brass, but on account of its many advantages would recommend it for lens mounts, corner clamps, and shutters.—*Wilson's Photographic Magazine.*

AMMONIA FORMED BY BURNING MAGNESIUM.*

BY P. L. ASLANOGLOU.

We all know that by burning metallic magnesium in contact with atmospheric air, it burns with a bright white light rich in chemically active rays, forming magnesium oxide (MgO)—the only oxide as yet known which is liberated from the metallic magnesium as a fine white powder; but there is still a portion of burnt magnesium remaining in the dish, and this is magnesium hydrate—$Mg(OH)_2$.

In November last (1889) I was experimenting with magnesium. I was burning an ounce of magnesium dust—superior quality—in an iron dish by setting fire directly to the powder; it burnt as usual, and, on cooling, I examined what remained, and found that a strong smell of ammonia proceeded from the remaining powder, magnesium hydrate. I have repeated the same experiment several times with all the different qualities or specimens of magnesium dust I could get, and they all gave the same result. I have also burnt magnesium wire, which likewise gave the same result.

From results obtained, I have concluded that magnesium burns in contact with the oxygen of the air, forming magnesium oxide; and that it also burns with the nitrogen and forms ammonia and magnesium hydrate, absorbing at the same time the aqueous vapour of the atmosphere.

$$Mg + O = MgO.$$
$$3Mg + 2N = Mg_3N_2.$$
$$Mg_3N_2 + 6H_2O = 2NH_3 + 3Mg(OH)_2.$$

It is evident, therefore, that the quantitative amount of nitrogen and aqueous vapour contained in this magnesium hydrate will vary with the different atmosphere found in different towns, countries, districts, &c.

I should think that by this experiment we could estimate the composition of the atmosphere, as its *constituents* are present in this magnesium mixture.

I have not yet made the quantitative analysis of the above experiment for the estimation of nitrogen, but the best way of estimating it would seem to be the following: By passing steam through the powder to collect the ammonia hydrate and receive it in a well-closed flask; then to precipitate it with platinum chloride, and estimate the ammonium platino-chloride precipitated. This will be sufficient to estimate the ammonia, and, consequently, also the nitrogen present, thus:—

$$H_2PtCl_6 + 2NH_3 = (NH_4)_2PtCl_6$$
$$\therefore (NH_4)_2PtCl_6 = 2NH_3.$$

N_2	= 28		
H_8	= 8		
Pt	= 197·5	=	N_2 = 28
Cl_6	= 213		H_6 = 6
	446·5	=	34

Suppose, for instance, we get by analysis 45 grms. of ammonium platino-chloride: then the amount of NH_3 contained will be—

$$446·5 : 34 :: 45 : x.$$

Six months after this experiment I was informed by an eminent authority on the science, to whom I imparted my observations, that this phenomenon had been previously observed by an American. Consequently I have hitherto doubted whether to insert it in the *Chemical News* or not; but, however, on second thoughts, I decided to send the above to the editor of the *Chemical News*, asking him to judge of my work, and to publish it or not, as he thinks advisable.

I myself have not yet seen a notice of the experiment in question in any English chemical paper; but I may have missed it, and thus have been anticipated in this record without my knowledge.

At the annual meeting of the Royal Archæological Institute recently held at Gloucester, a paper on "A Survey of Pigeon Houses in Herefordshire and Gower" was read by Mr. Alfred Watkins, of Hereford. It was fully illustrated by means of lantern photography.

* From the *Chemical News*.

THE EIKONOGEN DEVELOPER.

BY F. C. BEACH.

It is very nearly a year since this new developing agent was introduced to the photographic world; that it has rapidly grown into favour on its own merits, is attested by the increasing number of plate manufacturers who are recommending it as superior to the pyro developer, advising its use if the best results are to be obtained.

It is seldom a new developing agent is so favourably received, since it is hard to overcome prejudices in favour of old-time developers, but the advantages of eikonogen are so manifest to anyone who tries it fairly, that it frequently converts the most conservative at once.

It is an extremely simple developer, and, unlike pyro, will develop the latent image without the presence of an alkali, that is, as commonly understood, for we think it is the presence of the sodium salt in the sulphite of soda that supplies the alkali element in a small degree. It has been found, however, that a plain solution of eikonogen, without sulphite, will develop a plate.

The varied experiences of those who have given the developer a trial show that it does not work alike in all hands, which may be probably because of the different grades of preserving chemicals used. The best form of developer we have used is made with the clear, pale green crystals dissolved in a perfectly chemically pure solution of sodium sulphite; Merck's C. P. crystals is what we prefer. When mixed this gives a pale green solution, perfectly clear and very vigorous. We find this solution, if placed in a darkened room, keeps clear for a long time.

To make the stock solution, simply dissolve two ounces of sulphite of soda in forty ounces of warm distilled water, and add one ounce of eikonogen. By stirring with a rod it is soon dissolved. Where it was formerly advised to mix the alkali (carbonate of potash solution, three ounces dissolved in eight ounces of water) with the eikonogen, it is now recommended to begin the development with the simple plain eikonogen diluted one-fourth with water, until it has permeated through the film; then, after the image has started, or is too slow in coming out, add to two ounces of developer twenty minims of the alkali, or carbonate of potash solution. By pursuing this course the minimum amount of alkali introduced into the developer prevents the appearance of alkali fog, keeps the solution from getting thick, and reduces to a minimum the tendency of the plate to frill.

During the development more or less particles of the film along the edge of the plate will become detached, and if the solution is warm some of the gelatine will dissolve, which will cause the developer to thicken, perhaps, after the development of two or three plates; hence it is advisable to frequently filter it and to make good the loss by adding a little fresh eikonogen. The strength and activity of the solution is thus maintained.

When a series of plates have been developed, instead of pouring away all of the developer, some of it should be filtered and preserved in a small bottle kept tightly corked, for use in mixing with fresh developer, especially when time exposures are to be developed, since it has the same effect as the addition of a bromide—that is, aiding in producing density—without retarding the development.

A correspondent interested in the subject complains that he has difficulty in obtaining density, is troubled with frilling, and notices that the solution rapidly darkens after

use, though kept in a tight-stoppered bottle. He suggests that the first difficulty may be due to too large an amount of alkali in the developer, and the turning of the developer, possibly to an impure grade of sodium sulphite. His supposition is very nearly correct.

Want of density is sometimes due to too weak a solution of eikonogen, or in not leaving the plate in the developer long enough. The rapid change of the solution is accounted for by the use of insufficient sodium sulphite, or of a poor grade of the same.

From experiments, it has been determined that the larger the amount of sulphite in the developer, the slower it works.

It is rather interesting to note the varying quantities advised by different makers of plates. Our correspondent has gotten up a tabulated statement which shows clearly the differences alluded to, based on the ounce standard :—

	Eikonogen.	Sodium Sulphite.	Potassium Carbonate.	Sodium Carbonate.	Potassium Bromide.	Distilled Water.	Glycerine.	Potassium Ferrocyanide.	Sodium Sulphite, gr. to the oz. of solution.	Potassium Carbonate, gr. to the oz. of solution.
	oz.	oz.	oz.	oz.	oz.	oz.	oz.	oz.		
Formula of manufacturers of eikonogen...	1	2	$1\frac{5}{10}$		$\frac{1}{10}$	45			$17\frac{1}{2}$	$9\frac{1}{7}$

Ditto, for instantaneous exposures	1	4	2			40			$43\frac{7}{10}$	22
Ditto, bromide paper	1	3	2			128	1		$10\frac{1}{4}$	$6\frac{13}{64}$
Ditto, lantern slides ...	1	5	1	1		128	1	$\frac{1}{2}$	17	$3\frac{1}{2}$
Ditto, average for plates, bromide paper, and lantern slides	1	$3\frac{1}{5}$	$2\frac{1}{5}$			$74\frac{1}{3}$				

Remarks.

Most of the formulas are based on 437 grains to the ounce ; taking that as a standard, and summing up the number of grains to the ounce in the six separate formulas, of the sodium sulphite and carbonate of potash, then taking their average, the amount of sodium sulphite for the eikonogen developer is found to be twenty-four grains to each ounce, and carbonate of potash eleven grains to the ounce.

No satisfactory reason is given for the unusual amount of carbonate of potash recommended in the Eagle plate formula ; experience shows that it would have a tendency to fog the plate or to frill it if the gelatine is soft.

During the hot weather of the summer eikongen crystals have been observed to change in colour from a pale, clear green to a brown-black tint, even though sealed in bottles excluded from the outer air. When dissolved such altered crystals make a dark green solution, but the power of the eikonogen does not appear to be lost ; it is only in looks that it seems to be defective. This change may be brought about by heat, but as yet no reason is advanced, except that it is known that eikonogen which has been made for some time gradually discolours. It is to be presumed that further investigation will decide what is the actual cause of the discolouration, and doubtless before many months a way will be found to prevent it.

We are informed by the manufacturers that the discolouration will be prevented or checked if the salt is emptied from the package and spread out, so that the air may have access to it. We are also advised that a dark green solution of eikonogen may be clarified by the addition of a few drops of a saturated solution of bisulphite of soda. We dissolved 480 grains of the bisulphite in two ounces of water, and ascertained that half a dram (30 minims) added to one ounce of the dark green eikonogen solution was sufficient to change the colour from green to a light red, but it did not appear to make the solution any more transparent.

Applying this altered solution to a bromide print, we were unable to develop the picture after five minutes' immersion, except to see a slight image. A few minims of carbonate of potash solution were added, then the print developed out with moderate rapidity. The colour of the developer was also altered from red to green again.

It would seem from this experiment that the addition of sufficient bisulphite of sodium to the developer to change the colour is not advantageous. That it undoubtedly shows the action was manifest. We think it may be used to advantage in mixing up the original developer, and probably one ounce will equal in preservative quality that of two of sulphite of soda.—*The American Amateur Photographer.*

THE BRITISH ASSOCIATION AT LEEDS.

THE Leeds meeting of the British Association began on Wednesday evening last, when Sir Frederick Abel delivered his presidential address, which dealt with explosives, guns, and other subjects not connected with photography.

The number of the tickets issued at the Leeds meeting to yesterday (Thursday) evening was 1,578, and this number indicates that the meeting is likely to be a medium one, with neither a particularly large nor particularly small attendance. Amongst those present at the meeting are Mr. James Glaisher (president of the Photographic Society of Great Britain), Dr. J. W. L. Glaisher (president of Section A), Lord Rayleigh (secretary to the Royal Society), Mr. C. H. Bothamley (one of the secretaries to Section B), Sir H. Trueman Wood, Mr. John Spiller (who is the guest of the ex-mayor of Leeds), Mr. Frederick Varley, Miss Varley, Mr. Tate (of Belfast), Dr. John Hall Gladstone, Professor Liveing, Sir William Thomson, Professor Rucker, Sir Henry Roscoe, Professor Meldola, Professor Rowlands (of the United States), and Mr. and Mrs. Clement-le-Neve Foster yesterday afternoon.

Lord Rayleigh read a paper in section A upon colour blindness, and some experiments which he has made with colour-blind persons by means of the late Professor Clerk Maxwell's colour top. To a particular colour-blind observer he selected a mixture of 64 parts green, and 36 parts blue appeared to be the same as a mixture of 61 parts black and 39 parts white. In another instance 82 parts red and 18 parts blue, forming together a bright crimson to normal eyesight, appeared to the colour-blind person to be the same as a mixture of 22 parts green and 78 parts black.

All the best hotels at Leeds are full, and in one of them beds are made up in the baths minus the water.

TRANSPARENT celluloid films are now supplied in white, tinted, amber, black, blue, and ruby colours. This is of advantage in some classes of work.

Patent Intelligence.

Correspondence.

ARISTOTYPE PAPER.

Sir,—With reference to your note about Aristotype paper, I have used it since it first came out, and I believe there is no ready sensitised paper like it; but I have found much more satisfaction in using it since I took to the toning and fixing method given in your paper, No. 1,638, January 24th, 1890. It is quite true the paper often drops off the glass when dry; it never, by any chance, sticks to the glass. I believe the gold goes further by this plan than by any other. H. D.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

Sir,—Kindly permit me to remind intending exhibitors that Monday, September 15th, is the last day for receiving "packing cases" from the country, by our agent, Mr. Bourlet, 17, Nassau Street, Middlesex Hospital; and also that the same day is the only one for receiving pictures and apparatus at the Gallery, 5a, Pall Mall East, S.W.

Any further information may be obtained from me.

Edwin Cocking, *Assistant Secretary.*

Hiding Photographic Defects.—We often find a clear spot on the negative, or some defect of figure of such proportions that we cannot touch it out with the pencil or Indian ink so that it will not show on the print. In such cases the colour is generally applied so thickly on the negative, that it will leave a clear white spot on the print; and the usual method to correct this is to go over such portions with colouring material to hide the spot or defect by shading it to match the surroundings as much as possible; but any who have tried to get a quantity of colour to adhere to the surface of albumen paper know how difficult this is to accomplish. Such white spots on the print may be discoloured by light, applied by a species of double printing, by folding a piece of opaque paper so that it will entirely cover the print, but with the ends open and the wrapper somewhat larger than the print; a hole may then be cut in this wrapper at about where the white would come when the print is enclosed—the opening to be cut as near the shape of the spot as possible. Placing the print within the wrapper, so that all parts are protected from the light excepting where the opening is made, the print may be moved from the open ends until the white spot is at the opening, and, by exposing this to subdued light, it will gradually assume the shade desired. Upon occasional inspection to note progress, it may be found necessary to move the print a little, so that all portions of the spot receive a fair share of light, and even discolouration. In this way a spot is shaded more rapidly and easily than by applying colour to the print with the brush; the result is more even, and it will not change during burnishing, as is often the case when colouring matter is freely applied. The wrapper or mask, when once properly made, answers for any number of prints from the one negative, and with but little practice the novice may soon become quite proficient at spotting out by this process.—*Photographic Herald.*

Proceedings of Societies.

London and Provincial Photographic Association.

August 28th.—F. W. Hart in the chair.

Mr. F. A. Bridge showed a finder attached to the front part of his camera. A short tube with cross-lines inside fitted to the finder directed the eye to the centre of the field. He also exhibited a substitute for a ball and socket joint. The camera is screwed to a rod about three feet long; this rod is simply put through the tripod head; by grasping the end of this rod with the right hand the camera can be placed very quickly in any position, the pneumatic ball being held in the left hand.

Mr. A. Haddon preferred using a small camera as a finder, combining a finder and a view meter in one.

The Hon. Sec. read a paper on "The Use and Abuse of Hand-Cameras."

Mr. F. A. Bridge considered that the standard of lantern slides had been considerably lowered since the introduction of the hand-camera.

The Chairman said hand-cameras were objectionable when used to photograph people in awkward positions, and many users of the hand-camera seemed constantly on the look-out for pictures of this class.

Mr. Chang showed an album of views 7½ by 5 taken by him with a hand-camera.

The Chairman passed round prints of a stand to carry twenty flash-light lamps for out-door use; the stand was made of bamboo and screw joints. He also showed photographs of a portable studio, complete with curtains and other requisites, weighing, when packed, 35 lbs.

The last outing of the season will be at Hampstead Heath, on the 20th inst. Members will meet at the Bull and Bush.

Subject for discussion on the 11th, "Carbon Printing."

Hackney Photographic Society.

At the meeting held on Thursday last Mr. Arthur Dean presided.

Several prints were shown by Messrs. Pailthorpe, Roden, and Grant. The former were taken in a hand-camera of his own construction.

The Secretary announced that Mr. Jno. Reynolds had presented an album to the Society.

Mr. Hubert then gave a paper on "Portraiture and Retouching." He thought the rivalry that existed between amateurs—or, rather, professionals—was a mistake; they must move with the times. A good photographer must be an artist. He said that he preferred graduated backgrounds even to scenic ones, which ought not to be sharply defined, or they would detract from the picture. He always judged his background from the sitter's dress. A rapid rectilinear lens could be used out-of-doors; in a room, the portrait lens was best. The amateur should, when in a garden, find out the N.E. light, screen off S.W., and, with some light material, shade off (regulatable) the top light. He demonstrated the lighting with the assistance of two members, and concluded by giving a demonstration of retouching.

Birmingham Photographic Society.

A meeting was held at the Colonnade Hotel on August 28th, Mr. W. J. Harrison, F.G.S., in the chair.

Mr. Thomason gave a *résumé* of the half-day excursion to Warwick, and Mr. Leeson of the excursion to Lichfield.

The Chairman said that Mr. Moore had kindly put on the table an interesting and complete set of photographs by the late Mrs. Julia Cameron. They were the best set he (the Chairman) had seen. Mrs. Cameron, he said, was fifty-four years of age when she took up photography, and was the forerunner of the naturalistic school. She gave long exposures, and her negatives were wholly untouched. Artists of her day admired her work—photographers did not. One of the prints—Tennyson—is still the best photograph of the poet laureate in existence.

Mr. Godfree, Mr. Stait, Mr. Rushton, and others exhibited prints taken during the Lichfield excursion.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

A MEETING was held on the 28th ultimo at the Club Rooms, 3, Lord Street, Mr. PAUL LANGE in the chair; and there was a large attendance of members.

Mr. Thomas B. Blackburn was elected a member of the Association, thus making the forty-second new member added to the Association this year.

Mr. William P. Christian exhibited a frame containing tinted lantern slides of "The Alhambra" (Granada, Spain) and some scenes of Algerian life; he also explained the process of obtaining the tones.

The Hon. Sec. (Mr. E. M. Tunstall) exhibited a photographer's new exposure table, published by T. Munson, of Kendal.

A discussion took place on Scholzig's new method of obtaining platinotype results with matt surface silver paper, and printing under green glass. Messrs. F. K. Glazebrook, John Price, William Tomkinson, and E. M. Tunstall had made some experiments with the paper, but had only obtained very indifferent results so far, not approaching the *finest platinotype* tones, as stated by Mr. Scholzig.

A negative, belonging to Mr. F. K. Glazebrook, of a view taken at Llangollen, caused considerable discussion on account of a curious fog in the centre of the plate and the reproduction of a house in the fog. The lens was a "Ross" portable symmetrical, and the plate was the only one so marked out of a dozen or so exposed that day. It was agreed, after discussion, that Mr. Glazebrook write to Messrs. Ross, sending them the lens and negative, with the hope that they might explain the matter.

Mr. J. A. SINCLAIR gave a formula of a good eikonogen developer for lantern slides, as follows:—

No. 1.

Eikonogen	½ ounce
Sulphite of soda	2 ounces
Water	20 ,,

No. 2.

Washing soda	2 ,,
Carbonate of potassium	2 ,,
Water	20 ,,

No. 1. ... ... 1 ounce } to ½ ounce water for
No. 2. ... ... ½ ,, } 8 or 10 plates.

Mr. B. Boothroyd exhibited some fine bromide prints of views secured by him in Norway on a recent trip.

Several albums were exhibited, notably two by Mr. H. Luptou in silver and platinotype, of views taken in the English Lake district and in the south of Ireland.

Various novelties were handed round, viz., an ingenious bamboo tripod; ball and socket arrangements, exhibited by Col. Ellison; and the "Baroness" half-plate camera, by Mr. Tomkinson.

AN arrangement has been made by the Berlin Meteorological Society to undertake the photographing of lightning during the coming season at different stations up and down the country.

"SCRAPS," the broadsheet printed monthly by the Britannia Works Company, and always containing useful items of practical photographic information, has now completed the first year of its existence.

THE supreme Court of Minnesota has decided that a photographer has no right to sell photographs of his sitter without that sitter's permission. This decision is now common law in the courts of many of the States in the American Union.

THE Photographic Society of Geneva has organised an Exhibition which will be open from the 15th of this month until the 15th of October. The President of the Exhibition committee is H. C. Herdinger, and the secretary is Mr. Jules Bey.

THE FRY MANUFACTURING COMPANY send a copy of their new catalogue, in the introduction to which they take the opportunity of stating that they have purchased the business of Samuel Fry and Co., Limited, and that they will carry it on under the style of the Fry Manufacturing Co., and do all in their power to largely extend and increase the concern. The catalogue is well arranged, and, like so many of the price lists now issued by leading firms, contains a large amount of useful information.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

F. C. C.—*Photographs of Wye Scenery.* Your best plan would be either to advertise, or collect them from local photographers on your route. Easy terms might be arranged for right of reproduction if you mention the object of your proceeding, and agree to insert the artist's name. Be careful to avoid anything which may be construed as an act of piracy, and get in all cases written permission to use the photographs in the manner desired, so that your mutual interests may be properly safeguarded.

S. M. (Yeovil).—*Leather Case for Camera.* Unless you want to practise the fatigue duty, leave your camera case behind, and be content with folding the focussing cloth around your camera, and carry it by a double strap. There is usually enough exercise to be got without needlessly adding to your impedimenta.

J. E.—*Albumenised Paper Injured by Damp.* Before rejecting it as altogether unserviceable, try a few prints by sensitising on the wrong side, and print thereon your bolder landscape subjects; or try to use it for enlargements.

W. M. A.—*Portmanteau with Ruby Glass for Plate Changing.* As already stated, we do not find any such appliance sketched in the catalogues, and doubt its superiority over a compact form of folding lamp or screen *for working by night.* In which way is the portmanteau intended to be used—as a receptacle, with sleeves and hood, for manipulation either by day or night; or as a capacious and therefore tolerably safe lantern?

EXHIBITOR.—*The Pall Mall Regulations.* Monday, 15th inst., is the last day for reception of intended exhibits, whether delivered by hand at the Gallery, or sent (in packing cases) to Mr. James Bourlet, 17, Nassau Street, Middlesex Hospital. An entry form should be procured at once from the assistant secretary, 5A, Pall Mall East.

A. B. (Preston).—*Local Fading of Prints.* May not the circular mark seen in one of the prints be due to the fading of the mauve dye in the tinted paper by sunshine, rather than by the actual destruction of the photographic image by atmospheric exposure?

R. B. B.—*Manual of Photo-Engraving, &c.* We have received notice of the issue of a new edition of Mr. W. T. Wilkinson's book. It is now to be had of Messrs. England Brothers, 23, Charles Street, Notting Hill, W.

A. P. (Birmingham).—*Making a Vignette Direct on the Negative.* Excepting by transfer of a collodion or carbon graduated film to the face of a negative—a somewhat difficult operation—we do not know of any method of effecting the object you desire to accomplish. Can any of our correspondents oblige us by proposing a plan?

L. N.—*Magnesium Chloride from Sea Water.* A quart of sea water left to evaporate spontaneously in an open dish has given us barely an ounce of mother liquor, saturated with the chlorides of magnesium and sodium, when drained from the cubical crystals of common salt. It will be seen, therefore, that this method of preparation is, at best, a slow affair. Try a mixture of Epsom and chloride of calcium or common salt, which may be expected to furnish the chloride of magnesium by double decomposition.

M. E.—*Portable Furnace for Reducing Silver Residues.*—Usually a few bricks stacked by hand, if not built up too high, will enable you to extemporise a coke fire, or a kitchen stove may serve for small operations. Messrs. Fletcher and Co., of Warrington, offer a kerosine oil furnace, suitable for heating small crucibles in which silver residues may be reduced.

J. P. (Moss Side).—*Manufacture and Properties of Celluloid.* 1. Messrs. Carbutt and Co., The Eastman Company, and others. 2. May be softened by heat. 3. Nitro-cellulose, camphor, and sometimes castor oil.

M. D. and other Correspondents in our next.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1671.—*September* 12, 1890.

CONTENTS.

THE PRIMULINE PROCESS.

THE chief event, from a photographic point of view, connected with the meeting at Leeds of the British Association for the Advancement of Science, which closed yesterday, was a paper read last Tuesday in the Chemical Section by Mr. A. G. Green. He made known a new process, in which primuline, a recently-discovered coal-tar dye, was used to produce photographic prints of an entirely new character, and various particulars about it are published in this journal this week.

Mr. Green also gave a demonstration of the process to the Section. An enamelled iron basin contained about three pints of water kept nearly at boiling temperature by means of a Fletcher's gas burner below, and into this he projected, without weighing, a few grains of primuline, a light yellow powder, and, aided by stirring with a glass rod, it quickly dissolved. He then took a piece of white cotton cloth, perhaps 12 by 10 inches in size, and pushed it below the surface of the liquid by means of the glass rod. In one or two minutes the cloth was dyed light yellow. Then it was lifted from the liquid by the rod, and thoroughly washed in water; the surplus water was next wrung out of the cloth by hand, and the damp cloth placed upon a white backing in the printing frame, beneath a translucent, flexible coloured picture, such as used in windows in imitation of stained glass. When it is desired to obtain a print of a purple colour, the cloth, after the washing, is soaked in a mixture of a solution of nitrite of soda and acetic acid; this soaking somewhat deepens the yellow colour. The operations so far occupied five or six minutes.

The printing frame and its contents were then exposed at a window for ten minutes to rather dull daylight; there was no sunshine. The print was then developed by immersion for less than a minute in the solution described upon another page; then it was washed in water, and the whole operation would have been finished, except that in this instance, in order to fix the purple colour, which otherwise would have been liable to be acted upon by alkaline agents, it was passed through a bath of tartaric acid. The whole of the operations, from first to last, occupied about twenty minutes on a dull day; with sunshine but one minute's exposure would have been necessary, thereby reducing the total time to eleven minutes. The developer used in producing a purple colour has an evil smell.

Next a contact print, by artificial light, was made in about five minutes upon a dry plate which had been coated with a solution of primuline in gelatine. The time of exposure was five minutes to the lime light in front of an ordinary optical lantern condenser.

The colours produced by this process are not gaudy, but of an "artistic" nature, resembling those which predominate upon Indian silks. As yet a white ground to the prints has not been obtained, but a light grey, approaching to white, has been produced. For many subjects this absence of white is no drawback, because the pictures look as if intentionally coloured by hand; in fact, such power of producing colours in untouched photographs has never before been seen. One picture represented a classical head of large size against an artistic yellow background; the general result was excellent, and no one could have imagined a week ago that such a result could possibly have been produced by photography.

Numerous prints in various colours by this process were exhibited; some of them were on glass which had been coated with primuline dissolved in a solution of gelatine; others were upon paper, cloth, and various fabrics; most of them were of rather large size.

In relation to the action of the spectrum upon the new substance, Mr. Green stated that the decomposition is far more general over the whole spectrum than is the case with silver salts; although the action is greatest in the violet, it is fairly strong as far as the orange. He could not give a definite solution of the problem as to the nature of the chemical change produced by light, but could state that it is certain that nitrogen is set free; he thought it probable that some of the residue formed entered into the cellulose or gelatine vehicle; at all events, when no organic matter is present, the

decomposition produced by light is relatively excessively slow. In gelatine the nitrogen eliminated is locked up for some time, certainly for a day, and when the exposed gelatine film is placed in water, bubbles of nitrogen are given off.

Those present at the reading of the paper displayed a lively interest in its contents and in the demonstration. Mr. John Spiller, whose remarks will be found in last Wednesday's *Times*, stated that Mr. Green had not alone been the discoverer of primuline, but of the second stage of its application to photographic purposes. Mr. Spiller farther stated that he himself had been working with primuline upon paper, and had found it to be quite as sensitive to light as ordinary chloride of silver; he had tried to get an image upon it in the camera, but had obtained no result in ten minutes. The colouring matter in the finished print—say, the red colour—he believed to be wonderfully permanent; it was not affected by light, by acid, by alkali, nor by a variety of metallic salts, but was attacked by hydrosulphides. The new process, he thought, was likely to run the blue process very hard for engineers' drawings.

Among those present at the meeting was Professor Rowlands, of the United States, who has been so successful in the production of diffraction gratings. He asked whether the new substance had been tried for the orthochromatising of ordinary gelatino-bromide plates. Mr. Bothamley replied that it had never been so tried, but that only ten minutes previously Mr. Green had given him some primuline for the purpose.

In the course of this interesting meeting, Professor Thorpe, who presided, remarked that it was a curious fact that just thirty-two years ago, when the British Association was previously at Leeds, the inventor of the blue process, Sir John Herschel, occupied the chair in which he, Professor Thorpe, had just been listening to the description of a new process which Mr. Spiller had said was likely to "run the blue process hard."

So far as can be judged at present, the "running of the blue process hard" is one of the smallest things the new process is likely to do, for it gives a power never before seen of photographically producing coloured results, some of which may be artistically harmonious, and others the reverse. Ere a few months have passed away the merits and demerits of the primuline process will have been largely investigated by practical photographers, and it seems probable that some of the classes of pictures it is capable of producing will arrest the attention of the general public to an unusual extent.

Wilson's Photographic Magazine says that "Upon the completion of the new quarters of the Society of Amateur Photographers of New York, 113, West 38th Street, this Society will have the largest and most complete quarters in the world."

AMERICAN APPARATUS FOR THE FLASH LIGHT. — Take an ordinary clay pipe, wrap a piece of absorbent cotton round bowl, saturated with alcohol. Draw a piece of rubber tubing over pipe stem about a foot or so long. Weigh out magnesium powder, and place it in bowl of pipe. Focus your subject. Ignite the alcoholic cotton, and blow through the tube simultaneously. The powder will rise with an effective flash, the flame being about six inches above the bowl. Shut the eyes when blowing to prevent the mischief of sudden light shock.—*Scraps.*

HAND-CAMERAS.

A DISCUSSION recently took place before one of the societies which had for its subject "The Use and Abuse of Hand-Cameras," under which description are grouped all the various patterns of "detective" instruments which have been devised to delight the eyes of those who aspire to photography, and to vex the souls of others. The gentleman who opened this useful discussion very rightly deplored the danger which, he thinks, exists in the deterioration of picture making generally by the adoption of a system which at one fell swoop does away with tripod stand, rising-front, swing-back, and other appliances which accomplished photographers have hitherto regarded as necessary joints in their armour That the use of the hand-camera has become greatly extended during the last few months there can be no question at all; but that there is reason to suppose that its appearance has stopped the use of the older form of instrument to any important degree, or that masters of the craft are sacrificing the apparatus with which they have done so much good work, for a contrivance which, at the best, is limited in its applications, we must altogether refuse to believe.

Were it possible to take a census of those who purchase this new machine, we should, we feel certain, find that the buyers of hand-cameras are mostly those who take up photography because it is just now the fashionable craze. If the fashion had taken the form of pea-green hats, or sky-blue shoes, the hand-camera would have been left unnoticed by these butterflies of life. They care not for art, for they possess not the type of mind which can appreciate art; but they can no more afford to leave the last new craze alone than they can afford to miss the annual exhibition of the Royal Academy, or any other show or "function" to which the society fetich which they worship has set its approving seal. If they thought that the acquisition of the art involved any real trouble or the need of exertion, it would, perhaps, have been different, but the cunning dealers have met them half way, and have whispered to them, "You push the button, and we do the rest."

It is a comfortable way of acquiring a new accomplishment to dispense with any drudgery in connection with it, and photography seems to these recent aspirants to fame to be unique in the ease with which it may be learnt. "Touch the button," that is all; no need is there even for a button-hook. How different is it from acquiring the art of singing, with its practising at scales, and endless intervals—a laborious business which, after all, may end in the discovery that you have no ear. There is no royal road either to water-colour drawing, for you must know something about perspective and the theory of colour before you can paint well enough even for a charitable bazaar; but with this charming new acquirement, which is patronized by society, you merely touch a button, and somebody else is kind enough to do the rest.

It is quite evident that those who take up photography merely because they regard it as "the thing to do," will never be able to turn out good work. They

may produce a decent picture once in a way, for, as we all know, flukes are not confined to the billiard table, but the majority of the plates or films which they expose by the touch of that magic button are, in the nature of things, predestined to failure. The touch of the button—which they look upon as the chief, if not the only manipulation necessary—is in reality the last of a series of important operations, and the only one which is simply mechanical in its nature. The first operation is to *see* a picture in that which lies before us, and the number of those who have no eyes for such things is far greater than those who lack ears to guide them in singing a melody correctly. Then come the questions of distance, sufficiency of light, to say nothing of the knack of holding the camera level, and pointed in the right direction to include the required subject. To the thoughtless buyer of the touch-button contrivance these are simple things to surmount, and it will not be until someone else has "done the rest" that he will find out his error. He takes no heed of anything beyond the mere mechanical part. He sees something which he fancies will give him a first-class picture—an open landscape, a grove of trees thick with shadows, or even the interior of a room, it does not matter which—all is the same to him; he merely has to press the button. Then the plates or films are sent to the dealer, who must do his best to coax an image out of them, or to satisfy his customer that there is no image there to coax.

There is no doubt that this new type of photographic worker—or, rather, player—has been born of the hand-camera, and, while we feel inclined to smile at him, as we did last year when, from the same laudable motive, he took to banjo playing, we must acknowledge that he is harmless, and is, to some extent, serviceable. He will not, it is true, advance the progress of photography one jot, nor will he produce any picture worth looking at. His self-imposed task will not give birth in his mind to any fresh ideas; but he will spend money on his transient hobby, and in that way he will do good. So let them play at being photographers, and spend their money on apparatus as freely as they like. The hand-camera is not a dangerous weapon like the revolver, for if the shots do not hit the target, they do not go astray. In the meantime, the real workers will keep to their old ways, although they are ready enough to acknowledge the great value of a hand-camera when used with knowledge and discretion.

Portraiture by the Magnesium Light.—To Professor Schirm, of Berlin, belongs, we believe, the honour of re-establishing the practice of portrait photography by the magnesium light exclusively. Not only are all the negatives taken with this light, but the printing and copying are also done by the same means. The Professor uses Voigtlander's Euryscope lenses, and for printing, the chloride paper of Dr. Just, of Vienna. Last winter Professor Schirm attended a fancy dress ball, and between 9 p.m. and 5 a.m. secured no less than 318 pictures, some on orthochromatic plates, with yellow screens, all by means of the flash-light. All who have seen this collection pronounce the photographs most admirable. In consequence of this success, flash-light photography is rapidly becoming a feature in many of the studios of Berlin.—*Wilson's Photographic Magazine.*

BRITISH ASSOCIATION NOTES.

The Opening Meeting.

At the opening meeting of the British Association at Leeds on Wednesday, last week, and after the reading of the presidential address by Sir Frederick Abel, the Marquis of Ripon moved a vote of thanks to the president, which was seconded by Sir Frederick Bramwell. Mr. Emsley, the Mayor of Leeds, in "putting" the motion to the meeting, gave the Association a few words of welcome to the town in the usual Yorkshire highly hospitable fashion, and added that it was thirty-two years since the previous meeting of the British Association at Leeds, and that he had recently been looking over the list of names of those who then attended. He wondered that many of those names had not been commemorated by statues; but perhaps, as Cato observed, it was better that people should ask why there was no statue than why the statue existed. From this we infer that the Mayor is an amateur photographer, who had been reading Mr. Mew's remarks about the statue to Daguerre, published in these pages two or three weeks ago.

Geological Photography.

At a meeting of the General Committee of the Association, which had been held a few hours before the opening meeting, Sir Douglas Galton, the Secretary, read the report of the Council; then the report of the Corresponding Societies Committee was read, in which a little attention was paid to geological photography. It set forth that Professor Lebour had stated at the meeting at Newcastle last year that Section C, since the first conference, had had this matter referred to them for consideration, and he might say there was the greatest possible unanimity when it was brought up. The subject was one which all geologists would agree was a most useful one. Mr. Jeffs, as a member of Section C, explained the system which he and Mr. Adamson had so far adopted; the method was regarded as no doubt a good one, but the whole question of detail was left to the committee to report upon. He might say that it had been passed on to the Committee of Recommendations that same day. It was taken up by the president, Professor James Geikie, and was provisionally passed, he believed, without any opposition. The members of the committee were Professor Geikie (as Chairman), Professor Bonney, Mr. A. S. Reid, Mr. S. A. Adamson, Professor Boyd Dawkins, Mr. W. Gray, and Mr. Jeffs as secretary. He thought they would see that the committee was chosen with some thought as representing different parts of the country, so that a considerable area would be covered, and the different features of the various districts would not be overlooked. The committee was not only appointed to do the work of collecting, preserving, and registering in a systematic way the photographs of places of geological interest, geological sections, and so on, but he thought in the first instance it was chiefly for the purpose of seeing how the work could best be carried on in the future. One of the most important points they would have to consider was where the

photographs, when once obtained, were to be lodged and preserved in safety for consultation. He hoped hat they would hear to-morrow that the proposal had passed the Committee of Recommendations, and had become an actual committee of the British Association. A grant of £10 had been asked for at the same time.

The committee was subsequently appointed, and last week Professor Meldola became its secretary.

About the relations of photography to geological science we shall have more to say hereafter.

A NEW USE FOR COLLODION.

Last Monday Professor John Berry Haycroft communicated to the chemical Section a paper on "The Structure of Muscular Fibre as demonstrated by Castings taken in Collodion." The author, according to the official abstract of his memoir, had published ten years ago the results of an experimental research which showed that the cross striping of a muscle depended on the moniliform shape of the muscle fibrils, and not upon their fracture. It occurred to him some months since that the point could be definitely settled if castings could be made of muscular fibres. If the casts should exhibit the microscopical appearances of the muscle, then these appearances could only be due to its form. He had tried a great many methods in vain, but had at length devised a way of stamping moist collodion with the fibres. A drop of collodion was placed upon a glass slide, and, before it was quite dry, some muscle fibres were pressed upon it with the finger tip. These were then removed, and the film, being examined with the microscope, was seen to be covered by exquisite impressions of the fibre. One could see every stripe clearly and sharply defined, even those which were most minute and difficult to recognise in the actual muscle. Some of those were so minute in width as not to measure the twenty-thousandth part of an inch across. When the collodion dried, the film shrank owing to its surface tension, and the little impressions all disappeared. Here, of course, one was only dealing with the surface form, and it was clear there was absolutely no structure, and the proof of the author's views was complete. The castings showed the microscopical appearance of the fibre in whatever stage of contraction or relaxation it might happen to be, so that the inhibition theories of the German authors had to be discarded, as they were all founded on the fact that the stripes changed during contraction in size and arrangement, this change being due not to any enlargement or diminution in the size of actual structures, but, as the "casts" demonstrated, to an alteration in external form, and therefore of optical appearance of the fibrils themselves.

DR. GLAISHER AT THE BRITISH ASSOCIATION.

Mr. James Glaisher, president of the Photographic Society, is so respected in photographic circles from the large part of a life-time he has devoted to its interests, that it is pleasing to know that his son, Dr. J. W. L. Glaisher, has been steadily rising in influence in the scientific world, having been in the past the president of the Mathematical and some other London Societies, and at the recent British Association at Leeds he was president of Section A, Mathematical and Physical Science. Lord Rayleigh spoke in high terms of his opening address to the Section, and last Wednesday, at the close of the whole proceedings, Sir William Thomson said that he had never seen a president of the Section who had devoted himself more assiduously to the duties of his office. This characteristic seems to be hereditary in the family.

Last Saturday one of the British Association excursions was to the ancient town of Pontefract. The Castle and other archæological objects of interest were well explored by the visitors, who numbered 150, with Dr. J. W. L. Glaisher at their head; at least, upon him, as the only president of a section present with the party, fell the duty of returning thanks to the Mayor and Corporation, also to Mr., Mrs., and Miss Tew, and others, for their hospitality. Mr. Tew, in the course of a speech from the head of the table, remarked that the Association visitors had been also welcomed by the ancient Corporation of Pontefract, and by its Mayor, who had been in existence since the days of Richard III. Mr. John Rhodes, the Mayor, fixed his eyes on the mace and shook his head at this remark; he appeared to think that his age had been rather over-stated.

Pontefract thrives upon the curious industry of liquorice growing and liquorice preparing. The liquorice plant is a shrub with acacia-like leaves, and it takes three or four years to arrive at maturity. It sends its long tap roots about six feet deep into a soft, sandy soil, containing iron; as the root cannot be pulled up, it has to be dug out of its deep bed.

Miss Mene Muriel Dowie accompanied this excursion. Her paper entitled, "Notes on a Journey in the Carpathians and Ruthenia," created a great sensation, and was described by some of the Leeds daily newspapers as the best of those delivered at the British Association meeting in that town.

THE NEW PHOTOGRAPHIC PROCESS.

Mr. John Spiller exhibited last Tuesday, in the Chemical Section, some prints he had produced upon paper by the primuline process; their colours much resembled those of different varieties of sea-weeds, and it seems likely that the power is now placed in the hands of botanists of obtaining direct photographic prints of selected seaweeds in something approaching the natural monochromatic colour of each of them. No prints on fabrics were shown at the meeting in which the primuline pictures had been kept well on the surface by the use of a substratum.

FUTURE BRITISH ASSOCIATION MEETINGS.—Next year the British Association will meet at Cardiff, under the presidency of Dr. William Huggins. In 1892 it will meet in Edinburgh. The severity of its last reception there was publicly notorious; perhaps it arose from local dissentions, and 1892 may show that Edinburgh is not inferior to Glasgow in hospitality. Mr. Atchison, the much-liked secretary to the British Association, has been obliged to resign because of bad health, and this responsible position will henceforth be occupied by Mr. George Griffith, of Harrow, who was secretary to it for a long course of years, and knows its inmost workings. He is exceedingly popular with the members.

PHOTOGRAPHS OF THE INVISIBLE IN SOLAR SPECTROSCOPY.*

BY C. PIAZZI SMYTH, LL.D.

The photographs submitted on this occasion are two, each of them murally mounted, and measuring forty inches long by twenty inches high. They represent in reality only very small portions of the faint ultra-violet of the solar spectrum, but on a whole scale of fifty-seven feet long from red to violet, and are located quite outside the spectral limits of visibility to the human eye with the grating spectroscope concerned, whether under summer or winter sun.

Yet the previous empty fields of ultra-violet view became filled with wondrous detail as soon as they were entrusted for record to actinism and the photographic film. This, too, in dull winter weather, with a lamentably low sun on December 12th, 1889, or "where the eye could see only less than nothing."

Some degree of power in photography to record farther into the spectrum than the human eye has long been well known; but in this instance there had been supposed proof obtained of the positive incapacity of the metallic substance of the grating to reflect the ultra-violet or even violet light, yet here this accusation was shown to be false the moment photography was applied, and powerful pictures have been procured thereby, as witness these enlargements by Mr. S. H. Fry, at Kingston-on-Thames, from the author's original negatives on glass.

The definition is not indeed yet what the author desires, but he expects soon to make it so by the aid of a contribution lately received from the Government Grant Committee of the Royal Society, so that then, having a sufficient supply of electricity already on the premises, he may be able to photograph a more crucially telling comparison between certain earthly elements and the solar spectrum lines than has yet been accomplished, if, indeed, the present meeting will graciously extend to him, among their many annual votes for the promotion of science, a sufficient one for carrying on an end-on-gas-vacuum tube method of photographing, which is alone suitable to high spectroscopy.

THE BRITISH ASSOCIATION COMMITTEE ON GEOLOGICAL PHOTOGRAPHS.

The following is the report of the above Committee read last Tuesday, which Committee consists of Professor James Geikie (Chairman), Mr. S. A. Adamson, Professor T. G. Bonney, Professor W. Boyd Dawkins, Mr. William Gray, Mr. Arthur S. Reid, and Mr. Osmund W. Jeffs (Secretary), to arrange for the collection, preservation, and systematic registration of photographs of geological interest in the United Kingdom. (Drawn up by the Secretary.)

Your Committee have much pleasure in presenting the annexed list of geological photographs obtained as the result of their first year's operations.

In the report of the Corresponding Societies' Committee presented to the Newcastle meeting (1889), lengthened reference was made to a proposal by the Committee of Section C for the systematic collection and registration of geological photographs, following upon a suggestion contained in a paper read before the section at Bath by Mr. Jeffs. The subject was discussed several times by the delegates, many of whom contributed examples of such geological photographs as had been taken before any scheme to secure uniformity of action was mooted. Important suggestions were also offered as to the arrangements to be made to carry out the objects stated, but the details were ultimately left in the hands of the present Committee, the appointment of which was sanctioned at the Newcastle meeting.

In commencing operations, your Committee issued a circular inviting the co-operation of geological societies, field clubs, photographers, and all others interested in supplying them with the following information, viz. :—

1. Lists and details of photographs taken illustrating localities and sections.

2. Names of local societies, or persons, who may be willing to further the objects of the Committee in their own district.

3. Particulars of new localities, sections, boulders, or other features which it may be desirable to have photographed.

It was added that :—

"The Committee will also be glad to receive a copy of the print from each negative, which will be exhibited at the succeeding meetings of the Association and afterwards preserved for reference. It is thus hoped to form, eventually, a national collection of photographic views illustrating the geology of our country, and deposited in a centre where the collection will be available for purposes of study and comparison."

In order to secure uniformity of action, and as a guide to those willing to assist, a circular of instructions was issued embodying those points which were thought to be most desirable in effecting the objects of the Committee. The details given were drawn up after very careful consideration and consultation with practical photographers, and were so framed as to be applicable to most of the conditions to be met with in photographing the different classes of objects having geological interest worthy of permanent record.

The following is a copy of this circular, which is given here for convenience of reference.

[Circular No. 2.]

[Reduced Copy of Form A.]

Form A.	BRITISH ASSOCIATION COMMITTEE ON GEOLOGICAL PHOTOGRAPHS.	No. of Photo.*
County of	Photographed under the direction of Society.	
Name and position of Locality or Section.		
Special features shown.		
Details of Section.	Height / Length	Compass Direction.
	'In shade,' or 'direct light.' Time: a.m. p.m.	
Sketch, or other particulars, if nece-sary, may be given here :—		
Name of Photographer / Address	Date photographed	Registered No.

* This number should also be placed on the back of the Photograph.

Instructions for the Collection of Geological Photographs.

Photographs are desired illustrative of characteristic rock-sections, especially those of a typical character or temporary nature; railway cuttings; important boulders; localities affected by denudation, or where physiographical changes are in operation; raised beaches; old sea-cliffs; coast scenery and

* An abstract read at Section A of the British Association last Monday.

coast erosion; characteristic river-valleys, escarpments, and other landscape features; glacial phenomena, such as *roches moutonnèes*, moraines, drums, and kames, and natural views of geological interest.

1. The views should be taken under skilled geological direction, and in every case the most typical views should be secured in preference to general views. It may be convenient for societies to form a small committee for the purpose of noting suitable sections desirable to be photographed, and arranging such work as may be possible in each district. To this end it is anticipated that the services of many amateur photographers may be usefully brought into requisition.

2. Size of photograph recommended: 8½ by 6½ inches (whole plate). (In view of the difficulty of carrying a heavy camera and plates, it is not desired to exclude smaller views when these are well-defined and clear. The size, therefore, is optional.)

The views should be printed by a permanent process whenever practicable.

3. It is necessary, in order to preserve its scientific value, that each photograph should be accompanied by the following details, which may be given on forms supplied as per copy, and attached loosely to the photograph (not *fastened* on the back):—

(*a*) Name and position of section or locality.

(*b*) Special feature shown, with illustrative diagrams, when necessary. (Details may be given, if more convenient, on a separate tracing attached to the photograph.)

(*c*) Height and length of section, and compass direction.

(*d*) Name of photographer, and society under whose direction the view is taken.

(*e*) Date when photographed.

(*f*) Indication of direction of light and shade; *i.e.*, state whether taken in "direct light" or "in shade."

4. Each photograph sent in for registration should bear a *local* number, and the accompanying form should be numbered in accordance therewith.

5. Lists of photographs, copies of photographic prints, and the information relative thereto should be sent under cover to the Secretary to the Committee, *at the earliest possible date*, as the work of registration will be heavy.

The offers of help received in response to this circular were very numerous, and if all who had promised to send in copies of photographs had fulfilled their intention, the Committee would have been enabled to issue a much more extended list. As it is, the number of photographs sent in up to the end of July reached a total of 196, a result which, taking into consideration the difficulties incident to a first year's working, the Committee feel is an encouragement to persevere in their efforts, if permitted to do so, until an adequately complete series of photographs is obtained. It will be seen from the list appended that a large majority of the English counties, besides those of Scotland and Ireland, are as yet almost entirely unrepresented, and that, in the case of counties from which photographs have been received, the views taken have been confined to limited areas. Prior to the institution of this Committee, there has been little effort made to arrange for the systematic photography of local geological sections, although much has been accomplished in an irregular manner by individual workers. It has been difficult to obtain all the particulars desired of these earlier photographs, but it is believed that the more important of them, at any rate, are included in the list attached to this report. Acknowledgment is due to those societies (among which may be mentioned the Belfast Naturalists' Field Club, Chester Society of Natural Science, Croydon Microscopical and Natural History Society, Essex Field Club, Leicester Literary and Philosophical Society, Liverpool Geological Society, and the Yorkshire Geological and Polytechnic Society) for the care they had taken to preserve photographic records of important and interesting sections.

While a fairly large number of photographs has been obtained in response to the circular issued by the Committee, but little has been accomplished in the way of establishing county photographic surveys for geological purposes. It was hoped that the suggestion in circular No. 2 as to the formation of special local committees in different centres (the only satisfactory means of doing the work thoroughly) would have been more widely adopted. The only county which has so far undertaken such systematic work is Yorkshire. In this county, that valuable aid to scientific progress, the "Yorkshire Naturalists' Union," has already aided the work of the British Association by the establishment of local committees charged with special objects of research. As soon as possible a geological photographic section was formed, of which Mr. James W. Davis was appointed chairman, and Mr. James E. Bedford secretary. This section has sent over a hundred copies of photographic prints, with descriptions, the work of its members in the county of York, besides other localities further afield. This Committee are much indebted to the officers of the Yorkshire Geological Photographic Section for their valuable assistance.

There are not wanting indications also of the ripening of the scheme in other directions at an early date.

Mr. J. Hopkinson, of St. Albans, read a paper before the Hertfordshire Natural History Society on "Scientific Investigations in Hertfordshire in connection with the British Association," in which he pointed out several geological features in the county worthy of being photographed, and urged the formation of a local collection of geological views, to be commenced during the summer of 1890.

An important proposal was brought before the Photographic Society of Birmingham by Mr. W. Jerome Harrison, who advocated a photographic survey of the county of Warwick, to include pictorial, architectural, besides antiquarian and scientific subjects; and alluded specially to the work of this Committee.

Interest in the work of the Committee has been manifested abroad as well as in this country. Letters have been received from several foreign professors of geology asking for information and details of the scheme, and offering, in some cases, an exchange of photographs. Professor E. Reyer (of Vienna), Dr. A. Leppla (of Berlin), and Dr. G. Dewalque (of Liege), have each specially interested themselves in the objects of this Committee. Professor J. F. Kemp (of Cornell University, Ithaca, New York State, U.S.A.) has also taken steps to bring the subject before the Geological Society of America, with the view to the inauguration of a similar scheme in America.

The Committee regard it as highly important that as many photographs of sections, &c., should be taken as possible. Of these a careful selection of the most typical views should be made to be sent in for registration. During the first year *all* views sent in have been registered, but in future it will be necessary to make a selection of those most suitable, otherwise there will be an accumulation of photographs illustrating the same section or natural feature.

It has been found quite impracticable to restrict photographers to any special size of print; it is, therefore, merely recommended that the plate should be as large as possible, the "whole-plate" size (8½ by 6½ inches) being the most suitable.

Your Committee have not yet had an opportunity of fully discussing the question of the ultimate disposition of the photographs, and it has been thought advisable to defer a recommendation of this nature until a more complete series of photographs has been obtained.

Meantime, a suggestion has been made by Mr. Willem S. Logeman, principal of Newton School, Rock Ferry, that a volume of selected photographs illustrating typical geological features should be published, which would form a useful book of reference for educational purposes. At present the collection of photographs is not of sufficient proportions to warrant the reproduction of a really complete series of views from nature, such as it would be of advantage to students and others to possess; but the Committee are bearing in mind the suggestion for possible use in the future, should they see their way to recommend its adoption.

It is with great regret that the Committee have to record the decease of Mr. S. A. Adamson, who was a most active member, and to whose exertions and influence the progress of the work in Yorkshire is largely due.

The Committee desire to express their obligations to Mr. A. Norman Tate, editor of *Research*, for the loan of a block for the purpose of illustrating their circular of instructions.

The work of the Committee having been, so far, of a preliminary nature, they would respectfully solicit their re-appointment, in order to arrange for the further completion of the objects for which they were appointed, with a renewal of the grant of ten pounds.

(*To be continued.*)

Mr. J. SOLOMON, well-known as one of the earliest among English photographic dealers, died at the age of eighty-seven, on the 2nd of September, in New York, where he has been resident for the past nine years.

COPYING TRACINGS, BLACK LINES ON WHITE GROUND.—Cola's process, which gives a black line on a white ground, is now greatly in use for copying tracings. It prints quickly, and is very simple to work. The exposure ranges from five to ten minutes in the sunlight, and from twenty to forty minutes in the shade. I find the best results are got on a bright day, and printing in the strongest light. I have very often to reduce large drawings, made on yellow tracing paper to a small scale, to transfer to a stone for lithographic purposes, and use this process to get a more suitable copy to photograph from. To make a print, you put the tracing face downwards in the printing frame, and place the sensitive paper on the top of it, then a piece of thick felt, and then the backs, and put a good pressure on by means of screws, which are much better than springs, as you are able to get a more even pressure. To ascertain if sufficiently printed, lift up one corner, and if the greenish-yellow tint has disappeared, except where covered by the lines, it should be taken out and immersed, face upward, in a bath composed of gallic acid 20 parts, alcohol (methylated) 200 parts, and water 1,000 parts, and remain for three minutes, at end of which time the lines will be up strong and black. It should then be thoroughly washed in running water for a quarter of an hour, and the surface rubbed with a soft sponge, then taken out and hung up to dry. The following will be found a good formula for sensitising the paper:—

Water	300 parts
Gelatine	10 ,,
Perchloride of iron	20 ,,
Tartaric acid	10 ,,
Persulphate of zinc	10 ,,

Apply this by means of either a broad, flat camel-hair brush, or a fine sponge, to a hard, well-sized paper, then hang up to dry in a dark room. To over-expose a print means losing the lines, and under-exposure gives a very dirty, neutral tint ground and very faint lines.—*Scientific American.*

A NEW PHOTOGRAPHIC PRINTING PROCESS.*

BY ARTHUR G. GREEN, CHARLES F. CROSS, AND EDWARD J. BEVAN.

IN the early part of 1887 one of us (Green) discovered that, by heating paratoluidine (2 mols.) with sulphur (4 to 5 atoms) at 200°-300° C., a very complex amido base was obtained which, on treatment with fuming sulphuric at a low temperature, was converted into a sulphonic acid, the alkaline salts of which were easily soluble in water, and had the peculiar property of dyeing cotton primrose yellow from an alkaline or neutral bath without the use of a mordant. Further, the amido compound thus fixed upon the fibre could be diazotised *in situ* by passing the material through a weak solution of nitrous acid, and, when diazotised, could be combined with various phenols and amines, thus producing a variety of different colours, which, being formed within the fibre, were all distinguished by great fastness to washing. The soluble amido sulphonic acid was named "Primuline" by its discoverer, and has found a very extensive employment in cotton dyeing; the colours produced from it within the fibre were called "Ingrain colours."†

Although the chemical constitution of primuline base (of which primuline is the mono-sulphonic acid) has not yet been determined with certainty, there is no doubt that it is a condensed derivative of dehydrothiotoluidine, a body which always accompanies it in its formation, and that it differs from the latter in exactly the same way as dehydrothiotoluidine itself differs from para-toluidine. As there is scarcely any doubt that dehydrothiotoluidine has the formula—

$$C_6H_3(CH_3)<\overset{S}{N}>C.C_6H_4(NH_2)$$

i.e., is an amido-benzenyl-amido-thiocresol, it follows that the formula of primuline, or rather, of its chief constituent, is‡ probably

$$C_6H_3(CH_3)<\overset{S}{N}>C.C_6H_3<\overset{S}{N}>C.C_6H_3(NH_2)<\overset{S}{N}>C.C_6H_3(SO_3Na)$$

In a similar manner, by heating meta-xylidine or pseudo-cumidine with sulphur, homologues of primuline are obtained, which, like primuline itself, dye cotton without a mordant, and can be diazotised and combined with phenols within the fibre.

It has been long observed by one of us (Green) that the diazo compound of primuline was very sensitive to the action of light, being readily decomposed thereby, and losing its property of combining with phenols and amines. Upon this fact we have now founded a photographic process, by means of which designs can be produced in fast colours upon cotton, silk, wool, linen, or other fabrics. It can also be applied to wool, xyloidine, celluloid, paper, or to gelatine films upon glass, thus affording a very wide range of employment. The process, which is a very simple one, merely depends upon the fact that if a material containing diazotised primuline be exposed to light under a design, those parts which are acted upon by light will be decomposed, whilst the parts protected from the light will remain unaltered, and consequently, on subsequent development with a phenol or amine, will produce colours, whilst the decomposed por-

---

* Read at Section B, British Association. The full title of the paper was, "The Action of Light upon the Diazo Compounds of Primuline and Dehydrothiotoluidine: a Method of Photographic Dyeing and Printing."

† A. G. Green, *Journ. Soc. Chem. Ind.*, 1888, p. 179.

‡ A. G. Green, *Journ. Chem. Soc.*, 1889, p. 227; *Ber.* 22, 968; P. Jacobsen, *Ber.* 22, 330; L. Gattermann, *Ber.* 22, 422; W. Pfitzinger and L. Gattermann, *Ber.* 22, 1063.

tions will not. The details will, of course, depend somewhat upon the material to be treated. As an instance, we may take the production of a design upon cotton cloth, cotton velveteen, and so on. The material is first dyed with primuline from a hot bath containing common salt until the required depth is obtained. It is then washed and diazotised by being immersed for a quarter of a minute in a cold bath containing about ¼ per cent. of sodium nitrite, and strongly acidified with sulphuric or hydrochloric acid. The material is washed again, and exposed damp—or, if preferred, after having been dried in the dark—to the action of light beneath leaves, ferns, flowers, or other natural objects, or beneath glass or transparent paper upon which may be painted or printed any design which it is required to copy. Either the arc electric light or daylight may be employed; in the latter case, the time of exposure will, of course, vary with the intensity of the light—under half a minute is required in bright sunshine, and nearly half an hour in very dark, cloudy weather. When the decomposition is complete, which may be readily ascertained by means of a test slip exposed simultaneously, the material is removed from the light, and either passed into the developing bath at once, or is kept in the dark until it is convenient to develop it. The developing bath consists of a weak solution (¼ to ½ per cent.) of a phenol or amine made suitably alkaline or acid, the phenol or amine employed depending upon the colour in which it is required to produce the design, thus:—

For *red*, an alkaline solution of β-naphthol.
„ *maroon*, an alkaline solution of β-naphthol-di-sulphonic acid.
„ *yellow*, an alkaline solution of phenol.
„ *orange*, an alkaline solution of resorcin.
„ *brown*, a solution of phenylene diamine hydrochloride.
„ *purple*, a solution of α-naphthylamine hydrochloride.

If it is required to produce the design in two or more colours, the respective developers, suitably thickened with starch, may be applied locally by means of a brush or pad. After development the material is thoroughly washed, and requires no further fixing.

Linen, silk, and wool are treated in exactly the same way. Paper for copying drawings, and other purposes, is coated on the surface with primuline by means of a brush or roller. For the production of gelatine films upon glass the primuline is incorporated with the gelatine before being applied to the glass.

In place of ordinary primuline the homologues already mentioned may be used. For silk and wool the primuline may be replaced by dehydrothiotoluidine-sulphonic acid, by means of which colourless backgrounds may be obtained.

Concerning the reaction which occurs when the diazo-primuline or the diazo-dehydrothiotoluidine is decomposed by light, we cannot at present say anything definite, except that the diazo group is completely destroyed, for on treatment with sodium hydrosulphite (true hyposulphite) it cannot be converted into the amido group (re-forming primuline or dehydrothiotoluidine). The reaction may consist in a replacement of the N_2 group by OH or by H, or may be even more complex. Although we cannot affirm that this reaction to light is a property of the diazo-compounds of this group of bodies only, yet it is certain that they possess an extreme susceptibility to light far greater than that of other diazo-compounds, whilst, at the same time, they are far more stable to heat. It is thus possible that this property may depend in some way upon the sulphur which they contain.

THE BRITISH ASSOCIATION.

CHEMICAL SECTION.

BY C. H. BOTHAMLEY, F.I.C., F.C.S.

THE President, Professor T. E. Thorpe, formerly of the Yorkshire College, Leeds, and now of the Normal School of Science, South Kensington, is himself a photographer of very considerable ability, and whilst at Leeds was for some time President of the Leeds Photographic Society, which made considerable progress during his term of office. Some years ago Professor Thorpe produced a very fine series of more than 100 whole-plate negatives, illustrating the scenery, &c., of the Azores, and he has done valuable photographic and photometric work on several eclipse expeditions. The presidential address dealt mainly with the parts played by Priestley and Lavoisier in the early development of modern chemistry.

A very small proportion of the papers read before this section dealt with photo-chemical or photographic subjects. Dr. A. Richardson read a further interim report of a committee appointed two or three years ago to investigate the oxidation of the hydracids of the halogens in presence of sunlight. The results obtained, so far, are not of a very definite character, and are not altogether in agreement with those of other observers; but any detailed criticism would be out of place until we are in possession of the whole report. The fact observed by previous experimenters, that the decomposition of chlorine water is retarded by the presence of hydrochloric acid, is confirmed.

On Saturday and Monday the members of the section, together with members of Section A, engaged in discussions on "Electrolysis," and "Solution," which were mainly remarkable for the active part taken in them by Prof. J. H. Van Hoff, of Amsterdam, and Prof. W. Ostwald, of Leipsic.

On Tuesday, the President of the Section read a paper on "Phosphorous Oxide," P_4O_6, in the course of which he stated that this substance is very sensitive to the action of light, being resolved apparently into free phosphorus and a higher oxide.

One of the most interesting papers of the whole meeting was contributed by Messrs. A. G. Green, C. F. Cross, and E. J. Bevan, on "The Action of Light on the Diazo Compounds of Primuline and Dehydro-thiotoluidine." An abstract of this paper appears on page 707. It was illustrated by a large number of very interesting specimens, and experiments were made showing the mode of development, and illustrating the great sensitiveness of the compounds. Some of the results were really very fine, and as the images seem to resist any further action of light, and also to be unaffected by a large number of reagents, it is possible that the process will find many useful applications.

Prof. J. J. Hummel read a paper (see p. 712) on "Fast and Fugitive Coal-Tar Colours," which was illustrated by a large number of specimens. It was shown that the resistance which many coal-tar colours offer to the action of light depends on the nature of the mordant by means of which they have been applied to the fabrics, and whilst it is undoubtedly true that many coal-tar colours are of a very fugitive character, there are many others which, if applied with the proper mordants, offer a resistance to light little, if at all, inferior to that of the so-called fast natural dyes.

THE PHARMACEUTICAL CONFERENCE AT LEEDS.

Following the usual practice, the Pharmaceutical Conference met in Leeds on the days immediately preceding the meeting of the British Association. Mr. Reynolds, of the firm of Reynolds and Branson, well-known to photographers, is one of the past presidents of the Conference, and Mr. F. W. Branson was the local secretary for the Leeds meeting. The proceedings opened on Monday evening with an admirably arranged conversazione at the Philosophical Hall. One of the items of a full and varied programme was an exhibition of lantern slides, some of which were very fine, whilst of others it must be said that they showed too much of the chalk-and-sooty character which spoils so many otherwise good slides. Of especial interest were six slides by Mr. F. W. Branson, showing a complete series of the geological sections of Leeds. Many of these sections are no longer visible, and Mr. Branson is to be congratulated on having secured a series of really fine photographs of them, before they became hidden by débris and otherwise. A series of the fossils from the beds in these sections was on view in one of the rooms, and the two exhibits together formed an admirable example of the systematic application of photography to scientific purposes.

On Tuesday morning the president, Mr. C. Umney, delivered his address, which was followed by the reading of a large number of papers. Three of these have considerable photographic interest:—"Commercial Alkaline Sulphites," by C. H. Bothamley; "Chloroform as a Preservative," by J. F. Burnett, and a second paper on the same subject by H. Wyatt, junr. A paper on the quality and testing of glycerine, by Dr. J. Sewkowitsch, and a paper on the testing of methylated spirit, by E. J. Millard and A. C. Stark, may also be mentioned.

Alkaline Sulphites.—The object of this paper was to call attention to the character of commercial alkaline sulphites, a matter of importance to photographers as well as to practical chemists. The author pointed out that sulphurous acid, H_2SO_3, which is dibasic, is generally supposed to yield two classes of salts, normal sulphites, M_2SO_3, and acid sulphites (hydrogen-sulphites,. bisulphites) $MHSO_3$. A third class of sulphites, the so-called meta-sulphites or meta-bi-sulphites, with the general formula $M_2S_2O_5$, has recently been brought prominently into notice, and these salts are commonly believed to be new products. This, however, is not the case; they were described many years ago, by Muspratt, who gave them their correct name of anhydro-sulphites.

The only normal alkaline sulphite commonly met with is the sodium salt, which has the composition $Na_2SO_3\,7H_2O$. It is easily obtained in good crystals of a high degree of purity, but the presence of sodium carbonate is not uncommon, and some samples contain large quantities of this salt and of sodium sulphate. We may say, in passing, that we believe that the developing power, which has occasionally been attributed to the sulphites in conjunction with pyro and without the addition of any alkali, was really due to the presence of sodium carbonate as an impurity in the sulphite.

Sodium-bisulphite, acid-sulphite, or hydrogen-sulphite, whichever we please to call it, is not met with in commerce in anything like a satisfactory state of purity. The percentage amount of sulphurous anhydride which the pure salt would contain is 61·54. In four samples from different sources Mr. Bothamley found 8·1, 34·14, 22·3, and 39·0 per cent. respectively. The impurity is chiefly sulphate. It is very doubtful whether it is possible to obtain the acid sulphites in a pure condition, because even in solution they change into anhydro-sulphites.

The commercial anhydro-sulphites—or, as they are generally, but less suitably, called, metasulphites, or metabisulphites—are very satisfactory products if in the form of moderately large crystals. In three samples of the potassium salt the percentage of sulphurous anhydride found was 52·54, 56·02, and 57·42 respectively; the percentage amount in the pure salt is 57·63; a well-crystallised sample of the sodium salt contained 65·60 per cent. instead of 67·37, but a sample in very small crystals contained only 50·4 per cent.

The practical conclusion drawn from these results is that, whenever a pure acid sulphite is required, well-crystallised anhydro sulphites should be used. The same salts in small crystals are not so trustworthy; the crystals undergo a slight superficial alteration, and, since the surface exposed by a given weight of small crystals is much greater than that of the same weight of large crystals, the percentage effect of this superficial change is much greater in the first case than in the second.

Chloroform as a Preservative and Antiseptic.—The results recorded in these papers afford further evidence of the already well-known preservative action of chloroform. Solutions of various organic salts, such as tartrates and citrates, and of organic substances, such as starch, gelatine, sugar, &c., which readily grow fungi or moulds, under ordinary conditions, may be preserved for a long time without appreciable alteration if mixed with a small quantity of chloroform. In order to obtain the maximum effect, the liquid should be saturated with chloroform. Even under the latter condition the total quantity of chloroform present will be small, and, since this compound has no effect whatever in many photographic operations, its use as a preservative deserves more attention from photographers than they have hitherto given to it. For mountants and solutions of tartrates or citrates it is especially valuable.

Clearing Pyrogallol Stains.—One new doctrine recently put forward we pronounce to be an undoubted heresy. It was recently stated in a photographic journal that plain water was equal in effect as a clearer of pyro-made negatives to the acid clearing bath generally recommended. Now, this is a proposition that experience will at once disprove, and we can only imagine that the writer who put it forward had been misled by a misconception of the condition under which he worked, and that his results were due to some other cause than plain water.—*Scraps.*

Artistic Photography.—Rejlander said:—"I regard art as a means of making thought visible. If I can make a thought visible in a picture which people can understand, and be moved by it to laughter or tears, it is a work of art, whether I produce it by the aid of the camera or of the pencil. It is the mind of the artist, and not the nature of his materials, which makes his production a work of art. A man may paint, and not produce works of art, or he may photograph, and produce works of art."

Photographing Children.—Those who desire to make a speciality of photographing children should note what an English artist, Mr. R. Faulkner, whose photographs of children are used as Christmas cards all over the world, says about their management:—"Never allow any interference in your management of a child; if you require assistance from mother, nurse, or friend, give up the affair. Spoilt children will never make good pictures, so look upon them as merely worth so much money, and be content when you have obtained a photograph that has not moved."—*Wilson's Photographic Magazine.*

Notes.

Those who are interested in photographic studio building should make note of a caution published in a German newspaper, relative to the quick corrosion of sheet zinc when in contact with brickwork. It seems that in the Market Halls, Berlin, the zinc which rested upon the brick walls was found to be deeply pitted. Chemical examination of the bricks showed that they contained an appreciable quantity of soluble salts, to the agency of which the deterioration of the metal is credited. It is pointed out that this is possibly a feature of only certain kinds of bricks, and that danger from them might be obviated by placing between the walls and the zinc a protective layer of roofing felt or similar material.

The *Scientific American* gives an account of a machine for mounting photographic prints, but the description, in the absence of illustrations, is rather obscure. However, we learn that the contrivance consists of a couple of shallow boxes hinged together so that one forms a lid to the other. In one compartment are placed the trimmed mounting cards, and in the other the paper prints. Starch being applied to one of the latter, the box is closed, and "certain springs exercise their force," the result being that the starched print is brought into contact with its mount. When the box is again opened the mounted picture falls out, and is received into a receptacle lined with blotting paper. We do not know whether the machine deals effectually with those air bubbles and obstinate corners and edges, which generally cause trouble when pictures are mounted by hand.

When you select an amateur photographer for a companion on a walking tour, it is well to make sure that his tastes agree with yours. So says a naturalist. In the opinion of the latter, the enthusiastic amateur is a nuisance. He has not the smallest interest in your pursuit—that is, if you happen to be a naturalist—but expects you to be in full sympathy with his. He is always wanting to stop and take views in places which, as far as natural history is concerned, are about as productive as the Mile End Road. He invariably suggests that you should act as a sort of amateur policeman, and keep back the gathering crowds while he plants his apparatus in the midst of some busy thoroughfare; and, worse than all, he expects you to carry the camera. This last statement makes us doubt whether this naturalist is speaking the absolute truth, for giving his camera to other people to carry is just what the amateur does not do. We should like to hear what the amateur photographer has to say about the naturalist as a *compagnon de voyage*.

If the story that over the door of a certain photographic studio is the announcement, "Misfit photographs for sale," be not true, it is well found. The proprietor is reported to have said that mothers who have little children often buy pictures of children with long hair, when the hair of their loved ones hasn't grown, to send them to friends at a distance. Brides' pictures he can sell without any trouble. This photographer's opinion is that pictures of people are sometimes very much alike. No doubt this is true, but the rule is only a safe one as applied to babies. We have heard of a man, much goaded and worried over his failures to take an unruly infant, opening a drawer and exclaiming desperately, "You'll never get a photograph of your child; it's impossible. But there's a whole lot of other people's children in that drawer; pick out the nearest you can find." It would be a good thing if all babies could be photographed in this easy fashion.

The Abbé Collignon, curé of Bry-sur-Marne, in sending to the *Société Française de la Photographie* two photographs of the tomb of Daguerre, draws attention to the fact that the tomb itself and the paintings executed by Daguerre in the church of Bry-sur-Marne are in great need of repair. This is rather a reproach upon French photographers, and is almost a satire upon the enthusiasm which the jubilee of photography last year called forth. Daguerre's paintings in the church, besides being of interest as the work of his hand, are also worthy of preservation as remarkable examples of perspective, by which the church is made to appear twice its actual size. A full description appeared in the PHOTOGRAPHIC NEWS some months ago.

One can understand the indignation of the military officer at Cork, whose life his comrades made unbearable. The story, as told this week, is that they broke into his room and painted him with tar. This was bad enough, but not nearly so bad as what followed, for one of his persecutors brought his kodak, and, the outrage taking place in the early dawn, photographed the victim thus disfigured. There is something peculiarly irritating in this, because, though one may have sufficient philosophy to get over the tarry operation, to know that the scene may turn up in after years to one's shame and ignominy is beyond human endurance.

Dark rooms for tourists are multiplying. The proprietor of the Hotel de la Plage at Pouliguen, France, announces that his establishment possesses a photographic laboratory. At Manberg also tourists will find one at the establishment of M. Dandoy-Maillard. From establishing a dark room to keeping a stock of photographic requirements is but an easy step, and it may not be long before we shall hear of hotel proprietors being able to supply their customers with gelatine plates, pyrogallic acid, and hyposulphite of soda. When this time shall arrive it will be well if an international standard of sizes for plates were fixed. The continental makers do not adopt quite the same measurements as our English manufacturers, and much inconvenience is caused when an English tourist runs short of plates and has to purchase the nearest he can to fit his camera. This is one of the questions left out of the otherwise complete list discussed by the International Congress at Paris last year.

The successful photographing of snow scenes is a matter not unattended with difficulty. The exposure, as a rule, is not easy to arrive at accurately, and a peculiar flatness is often the result, the reason of which the photographer is puzzled to explain. It is not impossible that an investigation by Dr. Robert L. Bowles, of the effect of the sun when snow is on the ground, may throw a little light on this matter. Dr. Bowles remarks that sunlight reflected from freshly-fallen snow acts much more energetically on the skin than that reflected from older snow, and he decided the question by painting his face brown, and ascending, in company with eighty other persons, the Gorner Grat, where there was much snow. The result was, that in the evening all excepting Dr. Bowles were smarting from the effects of sunburn. Dr. Bowles concludes that heat is not the direct cause of sunburn, but that it is caused by the violet or ultra-violet rays which are reflected from the snow. If this be so, it is very clear that the photographer should make a considerable allowance in the exposure, according to the time the snow has been on the ground. The phenomenon presents, we fancy, a novelty to photographers, and it would be worth while to make some experiments on the subject.

The ushers in the Law Courts, it seems, make a collection of autographs, and as they come into contact with numerous celebrities who sometimes figure as the chief parties in an action or as witnesses, their albums must be full of interest. Possibly it may not be long before they add photographs to autographs. The latter, it seems, are not difficult to obtain, for ushers are privileged persons, and their requests for signatures are readily granted. Photographs possibly might be as easily procured. But if any objection were made, a sort of partnership between two ushers would bring about the desired result. While one usher might be looking after the autograph, the other would be arranging his camera, and when the celebrity sits down and takes the pen in hand, he could be photographed unconsciously. The two things would thus go nicely together, as in most instances the celebrity, while writing his name for usher number one, would hold his head steady sufficiently long to enable a photograph to be taken by usher number two.

It is rather curious that artists do not rely more than they do upon photographs for accuracy in points of detail. Blunders are constantly being made in the proper treatment of military uniforms and official robes. Even in so small a thing as a properly clad fisherman handling his tackle correctly, they come to grief. As an evening paper pointed out recently, a conscientious artist is obliged to resort to devices in order to get something like nature, and the paper we have just referred to speaks of visiting a professional fisherman, and finding him on his lawn in all his fishing dress, landing a brickbat with a salmon rod, for the information of what he called a "picture chap," who was sketching him in all sorts of attitudes. We have strong doubts whether any fisherman could get up sufficient enthusiasm over a brickbat to put any spirit into his attitudes. The instantaneous photograph of an angler in the act of landing a twenty pound salmon would be a very different thing. It would be worth while for amateur photographers, when on their travels, to bear in mind the requirements of artists. Some of their chance shots, not only of men, but of animals, might prove valuable from a commercial point of view as useful studies for artists.

Photography is now made so easy that the great majority of amateurs who buy a cheap outfit, and fancy they are at once photographers, never seem to take the trouble to master the very simplest preliminaries. A neophyte writes to a quasi-scientific contemporary as follows: "When I take the plates (one at a time) out of the dark slide, and put them in the developing dish, I cannot get the image to appear bold and sharp. Some are light, with all the details not visible; others are black, such as the face and arms of a person. But there is nothing to be seen after fixing except by looking through the plate when holding it between the light." This reminds us of the photographic experience of a young friend as related by a schoolfellow. "He tried to take my likeness, but nothing at all came out. Then he tried to take the cat, another blank. Afterwards he had a shot at the kitchen window, and got a chair, but there wasn't a bit of the window to be seen. Then he tried the water-butt—blank. Next he got the servant to stand for her likeness, and you could see something on the glass, but whether it was the girl's face or the eight day clock, no one knew. I didn't think much of any of his things excepting one, and that was a jolly good likeness of the chimney pots over the way. He hasn't done anything since. You see the servant doesn't like being turned out of the kitchen while he darkens the window and develops, or 'devilups' as *we* call it."

Mr. Du Maurier, in a recent number of the *Magazine of Art*, commences what promises to be an entertaining series of articles on "The Illustrating of Books." Mr. Du Maurier describes fully the two methods of drawing for wood; the one where the artist, having prepared his picture in washes of different degrees of intensity, leaves it to the mercy of the engraver; and the other of sketchy characteristics, where the engraver cuts a *facsimile*, and neither adds a line nor takes one away. Mr. Du Maurier writes pleasantly and kindly about his brother artists and their method of working, but at present has said nothing about himself and his own style. As Mr. Du Maurier was one of the first to make use of photography in book illustration, it is to be hoped he will give a little information on the subject. It is said that Mr. Du Maurier's drawings for *Punch* are photographed direct on to the wood by a process the details of which have never been made public, and it would be interesting to know if this is really the fact. Mr. Du Maurier himself is, of course, not the photographer.

FAST AND FUGITIVE DYE STUFFS.*

BY PROFESSOR J. J. HUMMEL.

THE stability or permanence of colours is a matter of very great importance both to the artist who uses them and to the general public who admires or buys the artist's productions. Some time ago it was noticed that many of the water-colour drawings of certain artists in our national galleries had faded so materially that it became really a serious question whether water-colour artists were doing themselves justice by spending time and talent in painting pictures the value of which would rapidly diminish, or whether the artistic public or the nation should spend large sums of money on possibly evanescent treasures. It was very desirable, therefore, that the permanence of the whole list of water-colours at present employed by artists should be thoroughly examined. This, indeed, was done during the years 1886-87-88 by Abney and Russell, and we cannot but be glad to learn that the result of their inquiry is eminently satisfactory, for, as they state, although many fugitive colours at present in use ought to be banished from the painter's palette, there still remains a good gamut of permanent colours available to the water-colour artist.

Now the work of the dyer is by no means to be compared with that of the painter in artistic merit; nevertheless, his productions frequently enter into the composition of real works of art of considerable value; I refer specially to art tapestry. And when, with melancholy regret, we admire the faded beauty of the productions of a former period at Hampton Court, Holyrood, the Gobelins, and elsewhere, we cannot but consider how necessary it is to know whether the colours of our modern tapestries are better or worse, in point of stability, than those formerly employed. But the dyer's art is not confined to tapestry; it finds a more important and useful application in the ornamentation of all manner of textile fabrics in common daily use, and hence it is surely incumbent upon dyers, manufacturers, and the public alike, to consider well the permanence or otherwise of the colours employed in the decoration of textile fabrics generally. In discussing the subject of fast and fugitive dyes, it is well that we should first define the meaning of the terms "fast" and "fugitive." Unfortunately, as usually employed, they have a very wide and indefinite signification. The term "a fast colour" means different things to different persons. To me it implies that the colour will not fade when exposed to light and atmospheric influences; to another, that it is not impoverished by washing with soap and water; to a third, it may mean that the colour will withstand the action of certain manufacturing operations, such as scouring, milling, stoving, &c.; while a fourth person might possibly be so exacting as to desire in a fast colour its resistance to all the varied influences I have mentioned. As a matter of fact, no dye colour is absolutely fast, even towards a single influence, and it certainly cannot pass unscathed through all the operations which it may be necessary to impose upon individual colours applied to this or that material. Many colours are fast to washing, or milling, and yet very fugitive to light; others are fast to light, but fugitive to milling; while others are fast to both influences—in short, each colour has its own characteristic properties. It is, however, by no means necessary to demand absolute fastness to a variety of influences from any colour. A colour may bleed in milling, and hence be unsuitable for tweeds, and yet be most excellent for curtains and hanging, because of its fastness to light. So, too, a dye capable of yielding rich and delicate tints, but only moderately fast to light, is still perfectly well adapted for the silks and satins of the ball-room, although it would be quite inadmissible for the pennon at the mast-head. The colours of carpets, curtains, and tapestry should certainly be fast to light, but no one expects them to undergo the fatigue of the weekly wash-tub, and just as little do we look for the exposure of flannels and hosiery, day by day and week by week, to the glare of sunlight, much as we desire that the colours shall not run in washing. Fortunately, we have for each material ranges of colouring matters admirably adapted to the foregoing several requirements, and although it is quite a laudable desire to wish that each and every colour should be of all-round stability, it is vain to hope for such an elysian state of things at present.

For all practical purposes, then, it is enough to define a "fast" colour as one which will not be materially affected by those influences to which, in the natural course of things, it will be submitted. Hence it becomes necessary, in speaking of a fast colour, to refer specially to the particular influence which it resists before the term acquires a definite meaning. The manufacturer who wishes to be precise should, for example, demand from the dyer a colour which is fast to light, or fast to milling, or fast to light and milling, and so on; and my belief is, that if more care were exercised in the use of definite terms of this kind, business transactions would run a little more smoothly than is now frequently the case. All I have said with respect to the term "fast" may with equal propriety be applied to the term "fugitive." This, too, has no very definite meaning until a qualifying statement, such as I have mentioned, gives it precision.

In view, then, of the considerations I have now placed before you, it is evident that everyone connected with the application of colouring matters should know the sensibilities of his colours towards various influences. It would, of course, be extremely convenient if we could arrange all colouring matters in two sharply defined classes of fast and fugitive dyes, and in the year 1669 the French Government actually attempted to do this, and prescribed certain simple tests to distinguish one from the other. The dyers of that day were also required to confine themselves to one or other of the two classes—*bon tint* and *petit tint*, as they were called—and, in accordance with their choice, they were restricted to the use of certain specified dyestuffs. The whole system, however, proved a failure; it hindered the progress of the dyer's art, and ere long it was abandoned.

(To be continued.)

* Paper read before the Chemical Section of the British Association.

LINED SCREEN PLATES.—M. Parisien gives the following process for making these plates. He fixes in a mandrel, on an ordinary turning-lathe, a copper or zinc tube, and on this tube he traces, with the aid of the proper tool, a very long and slender thread. This tube being split in the direction of its length, opened, and flattened in a copper-plate press between two sheets of cardboard, yields a plate having very regular parallel lines.—*Moniteur.*

ARRANGING THE SITTER.—Adam Salomon once wrote:—"The photographer's first care should be to study his model before placing it under the objective's inflexible and undiscriminating eye. Here begins the rôle of light, with the infinite gradations by which it can indicate form. It is, therefore, of the utmost importance to comprehend the characteristics of the model, and how they may be best rendered, so as to modify the action of light, and thus secure in the portrait suggestions of the true type and character of the sitter."

A NEW DIRECT READING PHOTOMETER MEASURING FROM UNITY TO INFINITY.*

BY FREDERICK H. VARLEY, M.I.E.E., F.R.A.S.

The object I had in view in designing this apparatus was to meet a want that has been felt by electrical engineers and others interested in the measurement of light, namely, a convenient form of apparatus as handy to manage as the usual set of measuring instruments which are provided, so as to take its position along with the voltmeter, the ani-meter, and the Watt-meter.

Incandescent lamps are now made of such generally uniform construction that if we can, with facility, measure the light produced, we can readily deduce, for all practical purposes, the amount of current delivered, and thereby determine the general efficient working of the installation. Or, conversely, if we know the current in Watt's passing through a glow-lamp, we can determine the suitability of the filament for the purpose required, provided we can readily obtain photometric measurements. The conditions imposed are, that the instrument should be portable, have a range from one-candle power to that of the electric arc, that the light to be measured, and that of the standard, should be exactly at the same distance from the screen.

This instrument consists of two discs, each pierced by two semi-ring-shaped windows or apertures. These openings extend to the half-circle (180°); both are of the same width, 1 inch broad. The openings in the two discs are placed in reverse positions to one another, so that if one half-ring is opened to its full extent (180°), the other half-ring is entirely closed; or, if the discs are shifted to an intermediate position, both apertures will be opened to an equal extent—namely, 90°.

If, in this position, the discs are rotated, it is obvious that an equal amount of light can pass through both rings, but if the light to be measured is as one to seventeen c.p., then the angular length of the two apertures must bear a proportionate ratio in order that the two shadows shall be of equal density; and accordingly, one aperture will be open to the extent of 10° for the brighter light, whilst that of the standard light is opened 170°. Instead of dividing the circle into the conventional 360°, I divide the half-circle into 2,000 parts, this giving a range from 1 to 1,999, or 2,000 in round numbers. By still farther shifting the discs, this aperture may be entirely closed and read up to infinity. The divisions of the half-circle are numbered from left to right and right to left, showing at once the fraction values of the angular extent of the opening or arc, and thereby giving the values of the light.

In order to make the discs turn one upon the other, I have devised a modification of the Fergusson paradox; that is to say, the discs are carried by independent shafts, one of which is hollow to allow the central axis to turn within it; at the end farthest from the discs a cog-wheel is fixed to each axis. By means of a sliding link the two wheels can be brought into gear with the axis also provided with cog-wheels, each being the same diameter, but one is cut with 100 teeth, whilst the other has 99 teeth. Thus, upon rotating the discs, each revolution of the gearing wheels advances the discs, and so changes the proportion of the openings, one decreasing whilst the other increases, and *vice versâ*; this we can do until the two shadows are of equal density, or approximately so, when the final adjustment can be given by hand. Behind the windows two hollow cones are placed which have their axes directed to a point common to both, but at some distance in front of the discs where the two shadows fall upon the screen. A second or back screen is then placed at the mouth of these cones, over which it fits, and effectively cuts off one light from the other, so that on one side is, say, the electric light, and on the other the standard candle. The light from both passes through axes of their respective cones, and through the discs, and on to the screen upon which the shadow image is cast.

This apparatus, in its present form, has only just been received from Mr. Lege, who has constructed it for us, and Mr. Friese Greene and myself are arranging a series of experiments which, we hope, will prove useful in photography.

In the course of the discussion, Sir William Thomson stated that it was a question whether integration by sensibility is the same as if continuous light be employed. There is a general idea that they are the same, but the point had not been, so far as he knew, absolutely settled. He had compared sunlight with the light of a candle by means of a pinhole one millimeter in diameter at a distance of a few yards from the paper screen, whilst the candle was at a distance of a few inches; he employed the shadow method. He considered the piece of apparatus exhibited by Mr. Varley to be well devised, and hoped that at the next meeting of the Association he would be able to give his results by both methods.

Professor J. D. Everett said that in colour experiments it is assumed that the penumbra method, such as just presented, holds true, because of the consistency of the results.

Professor G. F. Fitzgerald remarked that it has been calculated that if the energy of all the solar radiations falling upon the earth could be conserved and utilised, each square metre of the earth's surface would afford sustenance to ten individuals, so that—as someone, not an Irishman, had expressed it—"there would be so many people that there would not be room for anyone."

Dr. Oliver Lodge stated that experiments had been made in Germany showing that a curious physiological effect of flickering light under certain conditions was the production of colour, and that the colour disappeared when the motion was increased.

Mr. Frederick Varley, in reply to the speakers, said that he was glad to hear from Sir William Thomson the results of his experiments in comparing the light of the sun with a standard candle, and thanked him for the suggestions and encouraging opinions he had expressed. He would point out that the great object he had in view in constructing this apparatus was to obtain a portable and readily worked instrument which could be set up in any room or laboratory. The working of the Bunsen photometer required a room more than a hundred feet long in order to measure a 10,000 candle power arc light. After speaking of Professor Ayrton's photometer, he pointed out that by means of the new apparatus, measurements of the electric arc-light could be obtained in the space occupied by an ordinary table.

* Read last Wednesday at Section A of the British Association.

The Smithsonian Institute. — How many of our photographic friends who have been to the Convention in the body, or *via* the published accounts thereof, are acquainted with the fact that the Smithsonian Institute owes its existence to the generous endowment of the son of an English peer? Such, however, is the case, as the institution was founded by a bequest of 515,169 dols. "for the increase and diffusion of knowledge among men" by the Hon. James Smithson, who was the younger son of the Duke of Northumberland, and brother of Earl Percy, who led the British reinforcements at Lexington, and who also commanded a division in the attack on Fort Washington in this city during the Revolution. James Smithson was of an extremely studious temperament, having graduated from Oxford with an honorary degree the same year that his brother Hugh, Earl Percy, became Duke of Northumberland. His strong ambition was to leave behind him a name which should endure, and, from present appearances, his ambition and desire are in a fair way of accomplishment.—*Anthony's Bulletin.*

METEOROLOGICAL PHOTOGRAPHY.*

BY JOHN HOPKINSON, F.L.S., F.G.S., F.R.MET.S.

THE speaker called attention to the increasing importance attached to photography as a means of illustrating scientific subjects and aiding in scientific research. In no branch of science, he thought, could photography be of greater value than in the elucidation of meteorological phenomena, owing to the transient nature of such occurrences.

The appointment of a committee of the British Association on Meteorological Photography, by which committee instructions to photographers would be issued with the view of instituting a systematic method of working, would, he felt sure, greatly extend the interest taken in the subject, and increase the scientific value of the results. The chief object of such a committee would be to investigate and report upon the means by which photography can most advantageously be applied to the elucidation of meteorological phenomena, such as the forms of clouds, lightning flashes, and the effects of storms. The committee would also undertake the collection of photographs of such phenomena and keep a register of them, reporting the additions made each year, and would compile a bibliography of the subject, adding to it either annually or every few years.

In the study of the various forms of clouds, he believed that a satisfactory classification could best be made by the comparison of numerous photographs. The relation between cloud-forms and atmospheric pressure and temperature would be an interesting field for research, and an attempt might be made to devise means of overcoming the difficulty of photographing light clouds on a blue sky, due to blue rays being almost as powerfully actinic as white, either by devising some simple form of polarizer, or by the employment of a film particularly sensitive to the yellow rays, or more sensitive than usual towards the red than towards the violet end of the visible spectrum. In the investigation of lightning by photography, special attention would be given to the phenomenon of the appearance on the plate of so-called dark flashes, with the object of arriving at a conclusive explanation of the effect, and an endeavour might be made to determine whether lightning really always forms a streak, or sometimes only a point in extremely rapid motion. The collection and exhibition of photographs showing the destructive effects of storms, whether the destruction or damage were wrought by rain, by wind, or by lightning, might not be considered of such scientific importance as the investigation of clouds and lightning, but it would add much to the general interest of the inquiry.

ONE of the latest American fads is the photographing of miniature portraits on silver and gold watchcases and like articles, and burning in the images in such a manner as to render them indestructible. This is the outcome of a woman's effort.

THE GENESIS OF PORTRAITURE.—Portraiture is, after all, an art to which love is under long obligation; and it is fitting that the first rudimentary portraiture was, according to tradition, achieved by an Etrurian maiden, the daughter of a potter, who traced upon a wall the shadow of her swain. That was 776 B.C. After this, the first artists in monochrome—Crates of Sicyon, Philocles of Egypt, and Cleanthes of Corinth—practised the art, which then went by the name of skiagraphy.—A. W. TUER, in *Eng. Illustrated Mag.*

* Abstract of remarks made at Section A of the British Association last Monday.

THE TREATMENT OF SUBJECTS BY FOCUS.

THE BEARING OF SPHERICAL ABERRATION ON OUT-OF-FOCUS PLANES.

BY THOMAS R. DALLMEYER.

IF a lens is aplanatic in itself, and the means is also given of introducing spherical aberration temporarily and at will, it is evident that an extra power is available. A careful examination of the accompanying diagrams will show the true and intrinsic value of the introduction of positive spherical aberration as regards improvement of definition in out-of-focus planes.

Fig. A represents the course of a pencil of rays after passing through a perfectly corrected lens. If the lens is focussed for a point of light, every ray passes accurately through a point in the image, its focus. If a transverse section be made on either side of this one plane of the only exact focus, it is represented by a disc of uniformly illuminated light, smaller or larger and more or less intense, the nearer or further the plane be from that of the absolute focus. In effect, points or lines in the out-of-focus planes on either side are *uniformly enlarged and weakened.*

Fig. B represents the late Mr. Grubb's diagram for comparison with the above, illustrating a lens with positive spherical aberration outstanding. It is inadequate, first, because it *really* represents a lens of longer focus than that above; secondly, it implies that the least circle of aberration, or a plane very near it (his diagram is not quite clear) is the best focus. The first error would give this lens undue comparative advantages as regards the measurements (longitudinal and transversal) if two similar uncorrected lenses of the same aperture but different foci were compared. The second error misled certain photographers (amongst them Mr. W. E. Debenham) who, without studying the question from the correct optical standpoint, only compared the transversal measurements, that, taken alone, have *nothing* to do with the comparison to be made. The late Mr. Grubb dwelt on this aspect of the case, but was not blind to the true advantages, although his drawing is wrongly disposed. He was unfortunate in the way he puts the *real question* at issue: "As a last resource with those who would inculcate the opposite, it will probably be advanced that in the uncorrected lens the rays beyond the focus are more condensed in the centre—*i.e.*, near the axis—than they are in the corrected lens. This is true, no doubt, but the antidote to the advantage will be found at the opposite side of the focus, where the rays are concentrated as much outwardly in the pencil as they are after crossing the axis concentrated inwardly."

Fig. C represents a proper comparison of a lens with excessive spherical aberration of the same (best) quasi-focus as the aplanatic lens, fig. A. I have shown the transversal measurement at the best focus in fig. C, 75 units, equal in diameter to an out-of-focus circle in A, distant 185 units beyond the plane of accurate focus (or the same measurement as really has the best focus in Grubb's diagram, although he disposed it wrongly).

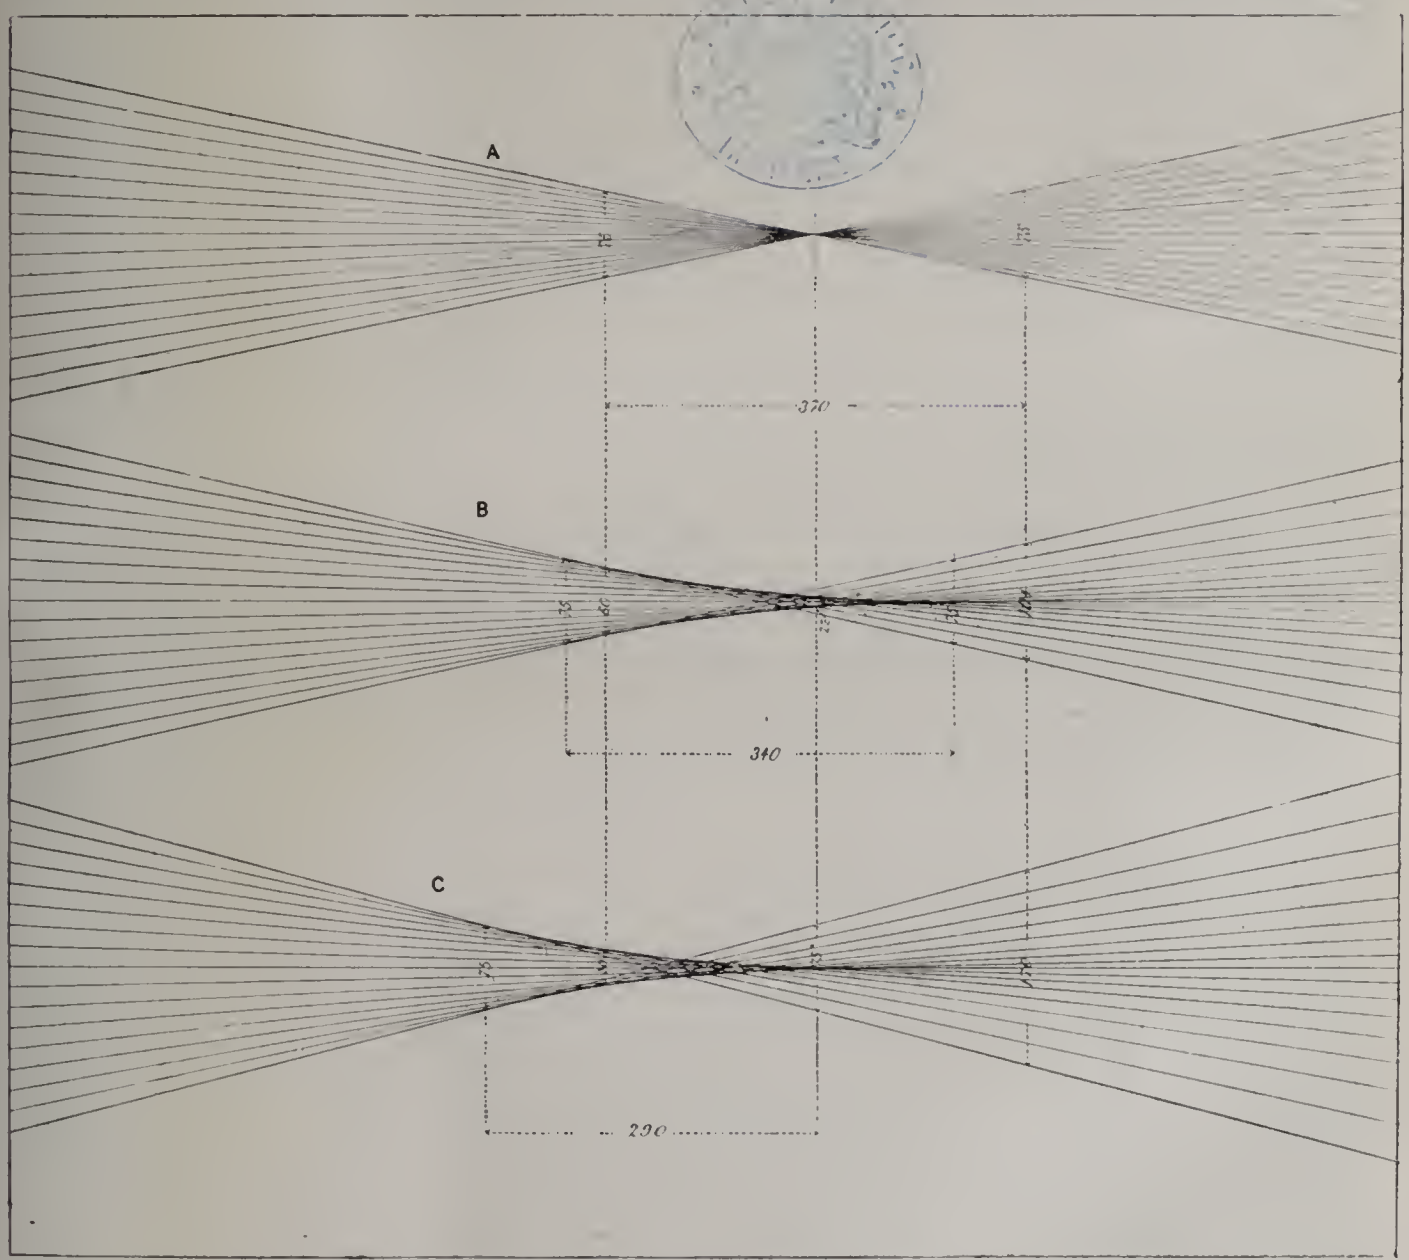
Now, at a distance of 185 units beyond the plane of best focus with the lens, fig. C, although the transversal measurement is very much greater—namely, 170 as against 75 in fig. A—the image is nevertheless, in this case, distinctly better defined than in fig. A, due to the *inward concentration* along the axis.

Comparing A and C on the lens side of the focus, and taking a transversal measurement, the same number of 185 units distant from the best focus, the uncorrected

lens would have a great advantage, 30 as against 75 units, but as there is a tendency to *outward concentration*, the corrected lens will have the best of it as regards its power of approximate image formation, being an uniformly illuminated disc as compared to a bright ring with a comparatively dark centre.

The case illustrated is intentionally exaggerated, but, of course, when aberration of this character is introduced to a less degree, the same reasoning applies. On the further side of the focus there is a tendency to *inward concentration* that benefits background, maintaining the structure better than in the case of a perfectly corrected lens. On the nearer side of the focus the tendency is to *outward concentration*, that results in destruction of structure for wide planes sooner than would be the case with a perfectly corrected lens between the same wide limits. Careful observation shows that the quality of definition at the position of the least circle of aberration in an uncorrected lens, fig. C, is almost identical in quality of definition with that given by a cone of rays in the aplanatic lens, fig. A, of the same diameter. This would give even an advantage for a small amount of foreground for the uncorrected lens.

Now, any unbiassed thinker can see that, comparing planes near the best focus of the uncorrected lens, fig. C (towards the lens), with those of the corrected lens, there



is little to choose between them for image-forming qualities, the advantage for a measurement up to the least circle of aberration resting with the uncorrected lens. When the separation of the conjugate points corresponding to the main feature of interest, and considerable foreground is great, then, of course, as before stated, the tendency to reversal and reversal itself comes in. Between the eye and nose or beard, for example, as put forward by one photographer, Mr. W. E. Debenham, if softness is a desideratum, the amount of out-of-focus effect for such a distance would hardly be distinguishable in cases taken with A or C, although there would be much stronger contrast employing lens A as compared to C. Beyond the plane of focussing, A, from keen sharpness, falls off rapidly, while C, on the other hand, softens more and more, but maintains structure better than when using lens A. The planes behind the point focussed for are *almost always* greater in the separation of their conjugate foci than is necessary for adequate foreground definition in portraiture. It is begging the question to include planes

that are not wanted in the use of a scientific application of optical laws to bring about the practical—and proven—utility of an instrument that *not only lessens contrast throughout*, but absolutely—and not relatively—*improves* definition in more distant planes—"*depth* of focus"—but also for nearer planes up to the extent usually required is practically as good, if not better, and relatively much more uniform, than in the case of a perfectly corrected lens. Carried to an *extreme* in this direction, the definition, as I have before pointed out, would be absolutely *worse*.

In conclusion, the comparison of figs. B and C may help to make clear the fact that the disposition of rays nearer the lens will correspond to foreground, and those farther from the focus to background, the plane of the plate being a fixture. Take fig. C, for example, as focussed for parallel rays, and let B represent the course of rays for some object nearer the lens. The rays here proceed to form a focus further from the lens. The rays that fall upon the plate are those tending towards the direction of *outward concentration*, and consequent bad definition.

THE ROYAL CORNWALL POLYTECHNIC EXHIBITION.

THE proceedings of the Society were opened by the President, the Rt. Hon. Leonard Courtney, M.P., who gave the presidential address in an able manner. The hall was packed to the full extent. The address was proposed by Sir Joseph Pease, M.P., and seconded by Sir Edward Siereking, M.D., physician to the Queen; and followed by a short speech by Mr. Pendarves Vivian; the Exhibition was then declared open. The photographic department is always an attractive feature. As usual, it is under the management of Mr. W. Brooks, of Reigate. The exhibits in this department are greatly in excess of any previous year, and in future the Society will have to grant more space to the department. The use of dark rooms can be obtained in the town, and also plates. In the neighbourhood there is plenty of work for the camera in all directions.

PHOTOGRAPHIC SECTION.—JUDGES' REPORT.

The judges have great pleasure in congratulating the Society on the maintenance of the high excellence of the exhibits in this department. As regards the number of pictures, they are far in excess of any previous year; several of the old exhibitors are again well to the front, and also many new exhibitors who are well known adepts in the art-science. The judges are well aware that many exhibitors have apparently been passed over whose productions are of high technical excellence; in some of the classes the judges have been obliged to double the awards on that account. In the professional section, the landscape subjects are not so numerous as in former years. Mr. R. W. Robinson is still persevering with his self-imposed task of artists at home, which, when completed, will form a very valuable and interesting collection. Platinum printing is fast driving silver printing out of the field, as quite two-thirds or more of the exhibits are printed by the former process. The Amateur Section is also well maintained. In the Photographic Appliance Department, Messrs. Oakshot and Co., of Falmouth, occupy a room, and exhibit almost every requisite for either amateur or professional photography, which will be very attractive during the exhibition.

Professional Section.—The Autotype Company, of London, are represented by some of their well-known work—enlargements in carbon—the best of which is a portrait-enlargement of the Right Hon. Earl Selborne, in his robes of office, and also two portraits of the Marquis of Salisbury and Mr. W. E. Gladstone. There is also a goodly number of pictures, chiefly enlarged portraits by a local photographer, Mr. W. M. Harrison. J. B. Gibson sends a series of cloud studies, which are of great value to artists; he also sends several landscapes, which show careful work. Mr. T. Protheroe, of Bristol, contributes three enlargements; for No. 23 he receives a first bronze medal. Mr. Lyd. Sawyer sends some master-pieces in instantaneous photography, and the judges think he might have shown better taste if he had left out those objectionable tickets which each frame contains, stating the awards received at other exhibitions; it might impress many people that they were put there for influencing the judges. Pictures sent in this way in future will at once be disqualified. No. 26 of this series, "On the Tyne," has been awarded a first silver medal; the treatment is admirable, and the whole series by this gentleman are well worthy of careful study. Mr. R. H. Lord sends two pictures (composition). No. 37, "Work and Play," is a very fine study, to which is given a first silver medal. Mr. T. G. Whaite takes a first bronze medal for an enlargement, a group on the sea-shore, which shows good work. Mr. W. E. Henry sends six frames; the subjects are of Lichfield Cathedral, which show skilful manipulation. Mr. H. P. Robinson is not so happy in his subjects this year; No. 51, "Gossip on the Beach," a composition picture, is a little too hard to be effective, and not by any means up to his usual standard. Mr. W. J. Ankorn sends two clever little pictures of the genre order. Mr. E. Spencer is represented by six pictures of merit. Mr. H. W. Reeves has some clever interiors, and No. 65 has been awarded a first bronze medal. Mr. Richard Keene, of Derby, receives first bronze medal for his series of pictures in platinum of Old Moreton Hall, Cheshire, which are very fine indeed. Mr. W. W. Winter, also of Derby, takes chief award in portraiture—viz., first silver medal, No. 81, "Miss Gibbs." This gentleman's work needs little or no comment. Mr. C. C. James shows several good pictures. Mr. B. Wyles shows several portrait studies of large size, and several other very clever studies. Mr. J. D. McNeille sends two pictures, the best of which is "Hoar Frost, Holy Trinity Church." To No. 110, by Mr. F. Whaley, has been awarded a first bronze medal for his clever and effective picture, "A Tale of the World." Miss Annie Blake shows some coloured work by the air brush, the colours being far too crude to give any artistic effect. Mr. S. W. Bhednor contributes a goodly number of small pictures, which receive honourable mention. Mr. R. W. Robinson takes first first bronze medal for his picture, landscape with cattle, which is well treated, and with good atmospheric effect; he also continues his series of "Artists at Home," which are exceedingly fine; to these honourable mention has been awarded. Mr. H. Hewitt forwards two pretty little pictures. Messrs. York and Sons, of London, exhibit a frame of lantern slides, the subjects being well chosen, and are awarded honourable mention. Mr. L. Berry shows two pictures of the High Altar of St. Mary's. Mr. F. W. Edwards is again represented by several of his well-known pictures of large size printed in platinum; one of a silver shield is a marvellous production. Mr. J. E. Goold shows some exceedingly good instantaneous pictures of ships of war. Mr. W. J. Byrne, of Richmond, is represented by three frames of panel portraits taken at the homes of the sitters, which leave nothing to be desired, being soft, brilliant, and well modelled; frame No. 179 receives the award of a second silver medal. Mr. F. Greene shows some fine cloud studies. Mr. G. Speight shows one picture. Mr. J. Lewis sends a series of pictures by Dr. Nichols' Kallitype process, similar in effect to platinum pictures.

Amateur Section.—Mr. Westly Fry has been awarded a first bronze medal for No. 203, "Young Naturalists," an enlargement on bromide paper. It is full of atmosphere, and the subject is very artistically treated. Mr. John Pike also sends some very fine enlargements on bromide paper, the best of which is "Castle Garth;" Mr. C. V. Shadbolt shows some very careful small work; Mr. A. G. Tagliaferro is represented this year by two productions, "Choragium," a classical subject treated in a masterly way, and the surroundings are well in keeping with the subject; to this has been awarded a first bronze medal. Dr. J. J. English has three frames of good work. The Rev. H. B. Hare carries off the chief award, viz., first bronze medal for the best landscape in the section, "Under

the Mendips," which is a gem in its way; the same gentleman is represented by several other pictures of equal merit. Mr. S. F. Clarke, L.D.S., forwards a pretty little picture, "What love hangs by," of the genre class. Mr. A. K. Dresser is very strong in his exhibits, which are very varied; No. 225, "Corbiere Rocks in a Gale," takes a first brouze medal. Mr. C. V. Roe shows several well-chosen subjects. Mr. J. W. Charlesworth sends a perfect little gem, No. 241 (instantaneous) "A Grey Day," very tenderly treated, and has been awarded a first bronze medal. Mr. T. H. Morton shows five frames, cathedral subjects; Mr. T. H. Hermon also sends five frames of good work. H. D. Amott, No. 256, a frame of interiors, takes a first brouze medal; these are exceedingly fine, and well rendered in every respect. Mr. J. Mountford shows some capital studies on the Avon. A. Steiglitz, F. P. Perkins, T. L. Buck, C. Court Cole, and several others show very good work; the latter gentleman's productions are printed by Blanchard's platinum toning process, and have a very pleasing effect.

Photographic Appliances.—Mr. James Wood, of Liverpool, exhibits a print-washer, with adjustable rack for plates, of improved pattern, which seems very effective. Mr. W. Rooke, of London, also exhibits a washing machine for prints, with spray bar which rises and falls by means of floats on each side, aud is automatic in its action. Mr. E. Spencer sends a head-rest of very ordinary character, similar to those used for children twenty-five years since, and at that time were in every dealer's catalogue.

The Art Union of Cornwall.

The drawing of the Art Union took place last Friday in the Polytechnic Exhibition; the prizes have to be selected from the Fine Art section, and also photographs from Professional Section. Result as follows:—319, W. N. Carné, 10s.; 776, W. N. Grylls, £1; 943, B. Freeman, £5; 926, W. H. Olni, £2; 220, Miss Simmons, £1; 676, E. Spencer, 10s.; 906, Dr. H. Moore, £2; 4, W. J. Hosking, £1; 802, Capt. Hrestendahl, £1; 592, R. Fox, £8; 648, R. Ledderdale, £15; 789, E. W. Newton, £3; 180, W. Johns, £3; 991, E. Hancock, jun., £1; 129, Earl of St. Germans, £5; 1808, Dr. Banks, £1.

PHOTOGRAPHIC MANUFACTURERS' AND DEALERS' ASSOCIATION.

With a copy of the Rules and Articles of Association of the above, we receive also a notice addressed to the trade as follows:—

To Manufacturers of and Dealers in Photographic Material.

Gentlemen,—The photographic trade having assumed very large dimeusious during the last few years, it has been felt desirable that there should be a society formed to specially protect the interests of the trade.

It is well known that many abuses have crept in which can ouly be effectually dealt with by an organised association, and many questions have arisen the mere discussion of which by such an association would undoubtedly be of great advantage to the trade generally.

A meeting was held at Anderton's Hotel on July 29th last, at which the leading London and some provincial manufacturers and dealers were present, when it was unanimously resolved that a trade association should be formed, and for that purpose a provisional council, consisting of Messrs. George Houghton, Conrad Beck (R. and J Beck), A. H. Harman (Britannia Works Co.), A. C. Edwards (B. J. Edwards and Co.), and W. H. Walker (Eastman Co.), was appointed to frame rules for the management of the proposed Association.

The provisional council having drawn up a set of rules, a farther meeting of the trade was held on the 2nd inst., at which the proposed rules were adopted—subject to confirmation at the next general meeting—and the Association duly formed with the following membership:—

Adams and Co. (81, Aldersgate Street), Autotype Co. (W. S. Bird), R. and J. Beck, Blackfriars Sensitising Co., Brittauia Works Co., Ilford (A. H. Harman), Henry Creuch, T. R. Dallmeyer, the Eastuan Co. (W. H. Walker), B. J. Edwards and Co., Elliott and Son (Barnet), England Bros., Jonathan Fallowfield (T. W. Hindley), Hinton (Bedford Street), Holmes, Sadler, and Holmes (Manchester), George Houghton and Son, W. Lancaster (Birmingham), London Stereoscopic Co. (Butler Humphrey), Percy Lund and Co. (Bradford), George Mason and Co. (Glasgow), Mawson and Swan (J. B. Payne), Morgan and Kidd, Noakes and Son (Greenwich), W. W. Rouch and Co., Ross and Co. (J. Stuart), Otto Scholzig, Jaues Swift and Son, R. W. Thomas and Co., Limited (J. T. Sandell), William Tylar (Birmingham), Walter Tyler, W. Watson and Sons, Wratten and Wainwright.

As it is desirable that the scope of the Association should be as broad as possible, I shall be pleased to forward on application a copy of the rules, together with form of application for membership.

The next general meetiug will be held on Monday, the 22nd inst., at 4 p.m., at Anderton's Hotel, Fleet Street, London.—Yours faithfully, Birt Acres, Hon. Sec., *pro. tem.*
131, *Richmond Road, Hackney, London, N.E.*

PHOTOGRAPHIC PORTRAIT GALLERY.

On the above subject the *Daily News* last week quoted the following letter from Mr. C. A. Ward:—"The suggestion is good to have a gallery of photographic portraits added to the picture gallery. The Dublin Gallery only the other day carried off the portrait of Richard Burke, the son of Edmund. That, except that it is very well painted, did not much matter, because Richard was nobody. But Lord Camden was also carried off, and that should have gone to the portrait gallery. The provincial galleries will become a positive nuisance if they are allowed to compete with the central gallery when the portrait of a celebrated character comes into the market. For national utility all these portraits should naturally gravitate to London as a centre, that they may be all collected under one roof. Photographs of them might be distributed to all who want them and can purchase them. So much for the portrait gallery. But why does not the National Gallery devote a room to photographs? We might have a perfect series containiug every picture in every gallery of Europe; and if the same room were fitted up with the authorised foreign catalogues also, we could have reminders of every great picture in the world without steppiug out of Trafalgar Sqnare. At first they might be done with each picture of the size of a threepenny piece, so that two or three sheets would comprise the whole gallery of Dresden or the Pitti. These miniature presentments could be brought out to any dimeusion by being placed under lenses fixed in the room they were shown in. Such comparative æsthetics would be a new discovery in art. This is so easy, so practicable, and so desirable, that it should be done.'

In a subsequent issue our contemporary gives a further communication from the same writer to the following effect:—"The thing to be attempted is this: take, say, the Dresden Gallery, which, amongst its 2,200 pictures, is very rich indeed in *chefs d'œuvre*. Have them all well photographed, reduce every picture to a uniform size, that of a threepenuy-piece, aud place some 500 of them in their rotation, and with the reference numbers of the gallery itself upon a card. In this way five cards would sum up the coutents of the eutire Dresden Gallery. Every public gallery in Europe could be similarly transferred to cards by photographic process. Enough would be realised if we could bring the image of any picture out of its European gallery before us iu a moment, for no one iu his right wits would resort to a photograph or to an engraving to study colour from. But what could be studied by the aid of photography is drapery, treatment, form, and design. This would be quite sufficient to lay well and solidly the foundation of a quite new study—that of comparative æsthetics, a study heretofore non-existent in art except in the minds of the very greatest painters, Raphael, Buonarotti, Titian, Rubens, and a few more men who travelled, thought, and saw. England should begin and photograph all her own pictures first, and theu reduce them on sheets as above. Then we should invite the co-operation of other couutries, and pro-

pose to present them with our gallery in miniature in exchange for that of their own. If co-operation failed, we could do their galleries for ourselves, and the photographs so obtained would would also sell with the public here.' "

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

THE following experiments show the influence of

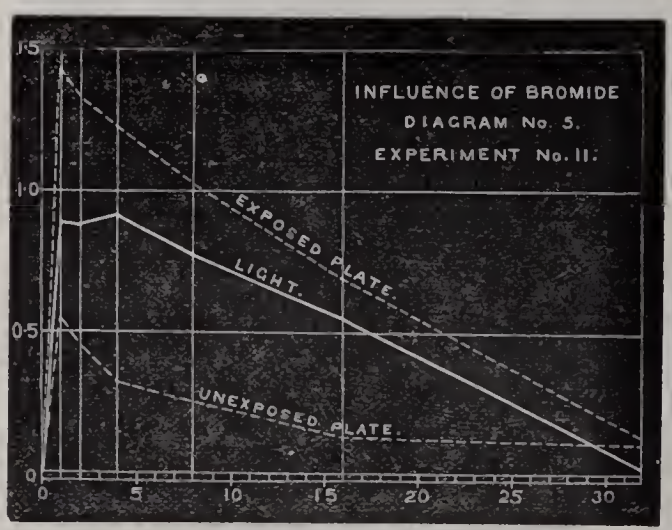
Variation of Ammonium Bromide.

Experiment 10.—Plate: "Wratten Ord."

Developed for 4 minutes, 100 c.c. = $\begin{cases} 0{\cdot}123\ NH_3 \\ 0{\cdot}375\ \text{Pyro.} \end{cases}$

Ammonium bromide grms. in 100 c.c.	0·00	0·10	0·20	0·40	0·80	1·28
Relative amount ...	0	1	2	4	8	12·8
Density	1·81	1·73	1·61	1·43	0·34	0·00

Experiment 11.—Plate: "Wratten Ord." Exposure = 40 C.M.S. Developed 4 minutes in 100 c.c. = $\begin{cases} 0{\cdot}162\ NH_3 \\ 0{\cdot}342\ \text{Pyro.} \end{cases}$ and various amounts of bromide. See Diagram No. 5.



Ammonium bromide	·057	·114	·228	·457	·918	1·828
Relative amount ...	1	2	4	8	16	32
Density exposed plate	1·450	1·335	1·235	1·025	·685	·120
Density unexposed plate	·560	·455	·315	·255	·130	·090
Density due to light	·890	·880	·920	·770	·555	·030

It is clear that development in both experiments was entirely prevented in these four minutes when the amount of bromide was about ten times that of ammonia present.

It also appears from our experiments that a rational developer would consist of a decinormal solution of ammonia, containing so much pyrogallol and ammonium bromide as would correspond with the formula—

$$C_6H_3(NH_4O)_3 + NH_4Br.$$

We have represented many of these results in the form of diagrams. It will be interesting just to point to diagrams Nos. 1, 3, and 4, to show the great amount of action which the alkaline developer may have on the bromide of silver, although it has never been exposed.

This disagreeable property is common to all alkaline developers, and it renders them unsuitable for scientific investigations. In all our important work we use exclusively the ferrous oxalate developer, for the reason that it attacks unexposed bromide of silver so slowly that within one hour and even more, no appreciable density can be developed upon a really good plate. Nor does its action vary much with its composition. The addition or omission of bromide from the constitution of this developer does not seem to have any great influence, and a greater or less concentration of the reagents within considerable limits does not affect its action; indeed, we have not found any variation to arise from alterations in its composition, excepting the length of time needed for completion of development.

The following table shows how the density of an exposed plate grows as the time of development is prolonged from five minutes to one hour.

Experiment 12.—Ferrous Oxalate.

Time.	Density exclusive of Fog.				
	I.	II.	III.	IV.	V.
Minutes					
5	·365	·350	...	...	·215
10	·525	·460	...	...	·305
15	·615	·550	·795	·570	·410
20	·615	·575	...	...	·420
25	·700	·650	...	...	...
30	·700	·660	·860	·670	·450
45	...	...	1·000	·715	·515
60	...	...	...	·740	...

Columns I. and II. are the results obtained upon the same plate, one (I.) portion of the strips developed in a developer consisting of 4 parts of a saturated solution of potassium oxalate, mixed with 1 part of a saturated solution of ferrous sulphate, the other (II.) portion of the strips developed in the same developer diluted with an equal volume of water. Columns III. and IV. represent other experiments, the plates being developed with the saturated solution. Whilst I. to IV. were developed with a small amount of bromide of potassium added to the developer, No. V. was developed without bromide. In not one instance did the density of the unexposed portions of the plate amount to more than 0·098, which is the density due to clear glass and gelatine. That ferrous oxalate does not, however used, attack silver bromide which has not been exposed to light is a most valuable and characteristic property of this developer.

(*To be continued.*)

INTENSIFYING NEGATIVES. — Dr. R. S. Liesegang recently published a new and interesting method of intensifying negatives by which no damage is done to the negative, as is often the case. This process is, first, to varnish the negative in the usual way, after which he again coats it with collodion or varnish, in which has been previously dissolved red or green colouring matter of an aniline nature which is sensitive to light. On exposure to direct light through the negative, the clear parts are bleached out, while the half tones and blacks change only in proportion to the density of the different parts. The principal objection to be urged to this method arises from the fact that the aniline colours will gradually fade as prints are made from the negatives so treated, and the process then has to be repeated; but Dr. Liesegang suggests that some of the iron salts, such as are employed in the making of the ferro-prussiate paper, may overcome this difficulty. If such salts were used, however, the negative would have to be re-developed. —*Anthony's Bulletin.*

* Continued from page 695.

INSTANTANEOUS PHOTOGRAPHS OF WATER JETS.*

BY LORD RAYLEIGH, SEC.R.S.

A battery of Leyden jars was charged by a Wimshurst machine, and discharged itself between brass balls held about half an inch apart in the optical lantern. By means of a large condenser a good proportion of the light was concentrated upon the lens of the camera. The jet of water regularised by a tuning fork fell in front of the condenser and was focussed upon the photographic plate. In the absence of anything to diffuse the light, the pictures formed were simple shadows, such as had been obtained without any optical appliances by Mr. Bell and Mr. Boys. The only "detail" was due to the lens-like action of the jets, and the drops into which it was resolved. This arrangement was quite sufficient to illustrate the mechanism of electrical jets. But the interposition of a plate of ground glass close to the condenser effected a great improvement in the pictures of bringing out half-tones, and the results printed on aristotype paper were now very good. The only difficulty was that due to the loss of light. In some of the experiments it was found most advantageous to diminish the diffusion by slightly oiling the ground glass. The degree of instantaneity required depended upon circumstances. In some cases the outlines would have lost their sharpness had the exposure exceeded one-ten-thousandth of a second; and it was probable that the actual duration of the principal illumination was decidedly less than that.

Correspondence.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES PHOTOGRAPHIC ASSOCIATION.

Sir,—The members of the Haltwhistle Photographic Society and the above Association will have an out-door meeting to Gilsland, Naworth, and Lowercost, on Thursday, the 18th September. *Leader*—Mr. M. Auty, of Tynemouth. Train leaves Newcastle at 6.25 a.m. for Gilsland station.

Edgar G. Lee *Hon. Sec.*

11, *Beverley Terrace, Cullercoats, September 6th.*

EXHIBITIONS AT THE CAMERA CLUB.

Sir, —Would you kindly note that the sixth of the series of One-Man Photographic Exhibitions at the Camera Club will be open for private and press view on Monday, October 6th, at 7.30 p.m., and on and after Tuesday, October 7th, it will be open to visitors on presentation of card.

The Exhibition will consist of photographs by Mr. Lyd. Sawyer, of Newcastle-on-Tyne, by whose kind co-operation we are able to exhibit a fully representative collection, including much new work prepared specially for this Exhibition. The pictures will be on view for about two months.

G. Davison, *Hon. Sec.*

Camera Club, 21, *Bedford Street, W.C., 10th Sept.*, 1890.

PHOTOGRAPHING AT FRENCH SEAPORTS.

Sir,—I notice in your current issue, and also in several recent ones, an article advising readers to undertake photographing in French seaside towns. May I beg you to permit me, as one who knows France and its people very well indeed, to state that a more dangerous and risky undertaking could scarcely be found. The laws of France absolutely forbid photographing or sketching any portion of fortified towns, or any roads or ways leading to them, and a very wide range is given to the meaning of such phrases. True, the "spy" idea has partially waned, but photographers have been quite recently exposed to gross insult and detention in police offices.

France swarms with petty functionaries of incredible ignorance, and bursting with official importance, who have repeatedly caused the arrest and most troublesome detention of photographers.

I should think no more risky undertaking, in its way, could be undertaken than attempting to take views of old gates, &c., such as you refer to. Nominally, in Paris, full permission has been given to take photographs in the streets; but a gentleman was last week requested to go to the Police Office for doing so, detained all day, and on dismissal and returning to his hotel, found an insulting reception, and that the police had searched his luggage. Better far go to Belgium or Holland, amongst friendly people, who give a warm welcome to the English amateur. F.

[This letter is founded upon a misquotation. Photographing at French seaport towns has always been described in these pages as dangerous work, and what was stated last week, in relation solely to Calais, consisted of information recently derived from English authorities constantly on the spot. The tax upon every passenger landing at and leaving Calais is "eighteenpence," not "eightpence," as printed last week in error. The French have not yet broken free from the ancient, rigid, bureaucratic system, which reduces the liberty of themselves and of visitors.—Ed.]

Proceedings of Societies.

London and Provincial Photographic Association.

September 4th.—Mr. T. Bolas in the chair.

Mr. F. W. Hart exhibited a lantern screen; the frame was of bamboo in lengths fitted with screw points; it had the merit of allowing the sheet to be fixed at an angle, when occasion required that the lantern should be tilted. By a re-arrangement of the frame work, it could be converted into a portable studio for the garden, and also used for suspending magnesium flash-light lamps for out-door work.

Mr. A. Cowan showed two plates that had received sensitometer exposures. In one case the plate had a preliminary exposure of half a second, eight feet from a gas burner; this plate registered a much higher reading. A second set of sensitometer exposures was made. One of the plates, after development, was exposed to white light, when further development of higher sensitometer numbers was noticeable. Mr. Cowan did not think all plates in a condition to receive preliminary or supplementary exposure; the latter he considered might be an advantage when used in the case of a hopelessly under-exposed plate. Preliminary exposure should always be shorter than the normal working exposure.

The South London Photographic Society.

At a meeting held on Friday, September 5th, Mr. F. W. Edwards was in the chair.

The business of the evening consisted of a demonstration of "Mounting and Finishing Photographs," by Mr. C. Hoddle, in the course of which he showed practically how to prepare self-adhesive mounts.

A hand-camera by Crouch and Co., together with specimens of the work done by it, were handed round.

During the evening five additional candidates were proposed as members.

Sheffield Photographic Society.

A meeting of the above Society was held in the Masonic Hall on September 2nd, with Mr. B. J. Taylor in the chair. A goodly number of the members of the Rotherham Photographic Society was present.

The Chairman announced that Mr. Leadbeater, of the Rotherham Photographic Society, had presented the Society with a photograph of the members and friends at the Bolton Abbey excursion.

Mr. Howson gave a practical demonstration on the subject of "Printing on Alpha Paper." He began by describing his apparatus for always exposing the same or any required distance

* Read last Tuesday before Section A, British Association.

from the light, which consisted of a movable base-board, marked in inches, which held the printiug-frame. After exposing several prints with various exposures, he proceeded to develop the same, showing the latitude of exposure.

LEWES PHOTOGRAPHIC SOCIETY.

THE annual meeting was held at the "George and Dragon" on Tuesday eveniug, when Mr. J. G. BRADEN presided.

The financial position of the Society proved to be satisfactory, the balance-sheet for the year showing a balance in hand of £11 10s. 3½d. There was a balance in hand from last year of £2 0s. 1d.; the subscriptions amounted to £11 5s., and the balauce from the Photographic Exhibition added to the funds of the Society the sum of £4 16s. 1d. The total expenditure for the year was £6 10s. 10½d.

The SECRETARY then read the following report:—"The Society still contiuues to prosper, numbering at present forty-five members against thirty-eight in the previous year. The treasurer's report is satisfactory, showing a balauce in hand of £11 10s. 3½d. This large amount, however, is owing to the sum of £4 16s. 1d. balance from the exhibition account. Ten ordinary meetings have beeu held duriug the year, which have been fairly well attended. The council would like to see more interest taken in the exeursions, which have not been well attended this season. The purchase of a lantern for members' use and also a book-case for the Society's books, has beeu contemplated for some time, and will be carried out as soon as possible."

The report and balance sheet were unanimously adopted.

The following is the list of offieers elected:—*President*—Mr. J. G. Braden. *Vice-President*—Mr. J. Tunks. *Hon. Secretary*—Mr. E. J. Bedford. *Committee*—Messrs. P. J. Morris, E. Miller, C. R. Wells, C. J. Wightman, and Mr. Funnell.

Mr. Potter (Brighton) was elected a member of the Society.

The SECRETARY reported that no entries had been received for the quarterly competition, which was considered to be due to the very unfavourable weather which had prevailed.

At an excursion held by the Brighton Photographic Society on Saturday, at Hayward's Heath and Balcombe, the Lewes Society was represented by Mr. E. J. Bedford. There were ten cameras at work.

Mr. A. H. C. CORDER will read a paper at the next monthly meeting on "Printing Processes."

PHOTOGRAPHIC CLUB.—The subject for discussion on September 17th will be "Extemporised Modifications of Cameras"; September 24th, "Photographing Interiors." Last out-door meeting of the season on Saturday, September 20th, for Hampstead Heath; meet at Flagstaff at 3; tea at Bull and Bush at 6.30.

PHOTOGRAPHING AN EXPLOSION.—We note from our exchanges an account of a most eourageous and interesting experiment in the way of photographing the explosion of a 250lb. charge of dynamite from a dangerously close point of view. The seene of the explosion was in Savin Hill, near Boston, and the negative made by Dr. George H. Bailey, of that city, who succeeded in obtaining a most interesting negative of the *débris* just as it reached the highest point in its ascent. He sueceeded in getting himself and camera out of the way only just in time to escape serious damage from falling rock.—*Anthony's Bulletin.*

RECEIVED.—From Gauthier-Villars et Fils, "Traité Practique de la Deterumination du Temps de Pose." The author (M. de Chapel d'Espinassoux) acknowledges his indebtedness to previous writers on the subject, and claims to have produced a work specially adapted for those who are unfamiliar with physico-chemical science and mathematical formulæ. The book, though elementary, is complete, dealing with both theory and practice, and contains thirteen useful tables, besides a well-arranged index.——Under the title "Names we Love and Places we Know," Messrs Hazell, Watson, and Viney issue a birthday text-book of literary gems, which is so arranged as to serve as an autograph album, and a souvenir of holidays spent with the camera. The book is handsomely got up, and well suited for a drawing-room volume.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

M. D.—*Dry Plate Developers.* You will find the information on page 698 of last week's NEWS, where the relative proportions of sulphite to eikonogen are tabulated by Mr. F. C. Beach.

A. W.—*Phototypic.* We have no information beyond the reference to the fact that the amateur's outfit is to be had in Paris, as stated by Mr. Julius Sachse on page 653. If procurable in this country, you might enquire of Mr. Walter S. Bird, of the Autotype Company, 74, New Oxford Street, W.C.

T. V. C.—*Chart of the Aniline Products.* Only indirectly are we interested in your undertaking, but we take note of the announcement that the chart may be obtained at No. 2, Bond Street, Leeds.

A. B. (Preston).—*Fading by Sun Exposure.* Twelve months is a period long enough to bring about very serious bleaching by exposing prints on mauve paper to direct sunshine in a show-case. Those of shorter duration—four months—are not so seriously affected, which is in accordance with the probabilities of the case.

ROBERT LEWIS.—*Photography at Virginia Water.* We cannot believe that any question will arise. It will not even be necessary to put the enquiry to the landlord of "The Wheatsheaf" before going on to the ground and pitching your camera, for you can get access another way.

R. M.—*Blue Prints.* It seems impossible to help you further in this matter. If none of the dealers mentioned are open to make an arrangement with you, it might yet be advisable to insert an advertisement, asking for a partner to assist you in bringing out the paper for commercial use. There ought to be a demand for both sorts.

W. P. (Birmingham).—*Wet Plate Developer.* The advantage of hydroquinone does not come out so clearly as the older practice with pyro. Try a one-grain solution of pyro with acetic acid added, and a little alcohol to promote the easy flow of the developer. Alkaline development need not be resorted to, and is a positive disadvantage.

T. N. (Reading).—*Blisters on Albumenised Prints.* The paper is at fault, and complaints have been numerous of late. See recent replies. Avoid too sudden trausition from a stroug solutiou of hypo iuto pure water by interposiug a more dilute fixing bath before proceeding to wash the prints. Another plan is to use salt brine as the intermediate washing bath, but this is not so successful iu practice.

AULD RIEKIE.—*British Association.* The meeting stands adjourned to the 19th August, 1891, at Cardiff, Dr. William Huggins, F.R.S., having been elected presideut. The next followiug year will find the members assembling in your town, at a date which has not yet been definitely fixed.

C. W.—*Photographs of Volcanic Eruptions.* A series of Vesuvius, Stromboli, and Volcano, Lipari Islands, were shown on Monday last, in the Geological Section, British Association, by Dr. H. J. Johnston-Lavis, who photographed the craters in active state of eruption during the last and present years. The outburst of vapour and lava is wonderfully well rendered in several of the plates.

RECEIVED.—Colonel J. Waterhouse, T. Forest, B.H.L., Taunton, A. G. Greeu, and another correspondent.

MR. JOHN JAMES SPENCER informs us that he has completed arrangements for the acquisition of the business carried on by his father, the late Mr. John Spencer, which will be carried on by him exactly as formerly, under the old name. Mr. J. J. Spencer was for many years associated with his father in his business, aud latterly had had the entire management.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1672.—*September* 19, 1890.

CONTENTS.

THE CHANGING BAG.

In spite of the introduction of improved films for the support of the negative image, with all the manifest advantages which they possess in freedom from breakage, absence of halation, and reduction of bulk, the sale of glass plates does not seem to suffer any abatement, and it is probable that if enquiry could be made, it would be found that manufacturers have been this season busier than ever. A radical change, such as that which would be indicated by the general adoption of celluloid in lieu of glass, and which is not actually a necessity, must bow to the consideration of expense. Those who are already equipped with good apparatus fitted for the reception of glass plates—and in some forms of changing boxes nothing but glass can be used—naturally hesitate before they launch out into costly alterations, and are wise in asking themselves beforehand how the change is likely to repay them. They are also apt to remember that the price of the glass plates compares very favourably with that of films, so that alteration means not only a capital charge, but involves a constant increase in the cost of negative production.

Seeing, then, that glass still holds its own, it will not be out of place to call attention to a most useful piece of apparatus, which every touring photographer should carry with him as part of his kit. We mean a simple form of changing bag, for filling or emptying double backs, without the necessity of having recourse to red light. Such a bag can be bought ready made, or can be made at home by willing fingers.

The first necessity in a changing bag is that it must be light-tight, and although it may seem superfluous to insist upon such an obvious point, we do so because it is a condition which is not quite so easy to fulfil as it at first appears. The material must be soft, so that it can be packed into small compass without injury; and unfortunately most materials of this nature are full of interstices through which light can easily find its way. Mackintosh cloth would seem to be free from this objection, but it will not bear rough handling without cracking, and it has a tendency to get sticky if subjected to heat, or if packed away unused for a time. The best way to surmount the difficulty is to employ several layers of fabric, and for some of these to be of a non-actinic colour. Italian cloth does well for the outside and inside surfaces, while sewn between these may be two layers of yellow or red material, and the sewing must be so done that no needle pricks will admit light to the interior.

Perhaps the best shape for the bag is square, the size being governed by the size of the plates to be changed therein, eighteen inches being ample for quarter-plate work. The pattern may be cut out of paper in the form of a square, with two of the corners at one side cut off. It is at these corners that short sleeves are attached, which, in the case of the quarter-plate size, need not be more than six inches long. These sleeves should have india-rubber bands sewn round them both at the outer orifice and at the shoulder, so that when the arm is inserted there is a grip upon the limb at two places. Care must of course be taken that the opening of the sleeve is sufficient to pass a double-back and a box of plates in or out without difficulty.

We have seen changing bags of far more elaborate pattern, in which there is a red window and an orifice opposite, through which the eyes can watch the operations going on within. Every such addition means risk of fogging, and in practice it will be found that all necessary manipulations can be carried out by the sense of touch alone. Of course there are horny-handed individuals who cannot distinguish things in this manner, and who find it impossible to differentiate between a peach and a brickbat; but the majority will soon learn easily to carry out the necessary work without the exercise of eyesight. At first there will be some little difficulty in distinguishing the gelatine side of the plate from the reverse, but the touch gradually becomes so educated in this respect that a mistake seldom or never occurs. The film has an unmistakably dry surface, while the glass is felt to be steamed, to a slight extent, by the touch of the warm hand. But

even this test may be disregarded if the attention is wholly fixed upon the operation in hand, and if the worker will bear in mind that the plates are packed in a certain order—generally film to film.

Do not attempt to use the changing bag in the open air, for, with the greatest care, light will sometimes stray through the sleeve, especially if the coat cuff should get displaced. It is best to place the bag on a table, and to sit in front of it facing the window. Thrusting one arm through its sleeve, the plate-box, the double backs, and an empty box—if required—for exposed plates are pulled through the other opening. The other arm is now inserted, and, without any difficulty, the plates can be handled and placed in the backs, or out of the backs into the spare box. It may be pleaded that, as the use of a dark room can generally be had for the asking, such a contrivance need not find a place in the photographic kit. It is true that there is now little difficulty in finding a dark room, even in the smallest town. But at the moment when wanted it may be occupied, or the owner may be away, or other difficulties may crop up. It is far better to be independent of outside aid, and when this independence is secured by the nominal addition to one's luggage of a small bag that weighs only a few ounces, it is purchased cheaply indeed.

PHOTOGRAPHY AT THE EXHIBITION OF THE MEDICAL CONGRESS IN BERLIN.*

AMONGST the interesting applications of photography is a representation by Professor Exner of the retinal image of the eye of a glow-worm. As is known, the eye of an insect is differently constructed from that of a human being, for, whilst the latter possesses a lens that, similarly to a photographic objective, projects an inverted image upon the retina, the eyes of insects are formed of a number of facets like small mosaic work, which are connected by tubes, each with the end of a nerve sensitive to light. The picture, as a whole, is similar to that which is projected by a small opening, only that it is not inverted, since it consists of an aggregate of very small sections corresponding with those of external objects.

The firm of Burstet and Fürstenberg presented the Exhibition with a series of glass pictures for projection in the lantern. They exhibit enlargements of anatomical, zoological, and botanical preparations printed upon gelatino-chloride of silver, and of singular delicacy. We have ourselves had the opportunity of examining the installation in the laboratory of these gentlemen. For considerable enlargement a microscopic objective is employed, and for those of a less degree the system of Hartneck is adopted, as in the laboratory of Charlottenberg.

The embryological photographs of Professor Hiss evidence the most perfect work. We must admire as much the skill of the dissector as the excellence of the photographic work.

A unique series of photographs is that shown by the Hygienic Institute of the University of Kiel (Prof. D. B. Fischer). As is well-known, certain unclean objects—fish-bones, decaying wood, crabshells, &c.—under some circumstances exhibit a vivid, phosphorescent light in the darkness. It was formerly accepted that this development of light was due to a slow oxidation of the decaying body. With the help of the microscope it was, later on, recognised that the light given out by these objects is due to colonies of a fungoid growth (bacteria), and that these bacteria, like the glowworm and the shining animalculæ of the sea, possess self-luminous properties. Prof. Fischer has now succeeded in photographing these bacteria by the light which they diffuse. This is so much the more remarkable an achievement as the light emitted is, both optically and chemically, exceedingly feeble.

Professor Cohn, with whose magnesium flash pictures of diseases of the eye our readers are acquainted, showed his "Rhomboidal" camera. This camera has, internally, an arrangement by which the rays collected by the objective are divided into two parts, so that by a single objective two neighbouring images are projected. By this means it is possible to get the image very sharp at the moment of taking the photograph. This is attained by means of glass prisms, in which the light is twice totally reflected. It may be further observed that the object of Cohn's apparatus may be effected in a much simpler manner, and without sacrificing the light from half of the objective. Another method, for example, is very advantageously seen in Loman's reflecting camera; and in the "Rhomboidal" camera itself, by another arrangement of the prism one of the reflections can be dispensed with.

Of very general interest are the photographs which Prof. Von Virchow shows of acrobats and contortionists. The muscular formation of these individuals stands forth so abnormally, that only by photographs is adequate representation practicable.

The photo-chemical laboratory of Charlottenberg is also represented by photographs of the spectrum made by Dr. Wollheim. The chlorophyl spectra exhibited by this gentleman are technically very perfect and characteristic.

The Legroin incandescent gaslight, so much in use in Austria, is shown applied to an enlarging apparatus by R. Leichner. Unfortunately we have not been able to see any proofs of its work and capability.

The foregoing may suffice to give an idea, though an imperfect one, of the accomplishments of photography in medical science. We may, from what we have seen, draw the conclusion that in this direction photography has achieved great triumphs, but that its application is as yet much too far from being general. In a great number of cases the laborious, uncertain, and subjective process of drawing is still employed, a process which has been ridiculed for more than twenty years. We have seen magnificent and immensely laborious drawings at the Exhibition, but ever so defective a photograph puts them into shade in the matter of accuracy.

* Concluded from page 665.

THE taste for water-colour painting possessed by the late Prince Consort, by the Princess Louise, and by the Princess Beatrice, is shared by the present Emperor of Germany, who, however, prefers oil as a medium. He has painted some very tolerable studies of Norwegian scenery on the panels of the ante-room in his State yacht. An imaginative attempt at "the Sea Serpent" is less successful. In another room are interesting and apparently life-like portraits of Prince Bismarck and Count Moltke, which appear, however, to have been reproduced from a photographic copy, and not from life. His Majesty is a better draughtsman than a colourist.—*The Artist.*

Literary Notices.

Die Mikrophotographie als Hilfsmittel Naturwissenschaftlicher Forschung. Gottlieb Marktanner-Turneretscher (1890: *Knapp, Halle*).

Micro-photography, as an aid to scientific research, has been illustrated in a very important manner at the recent Exhibition held in connection with the Medical Congress recently sitting at Berlin, and the continually increasing use made of micro-photography as a handmaid of science ensures a welcome to such a comprehensive and thorough hand-book as that of Herr Marktanner-Turneretscher, a hand-book which not only deals thoroughly with such matters of detail in the use of instruments as it is essential for a micro-photographist to master, but, with the characteristic thoroughness of the German bent, contains in a second part such photographic information as is necessary for the microscopist entering upon this branch of research to be acquainted with. So that, whether the reader is already a photographer, already a microscopist, or one unacquainted with either science, he need not go beyond the present manual for the information that he will require.

Half-a-dozen pages of historical and introductory matter, in which the early work of Davy (1802), Reade (1837 and 1839), Shadbolt, Wenham, and others are referred to, bring us to the essentially practical portion of the work, in which photo-micrography is studied in its various aspects, this part occupying over two hundred pages; whilst the remainder of the book, a hundred or so pages, is devoted to the definitely photographic instruction and details to which we have already referred.

The author recommends the compact and convenient "Zeiss" form of microscope so much employed on the Continent, and indeed very much in present use in our own medical and histological schools, and describes a slightly modified form made by Dr. Zeiss especially for photomicrographic work, the outer draw tube being of extra size (for photographic use without the eye-piece), although it will take the usual inner tube, with the millimeter scale as now engraved on all the newer instruments. The instrument is thus equally well adapted for ordinary microscopic work for photographic use, whether with or without an eye-piece.

Another advantage of the larger body tube of the Zeiss special form is that, when using objectives of very long focus, the lens can be attached to the inner draw tube, and so the requisite distance of the stage can be readily obtained, the larger body tube serving incidentally also as a shade. A light mechanical stage, with two graduated scales, serve to enable the position of any object on a slide to be registered, and a circular motion gives facility for bringing any part of the field to the top of the sensitive plate.

As regards objectives, the author points out that except in the case of instruments made specially for photographic use—and from what he says of the latter we infer that, on the whole, he prefers to use ordinary objectives—it is quite necessary to test for any difference that may exist between the position of the visual and the chemical foci, as the variation in this respect is quite independent of the reputation of the maker, and of the price of the combination. Still, in some cases this labour may be avoided by using monochromatic light, which may be green, blue, or yellow; the latter, however, being more especially useful for heightening the contrasts of slightly coloured preparations.

The exhaustive and well illustrated descriptions of the various arrangements of apparatus suggested and used is very instructive, and the photo-micrographic worker, even if he does not understand the German language, who can glance at the illustrations without getting some useful idea must either be very unobservant, or have already accumulated a very large store of knowledge of the subject.

As regards various means of illumination, the work is well up to date, showing intimate acquaintance with the latest improvements; the achromatic condenser of Zeiss, and the less complicated instruments of Abbé, of Seibert, and of Klonne and Muller being treated of, together with optical means (prismatic apparatus) for obtaining monochromatic light. After this we find several forms of heliostat described, and then we come to instantaneous shutters, the quickest of which are required in some cases when the electric arc is used as the source of illumination, a source far more convenient than that uncertain supply which those who work by sunlight employ. A simple carbon holder is described consisting of a shaft worked by hand on which is cut two threads, one right-handed and the other left-handed, and of such different pitch as to correspond with the consumption of the positive and negative carbons respectively. For steady work, however, our author recommends the positive motor lamp of Von Hefner Altneck (Siemens), and on page 125 he figures this in combination with a complex condenser system which is worth the study of those desirous of working in the highest attainable class. We also find details for using a small incandescent lamp which may be placed very near the object either for "over" or "under" illumination, much facilitating the work of the ordinary microscopist.

A comprehensive bibliography and a good index are useful features, and the whole work is a characteristic example of the thorough way in which German scientific men delight to complete as far as possible the work they undertake.

Custom House Examination of Baggage.—Travellers who have just returned from their autumn holiday must be disgusted to think that they did not wait a little longer before returning to harness. Dating from the present week, the stringency of the regulations respecting the search of passengers' baggage has been greatly relaxed, by order of those semi-mythical personages, my Lords of the Treasury; and, therefore, it will no longer be considered absolutely necessary for the well-being of this realm that one's shirt-fronts should be scrabbled by the inquisitive and unsympathetic claws of a Custom House official. The harmless and unnecessary amateur photographer will especially rejoice, for, in certain tents of the Philistines, to be an amateur anything is to court the treatment usually meted out to a mad dog, and the practical joker in office will no longer be able to insist on exposing a box of cherished but undeveloped negatives to the autumnal sun. The discomfort and annoyance experienced by many homeward-bound travellers during the last six years must be included in the little debt of gratitude we owe to the Irish-American patriots who were in the habit of bringing dynamite in their luggage in those occasional deviations from humanity, which seem so trifling to the man out of reach of the infernal machine; but now that most of these scoundrels are enjoying a well-earned repose in Her Majesty's prisons, the strictness of the search may safely be relaxed. Undoubtedly this right of search by the Custom House officials is a salutary thing; but so few articles are now-a-days worth smuggling, especially in the small quantities possible in a passenger's ordinary luggage, that the ordeal should be made as little obnoxious as may be to the much-tried gentleman who has been crossing the Channel.—*Graphic.*

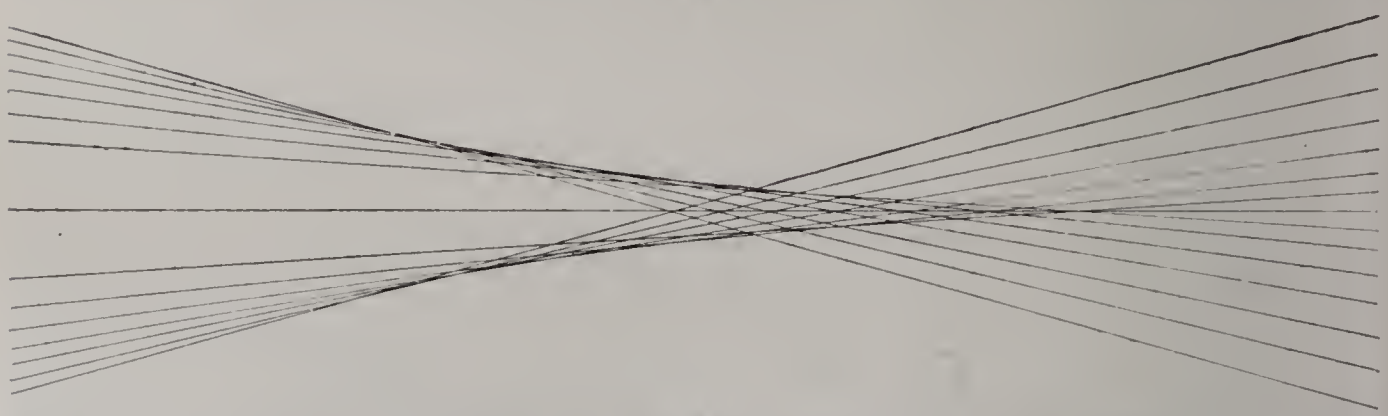
SPHERICAL ABERRATION AND DEPTH OF FOCUS.

BY W. E. DEBENHAM.

MR. THOS. R. DALLMEYER, in an article in the last issue of the PHOTOGRAPHIC NEWS, says that in the view that I have taken of the effect of the introduction of spherical aberration into a photographic lens, which agrees with that put forward by the late Mr. T. Grubb, I have been "misled" by that gentleman's diagram on the subject. Leaving for the moment the point as to which side of the question is supported by misleading propositions, the statement is singularly unhistorical, as my protest against the claim for increased "depth of focus" was made at the meeting of the Photographic Society of Great Britain in January, 1867, at which this claim was under discussion, a fact of which Mr. T. R. Dallmeyer can scarcely be supposed to be ignorant, whilst Mr. Grubb's protest and diagram were not issued until some weeks later, and were, indeed, very much called forth by Mr. Dallmeyer's reply to my criticisms.

Mr. Dallmeyer speaks of Mr. Grubb's diagram as containing a misleading error, and gives one himself which professes to be correctly disposed. He also professes to give a representation of Mr. Grubb's diagram. Between this representation and Mr. Grubb's orginal diagram, or the reproduction of it, illustrating Mr. Burton's article in the PHOTOGRAPHIC NEWS of the 1st of August last, there is a considerable difference. In Mr. Dallmeyer's representation there is the appearance of a long line of nearly equal illumination, which is very different from the effect seen in the original diagram, and even from Mr. Burton's reproduction of it. In both these, however, as well as in Mr. Dallmeyer's "correctly disposed" version, there is a suggestion to the eye of the observer who does not allow for the difference between linear and surface measurements, of a concentration of a greater part of the light along the centre than is actually available for building up the picture. In Mr. Grubb's case this suggestion was not material, as the diagram professed to illustrate the size of the circles of confusion. The question of concentration he disposed of by saying that any advantage in one direction was counterbalanced by loss in the other direction.

Mr. Dallmeyer's argument, however, is based upon this concentration, and the exaggeration of it is therefore material. Independent of the much greater concentration which exists in Mr. Dallmeyer's own and his version of Mr. Grubb's diagram than really existed in the latter, there is the fact that these diagrams only represent a section, and therefore only present a delineation of a line or band across the surface of the lens. Such a sectional drawing representing an equal amount of light passing through each linear unit of the diameter of the lens, presents to the eye an appearance of much larger proportion of light as passing through the centre of the lens and helping to build up the line of concentration, than is actually the case. The light, for instance, passing through the central inch of a 5-inch lens is represented as one-fifth of the total amount, whereas, in reality, it is but the one-twentyfifth. This is illustrated in the following diagram of spherical aberration, which does not represent the light passing



through a section of the lens, but represents the whole of the light passing through the lens gathered into one line, so as to show approximately the proportion transmitted by the centre and the outer circles for the formation of an image. The lines are spaced along the surface at points where each, as it recedes from the centre, would enclose an annulus of equal area.

This smallness of the proportion of light available to form the image along the axis of the lens is a phase of the case against spherical aberration that has not, I think, as yet been enforced. We are not dealing in portrait photography with a series of brilliant points, each against a black background, and each luminous enough to allow all but a small percentage of its light to be dispersed by the outer circles of the lens, whilst the residuum is sufficient to produce a definite image. In photographing a candle against a black background, for instance, if it be assumed that we might have ninety per cent. of the light passing through the lens spread as a halo round the flame, and still find a recognizable image in the centre, this argument would not apply to the lights indicating the hair, beard, &c., of a sitter in a properly exposed negative.

Mr. Dallmeyer, in his present paper, twice refers to me, as he has done before, as a photographer. That should scarcely be a term of reproach in the pages of the PHOTOGRAPHIC NEWS, and is quite beside the mark. If Mr. Grubb and I have been right in our contention—and I believe that no one but Mr. Dallmeyer denies this—it is of no consequence that the one was a distinguished optician, and the other a photographer interested in optical science, who, as long ago as the "sixties," constructed, for special purposes, photographic lenses, one of which was described in one of the journals of the time.

To come from theoretical to experimental tests, I some time since tried a "diffusion of focus" lens by photographing a test object, got up like Claudet's focimeter, but with such modifications as required by the case. These modifications were merely the use on each radiate arm of printed papers of four degress of fineness, and the arrangement of the arms, eighteen of them, at intervals of

an inch in advance of each other. Compared with the lens in corrected position—which was not, however, with the lens screwed quite home, when negative spherical aberration appeared, but unscrewed between two and three gradations—I could not find any increase in depth of focus, whatever amount of spherical aberration was introduced by separating the components. On my recently mentioning this trial at a meeting of the Photographic Society of Great Britian, Mr. Dallmeyer stated that the test was not a fair one.

It is difficult to see wherein the unfairness of such a test consists, or to find one more closely corresponding to the special case, that of large portrait heads, for which spherical aberration was particularly recommended. The test object was photographed at an ordinary distance for portraiture, and the various planes separated only by intervals of an inch each, round and near to the axial line of the lens, represent fairly enough, one might think, the various planes existing in a head photographed from nature.

A test, however, which Mr. Dallmeyer seems to consider fair enough for the purpose is published in the Conference number of *The Camera Club Journal*. An illustration by Mr. Dallmeyer here professes to represent images given respectively by an aplanatic lens, a lens with slight spherical aberration, and another lens with great spherical aberration, each at its best focus, and each at certain intervals from the focus in both directions. Plate 8 is marked "slight spherical aberration, best focus," whilst plate 9, representing the work of the same lens, is marked "inside focus $\frac{1}{10}$th inch." Similarly, plates 15 and 16 are marked respectively, "best focus," and "inside focus half inch." It is staggering to find that these marked as "inside focus" are actually in better focus than those marked as best focus, showing that the latter was not really the best focus, but that those which professed to be removed from the best focus by the distances mentioned were either themselves in the best focus, or were, at all events, more nearly so than those which professed to be taken at the focus. The fact, which will be evident to anyone who examines the plate, most strikingly in the case of 15 and 16, seems so astounding that I scarcely ventured to speak on my own observation till I asked the verdict of several well-known scientific photographers, whose judgment agreed decidedly with my own. Mr. Dallmeyer has overdone his proof; if the real best focus had been disposed about midway between that professing to be the best and the one at a certain distance, the thing might have passed undetected; but as it is, it serves as an illustration of how anything may be "proved" when it is desired to be so.

Wood Engraving in Eastern Schools.—The recent announcement of the Principal of the Cooper Union art schools to the pupils of the class in wood engraving, that hereafter there will be no instruction in that department, is most significant. The Hon. Abraham S. Hewitt, secretary of the Union, told a reporter of the *New York Sun* that he had made an investigation for the board of trustees, and had discovered that the wood engraving business had been destroyed by new processes, and was no longer able to afford a living to anyone not gifted with exceptional genius. It was the aim of the institution, he said, to adapt itself to commercial wants, and whenever any branch of instruction was discovered to furnish no longer a living to those who followed it, the study was to be abolished. For wood engraving, Mr. Hewitt said, instruction in pen and ink drawing would be substituted.

FAST AND FUGITIVE DYE STUFFS.*

BY PROFESSOR J. J. HUMMEL.

Colours may be classified with respect to their resistance to each particular influence, and may, as I have pointed out, occupy a very different rank in the different arrangements. The most important question to be considered is the influence of light on dyed colours, and to this alone I wish to confine your attention on the present occasion. It is well known that the sun's rays not only produce the sensation of light and heat, but also effect chemical action, either combination or decomposition. We know, further, that the most chemically active rays are those situated at the blue end of the spectrum, and it is doubtless these same rays which are the chief cause of the fading of dyed colours. Indeed, experiments have been made which prove this. Depierre and Clonet exposed a series of colours dyed on cotton to light which had passed through glasses stained red, orange, yellow, green, blue, and violet, corresponding to definite parts of the solar spectrum. They found that the blue light possessed the greatest fading power, red light the least. Abney and Russell exposed their water-colours under red, green, and blue glass, and also found that blue light faded the colours most, red light the least.

But the chemical activity of the sun's rays is not the only cause of the fading of colours. There are certain accessory or contributory causes of the greatest importance. Fifty years ago Chevreul carried out an elaborate series of experiments on the fading of the dyed colours of that day, and obtained some very interesting results which show what their accessory causes are, and I may add that his conclusions are confirmed by the recent experiments of Abney and Russell with respect to water-colours. Chevreul exposed samples of dyed silk, wool, and cotton to direct sunlight under varied conditions, *e.g.*, in a vacuum, in oxygen and hydrogen gas, in dry and moist air, and so on. Colours dyed with orchil, safflower, annatto, and indigo-extract were found not to fade during the course of two years if exposed to light in a vacuum, which is certainly a most striking and unexpected result, considering the acknowledged fugitive character of these colours. One or two colours, *e.g.*, Prussian blue and turmeric, faded even in a vacuum, but the general conclusion arrived at was that light, when acting alone—*i.e.*, without the aid of atmospheric agents—exercises a very feeble influence on most colours compared with what it does in conjunction with air and moisture. Further, it was determined that air and moisture have very little effect on colours without the aid of light. Abney and Russell, in their experiments with water-colours, obtained similar results. These conclusions, it appears to me, correspond exactly with our common knowledge of the old-fashioned method of bleaching cotton and linen, in which the wetted fabric is exposed to light on the grass, and frequently sprinkled with water. If the material becomes dry, through the absence of dew or rain, or the want of sprinkling, little or no bleaching takes place. They explain also, I think, the intense fading power of the Indian sun, namely, that it is due, not merely to the strong sunlight, but also to the fact that the air in India is so well charged with moisture. Another interesting result of Chevreul's work, and one not entirely unknown to practical men, is that colours are faster to light on some fibres than on others. For example: Indigo-extract blue is most stable on silk, least on cotton; vat-

* Continued from p. 712.

indigo blue is most stable on wool, least on silk; orchil purple is most stable on wool, least on cotton; safflower pink is most stable on cotton, least on wool. As to the reason of this different fastness, it has been suggested that it might be because the colouring matter is possibly in a different state of combination in the different fibres. The subject has, however, not been pursued, and I think we must confess that we are totally ignorant of the precise cause, but it is certainly important to remember this fact, that the fastness of a colour applied to one fibre is no index that it is equally fast when applied to another, and this may account, to some extent at least, for the discrepancies in the statements relative to the fastness to light of certain colours occasionally mentioned in the chemical journals. Perhaps one of the most striking effects of the action of light upon colours obtained by Chevreul was that in Prussian blue. Exposed to light, even in a vacuum, this colour fades; but, strange to say, on keeping the faded colour in the dark, but exposed to air, the blue colour is restored. Chevreul was able to show that during the exposure to light prussic acid was given off, and the colour was reduced to a colourless condition, while in the dark atmospheric oxygen was absorbed, with the formation of ferric oxide and the restoration of the blue. If the fading and restoring processes were repeated a great number of times, the colour would be at length destroyed entirely, leaving only ferric oxide on the fibre. Now, although the fading of Prussian blue in a vacuum is due to reduction, we know that with most other colours air and moisture play a most important part in the fading process, and it is very probable that in most cases the fading of colours is due to oxidation. During the evaporation of water in nature there seems to be formed ozone or hydrogen peroxide in small quantity, and both are powerful oxidising as well as bleaching agents. Now that we have such a large number of pure coal-tar colouring matters of known constitution, the rationale of the fading process offers an interesting field of research for the chemist. Turning now to another aspect of the question, we have, as you know, a large class of colouring matters which require the aid of mordants to develop and fix the colour upon the fibre, and it is well to know what influence the different mordants have upon the fastness of colours. In the dyeing department of the Yorkshire College it has been our custom to expose to light the coloured patterns dyed by the students, and I propose briefly to give you a few of the more prominent results obtained with respect to the influence of mordants. Some colouring matters are found to give fast colours with all mordants, *e.g.*, alizarin, madder, cochineal; others, *e.g.*, peachwood and young fustic, give always fugitive colours whatever mordant be employed; while others, again, *e.g.*, logwood, give fairly fast colours with some mordants, and fugitive colours with others. As a general rule, we find in the last-mentioned cases the tin and aluminium colours are fugitive, while those of copper, chromium, and iron are fast to light.

Knowing these facts, let us not fall into the error of supposing that it may be possible to discover a mordant capable of rendering all colours alike fast to light. Each colour of the class now referred to, in which a single colouring matter is combined with different mordants, represents really a distinct pigment or dye, each differing from the other in chemical and physical properties. All that we can do is to apply each colouring matter with all suitable mordants, and select that particular combination which gives the desired colour and fastness. By this method our selection would ultimately comprise a number of colouring matters paired with a variety of mordants. When dyeing compound shades, however, it is well to avoid the intricacy involved in the use of several mordants, if possible, and, although necessarily retaining the use of several colouring matters, to limit ourselves to a single mordant as far as possible, mainly in order to simplify the process of dyeing. In wool-dyeing, for example, since we have such an excellent mordant in bichromate of potash, it would be very desirable to have a good range of red, yellow, blue, and other colouring matters, all giving fast colours with this mordant. The problem, then, of producing fast colours is rather one for the colour manufacturer than for the textile colourist, and, indeed, in the so-called alizarin colours, we have already received at his hands a goodly range of fast-colouring matters, which makes it almost impossible for the dyer to dispense, if need be, with nearly every one of the dye-woods. In many cases questions of price render this entire abolition of old for new colouring matters impossible during this age of competition, neither would it be in all cases desirable. The textile colourist, however, can also do excellent service in the cause of fast colours by thoroughly examining the capabilities of all the colouring matters and mordants now at his command, and particularly by exercising a wise discretion in their combination and their use.

Unfortunately, here again trade competition steps in and mars the excellent results which might otherwise be obtained, and the general public suffers because this bane of modern commerce has too often compelled the dyer to employ colouring matters more or less unfitted for the material and its ultimate use. Some colours, we find, exhibit unusual qualities, *e.g.*, camwood brown, obtained by means of tin and alum mordants, becomes darker on exposure to light during the first month or two, and then begins to fade. Picric acid yellow presents similar features, the pure canary yellow of the fresh colour becoming rapidly orange, and this only fading after several months. The olive-green of Persian berries and copper mordant is remarkable by its becoming darker even after twelve months' exposure to light. It is interesting to inquire as to the action of light on compound colours. Is a fugitive colour rendered faster by being applied along with a fast colour? I am not aware that this subject has been carefully examined, but the result of general observation is, that when light acts upon a compound colour the unstable colour fades, and the stable colour remains behind. A woaded colour, for example, is only fast in respect of the vat-indigo which it contains. Indigo-extract and other fugitive colours are not rendered fast by woading. If there are exceptions to this rule, it seems to me to be only possible, when the fast and fugitive colouring matters simultaneously or successively applied, re-act chemically upon each other, in which case the resultant colour would really be due to a new colouring matter. Coming now to discuss the coal-tar colours, many of you are aware that, according to their chemical constitution, *i.e*, the arrangement of the various atoms composing them, chemists have arranged their colours in various groups, *e.g.*, the nitro-colours, the azo colours, and so on.

(To be concluded.)

THE *Review of Reviews* of Sept. 18th promises the preparation of a "catalogue of all the standard photographs at present on sale in the British Empire and the American Republic," the compilation of which it well characterises as an "immense labour."

ON THE REVERSAL OF THE NEGATIVE PHOTOGRAPHIC IMAGE BY THIO-CARBAMIDES.*

BY COLONEL J. WATERHOUSE, B.S.C., ASSISTANT SURVEYOR-GENERAL OF INDIA.

In the early part of last month, while carrying out some experiments to find a preservative for eikonogen, I discovered that phenyl-thio-carbamide (phenyl-sulpho-urea) added in a very minute quantity to the ordinary eikonogen developer, possessed the remarkable property of more or less completely transforming the negative photographic image into a positive, and that thus I was able to produce at will more or less perfect positive pictures in place of negative ones, under otherwise quite normal conditions of exposure in the camera and of development.

Later experiments have shown that allyl-thio-carbamide, or thio-sinamine, possesses the same property, perhaps in a stronger degree, and reverses the images developed with pyrogallol and hydroquinone, as also those developed with eikonogen. Thio-carbamide, or sulpho-urea, also produces reversal with the eikonogen developer, but not so markedly as the two alcoholic thio-carbamides. Carbamide, or urea, appears to cause no reversal with the eikonogen developer; and this observation, if confirmed by further investigation with other developers, would tend to show that sulphur has an active part in bringing about the reversal.

I have also found that the phenyl and allyl-thiocarbamides, when applied to precipitated bromide or chloride of silver, or to gelatine dry-plate films containing them, have no visible action upon them; but, if an alkali be added, a powerful darkening and reducing action is set up, even in the dark and entirely without the action of light. With the iodide this action is not so strong.

Thio-carbamide with alkali gives off ammonia and darkens and reduces the silver haloids; and a strong solution of it is capable of darkening a gelatine plate in the dark even without alkali.

Urea, even with alkali, does not visibly darken a gelatine dry-plate film, nor darken or reduce the silver haloids in the absence of light.

So far as I can ascertain, these peculiar actions of the thio-carbamides, in reversing the photographic image and in darkening and reducing the silver haloids in the absence of light, have not before been noticed.

The thio-carbamides of the alcoholic series are formed by the action of ammonia on the so-called "mustard oils," or thio-carbamides. *Phenyl-thio-carbamide*, formed from phenylic mustard oil, has, according to Watts, the formula $CS\begin{matrix}\diagup NH.\ C_6H_5\\ \diagdown NH_2\end{matrix}$.

It is a crystalline substance, very slightly soluble in cold, more easily in boiling, water and in alcohol. Watts further remarks that, when boiled with nitrate of silver, it exchanges its sulphur for oxygen, and is converted into phenyl-carbamide.

Applied by itself in solution to an ordinary gelatine dry plate containing bromide or bromo-iodide of silver, it has no visible reducing action, and, indeed, appears to act as a restrainer of development; but mixed with an alkali, such as sodium or potassium carbonate, it very powerfully darkens the film, even without the action of light. When fixed, the darkened part of the plate is of a deep yellowish olive colour, and is harder and less absorbent of water than the unaltered part of the film. The darkening action is the same on a gelatino-chloride of silver film, though I have not succeeded in obtaining the reversal of the image on chloride films developed with eikonogen, as noted below.

The alkaline solution of this thio-carbamide also darkens and reduces pure bromide of silver in the dark; and, if the darkened precipitate be treated with nitric acid, it clears in colour, and by the addition of muriatic acid to the clear fluid, chloride of silver will be precipitated. Eikonogen developer added to the darkened precipitate blackens it, and if, after washing the latter, nitric acid be added, only a very little unaltered bromide is left, together with a flocculent, brown, insoluble deposit.

Weak solutions of phenyl-thio-carbamide act more effectively in reversing the image than strong ones, and with the eikonogen developer the best proportion seems to be about 20 to 25 parts of the watery saturated solution in 100 parts of the mixed developer; and as a saturated solution in water, even at the comparatively high temperature we now have in Calcutta, seems to hold an almost inappreciable quantity of the salt, the proportion actually contained in the developer must be exceedingly small.

The eikonogen developer I have usually employed is that recommended by Dr. Nicol, which was given in the June number of the *Journal*, and contains sulphite of soda.* I have not found that the presence of this salt interferes, as might have been expected, with the reversal, and am inclined to think that its presence in moderate quantity is beneficial, though good reversals may be obtained with plain eikonogen and carbonate of soda.

The addition of a small quantity of potassium bromide (from ·5 to 1 part of a 10 per cent. solution to about 100 of developer) seems to aid in the reversal of the lights. In some cases a trace of ammonia also seems to be beneficial in aiding the complete reversal.

So far I have not found phenyl-thio-carbamide to have the same action of reversing the image when used with the ferrous oxalate, pyrogallol, or hydroquinone developers, as it has with eikonogen. With ferrous oxalate I have obtained traces of reversal. Applied in different strengths to an exposed dry bromide plate and developed with pyrogallol (Britannia formula), it acted as a powerful restrainer. It did so also with ordinary pyro-ammonia and bromide, and stained the plates a deep yellow. With the hydroquinone developer its action was quite different, and it appeared to be a powerful accelerator, reduction taking place over the touched parts, which, in fact, were fogged all over before the normal image was developed. No signs of reversal were obtained with this developer, but it is probable that with further investigation it will be found to reverse, as it does with thio-sinamine.

It may be here noted that different makes of plates show different capabilities of reversal, and, so far as my experiments have gone, Wratten's "Ordinary" and "Instantaneous" plates have given the best results; but, possibly, variations in the quantity of thio-carbamide and of bromide will have to be made for different makes of plates.

Apropos of this, I may remark that, now that dry plates are so invaluable, and so largely used for scientific researches of all kinds, it would be a great convenience, at any rate to distant workers, if dry-plate makers could

* From the *Journal of the Photographic Society of India*.

* A.—Eikonogen, 5; Sodum sulphite, 10; Water, 100. B.—Sodium carbonate (cryst.) 8; Water, 100. One part each of A and B to two parts of water.

indicate on their dry plate packages the nature and proportions of the haloid salts used in the emulsion.

Thio-sinamine, or *Allyl-thio-carbamide*, according to Watts, has the formula $CS<^{NH.\ C_3H_5}_{NH_2}$, and is prepared by treating allyl-thio-carbamide, or the essential oil of black mustard, with ammonia. It is more soluble in cold water than the phenyl-thio-carbamide, and is also soluble in alcohol. In some of my experiments I have used an almost saturated solution of the thio-carbamide formed by adding four parts of the strongest liquid ammonia to one part of the ordinary essential oil of mustard obtained from the druggist. As soon as the ammonia has taken up as much of the oil as it will, the solution may be decanted off, and the ammonia allowed to evaporate. Of the solution thus prepared about one part in 100 of the mixed eikonogen developer as above is sufficient to produce reversal on development; a little bromide may be added, and a slight trace of ammonia seems beneficial.

This solution has rather an unpleasantly strong smell of old cheese and garlic, and it is advisable to evaporate it, and obtain thio-sinamine in a crystalline and odourless form, in which it may also be purchased in Europe. Of the saturated solution of the crystals, from half to one part in 100 parts of the developer is enough.

The reversing action of the thio-sinamine seems to be stronger than with the phenyl-thio-carbamide, and it gives clearer whites. The colour of the images produced with it with eikonogen alone, without bromide or ammonia, is a beautiful rich chocolate brown verging to purple. It has given a very fair reversal with pyrogallol developer containing sulphite, though it did not do so with a pyro-ammonia developer prepared according to the "Britannia" formula with nitric acid, and a considerable quantity of bromide. With Thomas's hydroquinone developer it also did not reverse the image; but with a developer prepared with—

Hydroquinone	1 part
Sodium sulphite	2 parts
Carbonate of soda (cryst.)	10 ,,
Water	70 ,,

I obtained very clear reversals in copying, though I was not so successful in a landscape with considerable contrast between the sky and foreground. With eikonogen, also, the thio-sinamine seems to work best with sulphite.

Applied to pure precipitated bromide of silver in the dark, thio-sinamine does not darken it, but seems to enter into combination with it, forming a soft, pasty mass, and, if in sufficient quantity, dissolves it. Carbonate of soda solution darkens the soft mass at once, and the solution treated with dilute muriatic acid gives off a smell of sulphuretted hydrogen; nitric acid partly and slowly restores the colour. With muriatic acid the nitric acid solution gives chloride of silver. A very peculiar smell was evolved by the mixed acids. Eikonogen developer added to the darkened precipitate after treatment with soda turned it quite black. Nitric acid caused effervescence, and made the precipitate lighter in colour. It appeared to be a mixture of yellow bromide and a black substance with a little flocculent deposit. Muriatic acid added to the nitric acid solution gave a copious precipitate of silver chloride.

The alkaline solution applied to chloride of silver also darkens it very strongly. Nitric acid does not clear the precipitate much, but the solution gave a copious precipitate of chloride with muriatic acid. The action generally is much the same as with the bromide.

With silver iodide, thio-sinamine also forms a soft, waxy mass, and dissolves it. Carbonate of soda only very slightly discolours the mass, with the dirty yellow appearance of a sulphur compound of silver. Nitric acid set up a strong effervescence and nitrous fumes, and restored the iodide to its original colour. The acid solution gave no precipitate with muriatic acid, but the same peculiar smell as above.

These compounds of thio-sinamine with the haloid salts of silver seem very curious, and might be worth investigation by a more experienced chemist.

Thio-carbamide, or *Sulph-urea*, $CS<^{NH_2}_{NH_2}$, which may be prepared by heating well-dried sulpho-cyanate of ammonium in a flask in an oil bath for two hours at a temperature of 170° C. (338° F.), forms long silky needles which are very soluble in water. Its reactions with the silver haloids are peculiar, and somewhat resemble those of thio-sinamine.

With silver bromide it sets into a pasty mass, and does not discolour it. Carbonate of soda added liberates ammonia, darkens the bromide, and, from the smell, some sulphide of ammonium seems to be formed. Muriatic acid precipitates chloride with the nitric acid solution. Eikonogen developer blackens the bromide darkened with soda. The black precipitate is only partially soluble in nitric acid, and the clear solution gives chloride with muriatic acid.

With silver chloride it also forms a pasty mass, and there is the same evolution of ammonia and darkening with soda; a metallic deposit of a yellow colour is sometimes deposited on the glass vessel. Weak nitric acid has little action, but strong acid causes brisk effervescence and evolution of nitrous fumes, but does not readily dissolve the precipitate on the glass, nor entirely restore the white colour of the chloride. Muriatic acid added to the nitric acid solution precipitates chloride. Eikonogen developer blackens the darkened deposit at once. Nitric acid causes great effervescence with nitrous fumes, partially restores white chloride; the solution precipitates chloride with muriatic acid.

With silver iodide, thio-carbamide also sets in a pasty mass, which does not darken alone. Carbonate of soda gives off ammonia, but does not darken the iodide so strongly as the bromide and chloride, nor is any mirror formed on the glass. Nitric acid removes the darkened coat, but muriatic acid produces very little chloride with the acid solution.

(*To be continued.*)

THE *Daily Telegraph* publishes the following note with regard to modern street Photograph-Spoilers:—" 'Sky-signs,' as the huge hanging-letter advertisements on the house-tops are called, came before the Paddington Vestry in reference to a structure of this kind on the roof of an hotel in Elgin Avenue, which it was proposed to declare dangerous. Eventually the Vestry contented itself by denouncing the device as 'most objectionable.' The discussion showed that 'would curses kill as doth the mandrake's groan,' these eyesores would not have long life before them. Failing this remedy, it was resolved to petition the London County Council to frame bye-laws to control the raising of such structures. It has been seriously proposed to levy such a tax upon them as would sensibly swell the local revenues."

THE BRITISH ASSOCIATION COMMITTEE ON GEOLOGICAL PHOTOGRAPHS.*

First List of Geological Photographs (to July, 1890).

Note.—This list contains the subjects of all geological photographs known to have been issued. Copies of those *only* to which the *registered No.* is attached have been received by the Secretary of the Committee.

Copies of any photographs desired can, in most cases, be obtained either from the photographer direct—whose address is usually given—or from the officers of the local society under whose auspices the views were taken.

The Committee in no case has assumed the copyright of photographs registered, which is presumed to be held by the photographer.

The price at which the photographs may be obtained depends upon the size of print and local circumstances, over which the Committee has no control.

Cheshire.—Liverpool Geological Society, per W. Hewitt, secretary (photographed by E. Newall, 14, Elm Grove, Tranmere), size 8¼ by 6½ inches:—Registered No., 1, 3, 4, 5, Storeton Quarry, 1887—Various sections; 2, ditto, 1887—"Footprint bed"; 6, Wallasey, 1887—Quarry in Lower Keuper; 7, 8, ditto, Breck Road—Section showing "current bedding"; 9, Prenton Lane, Birkenhead, 1887—Junction of Keuper and Bunter; 10, Bidston Hill, 1887—Fissile Keuper sandstone; 11, Hilbre Island (mouth of River Dee)—Bunter; 12, 13, ditto (Middle Island)—Conglomerate bed; 14, Thurstaston Hill, 1887—"Thor's Stone," an outlier of the Bunter: 15, West Kirby, 1887—Fault at Calday Grange; 16, ditto—Junction of Keuper and Bunter; Flaybrick Hill, 1887—Ditto; ditto, 1885—Fault in Keuper; ditto—*Roche Moutonnée*; Poulton Quarry, Wirral, 1885 (2)—Jointing in Keuper. Per J. Lomas, 23, Avondale Road, Liverpool:—Dawpool, Wirral, 1888 (4)—Boulder clay cliffs on bank of River Dee showing interbedded sands, &c.; Hilbre Island (2)—Coast erosion; Wallasey (2)—Sand dunes, showing stratification; ditto, Breck Road—"Contortions" in Trias; Ince—Peat beds; ditto (Ship Canal sections)—Fault in Trias. Photographed by E. Timmins, Runcorn:—32, Runcorn (lane to Higher Runcorn)—Frodsham beds of Keuper.

Cornwall.—Photographed by Percy F. Kendall, 31, Parkfield Street, Manchester:—Land's End—Columnar jointing; St. Erth—Pliocene clays; ditto—Contorted strata; ditto—Pliocene sand resting on elvan. Per Rev. H. H. Winwood, 11, Cavendish Crescent, Bath:—Registered No., 36, Mitford Tunnel—Mitford sands; 37, Tucking Mill—William Smith's House; 38, ditto—Tablet to the memory of William Smith ("Father of English Geology").

Devonshire.—Photographed by J. J. Cole, Maryland, Sutton, Surrey:—Registered No., 57, Lulworth (Stare Cove)—Showing contorted strata. Per W. Pengelly, Lamorna, Torquay (photographed by William Widger, 44, Union Street, Torquay):—58, Torquay—Entrance to Kent's Cavern; 59, ditto—Entrance to Brixham Cave.

Isle of Man.—Photographed by Ed. Newall, Liverpool Geological Society:—Registered No., 31, Scarlett Point; 30, Port St. Mary—Glaciated limestone surface; and some others not designated. Per Yorkshire Naturalists' Union, Geol. Photo. Section (photographed by S. A. Warburton, 9, Banstead Terrace, Leeds, size 8 by 5 inches):—75, Douglas Head, 1885—Contorted slate. Photographed by J. E. Bedford, 9, Cardigan Road, Leeds, size 8 by 5 inches:—76, Scarlett Stack, 1888—Basaltic boss; 77, ditto—ditto, with dyke; 78, Scarlett Point, 1888—Upheaved limestone; 79, ditto—Weathered volcanic ash.

Kent.—Per Arthur S. Reid, Trinity College, Glenalmond, N.B.—Eltham Valley, 1889 (3)—Sections in Thanet chalk (railway cuttings); Canterbury (1, 2)—Pipe in chalk; ditto (3)—Thanet chalk; ditto (4)—ditto (incipient pipe).

Lancashire.—Photographed by E. Newall (Liverpool Geological Society):—Registered No., 17, 18, Woolton, Liverpool—Two views of the 'Calderstones' (stone circle). Photographed by E. Ward, 219, Oxford Street, Manchester—Series of views of the 'Oxford Road Boulder,' now in the Quadrangle of Owens College, Manchester; ditto Manchester Ship Canal. Photographed by Godfrey Bingley (Leeds Geological Association) for the Yorkshire Naturalists' Union (Geol. Photo. Section). Size 4 by 2¾ inches:—91, 92, Lindale, near Grange, 1889—Old sea cliffs in carboniferous limestone (2); 93, 97, Hampsfell, ditto, (5)—Escarpment in limestone showing weathering; 98, 105, ditto, (8)—Weathered carboniferous limestone; 106, 108, ditto (3)—Limestone boulders lying on carboniferous limestone; 109, 117, ditto (9)—Erratic boulders (various) lying on carboniferous limestone.

Leicestershire.—Leicester Literary and Philosophical Society—per James Plant, West Terrace, Leicester (photographed by John Burton and Sons, Leicester), size 12 by 10 inches:—29, Croft Hill, July, 1881—Syenite, Trias, and Boulder clay; ditto, May, 1882—ditto; Barrow-on-Soar, June, 1881—Arches in Lias limestone; Mount Sorrel, July, 1875—Hornblendic granite; ditto, Sept. 1877—ditto; Humberstone, May, 1881—The 'Holystone' erratic; Broombriggs, Charnwood Forest, July, 1875—Charnwood slate; Benscliff, Charnwood Forest, July, 1875—ditto; 'Hanging Stone,' Charnwood Forest, August, 1881; Woodhouse Eaves, Charnwood Forest, June, 1881; Saffron Lane, Leicester, June, 1882—Boulder clay; Breakneck Hill, Charnwood Forest, June, 1881—Keuper, lying upon Charnwood slate; Ring Pit Quarry, Charnwood Forest, June, 1881—Concentric rings in slate; Swithland, Charnwood Forest, June, 1881—Slate; Stoney Stanton, June, 1881—Southerly extension of Charnwood rocks; 28, Aylestone, 1881—Erratic block of Mount Sorrel granite.

Montgomeryshire.—Caradoc Field Club (photographed by W. W. Watts, Sidney College, Cambridge):—Registered No., 88, Corndon Hill, (S.E.), 1885, (12A)—Dolerite, resting on shales: 89, ditto—Base of Corndon laccolite; 90, ditto, (W. side)—Middle Arenig shales resting comformably on Dolerite.

Nottingham.—Photographed by John Burton and Sons, Leicester:—Nottingham, June, 1882—Church Cemetery, caverns in Pebble Beds; ditto, (2)—Castle Hill, Bunter; Himlack (or Hemlock Stone)—Showing denudation. Per James Shipman, Manning Grove, Nottingham:—Nottingham Castle—Pebble beds; Kimberley—Permian, resting on tilted Coal measures; Hemlock Stone, Nottingham; Nottingham—Faulted Keuper; Blidworth—Outliers of Keuper (supposed "Druidical" remains); Beeston—Interglacial sand and river gravel.

North Wales.—Chester Society of Natural Science, per George Frater, The Bank, Wrexham (photographed by Alfred O. Walker, Nant-y-Glyn, Colwyn Bay), size 6 by 4 inches:—Registered No. 42, Cefn Bueno Caves, Vale of Clwyd; 43, 45, 46, 47, Cefn-y-bedd, Wrexham; 44, Holywell, Bagillt—Lower Coal measures; 48, Colwyn Bay, Pen-y-Bont Farm, 1889—Drift with alternate beds of clay and sand. Leeds Geological Association, per J. E. Bedford, photographed by Godfrey Bingley, 15, Cardigan Road, Leeds, for the Yorkshire Naturalists' Union (Geol. Photo. Section), size various:—118, Llandudno, Great Orme's Head—Erratic boulder; 119, 121, ditto—Weathered blocks of Carboniferous limestone; 122, ditto—Escarpment of Carboniferous limestone; 123, ditto—Section in limestone quarry; 124, 128, ditto—Cliffs showing stratification; 129, 131, ditto—Fissure in limestone; 132, 137, ditto—Views of cliff sections.

* Continued from page 707.

Bath Photographic Society.—On Monday last the President and several members drove to Claverton for the purpose of photographing in and around the Church and Manor House. Widcombe Old Church was the next scene visited, and here again numerous pictures were secured. At six o'clock the party met at the President's residence, where Mr. and Mrs. Pumphrey entertained the visitors during the remainder of the evening.

Notes.

Photography might rightly be described as the advertiser's friend, so much is it made use of to render trade announcements attractive. One of the most effective methods is that recently adopted by an eminent manufacturer of sewing machines, who publishes an enormous sheet of collotype pictures, taken in different countries, and exhibiting the said machines in use by the inhabitants of far distant regions. Thus we have ——'s machine in India, ——'s machine in Japan, and so on. It is a pity that this bold advertiser cannot make capital out of the present furore which exists for everything pertaining to Darkest Africa, but, unfortunately for him, sewing machines are not used there at present. A picture of one tended by natives dressed in nothing sewable would be supremely ridiculous.

Mr. Spiller's opinion that primuline is likely to prove a formidable rival of the ferro-prussiate process, reminds us that this latter method of printing is not half as common as it ought to be. For the reproduction of engineers' and other plans it is, of course, largely used; but its convenience as a means for securing a rough proof from an ordinary negative does not seem to be fully recognised—at least, we judge so from the difficulty we lately experienced in procuring some from several dealers to whom we applied. The reply was in each case, "We do not stock it," varied by, "We have no demand for it." We feel convinced that, if tourists who venture to develop their plates *en route*, but who never dream of printing until they get home, were fully aware of the convenience of this method, which requires only plain water for development and fixing, this paper would be used a great deal more than it is at present.

There is a particular use for ferro-prussiate paper which we have not yet seen proposed, but which seems to us to suggest itself as one well worth the attention of those who make line drawings for reproduction in block form by photography. An artist who has devoted himself to this class of work would have no difficulty in tracing over the lines of a blue print in black ink, and in expressing the shadows by line-work, or "tints" of different depths. (Probably the paper would require sizing before this could be done satisfactorily, but of this point we have no certain knowledge.) When this drawing was re-photographed so as to obtain a negative, the black lines only would be reproduced, the blue colour being ignored by the sensitive surface. This seems to us to be a far more practical way of obtaining a line copy of a photograph than another which has often been proposed—namely, to trace the lines on an ordinary albumen print, and to render the photograph invisible afterwards by bleaching out with mercury. The ink lines would most surely run during this last operation.

So much ingenuity has been exerted in contriving methods by which plates at the back of a camera can be rapidly changed, that it would seem to be almost an impossibility to devise anything fresh. But we were recently shown a method which appears to us to be not only perfectly novel, but one which fulfils its purpose in a very admirable manner. The plates are held in sheaths, and are stored, faced upwards, in a receptacle above the camera. By the touch of a lever each plate is turned, flaps down, and assumes the vertical position at focussing distance. The sheath in which each plate is held is of special construction, and has a projection at each of the two upper corners, by which it is held during the movement. This clever contrivance is attached to the "Quadraut" detective camera manufactured by Messrs. Humphries, of Islington.

There are more uses for the photographic studio than merely taking photographs. When business is slack, plenty of opportunity presents itself for the photographer to exercise his active brain, and most photographers have active brains. The most successful grower of vegetables under glass is Mr. Bashford, who has establishments in Jersey and Guernsey. Mr. Bashford, a few years ago, was a photographer. In some way he conceived the idea of experimenting on raising vegetables under glass, and built his first greenhouse in 1874. His idea succeeded, and he has since then become a millionaire, and the principal grower for the London market. His houses are of colossal size. The latest addition to his establishment consists of a group of six, each a thousand feet long and thirty feet wide. Some are devoted to grapes, while in others tomatoes are forced, and in a third set potatoes are grown, a crop being obtained at Christmas, and another in April.

The *Moniteur de la Photographie* is politely ironical on the removal of the police restrictions which up to very recently prevented one photographing in the public streets. We in England possibly wonder why such a regulation should ever have been deemed necessary even by the police; but it seems that hitherto, in Paris, a photographic apparatus has been regarded as an obstruction. The *Moniteur* points out that the permission to photograph in the streets has only been given since the hand apparatus has been in almost universal use, and quietly insinuates that if the absurd rule had still been in force, any policeman attempting to carry it out would have found himself reproduced before he could even have thought of speaking about a charge which he could not establish.

Apropos, the constable who has charge of the newly opened Dulwich Park holds views very much in accord with his brethren across the Channel. The other day a well-known local amateur thought he would like to take some views of this, one of the latest lungs of London; but, being a law-abiding citizen, he first of all consulted the official in question. "No," said the latter; "you can't set up your machine here." "Well, but I don't want to set up any machine," said the amateur, showing a hand-camera; "this is my apparatus." The official

stared at the box, thought it looked harmless, and finally graciously accorded his permission. It is said that the amateur, while holding parley with the constable, slily took his photograph, which was afterwards published in a local paper; but this story we cannot verify.

What we should like to know is, has the constable in question any definite orders from the County Council on the subject of photography, and, if so, what are they? Seeing that cyclists are allowed in the public parks, it would seem very absurd if any restrictions were placed upon photographers. We can understand the itinerant variety having to submit to regulations; but surely rules are not necessary for the amateur. Possibly, to a constable, a photographer is a photographer, and nothing more; he knows not distinctions between amateurs and professionals.

It is an undoubted fact that there are few things about which people are so sensitive as their photographs. The amateur photographer may unwittingly get into great trouble through forgetfulness of this susceptibility. We know a case where a lady was properly offended because, by some mishap, a friend happened to see a proof of a photograph which had been taken by an amateur before she did. The reason is not far to seek. Most people have rather a dread of the amateur portrait photographer. They do not know how they may "come out," and if you are to be caricatured you like to see the caricature yourself before anybody else has the chance. There is one very excellent reason for this. You may like to destroy both the proof and the negative. Perhaps if the amateur bears this in mind he will not go far wrong. Therefore always let him show a proof of a portrait to the person concerned before anybody else sets eyes upon it.

A writer in the *Globe* draws a dreadful picture of the lady photographer. According to this authority, she is most exacting and unreasonable, even to the extent of pining for a sun which she can drag about the heavens with a cord and pulley so as to take the pictures she requires at all hours of the day. As for scenery, there is nothing which satisfies her. Her friends exert themselves to find choice "bits" of country, but to no purpose. Caverns are too dark, woodland bits are too scattered to fit on a plate, the church has a spire, and would require an upright plate, whereas the fair photographer has only narrow oblong plates. The lady photographer is also perpetually losing screws or other little impedimenta belonging to her apparatus, and always discovering that she has the wrong lens for some particular picture—a wide-angle when it should be a long-focus, and *vice versa*. Altogether, the article is in so caustic a strain, that we fancy it must have been written by a lady—a supposition which is all the more justified because the article is headed "Fashions and Fancies."

Mr. Frederick Harrison, it is very clear, has not followed the progress of photography in recent years, or we should not have him, in going through the details of his proposed treasure chamber for posterity, saying: "If experts could suggest a mode of protecting photographs from decay, or of transferring a photographic picture to some indestructible substance, it is clear that we might preserve for the twenty-ninth century photographic portraits of our great men, views of our public buildings, of our daily life, of many an historic incident." Mr. Harrison does not know that all this is practicable. Vitrified photographs would, we fancy, stand the test of time better even than the inscriptions on Cleopatra's Needle.

The paragraph that went the round of the press the other day, to the effect that a schoolboy had taken a photograph of his master while in the act of bestowing chastisement on a schoolboy, has obviously suggested the amusing sketch in the *St. James's Gazette*, entitled "Wilkins Caves in." The story is, shortly, this:—A boy breaks his leg, and to console him during his retirement, Mamma makes him a present of a Demon detective camera. Directly he gets the apparatus he conceives the idea of photographing Wilkins, the headmaster, towards whom he owes a grudge. When he recovers he starts upon the work. The first photograph is that of Wilkins sitting in his box, "because up there in his gown, he looks rather like a crow." The second one was secured when he was caning a schoolboy, "because he twists his face when caning." Wilkins was photographed a third time, "when he was looking out of the window, and the sash came down on his neck." These photographs were distributed among the boys, and gazed at with great pleasure. Unhappily, one of the under-masters discovered one of them, and the whole thing came out. Great was the wrath of Wilkins, and the young photographer had to account for all the photographs distributed. All were unearthed and destroyed save one, and this was eventually traced to the under-master who had made the discovery. Despite the indignation of the assistant, he too was secretly delighted at the photograph, and the boys are dying to know what the interview between him and Wilkins was like, and whether Wilkins administered the punishment which they themselves had received. Decidedly it is a risky thing to photograph your school-master.

A writer in the *Sunday Times* who has been surveying the world from China to Peru, as to the outlets for the energy of women in regard to remunerative employment, puts photography in the list. He is, however, rather guarded in his statement, observing that though there are one or two ladies in the provinces who are professionally successful, in London the sex has not yet come into anything approaching appreciable rivalry with men. To establish oneself successfully as a photographer now-a-days demands a large amount of energy, patience, and, above all, capital. The money necessary to equip a photographic establishment a lady could utilise much better elsewhere.

THE DAGUERRE CONVENTION IN AMERICA.

THE eleventh annual Convention of the Photograghers' Association of America is now a thing of the past, and everyone connected with it may be congratulated on the grand success of the whole affair.

The event that took the Association to the City of Washington was undoubtedly the unveiling of the monument to Daguerre, and we are glad to say that this beautiful tribute to the memory of the father of photography is now safely placed in charge of the United States Government, an accomplished fact.

There is no doubt that many members of the Association were afraid to venture to Washington on account of the great heat of the city at this time of year. But those who took the chances were delightfully surprised, and enjoyed some of the most agreeable weather ever experienced at any convention. Instead of the torrid heat usually found in the capital city at this time of year, the temperature was quite moderate, and except in the middle of the day was usually pleasant. Washington, with its beautiful parks and avenues of trees, had on a wonderfully refreshing dress of verdure seldom seen at this time of year; and all who were present at the Convention will remember its delights for many years to come.

The success of the meeting was due to these happy circumstances and the judicious management of the executive officers. Through the kindness of the United States officials, the sessions were held in the National Museum, which was kindly given up to the Association free of charge. We owe this to our good friend, Professor Smillie, the photographer of the department, and also to those associated with him. The Association cannot too heartily thank this gentleman for his untiring efforts for their comfort and the success of the whole Convention. The place of meeting was singularly appropriate, in spite of the crowded condition of the manufacturers' and art departments.

There is no doubt that many more photographers would have been present if it could have been foretold that we should have such delightful weather; and in spite of all the doubts in this direction nearly four hundred members were in attendance. Another element of success was the very able management of the executive officers in providing such an excellent programme, and in carrying it out. There has never been a Convention of the Association where everything worked so smoothly, and so much valuable instruction has been given to the members, as has been accomplished at Washington. There was an unusually large number of papers presented, and the discussions were entered into by the members in the most hearty and satisfactory manner.

The most important event was the unveiling of the Daguerre monument, and all members were very anxious to know how the committee who had it in charge had accomplished its task. It is only twelve months ago that the Association decided to erect this monument, and much cold water was thrown upon the project, owing to some severe criticism of the early design made public by the committeee. As a consequence, subscriptions came in very slowly, and on arriving at Washington the committee could only report the receipt of twelve hundred dollars. Since the monument was to cost six thousand dollars, there was much anxiety as to the action of the Convention. But thanks to the rallying speeches of Mr. Frank Pickerell and others, the good name of the Association was not allowed to be draggled in the mire. The Association was reminded that the honour of raising the monument was theirs, that their officers had obeyed orders, and had accomplished their task to the best of their judgment. It was undoubtedly the duty of every member to sustain the officers, and we are glad to have to record the fact that it has been done nobly. Never in the history of the Association has there been such a hearty support of the officers in their efforts to carry out the wishes of the members. When Mr. McMichael had made his report in a calm and business-like manner, stating simply what had been done, and appealed to the Association for judgment, there was a ripple of dissent for a moment, but the veteran voice of Mr. Pickerell called the members to their duty, and every one felt it was a time for action. Mr. Cramer, of St. Louis, pledged five hundred dollars, and then Mr. McMichael announced that Messrs. E. and H. T. Anthony and Co. would do likewise. This was a good start, and in less than one hour after the report the members had swelled the amount to two thousand dollars. After this subscriptions came in continuously, making it evident that the monument would be paid for by the photographers of America, and that speedily. There is still room for subscriptions, and every photographer in the country should be proud to have his name upon the list of those who honour the father of our art.

To those who did not like the designs that have been published, we would say that these were totally inadequate to express the beauty of the finished work. Those who saw the statue unveiled were very happily surprised, and joined in the general admiration of the finished work. We will not attempt to describe the beauty of this unique work of art, but would advise all to see the pictures of the completed monument that will soon be made. We can only say it is beautiful, unique, a credit to Scott Hartley, who designed it, and worthy of the admiration of every photographer in America. To those who have not yet subscribed we would say, send your subscriptions to Mr. McMichael, Main Street, Buffalo, or to us, and the day will come when you will be proud of having an interest in this tribute to Daguerre, even if it be but one dollar.

Our amateur friends must not forget that they also may share in the honour of raising this monument. Let the various amateur clubs send subscriptions to this noble work for the sake of the art that to them is a "joy for ever."

There is no doubt that these conventions are raising the standard of photography in the United States. Each year the work becomes more beautiful through the influence of the members of the Photographers' Associations scattered through this country. If more of the fraternity would only come into the ranks, and learn what can be done by united effort, they would soon find a better way to gain a larger remuneration for their work, better homes, and greater happiness for those that are near and dear to them. There has never before been such an exhibition of the strength of this Association as was seen at the Washington Convention, and all who wish to enjoy this strength and increase it should enter the ranks and grow with it.—*Anthony's Photographic Bulletin.*

THE Chemical Committee of the New York Society of Amateur Photographers some time since invited all the manufacturers of dry plates to send in plates for testing. This Committee has now issued its report, giving the sensitometer number, and the relative speed of each.

THE PRESENT STATE OF THE CARBON PROCESS.*

BY W. E. DEBENHAM.

When the process of printing that depends upon the locking up of pigment in gelatine rendered insoluble by exposure to light, and that is generally known as the carbon process, was popularised, to a certain extent, by the improvements of Swan and of Johnson, great hopes were expressed that a process capable of yielding results good in themselves, and—what rendered it essentially desirable—results that are permanent, would become generally adopted, at all events, for any work but that in which permanency was not much considered. Its use was, however, for a long time almost entirely limited to the reproduction of artistic and archæological designs, and to the purpose of producing such photographs as, being out of the convenient way of production by ordinary private photographic establishments, were naturally put out by them to houses who made a speciality of doing work for the profession. I refer particularly to enlargements, for which its use was pre-eminently selected. It was felt by photographers who desired to do justice to their customers that, where considerable sums were received for single pictures, on account very much of the artistic labour bestowed upon them, it was not fair to issue them on a basis liable to fade, and render the work worthless.

For a long time, however, although there was a great increase in the amount of work done, there was nothing to indicate the likelihood of any general adoption of carbon printing, but about fourteen or fifteen years ago this consummation seemed more likely to come about, owing to the introduction of the process of double transfer from a glazed surface. Many photographers went in for this process, some even exclusively, for their ordinary portrait work. Of these latter I don't know of any who have kept to the path which they entered upon with so much hope and confidence. What is the reason? Or, perhaps more properly, what are the reasons? For one thing, it may be said that the process was more expensive and troublesome than silver printing, and that the public did not care enough about permanency to pay an extra charge for that quality. Others may say that platinum printing has come to the front, and that they prefer the results of the latter process. We are not discussing platinum printing to-night, but I think it may be argued that, with both processes at their best, the carbon process will better register the gradations in the more transparent portions of the negative, and consequently will be freer from heaviness, and want of luminosity of the shadows, than platinum prints on a matt surface.

I think some real reasons for the decline of carbon printing amongst photographers and amateurs are to be found in certain defects to which prints by this process are frequently liable. The two failures most common in private hands are, perhaps, first, a want of richness and vigour in the blacks, unless negatives of extra density are used; and secondly, a liability to washing bare in the lighter half-tones, by which the delicacy of gradation at the end of the scale is lost. A third common fault is a want of purity of the high lights. If these defects were necessarily inherent in the process, it might not be worth while to say much about them; but such excellent results have been seen, and are so commonly produced by the houses who work for photographers, and who make a speciality of enlargements, that it may be supposed that the failings mentioned are due rather to a want of general knowledge of the means of guarding against them, than to a radical defect in the process itself. Perhaps the forthcoming discussion may do something towards making the way clearer.

* Read in opening the discussion at a meeting of the London and Provincial Photographic Association.

THE GENEVA PHOTOGRAPHIC EXHIBITION AND SOCIETY.

The photographic exhibitions connected with the Photographic Society of Geneva take place once in two years, and the third of them was opened last Monday in the Batiment Electoral, a handsome stone building in the best part of the city.

The best photographs on view at the Exhibition are artistic portraits by A. Ruffo, Prince de la Scaletta, of Rome; they are of rather larger than whole-plate size, and are printed in carbon direct from the original negatives; the head and shoulders are included in each picture. They are exceedingly fine specimens of the powers of the carbon process in the hands of a real artist. Words can no more describe pictures than scenery to those who have not seen them, and it would be interesting if, at some future time, these portraits could be placed on public view in England.

Amongst other first-class exhibits are some platinotype portraits by Jean Lacroix, of Geneva; they are of a high order of merit, rich in the most delicate half-tones and in artistic posing of the sitters. One of the small ones, representing a little girl in a fur cape, is among the best.

A fine piece of work, which attracts general attention, is Eccogia, representing wood and water scenery; the picture measures about 16 by 20 inches, and was printed from the original negative of the same size, so that a large camera had been employed. This is one of the numerous photographs placed on view by Frederick Boissonas, of Geneva; an orthochromatic plate had been used, and the print is upon albumen.

Also among the superior pictures in the Exhibition are carbon prints and enlargements, of all classes of subjects, by Mr. Pricam, of Geneva. His policy is that of Messrs. Gernzet Bros., of Brussels, to turn out none but permanent prints, so that after the lapse of years his prints will be found in good condition in albums, alongside old prints taken by others upon albumenised paper, which have changed to the colour of pea soup. In some of the lake and river scenes little touches of high light come out in the right place, and in strong contrast to the rest of the picture. He says that these have not been put in artificially, but are in the original negatives.

Madame A. de Rothschild, of Pregny, near Geneva: the landscapes are good, but without clouds, and some difficult interiors have been well rendered for an amateur. A defect in a considerable proportion of the landscapes in the Exhibition is the absence of clouds. Mr. and Mrs. Houston Chamberlain, of Vienna, are among those who have sent in some excellent work in clouds, and numerous good platinotype prints.

Adrien Peyrot exhibits good specimens of instantaneous work, including various pictures of mountain goats; one of these pictures is printed as an enlargement upon Eastman's bromide paper. A French camera called the "Kinegraphe" was used to take the negatives.

Mr. and Mrs. Alois Minutti, of Chaux de Fonds, exhibit good work, especially in one picture representing trees and

clouds, somewhat in Mr. Gale's style. Clouds are too much absent in their landscapes.

Mr. E. Sautter, an able amateur of Geneva, has succeeded in producing excellent group and other photographs by the magnesium light, some of them as good as if taken by daylight in the studio.

One of the most curious pictures in the Exhibition is a view of a bridge across the Rhone, and the moon, taken by moonlight. Some detail comes out in the distant mountains, and the gaslights on the bridge are well represented. Jupiter was in the field of view, and through moving during the exposure, is represented as a short streak in the sky; the motion of the moon also caused that orb to appear in the sky like a cylinder with rounded ends. This view was taken one night in July last.

Dr. Lindt, of Aarau, has taken up an unusual and difficult class of work, namely, that of photographing stained glass windows, and has succeeded in well representing the windows in the convent of Muri, of the sixteenth century. He uses orthochromatic plates. He has also well represented some ecclesiastical relievos; the originals were in dark wood.

F. E. Thévoz and Co., of Geneva, exhibit specimens of photomechanical work, and as a young firm, has made good progress in a short time. Among their prints are some closely imitating photographs on albumenised paper. Specimens of their work are to be found in the *Revue Suisse de la Photographie*.

To notice the work of all the numerous exhibitors is not possible with the space at command, and in some cases might not be pleasing to those criticised.

Lacombe and Son, of Geneva, exhibit photo-crayon pictures resembling good pencil drawings. A. Moynier, interiors, lake views, and portraits. Maurice Trembley, lake and mountain views. Mr. Müssbaumer, of Zurich, landscapes. Madame Paul Godet, of Neufchatel, engraving-like interiors on bromide paper. E. Fatio, mountain views in the Valais. E. Muller, of Aarau, mountain views. C. Criesis, some good instantaneous street and other views; in one of them he has caught a goose in the act of flapping its wings, and with good effect. Madame Elisée Reclus, of Clarens, views, including one of a lake-boat steaming past the camera, broadside on. Ed. du Bois, of Fleurier, excellent lantern slides of Swiss scenery. G. Pictet, yachts and landscapes.

In apparatus, Rauser and Co., of Geneva, exhibit cameras and stands of their own make. Messrs. Fabre and Borrey, general photographic goods, including developing dishes of enamelled iron, and an excellent lens-shutter by Steinheil. Boxes of dry plates by several English, Swiss, and French makers are on view. Mr. Goegg, of Geneva, exhibits photographic chemicals.

The Photographic Society of Geneva was founded in 1881, and its first president was Mr. Hermann Fol, professor of biology at the University, and who recently raised the question for photographic solution about the growth of resemblances between married couples. The present president is Mr. H. C. Nerdinger, to whose kindness in offering information, also to that of Mr. Pricam, we are much indebted.

Mr. Pricam was Secretary to the Photographic Jury of the late French Exhibition in Paris. He is President of the Jury of the present Exhibition in Geneva; the other members are Messrs. Fatio, Sarassin, Demole, all of Geneva; Mr. Welti, of Lausanne; Mr. Chable, of Neufchatel, and Mr. Barbieri, Professor of Photography at the Polytechnic School at Zurich.

Mr. Braun, of Dornach, produced a composite photograph, in which the Paris Exhibition jury is represented as the "Archers of St. George" dining together. The picture professes to be a copy of an old painting in the Municipal Museum at Harlem. In it Mr. William England is represented as a Dutch lieutenant-colonel, with a great ruff round his neck; the other members "taken off" are Messrs. Darlot, Pricam, Vidal, Davanne, Van Braam, Gaston Braun, Levy, Bilbaut, Audra, and C. S. Hastings. One copy of this remarkable picture was printed for each member of the jury, but no more prints were struck off.

Mr. Pricam is president of the Swiss Photographic Society, an organisation which meets once a year, and deals with commercial questions; its meeting next year will be in Lucerne. A burning question is the pirating of Swiss photographs; sometimes negatives are obtained at great cost and at high altitudes, but after the prints get into circulation foreign firms reproduce them as collotypes, and sell them at one-fourth the price charged by the owners of the negatives.

PHOTOGRAPHY IN GERMANY.

BY DR. H. W. VOGEL.

COLLODION *versus* GELATINE—GAEDICKE'S NEW INVENTION—GAEDICKE'S EXPERIMENTS WITH DEVELOPERS—PHOTOGRAPHIC TESTS OF RED GLASS FOR THE DARK ROOM—EFFECTS OF PAPER WRAPPERS ON THE KEEPING QUALITIES OF DRY PLATES.

SINCE the introduction of the gelatine process pains have been taken by many to improve the old collodion process to such an extent that it unites the facility and rapidity of development, fixing, and washing with the sensitiveness of the gelatine plate. The first attempt of this kind was probably my gelatine collodion. I dissolved dry gelatine emulsion in glacial acetic acid and mixed the same with methyl collodion. In this way an emulsion was formed which flowed in a warm state upon the plate; like collodion, was dry within an hour; and developed, fixed, and washed as quick as collodion plates. The film resisted even boiling water. The process has been applied more or less since 1883, but it lacked durability, because the gelatine decomposed from the collodion with formation of acetic ether. Several scientists experimented later on in a different way, but so far without success. It seems now that Gaedicke, the inventor of the flash-light, has at last succeeded. He makes the following communication. About the durability of the plates I have an experience of six months, during which time they have not decomposed, and there is no reason to doubt their durability any longer. The observation had been made that the old, the not very sensitive collodion dry plates produced with preservatives, had to be developed quickly after exposure, as otherwise the picture would disappear again. To test now my new plates with regard to this property, five small sensitomer plates were cut from a plate and exposed uniformly to gaslight. One of them was developed at once; the others were kept in the dark and developed at different periods. The first plate gave the number 16; the second was developed after two days, the third after eleven days, and the fourth after six weeks, and all gave uniformly the number 16. The fifth plate is still kept in the dark, and will be developed at some later time. As a preliminary, it is therefore confirmed that the impression of the image will remain unchanged for six weeks. The sensitiveness of my collodion dry plates resembles that of a gelatine plate of medium

rapidity, but remains behind the highly sensitive gelatine plates. Of course they are only produced colour-sensitive. The film is very thin and rich in silver, and in a dry condition easily injured, requiring great care in handling the same. After fixing in a wet condition the film is so tough that it can be rubbed with the fingers. Regarding the treatment, a considerable over-exposure will not do the least harm, having in the development the means to retard the same. After exposure, the plate is flowed with water and left to soak for fully a minute, because too rapid a development would produce fog. After the water has been poured off, the soaked plate is flowed with the developer. The most suitable is an old hydroquinone developer, to which has been added a small quantity (about $\frac{1}{10}$) of fresh developer. The picture appears in six to twenty seconds, according to time of exposure, and the development is completed in one to two minutes. The plate is now rinsed well and placed under the faucet for about five minutes, or in a dish with water, which is renewed several times. After this it is free from soda, and has lost also its pink colour. In a short time it can now be dried in the open air or with artificial heat.

Talking about Mr. Gaedicke, I will also mention his experiments with different developers on under, over, and correctly-exposed plates. He has compiled his results in the following table :—

A. Under-exposed Plates.—Exposure, 1 second. Gaslight at 72 c.m. distance from the flame—that is, one-fifth of the normal exposure.

No.	Kind of Development.	The Picture appears in	Time of Development.	Last Readable Number.	Character of the Picture, with Remarks.
1	Oxalate of iron, with addition	9 sec.	5 min.	14	Yellow fog, 1 and 2 show very little difference.
2	Pyro-potash	12 ,,	3 ,,	14	Red fog
3	Hydroquinone, with potash	20 ,,	3 ,,	15	Clear.
4	Eikonogen—potash, with preliminary bath	6 ,,	3 ,,	14	Yellow fog.

B. Fully Exposed Plates.—Exposure, 1 second. Gaslight at 32 c.m. distance from the flame.

5	Oxalate of iron, pure	12 sec.	3 min.	16	The negatives were all good and harmonious. By transmitted light the pyro negative was brown-black, the others blue-black, therefore better adapted for printing. The least clear was the picture made with iron developer.
6	Pyro-potash	8 ,,	$2\frac{3}{4}$,,	16	
7	Hydroquinone	25 ,,	$3\frac{1}{2}$,,	16	
8	Eikonogen—soda	12 ,,	3 ,,	16	

C. Over-exposed Plates.—Exposure, 4 seconds. Gaslight at 32 c.m. distance from the flame—that is, four times the normal exposure.

9	Oxalate of iron, with 4 drops bromide of potassium (1 : 10)	18 sec.	$3\frac{1}{2}$ min.	16	1 to 8 little gradation, weak, and not fit for use.
10	Pyro-potash, with 8 drops of bromide of potassium	20 ,,	$2\frac{1}{2}$,,	16	Better gradations than No. 9. Somewhat too hard, but still fit for use.
11	Hydroquinone, only old developer, with 8 drops of brom. of potassium	60 ,,	5 ,,	16	Normal negative the best of this group.
12	Eikonogen—soda, with 8 drops of bromide of potassium	30 ,,	$3\frac{1}{2}$,,	16	Weak and unfit for use.

The exposure was in gaslight, behind a sensitometer scale. Gaedicke says: "At quite a normal exposure good negatives can be obtained with all developers. But the hydroquinone developer is considered as the most convenient, most durable, and cheapest. It can be bought concentrated ready for use at a very low price; no measurements are required; no part is missing at a critical moment, and the dilution of a new bottle of the developer takes not more than two minutes. As generally two-thirds of old and only one-third of new developer are used, the hydroquinone developer is therefore the cheapest. For greatly over-exposed plates, as is oftentimes the case in landscape photography, pyro and hydroquinone are applicable, but hydroquinone is to be preferred. It is also oftentimes the case that negatives are to be developed of which the time of exposure is unknown, and the safest developer for this is hydroquinone, two trays being used with equal quantities of developer, the one being old, the other new developer. The plate is first flowed with the old developer, and then with the new. If no picture appears after the first minute, new developer should be carefully added, and a good result will be certain. But the hydroquinone developer has one dark side: it develops only with difficulty in cold weather, and the developing room should therefore have always a moderate temperature.

In my last letter I wrote to you about red glass for the dark room lamp. The result of this publication was that quite a number of red glasses were sent to me for examination; but almost all of them were useless. Complaints have also been made that I proposed a spectroscopic test instead of a photographic one, which could be made by everybody. But the thing is, after all, not so simple as we imagine, because the photographic test deceives much easier than the spectroscopic test, and there is considerably more danger to reject actually good glasses, as the following test will show. A red dark room light, pronounced good spectroscopically, was applied in front of a gas flame. The gaslight used varied, on Bunsen's photometer, between seven and eight candles. To test the good quality of the light, the most different kinds of plates, among them a number of scientific spectral views, were developed without fault, during four weeks, in the ordinary way, the tray being kept in the shade during development, and only from time to time they were examined for a few seconds in the light of the red lamp. After the plate had come to an advanced state of development, it was examined at about 20 c.m. distance from the gaslight for some seconds. The yellow side light of the lamp, which admitted the passage of remarkably blue light, remained open without the rays of the same touching the plate directly. The usefulness of the red light having been

determiued iu this manner, even for eosidc of silver and azalin plates (with the latter I kept the developing tray covered), the photographic test took place. 1. A Sachs plate was exposed for sixty seconds under a reproduction negative with very transparent clear parts at a distance of 18 c.m. from the gas light (by inserting the red light), and was theu developed with fresh hydroquinone developer without bromide of potassium. Result: weak but very distinct copy of the transparent parts of the negative after long development. After this result many would undoubtedly have discarded the red glass as useless. 2. The same experiment was repeated at 36 c.m. distance in the same manner. At this double distance the light was therefore four times weaker. The plate was then developed for a long time (until the beginning of fog). Result: very weak picture of the lightest parts of the negative. 3. The same experimeut (2) was repeated in thirty seconds' time of exposure. After long development the faint outlines of a picture were now only visible. Nine years ago, Abney made the observation that light having passed through the red glass is by uo meaus without effect upon ordinary plates, and he recommeuded at that time an addition of iodide of silver to the bromide of silver emulsion, to make it less sensitive to red light. If, therefore, such a dark room lantern is to be tested, it should be determined if it admits the readiug of common-size type at one foot distance; further, whether it will make only a faint light impression, or none at all, at a foot distance in thirty seconds. I remark here particularly that I uever advise daylight, but only gaslight, for the dark room.

I have writteu to you repeatedly about the great damage caused by bad paper wrappers used for packing dry plates, but my advice seems to have been unheeded so far. Recently I opened a package of dry plates of a well-known Berlin firm, three months old, and fouud that the plates had a black border of a third of an inch. That fog on the edges will form even without wrappers has been shown by Wilde; that it will occur easier with ammonia emulsiou has been observed by Armstrong; that the atmosphere, or, better expressed, evaporations, play a rôle has eouvincingly been demonstrated by E. Vogel, by showing that impure wrapping paper acts even through pure paper in which the plates were packed. Lately it has been particularly proveu that plates will fog very quickly on the edges in an ordinary pasteboard box, but that it will be much slower iu a box soaked with paraffin. Gebhardt observed that highly seusitive plates are more rapidly subject to fog on the edges (after four mouths 3 to 5 m.m. wide) thau less sensitive plates. Plates made in winter are more durable than those made during the summer. Different kinds of wrapping paper showed no difference. Gebhardt examined also the layers between the plates. Black soft and gray wrapping paper gave a strong fog after three weeks; while filter paper, tinfoil, aud yellow tissue paper had very little effect. Gebhardt's idea, that only the atmosphere, and not the wrapping papers, is the cause of decomposition, is therefore erroneous. Many wrapping papers act upon the atmosphere by evaporation. —*Anthony's Bulletin.*

A GENTLEMAN has been kind enough to send us a photograph of the back of a postcard upon which is written the word Prizes" 10,858 times. We have not read it through, but it appears to be very interesting.

THE CARTE-DE-VISITE.*

BY JAMES MEW.

THE author of the Essay on Man might, had he lived in the present age, have his portraits hung in the shop wiudows of our principal thoroughfares like ropes of onions. For cartes-de-visite are geuerally disposed in vertical or horizoutal lines, though the stationers and keepers of shops of fancy goods might well take a hint from the sausage merchants, and arrange in graceful festoons the many photographs of the favourites of the hour, hanging them in catenary curves of varied span across their shop fronts to feed the ever curious public eyes.

But what a lesson for the studeut of human nature, what a wealth of speculative content for the moral philosopher, is afforded by the carte-de-visite! The transitory nature of all human grandeur, the evanescent character of the highest fame, cannot be more clearly shown than in the shop window of a modern stationer. Where, in a few months—nay, in a few weeks—will be the favourite cartes-de-visite which, a little while ago, were thick as buttercups in the country fields in the month of May; the "snre cards" representing the different appearances and attitudes at different times and in different places of Lady Dunlo and Mr. Stanley?

Already their autumu has arrived, and their winter is close at hand. Who shall say what will become in that drear season of these faded pictorial leaves? To wrap up butter they are all too stiff, and a man—even the least sentimental of men—would think twice before consigning so much beauty and bravery to the dust-bin. No; there is another use for these. Let a few, only a few, years pass by, and their names will be surely forgotten; and theu, as a faded Colenso has done duty for a foreign cabinet minister, aud an ancient Tom Sayers for a modern Putney Pet, they will be sold in some sleepy old country hamlet for the adornment of humble homes, in which the children will learn to look on them as the exact pictures of the excelleut Miss Nightingale and of the venerable Mr. Spurgeon; or, perchance, in the flux of time, to prize and honour them as ancestral family portraits of their own.

It has been whispered that cartes-de-visite have thus done double duty. Truly, such things are. They form part of the mysteries of the trade, aud recall the practice of those old booksellers who sowed wood-cuts at random in their letter-press with such sublime indifference to any care of connection or relationship, that a picture originally intended for "Who Killed Cock Robiu?" adorned the moving history of the "Babes in the Wood"; aud the poetic legend of "Tom Thumb" presented amidst its pages, to the readers' astounded eyes, a full-length portrait of the pagan giant iu Bunyan's "Pilgrim's Progress."

Another fruit, as Bacon would call it, of the carte-de-visite is the cure of that enthusiasm or hero worship which is so great a factor in the sum of public sentiment. Nay, more than this, the opposite extreme of passion is sometimes engendered by this photographic picture. Mr. Jones, who, in his mind's eye, had looked upon, let us say, the Empress of all the Russians as a person not of human flesh and blood subsisting, but as a sort of demi-goddess nourished on nectar, and far too good for nature's daily food, finds familiarity breeding something dangerously near to contempt when he sees a carte of that distinguished lady differing in no material respect from the portrait of his rich aunt, the butterman's widow, which

* Continued from page 686.

occupies a prominent position above the beautifully bound Bible in his family parlour.

Cartes-de-visite, or card portraits, or C.D.V., as they have, by a species of trade gematria, been succinctly called, have been the occasion—as what indeed has not?—of imposition and of crime. Some years ago a man was convicted of obtaining money under false pretences. He advertised in a daily paper, "Two-and-sixpence per hour easily earned by beginners (either sex) by preparing cartes-de-visite at their own homes. Employment permanent. Trial paper and instructions, 1s. Jones Brothers, Birmingham." It is the kind of advertisement with which we are most of us only too well acquainted. The same sort of thing meets us every day in almost every paper. The admission of "either sex," the easy labour, the advantage of that labour at "their own homes," and the "permanent employment," still bring many shillings into the pockets of advertisers at the present time, as they brought them into the pockets of Jones Brothers until Jones was taken red-handed, and rendered impotent awhile for the public weal.

On another occasion, the cartes-de-visite of a large family were industriously circulated among the richer section of the London population, with a modest request to pay for the board and education of any one or more of that numerous family, whom the benevolent or charitably disposed person receiving their photographs might select. The children were "British-born Protestants," their father an "elderly gentleman ruined by competition in business," their mother in a very "precarious state of health." This bold application may have been the mere outcome of genuine distress, but the "British-born Protestants," the "gentleman ruined by competition," and, above all, the "precarious state of health," bear a stamp very closely resembling that of the begging letter impostor who has given, and will, doubtless, continue to give, so much trouble to the executive of our constabulary.

On cartes-de-visite the celebrated astrologer, Mr. Smith, flourished for a considerable time, like the green bay tree. This worthy gentleman used to advertise his ability to describe the outward shape or form of "your future husband or wife." His knowledge, however, was not sufficient to enable him to divine which of the two was wanted by his customers; he therefore added to his advertisement, "State age and sex." Nor was this reader of stars, this extraordinary being to whom future events were seen clearly as the letters in a child's copy-book, above the consideration of the value of postage stamps. "Send stamped directed envelope," follows immediately on "State age and sex." "For sixteen stamps the true carte-de-visite of your intended, with name, age, and date of marriage." What more could widower or bachelor, maid or widow desire? Moreover, this Mr. Smith, this celebrated astrologer, with a strange thirst for postage stamps, which might denounce him as an impostor in the eyes of those who are unaccustomed to gaze upon the modesty of true wisdom, would, for thirty more stamps, answer three questions. "Three questions," says the advertisement, "answered for two-and-sixpence." Only ten stamps for a question in a field of infinite area. What shall I have for dinner to-morrow? What is the modulus of Brigg's system? Where is the burial-place of Moses? On the whole, it would be a cheap half-a-crown's worth.

Finally, the carte-de-visite is the money-making portion of the photographic profession. It is, in artistic slang, the pot-boiler. It is the necessary staple in the market of photography, and is, consequently, the variety most commonly produced of the photographic picture. When old Kircher—in his prophetic vision of what the camera might give birth to, the sun pictures of the days to come—saw temples and palaces, streets and houses, triumphal arches and lofty columns, obelisks and pyramids, sunrise and sunset, the falling star and the descending angel, nay, he adds in his inspiration all the actions of the universe, flaming thunderbolts, coruscating planets, moving animals, flying birds, the customs of cities and the manners of men, he strangely omits these pictures of their faces and forms, which are dearer to most of us, and far more important in our own estimation than any resemblance of star or sunset, of triumphal arch, or descending angel.

It is the *personnel* of our dearly cherished individuality which the public hankers after, and can comprehend better than any history of learned speech or famous deed, the picture which needs no longer the professional skill and the highly paid service of the miniaturist or painter in oils or water colours, the little fox among the animals of larger growth, the small change in the domain of art, the democracy of portraiture—in a word, the carte-de-visite.

COLLOTYPE PLATE-MAKING.*

I DO not wish to trespass on your valuable time with a long paper, but to give plain instructions and formulæ, and show results, so that any of you interested in photo-mechanical printing can go home and try it for yourselves without being confused with unnecessary matter. The first thing is some good plate glass ground with emery, such as the piece here shown. It is very simple. I take two pieces and put a little emery moistened with water between them, and rub them round and round till I get as fine a grain as possible, and then well wash and clean with spirits and ammonia, when they are ready for the first coating, which is made as follows:—

Four ale or porter	...	...	...	30 ounces
Silicate of soda	...	...	...	3 ,,

This is carefully filtered, and a little poured on the plate, and spread over with the palm of the hand; then put in a rack or stand on blotting-paper to drain; no heat is necessary. They ought to be done over night ready for next day, when, after a good washing under the tap, at the same time rubbing with a soft sponge, and again dried, they are ready for the second coating, which I make as follows —

Coignet's gelatine ...	...	...	...	5 ounces
Nelson's sheet gelatine	...	...	...	2 ,,

Soak in 80 ounces of water, then dissolve, and add bichromate of ammonia 2 ounces dissolved in 10 ounces of water, to which has been added ½ ounce of liquid ammonia. The plates which have been previously described are carefully levelled in the drying oven, and the temperature raised to about 100°, when they are carefully coated with the second preparation just described, and dried at a temperature of 150°, when the gas or hot water is turned off, and they are allowed to cool gradually. They ought not to be used till next day, and they will keep good for about one week; after that time they become insoluble. The next operation is to expose under a reversed negative, either wet or dry plates; but I have never seen a dry plate negative yet that can compare with a wet collodion one, although I have had nearly twenty-five years' experience. The exposure to light is difficult to describe; the best way is to use an actinometer, and give about the same time as you would for a silver print from the same negative; but a few trials will be of more service than a book full of instructions. After the plate is exposed sufficiently, take off the backing, and expose the back to light for five or ten minutes, according to the subject; this helps to bind the film to the

* Read before the North Middlesex Photographic Club.

glass, and prevents too much relief. The plate is now put into water, and allowed to soak till all the unaltered bichromate is washed out ; then give a good rinse under the tap, well clean the back, and put away to dry spontaneously. They should not be used at once, but allowed to get thoroughly hard. The plate, after being put under the tap and dried with a cloth, is soaked with a mixture of glycerine 40 ounces, saltpetre 2 ounces, ammonia 7 ounces, for about five minutes, and dried again with a cloth, and is then ready for the printing, which can either be done in a hand press, or by steam. The ink is very much like litho, and the machine the same.

I don't pretend to anything new, but I have tried to show how collotype is worked, and the foregoing is exactly how it is worked every day by one of the largest firms in the world.

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

An important result of this series of experiments is that the density reached is dependent upon the time of development as well as upon the exposure of the plate. The time it takes to reach a given density varies much with the gelatine employed in making the emulsion and the age of the plate. But with each plate it obeys a certain law, which is more or less clearly visible in every one of the five experiments. The density grows rapidly at first, its growth becoming slower as time advances, and finally tends to a limit. Each experiment is, taken by itself, liable to many errors; but by reducing every experiment to the densities obtained in No. IV., in simple proportion, the following tabulated series of numbers is obtained. The columns marked I., II., &c., are the reduced densities of the corresponding columns of experiment 12. The column marked "Mean" shows the arithmetical mean for any period of development obtained from the five series. The column "Calculated" is obtained by means of a formula based upon the idea that the number of particles of bromide of silver affected by the light is greatest in the front layer of the film, and decreases in geometrical progression as each succeeding layer of the film is reached, an idea which will be better appreciated when we have explained the action of the light upon the film. This idea, expressed algebraically, leads to the formula—

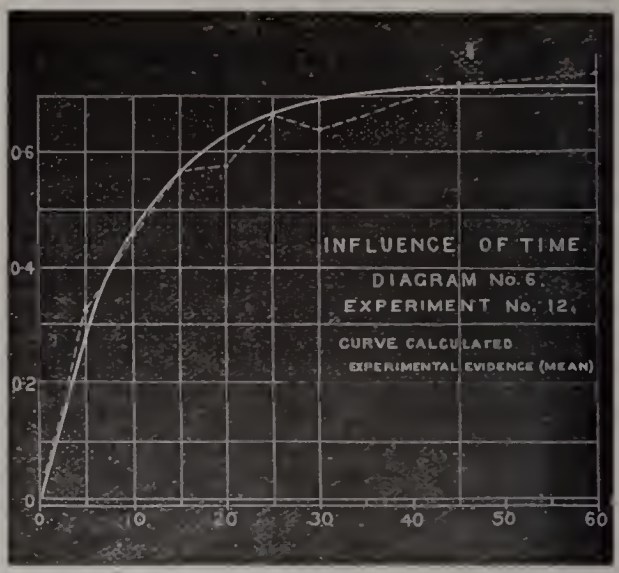
$$D_t = D\,(1 - a^t)$$

where D_t is the density after t minutes development, D the limit of density reached by very prolonged development, and t the time of development; a is a fraction depending upon the nature of the film, concentration of developer, temperature, &c. The constants for the series of figures below are $D = 0{\cdot}720$, $a = 0{\cdot}9015$.

Time.	Recalculated.—Densities.						
	I.	II.	III.	IV.	V.	Mean.	Calculated.
Min.							
5	·349	·350	...	...	·298	·332	·290
10	·502	·460	...	...	·423	·462	·464
15	·588	·550	·569	·570	·569	·569	·568
20	·588	·575	...	...	·583	·582	·628
25	·670	·650	...	...	...	·660	·665
30	·670	·660	·615	·670	·625	·645	·687
45	...	...	·715	·715	·715	·715	·713
60	...	...	...	·740	...	·740	·719

* Continued from page 718.

The relation of the calculated figures to the experimental data is best seen in diagram.



A very important conclusion can be shown to proceed from the formula representing the course of development.

If on any one plate two exposures are given, one of which would ultimately yield density D_1 and the other D_2, and if this plate were developed for a time t, then two densities, d_1 and d_2, would result such that :—

$$d_1 = D_1\,(1 - a^t)$$
$$d_2 = D_2\,(1 - a^t)$$

and it will be seen that on dividing these equations,

$$\frac{d_1}{d_2} = \frac{D_1}{D_2}$$

the resulting ratio is independent of the time of development, and is equal to the ratio of the ultimate densities which would be reached, so that the gradation of negatives appears to be independent of the time of development.

(To be continued.)

WEIGHTS AND MEASURES IN PHOTOGRAPHY.

In the course of a criticism of the Chester Convention report on the above subject, *Anthony's Bulletin* says that the recommendations of the Convention are exceedingly simple, and well worthy of trial by all intelligent photographers. "The metric system is most assuredly the best to use, since measures and weights in this system can be purchased from any manufacturer of chemical apparatus, and the more enterprising of the photographic merchants. These weights and measures are just as cheap as those made upon the old system, notwithstanding any statement to the contrary. We have before us a price list of metric weights in which a set, 20 grams to $\frac{1}{100}$ of a gram, is marked at less than $2. These would be used for all small quantities. For larger quantities, up to 1,000 grams, a set of iron weights are listed at $1.25. Therefore, by the investment of $3.25 for weights, and not more than the same amount for measures for cubic centimetres, every possible contingency in the metric system would be met. This part of the recommendations given above we entirely agree with, but the use of ounces and grains is, to our minds, a delusion and a snare, and only tends to complicate a decimal system. If you get a set of weights on the grain system, you would need a set of measures on the same system, and these are not easily obtained. If you use ounces, and follow the decimal system, weights of

decimal parts of ounces would be necessary, and the corresponding fluid measures. At the present time decimal fractions of ounces and fluid ounces are unknown to us. We therefore protest most emphatically against the adoption of any such system. The metric system is so simple that we cannot believe there is a living photographer who is not intelligent enough to use it. All that has to be remembered is that 1 gram of water measures 1 cubic centimetre, and that these are multiplied and divided by tens. It seems to us almost impossible to conceive anything more simple. The difficulty has been, as we have said on a previous occasion, that writers on this subject have tended to complicate the system, as far as weights and measures are concerned, by introducing a lot of terms that are valueless, and serve only as an exhibition of their knowledge of Latin and Greek prefixes. The beauty of the metric system to all those who have used it is that the measures and weights are expressed in cubic centimetres and grams, and that the sub-divisions are decimal. If we were to write for a week we could not add anything to this, and the mere statement teaches the metric system. All that is necessary to carry it out is to buy the weights and measures and use them; they are infinitely easier to manage than any other system yet devised.

"The use of the metric system has become so important, and is so simple, that the Committee of Revision of the United States Pharmacopœia have decided to introduce it into the next edition of that important volume, which is now under consideration. This has been done after the mature deliberations of hundreds of physicians and druggists in the United States, who recently met in Washington, D.C., to consider the revision of the United States Pharmacopœia. It will therefore be essential for every druggist to understand the system, and surely photographers may readily do so.

"The other recommendations in the English report we heartily endorse. We would call special attention to paragraphs 5 and 6. It is extremely important to make solutions containing a definite number of parts of chemicals *in* a given volume, and not parts added *to* such volume. The use of correct terms either in weight or measure for liquids heavier or lighter than water is also often neglected.

"We hope that the time is near at hand when, 20 grains = 1 scruple; 3 scruples = 1 drachm; 8 drachms = 1 ounce; 16 ounces = 1 pound; with the fluid measure, 60 minims = 1 drachm; 8 drachms = 1 ounce; 16 ounces = 1 pint—will be things of the past. How different the metric system, 1 cubic centimetre of water = 1 grain!"

Photographic Club.—Subject for discussion on September 24, "Photographing Interiors"; October 1st, "Printing Clouds in Lantern Slides."

Meissonier's original painting named "1814," has been lately sold for £31,000. The picture measures nineteen inches high, and less than thirty inches in breadth, and a contemporary observes that the price given amounts to £58 per square inch, thus beating, by £2 per inch, Mr. Ruskin's Meissonier, measuring twelve inches by nine, which was sold in 1882 for £6,090. The Blenheim Raphael in the National Gallery, it is calculated, realised only £14 per inch; the Terburg, £21; and the small Correggio, £29. But it makes one sad to think of works of art being valued according to size. If this pernicious system received general adoption, the measurement in the case of certain large canvases hung so copiously in public galleries, especially in France, would have to be taken by the yard. The same rule would also apply to the enormous surfaces covered by the late Gustave Doré, and which are still the admiration of country visitors to Bond Street.

Correspondence.

EDINBURGH PHOTOGRAPHIC EXHIBITION.

Dear Sir,—Will you please allow me, through your columns, to remind intending exhibitors at this Exhibition that applications for space should be in my hands not later than the end of the current month? I shall be happy to forward the official form of application to any who have not already received it, on applying to me at 180, Dalkeith Road, Edinburgh.

Edinburgh, 12th September. F. Barclay, *Secretary.*

HIDING DEFECTS IN PHOTOGRAPHIC PRINTS.

Sir,—As I read your paragraph (p. 699, September 5th, 1890), on "Hiding Photographic Defects," I am prompted to tell you a plan (a better plan, as I think, than the one described) which I have occasionally adopted for stopping out whites in the positive. Take a piece of ruby glass (pot metal) and place it upon a pad of soft putty, and with the coloured side up; then take a small archimedean drill moistened with turpentine, and drill away a spot of the coloured surface of the glass. The glass then can be manipulated over a positive, and the spot of white glass brought over the white or pale spot on the print, which may be thus actinically touched out. The process is, however, too tedious for extensive use. H. W.

Proceedings of Societies.

London and Provincial Photographic Association.

September 18th.—Mr. A. Mackie in the chair.

Mr. J. J. Briginshaw exhibited a flash-light lamp which embraced a novelty in the principle of its working. It consisted of a metal tube bent at right angles, at the top of which is fixed a vessel covered with fine gauze holding methylated spirit; at the other end of the tube a smaller tube is inserted sliding easily backward and forward; near the end of the inner tube is a small chamber with a slot corresponding with a similar opening in the outer tube, over which is fixed an upright cylindrical reservoir holding a quantity of magnesium powder; by sliding the inner tube forward the two openings are brought together, allowing sufficient magnesium powder for a charge to fall through into the chamber beneath, a spring forcing the inner tube back into position, ready for a discharge, which is made by pressure of a pneumatic ball and tube. This can be repeated until all the magnesium powder is exhausted. The lamp has been placed in the market by Messrs. Watson and Sons. An arrangement for fixing the tripod legs of a camera to prevent slipping was also shown.

Mr. F. A. Bridge exhibited some mechanical prints presented to him, when in Antwerp, by Mr. J. Maes, of that city.

Mr. W. E. Debenham read a paper on "Carbon Printing" (see page 733).

In reply to a question, what means he used to get purity of the high-lights in a carbon print, Mr. Debenham said he prepared the paper himself, omitting chrome alum, which is generally used in its preparation; the remaining trace of gelatine left in the high-lights must, of necessity, contain a trace of colour.

Mr. C. H. COOK had found, when squeegeeing the tissue on to the support, that bubbles sometimes appeared.

Mr. A. COWAN said, allowing bubbles to remain on the tissue in the preliminary soaking would be the cause; these should always be brushed off.

The CHAIRMAN asked if carbon prints could be intensified?

Mr. DEBENHAM would use permanganate of potash; he would always use a fresh bath each time for sensitising, adding sufficient ammouia to discharge the colour until it was of a pale lemon colour.

A questiou was raised whether any means existed to ascertain if carbon tissue had been exposed.

The CHAIRMAN said that if breathed upon the tissue would show the image.

Mr. C. E. Atkins was elected a member.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

September 8th.—Mr. HUMPHRIES, who occupied the chair, announced that it had been decided that articles which members only desired to dispose of might have a description of them placed upon the notice board, in the Club Room, if sent to the secretary, the usual commission of 5 per cent. being charged on sales effected.

The SECRETARY then read a paper which had been contributed on the subject of "Collotype Plate Making" (see page 737).

Mr. CHERRY said that in the specimen plates now placed before them for inspection in the different stages of preparation, there was one which, he understood, was ready to be inked up and printed from, but from an examiuation of it he failed to see how it could be possible to obtain any print from it, as there was scarcely any relief perceptible, and the image almost impossible to be seen except when so held that the light was reflected, and therefore the iuk would spread equally all over and block up the lights, and he should like to have the process explained more fully after the plate had been exposed behind the negative.

The SECRETARY (answering for the author of the paper, who had to leave before the discussion) said: The inability to appreciate the manner in which a print is made from such a plate arises from a misconception of the basis upon which the process is worked, as it does not depend upou the relief for the lights; but when the prepared gelatine is exposed behiud the negative, the light penetrating through that made it insoluble in those places, and incapable of absorbiug the hygroscopic substance, with which it was afterwards flooded, which was doue to cause those parts which had not been exposed to the light to repel the fatty ink; thus, the parts which had absorbed most moisture would not receive auy, while to that which was less moist more ink would attach, and in the parts most exposed to light the ink would attach itself thickly, forming deep shadows in the prints.

Mr. FORBES wished to know whether all those shown were collotype prints, or whether some which he pointed out were not on albumenised paper?

The SECRETARY: Those prints are all produced by the collotype process, the glossy surface beiug produced after printing.

Mr. PITHER: I notice that while some of these prints have an entirely matt surface, others have a finished glazed surface, and I should like to have an explanation of the manner in which this is produced.

The SECRETARY: It is obtained by what is known as the water varnish—that is, a solution is made of borax in water, and shellac is then dissolved in it; the paper is then floated on this which gives it the prepared face.

Ou Monday, September 22nd, Mr. C. Beadle will give a demonstration of lantern slide making. If time should permit, there will be a short discussion upon the merits of retouching on the same evening. Visitors are invited to attend.

ALL photographers will learn with regret that part of the Spanish Alhambra—the finest specimen of Moorish architecture extant—has fallen a victim to what is commonly called "the devouring element." We learn that steps have been taken to proceed with the work of restoration without delay.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

COLONEL WATERHOUSE.—*Reversed Prints.* Your photo-etchings from direct positives reversed with phenyl-thio-carbamide, appeared to us so extremely interesting and important, that we have had them framed and sent to the Pall Mall Exhibition. They arrived just in time to enable us to comply with the official regulations. We thank you for the accouut of the process by which they were produced.

H. R. L. (Taunton).—*Instantaneous Shutters.* Messrs. Sands and Hunter have a shutter which is capable of giving the extremely rapid exposures which you desire. We are, however, surprised to hear that you have failed with the iustrument mentioned in your letter; the large size of your plates increases the difficulty.

TOM (South Wales).—*Card Mounts.* The letter of advice and specimens, having been sent on to Leeds and just missed us there, prevents our reporting upon them this week.

A. P. (Birmingham).—*Making a Vignette Direct on the Negative.* A correspondent, under signature B. H. L., Loudon, W., has obligiugly furnished us with the following suggestion, founded upon his practice of thirty years ago:—"After exposure the plate was taken into the dark room. A candle was lighted, and the plate being removed from the carrier was held a few inches from the flame, whilst a disc, properly shaped aud made of blackened cardboard, was kept gently moving over the part inteuded to be preserved. The effect of this was to obliterate, by the stronger action of light, all the parts exposed to the candle, round about the portrait, leaviug a viguetted bust on development. A glass positive made in this way was easily reproduced as a negative."

B. H. L. is thanked for sending the preceding communication.

G. W. H. (Paignton).—*Ceramic Photography.* We are not aware that any full compendium of these processes has ever been published, but you will find much information on the subject in back numbers of the NEWS. Thus, "Mr. A. L. Henderson at Home; Euamel Photography in Practice," is to be found in our issue of March 16th, 1883; and MM. Joubert's and Germeuil-Bonnaud's processes were described iu the NEWS of July 12th and 19th, 1889.

A. B. (Preston) *Fading of Prints.* Received your letter of 7th inst., together with the two years old print, which entirely disposes of one of the causes suggested, viz., dampness of climate. Having been away from home, attending the Leeds meeting of the British Association, we have not yet had time to examine the mounts for any deleterious ingredients.

ENGRAVER.—*Sale of Photographs Produced on Commission.* You can restrain the promiscuous sale of photographs produced to your order, if executed as a commission, and paid for in such a manner as to cover the cost of taking the negative. In order to secure the copyright you might have registered the picture, but failing this, your rights ought to be respected.

L. P. S.—*Egg Albumen.* Except for leather dressing or as a mordant in calico printing, we do not know how the yolks of eggs could be applied. We presume you have offered them to local confectioners, who might go some length in assisting you.

G. B.—*The Photographic Exhibition.* It is now too late to seud in your intended exhibit. Monday, 15th inst., was the last day for receiving at Pall Mall.

H. F. L. (Rochdale).—*Retoucher's Manual.* Our publishers have a small work entitled "The Art of Retouching," by P. Piquepé, which gives all the inforuiation you require.

ANASTATIC.—*Course of Practical Instruction.* Ask for the prospectus of the Polytechnic Institution. Out-door practice is included.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1673.—*September* 26, 1890.

CONTENTS.

SERMONS IN STONES.

THERE are now happily so many cameras at work throughout the world—thanks to the convenience of dry plates—that it is only natural that the more earnest workers with the instrument should have begun to look upon it as something more than a mere toy, and a solace for idle hours. In this they follow the example of microscopists, many of whom originally took up that instrument as a source of amusement, the occupation gradually assuming the form of a hobby, until at last they devoted themselves to a definite branch of work, perhaps leading to the elucidation of some problem which had hitherto taxed all the resources of science. In like manner we can now point to photographers who have ceased to regard the camera save as a means of recording observations of various kinds, one devoting himself to a study of animal life, another to architecture, and so on.

But it is only recently that a serious attempt has been made to illustrate the noble science of geology in the only way that it can be satisfactorily pictured. One has only to turn to the crude pictures which a few years back were thought good enough to illustrate our text-books to know how much improvement was possible in this direction. A rough drawing, an imaginary section of the earth, or perhaps a sketch actually made in a quarry or railway cutting, was translated by the wood engraver to the best of his ability, with a result that was very far removed from the actual appearance of the thing represented. Still more is this observable in the case of other more marked physical phenomena—waterspouts, whirlpools, petrefactions, &c.—and more especially the lightning flash. Photography has changed all this, and we are now entering upon a new era, when the truthful lens, aided by the modern means of reproducing photographs for book illustration, will most certainly cast the rough woodcut to the winds.

Our readers have already learnt that the British Association some time back appointed a committee to collect and tabulate as many photographs having reference to geology as they could collect, and that their endeavours have met with a very encouraging result. It is in the power of nearly everyone who possesses a camera to contribute to this collection. He may possibly at first know not how to begin, and if he take up a book dealing with the subject, will perhaps be frightened by the number of unfamiliar terms which meet his eye. Of course much depends upon the particular volume which he selects, for some authors with heads full of knowledge of the matter in hand fail in their endeavours to convey it to others, except in a dry-as-dust kind of way which repels, rather than attracts. Others again make the most recondite subject so palatable, that it is like a pleasant story to read, and these gifted ones have made "fairy tales of science" a true title for their works. The would be-student can easily find out by enquiry in which author to put his trust, and with a little patient attention he will soon glean a general, if superficial, knowledge of geology, which will give every excursion from home a new interest, and which will most surely lead him to seek more information about the crust of the earth on which his life is passed.

There are naturally certain districts which are far richer in materials for study than others, and dwellers in those places have a great advantage from a photographic point of view. In the north of Ireland, for instance, where the molten basaltic rock at a past period of the earth's history has been forced through the overlying strata, until it to-day forms a vast district built up of columns, and hexagonal paving stones, we have a wonderland which culminates in the Giant's Causeway. But nearer home, in Yorkshire, there is a district of great interest which has not yet tempted as many photographers to visit it as one might wish. We mean the great limestone country—which is pierced in every direction with caverns—some with rivers and cataracts rushing through them, and some encrusted with stalactite and stalagmite.

But there are, in this country, many places where nature is pursuing her restless work in quieter fashion,

where photographic records would be valuable. Look at the many places on our Eastern coast, for example, where the sea is slowly eating up the land. Go south, and we can point to places where the soil is being silted up to such an extent that the reverse action is taking place, and new land is being formed. This is the case at more than one place on the Solent, and most notably at Sandwich, in Kent, which, at one time one of the famous Cinque ports, is now desolate, and two miles away from the breakers. It is pleasant, no doubt, to wander among the fields, or along the river bank with a camera, and to take pretty rustic pictures, but it gives a higher zest to one's leisure if there is some more definite purpose in view. The camera is a faithful reporter, and we can put it to less useful work than taking shorthand notes of "Sermons in Stones."

PHOTOGRAPHIC CONDITIONS IN SWITZERLAND.

THE tourist season in the heaven of photographers, Switzerland, is now over, and, taking it all through, it has not been a good one. The London daily newspapers have told, some weeks back, of storms and floods driving the majority of visitors back to the lowlands, and for a week the weather which preceded the opening of the Photographic Exhibition at Geneva, described last week in these pages, was bad. The Bise, a cold, dry northern wind, which afflicts Swiss localities, had been driving visitors from Geneva itself, to seek relaxation in the Riviera and more southern quarters, and Mr. and Mrs. Stanley, who were expected in Geneva, remained on the shores of the Lago Maggiore, and have since moved farther south.

Just before the opening of the Exhibition, however, the weather became sultry, and at its opening, and for four days thereafter, not a cloud obscured the face of the sun from morning till eve; the temperature at mid-day was sub-tropical, though cold at night. A fine time, this might be supposed, for photographing Mont Blanc and the higher Alps from points of view on the north of the lake. But the higher Alps are coy in presenting themselves. Sometimes, in a bad season, a photographer may be in the midst of the Alps for a month, and not see the higher summits because of the clouds. At Geneva last week they were hidden from another cause, the prevailing heat-haze, which limited vision to a few miles, although the weather would have been considered clear for work in less mountainous countries.

Those photographers who leave England for a limited time may have other causes of disappointment in attempting to work upon Swiss scenery. For instance, in the beautiful scenery of the valley of the Rhone, last week, the weather and the clouds were all that could have been desired, but the Föhn came down; the Föhn is a hot wind from Arabia, and in Italy is known as the Sirocco. Usually it is somewhat humid; this time it was as dry as a bone. Sometimes it lasts but four or five days; occasionally it continues for eleven or twelve days. Until last Tuesday it was blowing enough to carry any camera and its legs over precipices, and the ordinary devices of loading the camera with suspended stones, or steadying it with the india-rubber loop-link, would either have been of no use at all, or such an inconvenience as to have rendered life a burden. Those buildings in the Valais which were built of wood rocked to their foundations, and the cracking ceilings deposited pieces of mortar, like walnuts, upon the dwellers therein. The Föhn was particularly aggravating at night, destroying sleep, and performing its worst devilries just before daybreak. Only last Tuesday did it begin to calm, and to leave in its place rain and clouds.

Thus the higher Alps require waiting upon by the photographer, and are not at the beck and call of every visitor. In times past, we have known this hot wind to come over the Alps, and to put the Lake of Lucerne into such a boil that the large passenger steamboats were unable to run, and at Lucerne the waves were breaking upon the banks sufficiently to remind one of the sea-shore at Dover upon a breezy day.

Such facts are not advertised in guide-books, which do not state that it is possible to spend a limited time, more or less, close to the higher Alps without being able to see them. Practically, however, this is a minor loss. The scenery in view, under any conditions but those brought about by fog, is so fine, that the loss of a few white mountains in the distance need not be deplored, but the Föhn, when it is in high spirits, stops everything.

Once upon a time, the Lucernoise took their revenge upon the Föhn by burlesquing it at a carnival, in which it was represented as a great green dragon, disposed upon two cars drawn by six cream coloured bulls. The dragon was an effective one, having been designed by a French artist, and in its inside had about six men, who fired squibs through its mouth as it was drawn through the streets. A fairy, backed by a gigantic iridescent shell, stood upon its back, and holding the reins, apparently drove the ferocious beast, though the bulls had most to do with the locomotion, and we photographed the whole arrangement from the balconies af the Englisherof at Lucerne.

At Zermatt there was a spell of fine weather until last Monday night, and tourists had been up the Riffel pretty freely. The churchyard at Zermatt has a mournful record in the various tombs of those who have fallen victims to Alpine climbing, and at the present there is psychological gloom over the place, owing to the death of a German amateur photographer, M. Gœhrs, a young merchant of twenty-seven years of age, who had been staying at the Hotel Mont-Cervin since the 5th inst. On Thursday the 11th he set out with two guides and his apparatus, to make the ascension of the Matterhorn. That night they slept at the Cabin. The next morning they were joined by another party, and though they were occasionally separated, the two parties never lost sight of each other. At about half past seven the weather, which up to that time had been good, became very

RICHMOND BRIDGE.

stormy. The two caravans decided to return. A few minutes afterwards a guide belonging to the lower caravan, hearing some stones fall, turned, and saw Gœhrs, with his two unfortunate guides, all tied together by the rope, falling down the precipice which only ends in the glacier at Zermatt, where the three bodies were found the next morning. A pathetic incident connected with the accident is that on Thursday evening the mother, sister, and uncle of the deceased arrived at Zermatt. Gœhrs was the favourite of his family, and being anxious to "do" the Matterhorn, and at the same time cause no anxiety, had given orders at the hotel to say he had gone to the Breithorn. He had a future before him. His elder brother was killed on the battle-field of Beaugency in 1870.

The conditions affecting the establishment of a meteorological observatory at the Chalet des Bosses, near the top of Mont Blanc, attracted the attention of Section A at the meeting of the British Association at Leeds, the idea being to place there, during the summer months, self-recording instruments which will work by themselves for a few weeks, and then be visited by the responsible official. On inquiry, we were informed that these instruments were to be of a purely mechanical nature. It was admitted that photographic self-recording instruments would do better work; but the objection was the higher first cost of the photographic instruments.

Dr. Janssen has thus communicated his views of his recent ascent of Mont Blanc to the representative of *The Voltaire*:—"The ascent is an exceedingly painful task. You think only of one thing: to look where you step, so that you lose sight of the marvellous panorama unfolded on all sides. You have scarcely reached the summit when the guides hurry you off again. I have proved the possibility of mounting those precipitous heights in a sledge without bodily fatigue. During the entire ascent in that manner I was able to contemplate and admire the scenery. On reaching the top my brain seemed clearer than usual, and I was able to set about my observations and experiments without delay. I see no reason why an observatory should not be established at the Chalet des Bosses, two hours' distance from the summit, and at a height of 4,400 metres above the level of the sea."

OUR ILLUSTRATION.

We place before our readers this week a collotype print on rough paper in imitation of a sepia drawing, Mr. Cembrano kindly yielding to our request that he would lend us his negative for reproduction in this form. The subject is familiar enough to Londoners, for most of us manage to pay an occasional visit to Richmond, which is now so easy of access from the metropolis. But we venture to say that few would have been able to make such an effective picture from this view of Richmond Bridge. Mr. Cembrano has the rare faculty of appreciating a fine effect, and knows well enough whether it is capable of being reproduced as a photograph. He has seized upon this one at just the right moment, and the result is very charming. We may add that the negative is quite untouched.

ON THE REVERSAL OF THE NEGATIVE PHOTOGRAPHIC IMAGE BY THIO-CARBAMIDES.*

BY COLONEL J. WATERHOUSE, B.S.C., ASSISTANT SURVEYOR-GENERAL OF INDIA.

Eikonogen does not blacken or darken the alkaline precipitate much. Nitric acid clears the iodide, but the solution gives but little chloride with muriatic acid. This would seem to show that the iodide is not strongly reduced even by treatment with eikonogen.

Applied in a *strong* solution to a gelatino-bromide film, I have found it darkens the haloid salt of silver in the dark even without alkali, though this does not agree with its behaviour on the precipitated bromide.† When added in very small quantities to the eikonogen developer, it also causes reversal of the image, but in larger quantities it stops reversal. Its action generally seems much more irregular than that of the other thio-carbamides, and I have not yet been able to fully investigate it. It seems difficult to prepare the salt entirely free from the ordinary sulpho-cyanate of ammonia, and to this some of the irregular action may be due. With the hydroquinone developer given above, it produces reversal on Wratten's "ordinary" plates, and appears to be a very powerful accelerator both with this developer and with eikonogen.

I have also made a cursory examination of the effects of the simple *Carbamide or Urea*, which differs from thio-carbamide in containing oxygen in place of sulphur, its formula being $CO<^{NH_2}_{NH_2}$.

A 10 per cent. solution of urea produces no visible effect on silver bromide in the dark. Carbonate of soda added gives off no ammonia, but rather a smell of caustic alkali, and did not darken the bromide. Nitric acid dissolves no silver in the dark. With eikonogen the alkaline bromide was reduced at once to a dark grey. Nitric acid cleared off darkened product, and the solution gave an abundant precipitate of chloride with muriatic acid. With silver chloride treated in the same way carbonate of soda gives off no ammonia, but the same alkaline smell, and causes no darkening of the chloride. With eikonogen the alkaline chloride turned grey at once; nitric acid cleared, and muriatic acid gave a plentiful precipitate of chloride.

With the iodide very little visible change was effected by the soda solution or by eikonogen, though the latter turned it of a greenish-yellow.

Applied to an ordinary gelatine dry plate, a 10 per cent. solution did not *visibly* darken the film, either by itself or with carbonate of soda.†

Urea, used with the eikonogen developer, shows no tendency to cause reversal, whether used in the same small proportions as the thio-carbamides, or in larger ones. I have not yet tried it with other developers. As remarked before, this would seem to indicate that sulphur exerts a very important influence in causing the reversal. It may be noted, however, that sulpho-cyanate of ammonium, added to the eikonogen developer, though it produces a curious silvery metallic surface on the plate, shows no tendency to reversal; nor does hydrosulphate of ammonia, nor hyposulphite of soda. Mustard oil is itself somewhat soluble in water, and phenyl mustard oil (phenyl-thio-

* Continued from page 707.

† The experiments on the darkening and reducing action of all these thio-carbamides and urea on the silver haloids have given somewhat variable results, and require further investigation. There can, however, be no doubt of a *reducing* action taking place without the aid of light.

carbamide) slightly so when boiled. Mustard oil, with or without sulphite, seemed to act as a strong restrainer, the images being clear and weak, with no sign whatever of reversal. The phenyl-thio-carbamide gave a good, dense image with no abnormal effect whatever.

Alloxan, which is produced by the action of strong nitric acid on uric acid, proved a strong restrainer, and gave no sign of reversal when added to the eikonogen developer; indeed, its action seemed beneficial, as also did that of bichromate of potash, which equally showed no tendency to produce reversal.

I have not yet had an opportunity of investigating the action of the spectrum with reference to the reversal of the image with these thio-carbamides, but, from a trial made with a small direct-vision spectrograph on Wratten's plates, developed with eikonogen containing thio-sinamine, it was found that reversal took place only in the ultra-violet from the H-lines onwards; the blue and other rays towards the less refrangible end remained unreversed. With orthochromatic plates the same result was obtained. The addition of bromide to the developer was a great advantage in promoting the reversal and obtaining clear definition. Further trials with the diffraction spectrum appear to show that the reversal is almost entirely a matter of exposure, and may be obtained in any part of the spectrum.

The peculiar feature in these reversals with the thio-carbamides is, that the camera exposures are perfectly normal. Over-exposure prevents reversal, and the best results are obtained by somewhat under-exposing. Views with bright sky and dark foregrounds, or other subjects with strong contrasts of light and shade, are most difficult to obtain fully reversed. In copying it is not so difficult to obtain perfect reversal, though the lights leave much to be desired in clearness. I have tried various clearing agents, but so far without success, though further trial will probably give better results. The addition of bromide to the developer aids in keeping the lights clear, but in excess it attacks the lighter half-tones.

With the phenyl and allyl-thio-carbamides in some cases the image first of all develops quite normally, and then gradually changes, the shadows becoming dark and the lights paler, so as to show a positive image before fixing. In others, especially if a large proportion of the thio-carbamide is used, the image comes up foggy all over, and the reversal only appears on fixing. The reversing effect is most noticeable on the unexposed edges of the plate protected by the rabbet of the carrier, and these generally develop into a strong, dark border round the plate. Some of the images obtained have a beatiful rich effect, though not always perfect in the reversal nor clear in the lights.

On the whole, the best results have been obtained with the allyl-thio-carbamide, or thio-sinamine, and it seems likely that it will work well with hydroquinone, at any rate for copying. The images obtained with it are dense and full of detail, and quite different to the weak, grey reversed images produced by solarisation or over-exposure. Phenyl-thio-carbamide with bromide and ammonia, also works well with eikonogen, and gives fair clearness and density in copying.

As regards the theory of the action of these thio-carbamides in producing this remarkable reversal of the images, I have been so fully occupied with endeavouring to obtain some facts from which a theory might be deduced, and also to work out a practical process, that I have not yet been able to give much attention to the question of how the results are obtained. In any case, it would be difficult to offer a valid opinion in the present state of our knowledge of the curious phenomena connected with reversal and solarisation, and without knowing more of the delicate and complicated chemical reactions involved. The difficulty is increased by the fact that—at least, so far as I can ascertain from the text-books—there is no record of a substance which, added to the developer, will produce reversal with certainty. Eder notes that an excess of hyposulphite of soda in the ferrous oxalate developer will sometimes cause it.

The only parallel case of reversal I have been able to find is that recorded by Carey Lea as caused by the action of hypophosphite of soda on silver bromide films. I have, however, tried the hypophosphite in various ways on ordinary dry plates by treating them with solutions of different strengths, and then developing either wet or dry, or by adding the salt in various proportions to the developer; but neither with the eikonogen nor ferrous oxalate developers have I been able to obtain any sign of a tendency to reversal, and the same applies to solutions of glucose alone, or with ammonia, and of manna with soda. All these substances, applied to the film in various proportions, showed, especially the last, a marked increase of reduction and density on development, but no sign of reversal. The effect was quite different to that of the thio-carbamides, and the action of the latter in darkening and reducing the haloid salts of silver without the aid of light is immensely stronger.

I have not yet been able to enter into the question, but it seems not impossible that this darkening and reducing action of the thio-carbamides may have some bearing on the production of Carey Lea's photo-salts, though, if any such salts are produced, they would probably contain sulphur.

(*To be continued.*)

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.—A technical meeting will be held on Tuesday, September 30th, at 8 p.m., in the Exhibition Gallery, 5A, Pall Mall East.

THE true value of art lies in choice of subject. It is idle to talk about the lofty and the ideal in an art unless the subjects upon which that art is exercised are worthy. There must be a subject which demands the artist's best powers for its expression; the treatment of the subject must be in a measure governed by the emphasis laid upon its poetic elements, and the artist himself must have that seer's insight which reveals to him the deeper meanings in all that his art is exercised upon. It is said that Millet imposed upon himself a "mission;" that he felt impelled by strong convictions of duty to paint the sadness and dignity of agricultural life; that he read his Bible nightly, and believed what he read. That a man should paint under the influence of such impulses, and paint pictures of striking power, seems to a technical critic not only distasteful, but incomprehensible. Indeed, one of the modern critics, in despair at such a phenomenon in the French art world, is driven to express his opinion that this peasant, with his Bible readings, his convictions, his love of the labourer, and his wooden sabots, must have been a good deal of a charlatan, and all these things a kind of pose. But if Millet had a "mission," let us hope that more artists will be inspired in the same way. There are none too many prophets willing to go into the wilderness and endure hardship for the truth's sake. The world needs such in art to protest against mere cunning imitation, and to insist upon offering to man's love of the beautiful something better than sensuous beauty, something which is not only beautiful to the eye, but lovely to the thought, inspiring to the imagination, charming to the fancy, and uplifting to the spirit.—*Scribner's Magazine.*

THE CHEMISTRY OF PHOTOGRAPHY.*

BY DR. F. CRESSWELL, L.R.C.P., M.R.C.S.

Many substances undergo change under the influence of light; for instance, carmine slowly decolourises: on the other hand, plants, if grown in the dark, are colourless, but become green by exposure to light. But the changes which take place in photography are chiefly :—

1st. The reduction to the metallic state of haloid salts of silver.

2nd. The reduction of the persalts of iron to protosalts.

3rd. The reduction of chromic acid to chromic oxide.

Of these the *first* is the essential of Daguerreotype, Talbot-type, collodion process of Archer, dry plates, bromide and silver printing, and all the modifications of gelatino and collodio printing-out emulsions, such as aristotype, Obernetter, &c.

The *second* is the basis of platinotype, ferro-prussiate, cyanotype, and the new Kalitype process. The latter Dr. Cresswell thinks will have a good future, now that the price of platinum is so high, and supply so limited, and as results almost equal to platinotype appear to be obtainable by it.

The *third* is used in carbon or autotype printing, the dusting-on process, and most of the photo-mechanical processes.

The object of albumenizing the paper, or adding gelatine to the salting solution in the case of plain paper, is to retain the silver chloride on the surface, and prevent waste by its sinking into the fibre. It is usual to tone the prints with a solution of chloride of gold.

The sub-chloride will remove chlorine from the gold, which consequently is deposited, and chloride of silver is formed; hence the reason for toning before fixing. It is perfectly easy to tone after fixing, but the result would be a fresh formation of chloride of silver, which, not being soluble in the toning bath, would be liable to blacken and deteriorate the print; but in the fixing bath the chloride is removed at the same time as that which was unacted on by light. By using borax, acetate, phosphate, or tungstate of soda in the toning bath, they have a slight attraction for chlorine, and reduce the trichloride of gold to the state of mono-chloride, and thus one molecule of sub-chloride of silver deposits one atom of gold, instead of its requiring three molecules to deposit this amount, and thus the image is less weakened than it otherwise would be. The state of aggregation, and also the colour of the deposit, are also modified by the special salt used.

An emulsion differs from a solution in that it consists of particles not dissolved, but merely suspended in a more or less viscid fluid; milk is a good example of an emulsion. Photographic emulsions require to be boiled for a certain time; the molecules appear to become disturbed in the same way that they do under the influence of light. If the boiling is too long, a plate coated with the emulsion will fog on development without having been exposed.

Gallic acid is a feeble reducing agent, but now pyrogallic acid, which is really a triatomic alcohol, and hydrokinone and pyrocatechin, which are its allied diatomic alcohols, are far more generally used; and now eikonogen, which is merely a fanciful name for amido-β-naphthol-monosulphonate of soda, seems likely to be very generally used where softness is the object in view.

* Report of a paper read at the Enfield Camera Club.

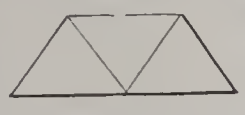
The restraining effect of a soluble bromide in the developer is not easy to explain satisfactorily. It is possible that it offers a distraction, if one may so term it, almost yielding its own bromide to assist in oxidising the developer, and possibly tending also to restore the bromide of silver to its primitive condition, and suppress the latent image.

Alum tends greatly to interfere with the absorption of water by gelatine, and its consequent swelling; it also (especially in the presence of free acids) can dissolve out the brown stain left by some of the oxidation products of pyrogallol; hence a bath of it is recommended either before or after fixing, or both. Many makers now add a small quantity of chrome alum to the emulsion, which is far more active than ordinary alum, and prevents the film swelling, and consequently blistering and frilling. If to the fixing bath some bisulphite of soda, commonly called acid sulphite of soda, be added, it will completely bleach all pyro stain; and what is more, the hyposulphite of silver and soda formed in fixing will remain dissolved indefinitely, instead of being deposited as a dirty brown mud as usual, the fixing bath remaining for weeks perfectly clear and bright.

It is a very good plan with both plates and emulsion paper, after fixing, to immerse them for about fifteen minutes in a 2 per cent. or 3 per cent. solution of chrome alum; this causes the gelatine to shrink and eliminate most of its absorbed water, and also renders it quite insoluble; and further, it destroys any hypo which may have been left in the film. After this treatment it is possible to dry a plate at the fire without fear of the film melting; the film, when dry, is exceedingly hard and horny. The plate must be washed both before and after using the chrome alum, but a much shorter time will be sufficient, as no hypo can exist for more than a few minutes in its presence.

FLUOR SPAR IN OPTICAL INSTRUMENTS.

In a paper upon the above subject by Professor Sylvanus Thompson, read before Section A of the British Association, the author said that the use of fluor spar in lenses renders less curvature necessary, therefore higher definition is obtained. He described a new direct vision prism made as represented in the accompanying cut, in which an Iceland spar prism is cemented between two fluor spar prisms, by which means the light is polarised as well as dispersed. He also described a compound prism in which a dense flint glass prism is sandwiched between the other two of fluor spar; this arrangement gives wider dispersion.



A discussion followed, in the course of which Sir William Thompson said that the arrangement was a beautiful one. Mr. Glazebrook stated that he had had difficulty in getting suitable fluor spar for optical purposes: the largest piece he could obtain was of pyramidal form, two inches square at the base, and about two inches high. Professor Fitzgerald stated that fluor spar is not very hard, but a little harder than Iceland spar.

Nitric Acid Fumes.—Two members of the Newcastle Fire Brigade, it is reported, died on Tuesday, while the superintendent remains in a dangerous condition, from the effects of the fumes of nitric acid inhaled in extinguishing a fire on the premises of Messrs. Mawson and Swan, Mosley Street, Newcastle.

PHOTOGRAPHIC COPYING AND PROJECTION APPLIANCES.

ONE of the papers read before Section A of the British Association was by Professors Barr and Stroud, of Leeds, who said that photographic lantern slides were much used in popular lectures, but had not hitherto been applied to any great extent in class-room work because of various drawbacks, such as the necessity for employing an assistant and the darkening of the room. By the method they were about to describe, a slight darkening only of the room was necessary, so slight that the students could see to take notes.

Their class-room, they said, has a number of beams, such as A E F, across the celling, with lights at H K on both sides of the beam A. L N are two black-boards, and M an inclined white lantern screen, with a projecting ledge at the top to prevent direct light from H and K falling upon the face of the screen. T is the lecturer's table, and W the optical lantern pointing upwards to the screen M, and under the direct control of the speaker. The projection-lens of the lantern is of short focus. The slides are laid out upon white paper alongside the lantern upon the table, and the direct light from above enables the speaker with ease to select any slide he requires for the purposes of illustration. The lantern slides are made on the premises, and about fifty per week are turned out for teaching purposes in the Yorkshire College of Science.

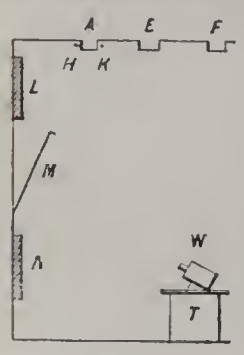


Fig. 1.

An optical lantern in use at the College is represented in fig. 2, in which A is the light, E a lantern condenser consisting of two plano-convex lenses, at such a distance from the light as to give parallel rays; F is a mirror hinged at its upper end, and in the diagram it is represented as placed at an angle of 45° to throw the rays upwards through the lens K, which renders the rays convergent; they next pass through the projection-lens N, and are reflected to the screen by the mirror W. When the mirror F is raised until it is parallel with the top of the lantern the light is cut off from the lens K, and passes through the lens H, after which it may be made to pass through a lantern slide and projection-lens, so as to throw an image upon the screen direct. Drawings may be made upon any transparent film or plate laid upon the top of the lens K, and the progress of the drawing be seen upon the screen; and certain suitable chemical or physical experiments may be performed on the top of the lens K, and thus be represented on an enlarged scale on the screen. When one lantern slide is placed just before H, and another just over the lens K, dissolving-view effects can be produced by suitably moving the mirror F.

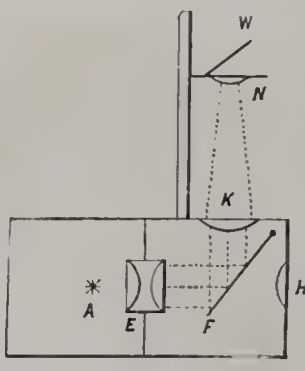

Fig. 2.

A part of the apparatus used at the Yorkshire College in copying may be explained by the aid of fig. 3, in which A E is a board, upon which rests the open book H, with one of its covers and some of its pages hanging down; the front vertical page opposite A K contains the engraving which has to be copied, and which is illuminated from the front by two artificial lights. The general appearance of the arrangement from the front may be indicated by fig. 4, in which A H is a kind of box, but open at the front and back, and N M is the page of the book hanging down. K L are two small vertical boards, which can be moved towards or from each other, but the boards are always equadistant from an imaginary vertical line between them. The shaded portion of the diagram represents the engraving to be copied. Thus, when any picture is arranged so that it is bounded by the two boards, it is truly centred so far as the horizontal position is concerned. The two boards also serve the purpose of keeping the pages flat.

Fig. 3.

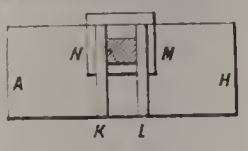

Fig. 4.

The picture in the book being always truly centred horizontally, the camera requires but adjustment for the vertical position, and the principle by which this is effected may be explained by the aid of fig. 5, in which the base A H is always at the same level, and base L Z, on which the camera is fixed, can be placed at any level by a slot and screw arrangement represented above N. To keep the upper base-board steady, two boards, W M, are hinged to the upper and lower bases; they are likewise firmly hinged to each other at K; this prevents vibration in one direction. Another pair of hinged boards, T V, is at right angles to the pair of boards just described, and prevents vibration in another direction. The whole of the arrangement just described runs upon rails in front of the picture, and can be fixed at any point. No focussing by the aid of vision is necessary with this apparatus, which is suitably provided with pointers and graduated scales, so that all can be done by measurement.

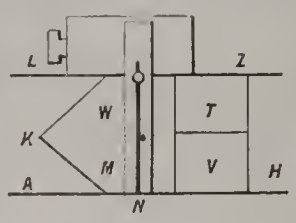

Fig. 5.

After Professors Barr and Stroud had explained the nature of the apparatus, the following discussion took place:—

Dr. Oliver Lodge was pleased with the extreme beauty of the contrivance for centreing. He was in the habit of throwing lantern views upon the screen without darkening the room; he used an oil-silk screen, very translucent, and but three feet square, so as to obtain strong illumination; stray light must be excluded from the back of this arrangement, but light in front does no harm.

Dr. Jacobs had for a long time used the apparatus described by the authors of the paper, and lantern slides could quickly be turned out by its employment. He used daylight instead of artificial illumination. At a large technical school connected with the Mechanics' Institute in Leeds they had two screens fitted up as described, so that such were not in use at the Yorkshire College alone.

Professor Barrett used a small screen and a strong light. He did not quite agree with Professor Lodge as to the value of highly translucent screens; they were all very well for observers in front, but those at the side could not see so perfectly. He had tried glow lamps in the lantern, but they gave off too much heat.

Professor Fitzgerald asked if it was easy to colour slides, for the introduction of colour was sometimes necessary for scientific purposes.

Professor Barr said that the screen the authors of the paper

used was about five feet square; with a translucent screen, the speaker for some purposes requires the assistance of another person. An objection to the use of daylight in making the slides was the varying character of the illumination, and the operator then cannot always depend upon working with ease and certainty all day, whereas suitable artificial light can always be trusted. The apparatus which had been described could be used for copying negatives, and in some cases for copying natural objects; in copyiug negatives a sheet of white paper was placed behind. He had had no experience in colouriug lantern slides, but any man who did the colouring for scientific purposes should have a knowledge of the subject in relation to which each slide was to be used.

Professor Stroud said that there was little loss of light by the use of the two reflecting mirrors in the lantern he had described; the upper mirror must be a true one, but good looking-glass would answer for the lower.

The chairman, Dr. J. W. L. Glaisher, remarked that much mechanical skill had been devoted to the construction of the apparatus brought before the Section.

THE BRITISH ASSOCIATION COMMITTEE ON GEOLOGICAL PHOTOGRAPHS.*

Shropshire.—Caradoc Field Club (photographed by W. W. Watts, Sidney College, Cambridge), size 4 by 3½ inches:—Registered No., 80, Minsterley (road to Bishop's Castle), 1887 (1)—Section at Hope Dingle, showing unconformable junction of Silurian on Ordovician; 81, ditto (near Fox Inn), 3—Basin produced by folding of beds of Middle Areuig Ash; 82, Pontesbury (Nills Hill) 1887, 6—Stiperstones (Quartzite); 83, ditto (7)—ditto; 84, Minsterley (Tasgar Quarry), 8—Upper Arenig Ash; 85, Whitlery Bridge (9)—Whitlery Ash (Bala or Lower Caradoc age); 86, Wotherton (Barytes Mine), 1885 (10)—Fault in Whitlery Ash; 87, Todleth Hill (E. Side Farm), 1885, 11—Crags overlooking Hurdley, columnar intrusive andesite; Much Wenlock—Wenlock limestones; Wrekiu, from Beuthal Edge, Broseley (Corbett's Dingle)—Bedding and jointing in carboniferous saudstone.

Yorkshire.—Per Arthur S. Reid, Trinity College, Glenalmond, N.B. (photographed by Dr. E. S. Reid):—Registered Ro., 39, 40, Draughton (near Skipton)—Contorted limestoue; 41, Boltou Abbey—Faulted synclinal in limestone. Yorkshire Geological and Polytechnic Society (per James W. Davis) Chevinedge, Halifax; size 11 by 8 inches:—Registered No. 19, Raygill Quarries, with fissures, 1875; 20, Plumpton Rocks, 1879; 21, Scarborough Castle, 1883—Nodular concretions in calcareous grit; 22, Wadsley (near Sheffield), 1876—Fossil trees in lower coal measures; 23, 24, Flamboro' Head, 1882—Erosion of chalk; 25, ditto—Thorwick Bay—Chalk surmouuted by drift: 26, Clayton (near Halifax), 1886—Roots of stigmaria; 27, Hilderthorpe, 1887—Current-bedded sands; Draughton, 1871—Contorted limestone; Moughton Fell, 1877—Junction of Silurian with Carboniferous limestone; Gordale Scar, 1878; Raygill Fissure, 1880—During exploration; Norber, 1881—Erratic blocks; Bempton Cliffs, 1885—Contorted chalk. Per Yorkshire Naturalists' Union, Geol. Photo. Section (photographs taken for the Leeds Geological Association,† by F. W. Branson, 14, Commercial Street, Leeds), size 7 by 5 inches; enlarged series 14 by 10 inches:—138, Longley's Brick Works, Leeds—Coal measures above "Beeston" bed; 139, Grosvenor's Yard—"Beestou" bed (8 to 9 feet) and Coal measures; 140, Boyle's Quarry—General Section, "Crow coal" and Coal measures above and below; 141, ditto—ditto (detailed); 142, Dolly Lane, Brick Yard—"Black red" coal; 143, Benson Street, Brick Yard—"Better bed" coal, &c.; (photographed by J. E. Bedford, Cardigan Road, Leeds (for Leeds Geological Associatiou, size 6 by 4 inches):—144, Armley (near Leeds) 1882—Elland flagstones; ruptured shales and flagstones; 145, Draughton (near Skipton) 1885—Contorted limestone (anticlinal and synclinal); 146, ditto, 1885—Slickenside at side of an anticlinal; 147, Bridlington, 1886—Cross-bedding in gravel; 148, ditto—Freshwater gravel on boulder clay; 149, ditto—Lake deposit lying on boulder clay; 150, Filey, 1886—Drift lying upon Oolitic limestone, showing atmospheric denudation; 151, ditto—ditto; 152, The Brig Filey—Oolitic beds at the Brig; (photographed by A. E. Nicholls, Borough Engineer's Office, Leeds, for Leeds Geological Association, size 6 by 4 inches):—153-5, Castleford, 1890—Three views of fossil tree stem *in situ* in coal measures; 156, Haddockstones, 1889, between Markington and Ripon—Isolated blocks of Plumpton grit; 157, 158, Sections on new railway, 1889, Ilkley to Skipton—Vertical and contorted Carboniferous limestone; 159-164, Garforth and S. Milford, 1889—Six views of Quarries in Magnesium limestone, showing methods of quarrying and varieties in bedding; 165, Knaresborough Castle, 1888—Base of Magnesium limestoue, with underlying "3rd" grit; 166, ditto, 1888—Plumpton rocks; 167, Dudley Hill, Bradford, 1890—Lower Carboniferous sandstone; 168, 169, Brough (near Hull), 1889—Post-tertiary gravels, resting on Oolitic outlier at base of the chalk wolds. Photographed by Godfrey Biugley (for Leeds Geological Association), 15 Cardigan Road, Headingley, Leeds; size various:—Registered No. 170, 171, Burnsall (near Skipton) 1890—Ridge of limestone crossing valley of the Wharfe: 172, Saltburn, 1888—View of drift hills; 173, ditto—Valley cut in drift; 174, ditto—Sandhills and drift; 175, ditto, Hunt Cliff, 1888—Middle Lias and ironstone band; 176, Whitby Scar, 1888—Lias and Oolite; 177, Staithes (Penny Nab) 1888—Middle Lias; 178, ditto (Colborn Nab) 1888—ditto; 179, Hayburn Wyke (near Scarborough) 1887—Sea cliff and waterfall; 187, ditto—Lower Shale and sandstone, Oolite; 180, Thornton Force, Ingleton, 1890—Base of Carboniferous limestone, resting uncomformably on Silurian; 181-184, Norber (near Clapham) 1889—Erratic blocks of Silurian grit resting on Carboniferous limestone; 185, Ewe Nab, Carnehan Bay, 1887; 186, Scarborough Cliffs (near the Spa); 188, Headingley, Leeds, 1888—Cliff in Lower coal measures; 189, 190, Adel Moor, Leeds, 1890—Large weathered blocks of Millstone grit (*in situ*); 191, Bolton Abbey—Yoredale shales; 192, Bolton Woods, 1888—Valley of the Strid through Millstone grit; 193, Flamborough, 1887—Arch in chalk cliff; 194, ditto, Chalk cliff; 195, ditto, Thornwick Bay—Caves in chalk; 196, ditto—showing marine erosion of chalk beneath and atmospheric action denuding drift above.

(To be continued.)

* Continued from page 729.

† These were photographed in 1885, and were temporary sections, but extremely valuable as showing the succession in the Lower coal measures from above the "Beeston" bed to those immediately above the Elland flagstone.—S. A. Adamson.

London and Provincial Photographic Association.—The following will be the subjects for consideration on the dates named:—October 2nd, "Keeping and Testing Sulphite of Soda"; October 9th, first Lantern Night, and Demonstration on Lantern Objectives by Mr. T. E. Freshwater; October 11th, "Pictorial Definition," adjourned discussion resumed by Mr. W. E. Debenham.

A Useful Novelty.—We have received a variety of samples of a novelty which photographers can turn to good advantage. The novelty consists in producing transparent or water-marks in paper, which is accomplished in the following manner:—Paper is first coated with a mixture of gelatine, sugar, and bichromate of potassium. When dry, print under a negative in direct sunlight. Develop simply in hot water, same as a carbon print; the hot water washes out all the gelatine not rendered insoluble by the action of light, leaving a picture in high relief, which is hardened with alum. After being thoroughly dried, it is simply passed through a roller press, together with a sheet of thin paper or cardboard, which produces the water-mark effect. There are many applications to which this process can be applied for advertising purposes, for making bank cheques and official documents with a peculiar private mark, or the portrait of the individual who signs the cheque; or it can be used in making fancy stationery, note paper, visiting cards, with portrait of sender, fancy designs, &c., all of which are prominently visible when viewed by transmitted light. There are many ways where this process may be made useful as well as ornamental, which will suggest themselves to the ingenious worker. We are not certain that the relief could not be used for taking inked impressions from.—*St. Louis Photographer.*

Notes.

"The greatest wonder of the age! It will take your portrait as good as a photograph, and much more like the original." These words arrested our attention the other day, hard by the Strand, where an itinerant vendor was surrounded by a small knot of idlers. We had before heard of cheap apparatus, but were not prepared to learn that it had at last come down to the level of the humble penny; so we paused in order to become better informed. The street merchant produced a tiny metal frame—like that commonly used for ferrotype portraits—which appeared to have in it a piece of plain, transparent glass. He invited one of the crowd to breathe on the back of this glass, when there appeared thereon the word "myself." The frame was now reversed and again breathed upon, when there appeared the head of an animal with elongated ears—the only token that it was meant to portray the genus "moke."

A short time ago this time-honoured joke was met with in Paris in yet another form, through the medium of the penny-in-the-slot principle. You were invited to drop your coin into the apparatus, when your portrait would appear, and you were rewarded for the loss of your money by the apparition of a donkey's head. It would be interesting to know why the patient animal with the ears should be associated with foolishness, for a properly cared for donkey is by no means a stupid creature. But the joke is certainly an old one, as is evident from certain well-known carieatures which date from the beginning of the Christian era. It was, we believe, Scribe who, in reply to a nobleman who wished that writer to produce a work with his (the nobleman's) name attached to it as author, said that it was forbidden by scripture to link the horse and the ass together. The nobleman was equal to the occasion, and demanded in return what Scribe meant by calling him a horse?

The seller of penny toys has not, as yet, invaded the photographic world to any great extent. Expense, trouble, and ignorance of chemical operations stand in his way. It would hardly pay him to produce "magic photographs"—*i.e.*, prints bleached out with mercury, and capable of being rendered visible once more by hypo-saturated blotting paper—for one penny, but perhaps it will be done some day. The penny-in-the slot company is the nearest approach to abnormal cheapness, but this, for some reason, hangs fire, although the requisite capital to launch the enterprise was long ago subscribed by a confiding public.

These penny vendors and street sellers generally would themselves form a not uninteresting portrait gallery. How familiar are some of those faces to him whose work takes him citywards day by day, and how some of the unfortunate creatures have disappeared from the seedy ranks even within our own memory. Where, for instance, is the simpering vendor of "brandy balls! balls! balls!" with his tasselled cap and white apron? Where is the hump-backed man who used to sell newspapers on London Bridge Steamboat Pier, and where is the blind man with one ear who used to haunt the neighbourhood of Charing Cross? It is not, perhaps, generally known who these last two really were. The first was a released convict, who, at one time, grossly insulted the Queen; and the man with one ear was Burke, who gave evidence against his accomplice Hare in the awful body-snatching cases at Edinburgh. What experiences of human misery could not some of these wanderers tell us about.

"Fools rush in where angels fear to tread." We rather fancy this proverb will have to be reversed in the case of lady photographers. Gallantry forbids us to call them fools. The reflection is suggested by the statement that Mrs. N. Grey Bartlett, of Chicago, the wife of a prominent analytical chemist, has made an important discovery, by which photographs can be produced without the old-time process of working in a dark room for hours, and staining the fingers. By her process, there is nothing to be done but to expose the negative, with the sheet of paper beneath it, for a few minutes to the light. The pictures produced by Mrs. Bartlett's process are said to have the appearance of fine etchings. The developing solution is stained with ruby dye, which prevents white light from reaching the plate after being immersed in the liquid. This is very interesting, but so very, very old.

A useful association, called the Fire Brigade Reserve—the object of which is to find employment for private firemen out of situations, and form for them a sort of provident association—has, on its application sheet for membership, what appears at first sight a rather curious question. The question runs thus: "If elected, would you deliver to the manager a recently executed photograph of yourself?" On enquiring the reason for this rule, we were told that the photographs were found very useful in two ways. When an employer wants a fireman to take charge of his theatre, warehouse, manufactory, or what not, the collection of photographs is shown him, and he picks out the man he fancies. The second object to which the photograph may be applied is one which, we hope, is rarely necessary. Supposing a man, when in a place of trust, should commit an offence and abscond, the photograph is very useful for purposes of identification.

There is, after all, nothing very new in the first purpose for which the photograph is needed, as for some years past the sending of a photograph has been made an essential condition on the part of applicants who from a distance apply for a situation. As to the second purpose, it might be extended with advantage. Occasionally, bank clerks disappear mysteriously, and so do collectors in various establishments. If the depositing of a photograph were made a *sine quâ non* on the part of all employées who have the handling of

money, it might act as a deterrent to those who are dishonestly inclined, and who find a difficulty in resisting temptation.

A Canadian photographer has just been distinguishing himself as an acrobat. His name is Samuel Dixon, and he hails from Toronto. Recently, in the presence of a multitude of spectators, he crossed the Niagara Falls on a rope stretched from shore to shore. When midway across, he stopped and performed various acrobatic feats; but we are not told whether he was accompanied by his camera, and whether he took a photograph of the multitude while on the tight-rope. This would be an altogether unique achievement, and we trust Mr. Dixon was not so wanting in professional ardour as to neglect this splendid opportunity of what may be called elevated photography.

Mr. Dixon, however, is not the first gymnastic photographer. The celebrated "Lu-lu," known, perhaps, better now as Mr. Farini, is a skilled photographer, and the elder Mr. Farini's book, "Across the Kalihari Desert," contains several astonishing photographic feats, as we noted at the time the book was published. It may be interesting also to know, as a matter of photographic history, that, in the old glass-positive days, photography was found to work very well with acrobatism. Not a few hard-working men practised photography in the daytime, and twisted their bodies into knots at the various minor music-halls in the evening.

Art is progressing rapidly. Even the humble chalk artist of the paving stones finds it necessary to move with the times. The other afternoon, in a well-known London thoroughfare, we noticed a gentleman of the pavement preparing his work, and was busily rubbing in a portrait of Mr. H. M. Stanley from a photograph which he had before him. Next we shall be seeing him draw from life the broken plate, the mackerel, the pound of cheese, and all the rest of the still life which this particular school of art affects.

Judging by the reluctance which convicts generally show when requested to have their portraits taken, it would be interesting to know what the gentlemen incarcerated in the Parkhurst Prison think at being asked to build a studio for taking their own photographs, for witness against themselves should they ever be re-convicted. But perhaps the authorities were sufficiently astute to deceive them on this point; and yet, on second thoughts, this would be rather a difficult undertaking. Somehow a photographic studio—or, as the convict would put it, a place for taking likenesses in—is unlike anything else. It certainly bears a resemblance to a conservatory, and yet it is totally unlike, unless, indeed, the studio now building at Parkhurst is anything like the one in the Ordnance Office, Southampton. The Southampton establishment is a conservatory pure and simple, in an isolated position, and elevated in the air. Probably it is none the worse for this.

The difficulty which all amateur photographers have in instantaneous work in the streets is to make sure they have got upon the field the object they want to take. An amateur came home in the seventh heaven of delight the other day from the laying of a foundation-stone. He had got a portrait of the Prince and Princess of Wales with his detective camera, having been fortunate enough to secure a capital position. He at once rushed to his dark room, proceeded to develop, and the plate revealed a capital picture of two uninteresting reporters! We need not record the language used by the amateur on this occasion. He believed that some ill-natured person jogged his arm at the very moment of exposure.

It is said that a certain Capt. Illarinoff, a Russian, is about to start on a riding tour, visiting all the European capitals. He is armed with a phonograph, and also with a detective camera. With the first he will record the utterances of the victims he intends to interview; with the second he will secure their portraits. The material, literary and pictorial, he will afterwards manipulate into a lecture, which, of course, will be illustrated by the indispensable optical lantern. This seems to be a very admirable idea, but will require an enormous amount of coolness, tact, courage, and endurance. Some celebrities—Bismarck, for instance—have a rooted and unreasonable objection to being interviewed. The probability is, that Capt. Illarinoff will have the opportunity of exhibiting a photograph of an irate celebrity ejecting him forcibly from his premises, accompanied by a phonographic record of what the celebrity said on this occasion.

The photograph taken of a great fishing contest, on Sunday week, on the Arun, when nearly three hundred anglers competed, ought to make a very interesting picture. We are not informed whether the photographer was also an angler. We believe that the angler-photographer is considered by his friends who practise the gentle craft as rather a nuisance. He is wanting in that steadfastness of purpose and patience which are necessary qualities in your angler. We are inclined to think that the better way to get over the difficulty would be to have an amateur photographer who is not an angler attached to each angling club. The photographer's work should be confined to photographing the spoil, because this is all the angler cares for; beauty of scenery is to him of no importance. Artists are generally very inaccurate when they make drawings of fish, and photographs would be very valuable in this direction. Besides, photographs would also be useful in the interests of truth. Anglers have an amiable weakness of enlarging the weight and size of the fish abnormally, and a photograph might act as a valuable check upon the imagination.

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

IV.—GRADATION.

THE above experiments have shown that, with a well-balanced developer, there is a limit to density, which depends upon the action of the light, and that, so far, the only control the photographer has lies in deciding whether he will reach that limit or not.

It also became evident that if two different densities be developed upon the same plate to their extreme limits, the ratio existing between these limits must depend solely upon the action of the light. The question we have now to consider is whether it is possible, by any modification of development, to influence this ratio, and whether this same ratio exists at all stages of development.

In making these experiments, the source of light we have adopted is a standard candle placed at one metre distance from the plate. We then produce a number of gradations upon the plate by exposing different portions of it to the light for different periods of time, always leaving one portion of the plate unexposed.

In order to show that the length of time of development does not affect the ratio of densities among themselves, but increases every density by proportional amounts, we give the following experiments, made with various plates, ferrous oxalate being the developer used. The tables show the densities obtained, their ratio among themselves, and the ratios of the two corresponding densities obtained by long and short development.

All densities are given exclusive of fog (the density of unexposed plate being subtracted from density of exposed plate).

Experiment 13.—Gradations. Ferrous oxalate.

Plate used	Exposure C.M.S.	Short Development, 4 Minutes		Long Development. 12 Minutes		Ratio. $\frac{D_2}{D_1}$	Remarks.
		Density D_1.	Ratio.	Density D_2.	Ratio		
Ilford Red Label. (1.)	10	·775	1·0	1·260	1·0	1·63	Greatest error, ± 2·4 per cent.
	20	1·000	1·29	1·660	1·31	1·66	
	40	1·180	1·52	1·96	1·55	1·66	
	80	1·250	1·61	2·08	1·65	1·60	
					Mean.....	1·64	
Wratten's Drop Shutter. (2.)	10	1·17	1·0	1·74	1·0	1·50	Greatest error, ± 3·4 per cent.
	20	1·67	1·42	2·37	1·36	1·42	
	40	2·06	1·76	2·91	1·67	1·41	
	80	2·26	1·93	3·33	1·91	1·47	
					Mean.....	1·45	
"United Kingdom." (3.)	10	·160	1·0	·275	1·0	1·70	Greatest error, ± 5 per cent.
	20	·313	1·95	·485	1·76	1·55	
	40	·518	3·23	·830	3·01	1·60	
	80	·703	4·39	1·145	4·14	1·63	
					Mean.....	1·62	

The greatest errors are comprised within those limits within which our method of measuring densities is only reliable.

The results clearly show that the ratio of densities is given by the light alone, and is not affected by the time of development, a fact quite in accordance with the conclusions previously arrived at.

This ratio, we find, is altogether unalterable. No modifications we have made in developers or in development have ever seriously disturbed this ratio of the densities. We quote the following few experiments in support of this statement.

Experiment 14.—The plate, a "Manchester Slow," having received three different exposures, was cut into four portions; two were developed with hydroquinone, and two with eikonogen for different lengths of time. The densities are given exclusive of fog, which, with both developers, was very considerable.

Developer.	Exposure C.M.S.	Short Develop.		Long Develop.		Ratio $\frac{D_2}{D_1}$.	Remarks.
		Density D_1.	Ratio	Density D_2.	Ratio.		
Hydroquinone.	Seconds.						Short time = 2·5 m.
	10	·485	1·0	·785	1·0	1·61	Long time = 7·5 m.
	20	·875	1·80	1·385	1·76	1·58	Mean ratio, 1·55.
	40	1·450	3·0	2·120	2·70	1·47	Greatest error, 1 per cent.
Eikonogen.							Short time = 4 m.
	10	·310	1·0	·580	1·0	1·87	Long time = 12 m.
	20	·560	1·81	·980	1·7	1·75	Mean ratio, 1·79.
	40	·905	2·92	1·600	2·76	1·76	Greatest error, 4·1 per cent.

Experiment 15 shows that the same result is obtained with pyrogallol development. Plate used: "Manchester Slow." Densities exclusive of fog.

Exposure.	Developed, 3 min. Ammonia added at once.		Developed, 18 min. Ammonia added in 6 doses every 3 min.		Ratio. $\frac{D_2}{D_1}$.	Remarks.
	Density D_1.	Ratio.	Density D_2.	Ratio.		
Seconds.						Mean ratio, 1·15.
10	·385	1·0	·420	1·0	1·09	
20	·770	2·0	·850	2·0	1·10	Greatest error, 5 per cent.
40	1·095	2·84	1·315	3·1	1·19	
80	1·455	3·7	1·765	4·0	1·21	

Experiment 16 is important because it contradicts emphatically the belief that gradations of an over-exposed negative can be altered by using greater amounts of bromide. Plate: "Manchester Slow."

Exposure.	Developed, 4 min. 100 c.c. = 0·22 NH_4Br.		Developed, 12 min. 100 c.c. = 0·66 g. NH_4Br.		Ratio $\frac{D_2}{D_1}$.	Remarks.
	Density D_1.	Ratio.	Density D_2.	Ratio.		
Seconds.						Mean ratio, 1·15.
10	·440	1·0	·485	1·0	1·10	
20	·840	1·91	·965	1·98	1·15	Greatest error, 1·3 per cent.
40	1·200	2·73	1·440	2·97	1·20	
80	1·625	3·70	1·900	3·90	1·16	

Experiment 17.—For this experiment a "Wratten Ordinary" plate received four different exposures. It was then cut into four portions, and each portion was developed with a different developer. The result is extremely interesting and important, since it shows that the ratio between the various densities is identically the same whatever developer is employed, except in the case of eikonogen, in which the ratios are a little different. We shall recur to this difference in another place.

* Continued from page 738.

Time of Development Different for each Developer.

Exposure.	Ferrous Oxalate		Pyrogallol.		Hydroquinone.		Eikonogen.	
	Density.	Ratio.	Density.	Ratio.	Density.	Ratio.	Density.	Ratio
C.M.S.								
10	·310	1·0	·320	1·0	·410	1·0	·300	1·0
20	·535	1·7	·550	1·7	·695	1·7	·470	1·6
40	·810	2·6	·805	2·5	1·000	2·4	·645	2·2
80	1·080	3·5	1·005	3·1	1·400	3·4	·820	2·7

These experiments all confirm the statement that the gradations of a negative, as expressed by the ratios of the densities, are independent of time of development, cannot be affected by alterations in the composition of the developers, and are almost identically the same whatever developer is employed. We are thus driven to the conclusion that the photographer has no control over the gradations of the negative, the ratios of the amount of silver deposited on the film being solely dependent upon the exposure. The photographer has the power to increase the total density by prolonged development, but by no means at his disposal can he alter the ratios existing between the amounts of silver reduced in the various parts of the negative; they are regulated entirely by the exposure. These ratios are not even altered by intensification after development, as is shown by the following results:—

INTENSIFICATION.

Experiment 11.—Plate, "Wratten Ordinary," exposed and developed with ferrous oxalate, measured, and afterwards intensified and measured again.

Exposure.	Before Intensification.		After Intensification.		$\frac{D_2}{D_1}$.
	Density D_1.	Ratio.	Density D_2.	Ratio.	
10	·31	1·0	·60	1·0	1·93
14	·50	1·61	·91	1·5	1·82
20·5	·67	2·16	1·30	2·16	1·94
29·3	·86	2·77	1·71	2·85	1·98
11·9	1·03	3·32	2·15	3·5	2·08
60	1·30	4·19	2·56	4·2	1·96
				Mean ...	1·95

It will be seen that the process of intensification has almost exactly doubled the amount of silver on the plate. Almost the same result was found in the following experiment:—

Experiment 19.—Similar to last experiment.

Exposure.	Before Intensification		After Intensification.		Ratio $\frac{D_2}{D_1}$.
	Density D_1.	Ratio.	Density D_2.	Ratio.	
10	·260	1·0	·475	1·0	1·82
20	·460	1·8	·850	1·8	1·85
40	·700	2·7	1·270	2·6	1·81
80	·950	3·6	1·700	3·6	1·79
				Mean ...	1·82

In this case intensification did not quite, but very nearly, double the amount of silver in each density, but the ratio existing between the several gradations is again not affected at all.

We see, therefore, that whatever may have been the mode of development employed, and whether intensified or not, the ratios of densities are characteristic of the action of the light, and can be alone relied on in investigations respecting the action of the light on the sensitive film.

REDUCTION.

There is only one process known to us, so far, which will totally alter the ratios existing between the deposits of silver on a negative, viz., the process of reduction, that process consisting in immersing the developed plate into a solution of potassium ferricyanide and sodium thiosulphate (hyposulphite). This process so alters the ratios, that photographers ought to use it very cautiously.

Experiment 20.—Plate exposed, measured, and reduced by immersion in potassium ferricyanide and sodium thiosulphate.

Exposure.	Before Reduction.		After Reduction.		Ratio $\frac{D_1}{D_2}$.
	Density D_1.	Ratio.	Density D_2.	Ratio.	
10	·410	1·0	·020	1·0	20·5
20	·655	1·6	·130	6·5	5·0
40	1·010	2·46	·365	18·2	2·7
80	1·450	3·5	·680	34·0	2·1

(To be continued).

FAST AND FUGITIVE DYE STUFFS.*

BY PROFESSOR J. J. HUMMEL.

Now, when we study the action of light in these various coal-tar colours, we find that, whereas the members of some groups are for the most part fugitive, the members of other groups are nearly all fast, and it becomes at once evident that the chemical constitution of a colouring matter exercises a profound influence upon its behaviour towards light. Those colouring matters in which the atomic arrangement is similar to that in magenta—*e.g.*, malachite green, methyl violet, victoria blue, &c.—are all similarly fugitive to light. On the other hand, those colouring matters which are closely allied to alizarin possess generally the quality of fastness to light. Members of the eosin group are, for the most part, extremely fugitive; those of the indulin group are comparatively fast. In the Azo group some are fast and others fugitive. It is scarcely necessary to say that the fastness to light of a colour is independent of its commercial value, this being mainly determined by the price of the raw material from which it is manufactured. Neither must we suppose that facility of application of a colouring matter necessarily interferes with its fastness to light, for as a matter of fact, some of the fastest coal-tar colours on wool, *e.g.*, tartrazin, are applied in the simplest possible manner.

On the other hand, the intensity of depth of a colour has more influence on its fastness. Dark, full shades invariably appear faster than pale ones from the same colouring matter, simply because of the larger body of pigment present, and the fading is, consequently, not so perceptible. A pale shade of even a very fast colour will fade with comparative rapidity, and it appears to me that the fugitive character of many of the coal-tar colours is rendered more marked because, owing to their intense colouring power, there is often such an infinitesimal amount of colouring matter on the dyed fibre. I would here ask everyone to get rid of the still prevalent popular idea that the modern coal-tar colours are all fugitive, while those of the older vegetable dye-stuffs are all fast. We have, as I have told you, fast and fugitive dyes in both classes. Of coal-tar colours we have at the present time about three hundred distinct kinds, of which about thirty give extremely fast colours, and an equal

* Continued from p. 712.

number or more give moderately fast colours. On the other hand, out of about the thirty natural dye-stuffs usually employed, we may count ten as giving fast colours. We have, therefore, a total of about three times as many fast coal-tar colours as we have of fast natural dye-stuffs.

This pitting of natural *versus* artificial colouring matters ought surely now to cease, when, through the researches of modern science, two such old and valued friends as madder and indigo have been shown to contain colouring matters also obtainable from coal-tar; and it is by no means improbable—indeed, it is very probable—that in time it will also become possible to prepare the colouring matters of logwood, Brazilwood, camwood, cochineal, and others from this protean wonder of modern times, coal-tar. Of course it is not to be denied that we have a very large number of fugitive coal-tar dyes, and the indiscriminate use of these, due largely to competition, has no doubt injured the reputation of the whole class. Not unfrequently one is asked if there is no method of rendering the fugitive colours fast? My answer is—no. The fast or fugitive character of a colour is an inherent property of the colouring matter used, and dependent mainly, if not entirely, upon its chemical constitution, as I have already said. What, then, can the dyer do to improve the fastness of his coal-tar colours? My answer again is, he must examine very thoroughly the characteristics of every colouring matter, then choose the fastest and reject the rest, or, at any rate, only employ them where they are perfectly admissible.

Such a process of selecting the fittest has gone on in the past with respect to the dye-woods, and such is the sifting process now at work even among the coal-tar colours. Side by side with this there must run the selection of the most brilliant and most easily applied of the fast colours, so that the ultimate goal of perfection to which we should thus attain would be to have all our colours fast, brilliant, and easily applied. I do not forget that many people abhor excessively bright colours, and the much maligned aniline dyes are considered on this account most unworthy of our attention; they jar the æsthetic taste, they are crude, and inartistic. No doubt this is perfectly true when they are used singly, and are inharmoniously arranged, but, given a good range of brilliant colours, it becomes possible, by their varied combination, to produce the most thoroughly pleasing and attractive shades of greys, and olives, and browns, and the thousand-and-one delicate tints beloved by the artist, and they yield, when desired, such as possess a richness and life and body of colour, compared with which the older colours are poor and lifeless.

Let the artist inexperienced, perchance, in the application and proper use of coal-tar colours, confine his attention, if he wishes, to the more sombre and older dye-stuffs, but do not allow him to persuade you that there is neither beauty nor permanence, nor other quality of excellence, in any of the coal-tar colours of to-day. Employ them aright with discretion, with intelligence, and they will not fail to recommend themselves to your better judgment. Rather than describe their discovery as useless, even from an artistic point of view, I would say, all honour to the founders of the coal-tar colour industry. If, in the beginning, he gave us the fugitive mauve, did he not afterwards labour hard and successfully in the cause of the fast artificial alizarin? All honour, then, I say, to Dr. Perkin, who has been instrumental in giving to the world not only fugitive, but fast coal-tar colours.

PHOTOGRAPHY IN GERMANY.

BY HERMANN E. GUNTHER.

BLISTERING ALBUMEN PAPER—WET ORTHOCHROMATIC PROCESS—DARK ROOM LIGHT—COMBINED HYDROQUINONE AND EIKONOGEN DEVELOPER—EIKONOGEN DEVELOPER FOR BROMIDE PRINTS.

Blistering Albumen Paper.—Complaints about blisters on albumenised paper have been numerous of late. The trouble may, however, in almost all cases be avoided by using the method of Mr. Rudolph, which I have recently described in these pages. Another good, though, I think, not quite new remedy, is given by Mr. B. Kröhnke in the last issue of *Liesegang's Photographische Archiv*. He suggests, not to place the prints, after removing them from the printing-frame, directly in water, but to soak them first thoroughly in a solution of 1 part of glycerine in 5 to 6 parts of water for at least five minutes; then to pour off the solution, and to wash well with water before toning them. The glycerine solution may be used over again; it is only necessary to add to it from time to time a small quantity of common salt (½ to 1 gramme to the sheet), in order to render the soluble silver contained in the paper insoluble. It will, perhaps, be more convenient to add to it from the very beginning, and once for all, 5 per cent. of common salt; the glycerine solution will then remain clear, and does not require to be filtered.

The "Wet" Orthochromatic Process.—Mr. Max Jaffé, proprietor of a photographic art printing and engraving establishment at Vienna, publishes in *Photographie* the orthochromatic process which is in practical use in his establishment, and which, as he says, is a modification of the process published in 1878 by Ducos du Hauron. The main points af this practical process are the following:—In 250 c.c. of alcohol of 95 per cent., 2·2 grammes of eosine are dissolved, then 45 grammes of cadmium bromide; the solution is filtered, and 250 c.c. of sulphuric ether added to it. The whole is, with repeated shaking, added to 1,000 c.c. of 2 per cent. plain collodion. The sensitising solution consists of—

Water	... 1,000 c.c.
Silver nitrate	... 165 grammes
Conc. nitric acid	... about 10 drops

The plates are allowed to remain in this solution until the film has acquired a good density, which will take about ten minutes. The plates being highly yellow-sensitive, yellow light must of course be avoided in the dark room. The exposure must be increased for about one half of that required in the case of ordinary wet collodion plates. After exposure the plate is directly developed with the following iron developer:—

Water	... 1,000 c.c.
Sulphate of iron	... 40 grammes
Alcohol...	... 30 c.c.
Sulphuric acid	... 12 drops

The image comes out quickly, the deposit being produced at the end of the development: it disappears if the plate is sufficiently rinsed; the plate is then, as usual, fixed in a concentrated solution of hypo, and then washed. The red tint of the film, owing to the eosine with which it has been stained, renders it difficult to judge whether the plates have been correctly exposed; it is therefore desirable to remove the red stain. This may be done at once by pouring over them water to which a few drops of hydrochloric acid have been added. The same end is, of course, attained by prolonged washing with plain water.

The plates treated by this method are specially sensitive to yellow and green; if the subject to be reproduced contains a good deal of blue, a yellow screen must be used. Deep red comes in the reproduction as dark as in the ordinary process; this may, however, be compensated for by intensifying the parts of the negative which are without the required density. Mr. Jaffé suggests to make use in such cases of very fine graphite (black-lead), which is applied to the weak parts of the negative by means of a leather stump. This method of local intensification may as well be employed in cases where there have been two different colours side by side in the original of equal luminosity, and which on the negative have been reproduced equal in tone, in order to produce a certain amount of contrast.

Dark Room Light.—Recent spectroscopic tests made by Professor H. W. Vogel have shown that few of the commercial dark room glasses are so safe as could be desired. Mr. E. Vogel therefore suggests that the safe ruby glasses, so difficult to obtain, should be replaced by coloured gelatine films, which cut off much less of the light of the flame, being, however, absolutely safe. He proceeds as follows:—1 gramme of aurantia is dissolved, by aid of heat, in 100 c.c. of distilled water. Unless the whole of the aurantia dissolves, a few drops of ammonia should be added. On the other hand, 20 grammes of gelatine are dissolved in 100 c.c. of water. Of the aurantia solution 25 c.c. are taken and mixed with 25 c.c. of the gelatine solution; the mixture is filtered through moistened flannel. With this coloured gelatine solution, thoroughly cleaned and perfectly levelled glass plates are coated, care being taken to avoid air-bubbles. About 30 c.c. of the above solution will be required for a plate of 18 by 20 centimetres. Mr. E. Vogel asserts that, thus prepared, plates completely absorb the blue light, and that they serve very well for dark rooms in which wet collodion or gelatino-chloride papers of low sensitiveness are developed. For the development of highly-sensitive gelatine plates and of orthochromatic plates they are, however, not suitable, since only the blue light is absorbed by them, the yellow, green, and red light passing through freely. For plates absorbing green and red, a red colour, called rhodamine, is recommended by Mr. Vogel; a concentrated solution of it absorbs yellow, green, and violet completely, whilst blue and red light passes through freely. The rhodamine films are prepared as follows:—8 grammes of rhodamine—manufactured by the Badische Anilin und Soda Fabriken, of Ludwigshafen—are dissolved in 250 c.c. of water; also 20 grammes of gelatine in 100 c.c. of water. Then 25 c.c. of the gelatine solution are mixed with 30 c.c. of the rhodamine solution, and the mixture is filtered through moistened flannel. For a glass plate of 18 by 20 centimetres, 50 c.c. of this mixture are taken. If a glass plate coated with rhodamine solution is combined with an aurantia glass plate, a screen is obtained which lets through the red light rays exclusively, and which may be used, therefore, for the development of ordinary gelatine plates. The two plates should be placed with the film sides together after drying, to protect them against injurious liquids. If the glass plates, before coating, are provided with a substratum of collodion, the gelatine films may be easily stripped off after drying, and employed for tourists' dark room lamps. It is said that also the ultra-violet light rays are entirely cut off by the above-described coloured-glass plates. As to the keeping qualities, it seems that the rhodamine films keep best. But also an aurantia glass screen has been used by Mr. Vogel for four weeks daily without showing any alteration.

Combined Hydroquinone and Eikonogen Developer.—In consideration of the fact that eikonogen, *per se*, tends to give flat negatives, though the energy of the developer is impaired, and that hydroquinone, *per se*, acts rather slowly, giving, however, great density, a combined hydroquinone and eikonogen developer is used and strongly recommended by a well-known amateur photographer. Its composition is the following:—

No. 1.

Sulphite of soda, cryst.	60 grammes
Cryst. soda	40 ,,
Distilled water	...1,000 c.c.

After solution to be filtered; keeps any time.

No. 2.

Eikonogen	50 grammes
Hydroquinone	50 ,,

Are placed together in a porcelain mortar, rubbed down to fine powder, and then kept dry for use in a well-stoppered glass bottle. For use, take 1 gramme of No. 2 and dissolve it in 100 c.c. of No. 1. The solution keeps well for several weeks. This developer is said to possess all the advantages of the hydroquinone, iron oxalate, and pyro developers, without their disadvantages. The greatest advantage, however, consists of the fact that the developer, if larger quantities are to be prepared, is always ready at hand, and that larger or smaller quantities may always be prepared without any delay.

Eikonogen Developer for Gelatino-Bromide Prints and Enlargements.—Dr. E. A. Just, of Vienna, recommends the following developer for prints and enlargements on gelatino-bromide paper:—

Sulphite of soda	32 grammes
Carbonate of soda, cryst.	24 ,,
Eikonogen	8 ,,
Distilled water	960 c.c.

Bromide of potassium may be added if required, from 1 to 10 drops, to 1,000 c.c. of the developer. It is recommended to use part freshly-prepared developer with some old added for each print as developed, this being preferable to a quite fresh solution.

Herr Siegsfeld, a German meteorologist, proposes to determine the temperature of the atmosphere at different heights by sending up at night small balloons, each carrying a thermometer and miniature camera, with a flash-light arrangement that may be discharged by electricity.—*The Beacon.*

Speaking of Automatic Machine Companies—the drop-a-nickel-in-the-slot and get your photograph—the *Financial Times* says: "The worst of these automatic companies is that they bear rather too close a resemblance to the machines they profess to work. When the coin has gone into the 'slot' it is next to impossible to get it back again."

Gum Picking in Trieste.—Among the working population of Trieste the "sessolotte"—or "shovellers"—form a distinct and easily recognizable class. These "sessolotte" are the girls employed in sorting and classifying gums, figs, dates, and other produce for which Trieste is an important market centre. They lift the goods out of the original packages by means of a "sessola," or small wooden scoop, and place a supply on a smaller wooden table made for the purpose. The "sessolotta" holds a knife in her right hand, and with this and the fingers of the left hand she is able to sort, in an incredibly short time, the gum or other material which she is told to pick according to size and quality. It is said that the natural gum arabic, as it arrives in Trieste, has to be picked twelve times in this manner before it is finally fit to be brought into commerce as finest hand-picked quality.

THE ABOLITION OF LONDON SMOKE.*

EXPERIMENTS on the question as to whether the illuminating power of gas suffers from travelling long distances, have been made in connection with the gas which travels from the extensive gas works at Beckton to London, and it has been found that its illuminating power is not appreciably affected. The gas from the Beckton gas works is supplied in unusually large quantity, and in a pipe 4ft. in diameter, nine miles long; and there are circumstances in its transit which materially tend to counteract any evil effects from the distance which the gas has to travel. In the first place, the great quantity helps to maintain the conducting pipe at a suitable temperature, thereby lessening the tendency towards undue condensation; and secondly, by lessening the amount of friction to which the gas is subjected. It has been thought also that the adverse influences of distance are fully balanced by the large diminution which occurs in the amount of aqueous vapour.

The capital which is authorised to be raised by the London and suburban gas companies amounts to £21,500,000. Of this about £17,000,000 are actually raised. Another £20,000,000 at least are invested in rolling stock, in railway sidings, wharves, coal waggons, horses, and fixtures by those interested in the coal supply. Thus, it will be seen that nearly £40,000,000 are now in use, invested in the business in one way or the other, apart from the enormous investments by railway companies in connection with the transit. Assuming that the present plan is adopted, I do not myself see any tangible reasons why sufficient capital could not be easily obtained to construct the new system. We have recently seen in the prodigious undertaking of the Manchester Ship Canal, how investors are ready to obtain fresh outlets for their accumulating sources of wealth; and it is notorious that whenever there are schemes which are of service and profit to the community afloat, there is little difficulty generally felt in obtaining the capital required to carry them out. The total income, less public lamp charges of the metropolitan and suburban companies in 1888, arising from gas rentals, meter and stove rentals, rent, and miscellaneous receipts, amounted to £5,087,942. The net profit of these companies in that year was about £1,600,000, and they paid about £210,000 in rates and taxes. This represents, of course, only the side of the question relating to the gas manufacture. It is difficult to arrive at the actual amount of profit obtained by the coal retailers, all of which would be saved by having London lit, heated, and worked by gaseous fuel. For the enormous amount of capital which is at present invested in gas works, in mains, in the undertakings of the London companies, and in the railway stock and gear which it is necessary to use, it would be exceedingly easy to reconstruct, on a scientific and satisfactory basis, the whole of the lighting and heating arrangements of the metropolis.

There remains one other consideration in this scheme which presents, I confess, most difficulty. It is the question of coal fields, where the gas is to be manufactured. The coal supplies of this country are supposed to be rapidly coming to an end; and it has been prognosticated that the day is not far distant when the supremacy of this country will be seriously affected by the termination of her coal resources. One result of adopting the plan of supplying London with gaseous fuel will be the great economy of coal, through its consumption not being required and reduced to a minimum in the metropolis. The estimates formed of our coal supplies are, however, probably too low, and we find, for instance, in South Wales, at the present time, fresh sources of coal supply being opened in many places. The coal field which is nearest to London will be that of North and South Staffordshire. The coal field which would probably be most useful to select would be either this district or that of South Wales. The only question would be that of additional expense for the laying down of main pipes, and, whilst recognising that as a serious item, one must also remember the corresponding advantages to be derived. I think that once this principle of removing gas manufactories to the more suitable locations of the coal fields is adopted, the difficulty of selecting the coal field will be easily overcome. The expense need not frighten us; the saving would, in the long run, be so enormous and far-reaching that the initial cost could not be prohibitory. The experiments which have be been tried at Manchester by removing mills into the country will be repeated here on an immense scale, and the ensuing benefits will be relatively enormous. Capital being easily procurable, there can be no reason why we should not do for London in gas what the enterprising Liverpool corporation have done for their town, in bringing the more difficult element of water from the wilds of North Wales.

* Continued from page 696.

In commencing this statement, I endeavoured to summarize before you the manifest inconveniences (or some of them) attendant upon our present system of coal consumption in the metropolitan area. I have also attempted to show you upon what lines the reform of that system should, in my opinion, be carried out. The confessed inability of our authorities in dealing with the serious questions before us is due to one great fact: they do not care to face the storm of criticism which must come upon the heads of those who interfere with branches of industry which have become settled sources of livelihood and remuneration. No remedy for fogs and for the winter miseries of our climate can ever be suggested which does not go to the root of the matter. Nothing can ever be done in alleviating the pains and penalties of our present system which does not leave the coal burning out of the question. Free from mist we can never be, but surely it is not too much to hope and to strive for freedom from that black canopy which so frequently deadens the life and lights of London, and which imposes such fearful burdens upon the community. Some amount of mist will, of course, be present under the best conditions, but it is quite possible to rid that mist from the pernicious ingredients resulting from the indiscriminate use of coal in our fires. Some maintain that fogs are good, inasmuch as some of the products of the combustion of coal in the air exercise an antiseptic and disinfecting influence; but, notwithstanding this slight and doubtful advantage, it is certain that whatever degree of purification of the air may be reached in our large towns, there will probably be enough left to exercise this questionable effect. What we have to get rid of is the smoke, which is the dangerous element in the comparatively innocuous mist. There seems no valid reason why our domestic fires should not be supplied by gas in the way which has already been indicated. During the past few years the marked improvement in gas stoves, ovens, heating apparatus, and open gas fires have been so great that we can be said to be only at the threshold of its development as a heating agent. This is the only method by which we can secure smokeless chimneys, and these smokeless fires and economical grates would do away with the present smoke. The advantages of gas fires and stoves are now thoroughly established, and have been well set forth and illustrated by Dr. Carpenter, Mr Fletcher (of Warrington), and others. It only requires inspection of some of the various modern gas stoves in use to prove that they are in every way as pleasant, cheerful, and comfortable as the present dirty fires.

By this means the products and equivalent of coal for heating and lighting purposes would be brought to London at a cost of about one-tenth of the present expense of transit.

By the plan suggested an immense amount would be saved, even in the price of gas itself. It would be safe to say that gas could be reduced to one-half of its present cost, and thus we would have a cheaper, a cleaner, and an efficient mode of heating and lighting hitherto denied to us. There would be the saving in health and comfort, in public resources, the economy of precious time and money. We should have a cloudless sky and a healthy atmosphere, and should stand a better chance of perceiving the rays of the sun than at present. There would be the prolongation of life and the incalculable additions to comfort and ease. Beyond these also we could obtain for the poorer classes benefits of a kind which they would appreciate directly. We could procure a more sanitary and cleanly state of affairs in their homes, and this is no small gain when their normal condition at present is considered. We boast of our wealth, our science, freedom, our

powers of combined exertion, our sense of cleanliness ; we glory in our civilization, but our glory becomes a shame if the present wasteful system is continued.

Even if it were necessary that a vast stock of unused capital should be expended to bring about the reform, I think that it would not be money ill-spent. Not that I agree for a moment that the present capital would be destroyed. It would only be diverted into new channels, just as when gas was first introduced into this country, and when towns were illuminated first by gas, the old musket barrels, laid by in quiet retirement after the fatigues of the great Continental wars, were employed for the conveyance of the gas in lieu of pipes ; and, by a remarkable coincidence, various iron-founders desisted in a great measure from the manufacture of iron ordnance and took up the peaceful employment of casting pipes for gas and water. There would be on the asset side the priceless boon of a healthier and more comfortable people. Besides that we could point to the saving of at least £6,000,000 per year in carriage and distribution and domestic labour, putting aside the question of depreciation of property. If we could total up the fairest estimate of the approximate money waste occasioned by London fogs in the course of a single year, it would be expressed, no doubt, in terms of millions sterling ; and no plan should be set aside without due and reasonable consideration if it presents some practical scheme of reform. The question of expense, of the raising of capital, is in reality not the most formidable. The existing prejudices, the national sentiments of English people in favour of the present English fire, are stronger obstacles to a thorough eradication of the smoke evil than the obtaining of the necessary capital. One does not see why the cheerful fire will not be perpetuated in the equally cheerful, the far more convenient and cleanly gas fire which would be introduced in the new era. Something must be done, and I am certain that when it comes to be done it will be found in the direction which I have endeavoured to point out in this letter.

Aluminium.—The following sanguine reference to a new process for producing this metal we clip from an American journal :—"Photographers and all who handle optical apparatus will be glad to hear that cheap aluminium is now an accomplished fact : a chemist in this city—Chicago—having discovered a method by which it can be produced at less than fifteen cents (sevenpence halfpenny) per pound. It may be made as soft as copper or as hard as steel, and is likely to revolutionise the metallic industries of the country, as everything that is now made of iron in one or other of its forms may be made of the cheapened aluminium. The process has passed the experimental stage, and a company has been formed and a large factory is in course of erection. In the meantime the company will not supply the metal, but only articles manufactured therefrom ; but of course that arrangement will only be temporary."

Correspondence.

LIVERPOOL AMATEUR PHOTOGRAPHIC ASSOCIATION.

Sir,—It may be of interest to hon. secretaries of the photographic societies of the U. K. who are making their arrangements for lantern exhibitions during the coming winter to know that the Boston Camera Club (U. S. A.) are sending us another lecture entitled "In and about Columbus," to be here about end of this month. This is a gift to the Amateur Photographic Society of England by the Columbus Camera Club, on the same general terms as "Illustrated Boston." and "The White Mountains of New Hampshire."

There will then be three sets of lantern slides of about eighty each, with accompanying lecture neatly mounted in type, of American scenery in free circulation in this country, and which can be loaned to any society on application to me.

G. M. Tunstall, hon. sec.

Liverpool Amateur Photographic Society, September 20th.

GLOUCESTERSHIRE PHOTOGRAPHIC SOCIETY.

Sir,—The date being now fixed for our triennial Exhibition, we shall feel obliged if you will kindly announce the same.

The conditions and schedule of awards have been revised, and are now more in accordance with prevailing opinions than the one issued in 1888, although that exhibition proved a success in every way, with its 140 exhibitors, and upwards of 600 frames, besides a large show of apparatus. We hope as before to secure the support of leading amateurs and professionals. The Exhibition will open Wednesday, April 17th, and close on Saturday, April 27th, 1891.

A. H. Clinch, F. H. Burr. } *Hon. Secs.*

P.S.—Prospectus will shortly be issued, and duly advertised.

Proceedings of Societies.

The London and Provincial Photographic Association.

September 18th.—Mr. F. P. Cembrano in the chair.

Mr. A. Cowan spoke of the advantage gained by using spectacle lenses in conjunction with other lenses, when an alteration of focal length was required. He exhibited several prints from negatives taken with a 7½ inch focus lens, with and without the combination of the spectacle lens, showing alteration of size of image. The additional lens should be used as close to the stop as possible, preferably behind it, and if of the meniscus form the convex side should be nearest the back lens.

The Chairman had tried a combination of this kind, but had not succeeded in obtaining such good results, with additional lenses, as a lens of the same normal length would give of itself.

Mr. T. E. Freshwater exhibited a series of micrographs of sections of some chalk formations ; the prints showed very fine detail.

The subject down for discussion was the powder process, which was opened by Mr. A. Cowan, who exhibited a specimen of the process on smooth opal.

Mr. Cowan proceeded to explained the rationale of the process. A tacky organic substance to which potassium dichromate has been added is allowed to dry ; if it is exposed under a negative, it will take different degrees of tackiness according to the intensity of the light acting upon it, a fine powder dusted over the surface adhering to it in proportion to the tackiness. To prepare a plate, it must be absolutely clean ; it is then coated with collodion, and allowed to set. A second coating is given of the formula selected. Mr. Cowan used dextrine, glucose, dichromate potassium, glycerine, and water, modifying the proportions according to the moisture of the atmosphere. After exposure the powder can be applied with a flat brush. He considered it the best of the carbon processes.

Mr. A. Haddon had tried the process, using five to six drops of glycerine to each ounce solution. By omitting the glycerine

be obtained finer high lights. He had used the process in making photo-enamels. Two specimens were handed round. In order to obtain a positive picture a reversed positive must be used. Mr. Haddon, after dusting, reversed the film after floating it off the glass support.

Mr. A. MACKIE considered the powder process might be used with advantage to intensify negatives.

The opening night of the lantern season was fixed for Thursday, 9th of October.

THE SOUTH LONDON PHOTOGRAPHIC SOCIETY.

A MEETING was held at 76, Peckham Rye, on Friday, September 19th, with the PRESIDENT of the Society in the chair. Five new members were elected.

Mr. F. W. HART gave a demonstration in flash-light photography. He brought with him specimens of his various patented lamps, and also of his stands for screens, &c. The demonstrator practically showed the method of using flash-light in the studio, and handed round a large number of specimens of work done by his apparatus. Shortly after the introduction of his lamps, Mr. Hart found the necessity of properly adapted supports for them, and soon contrived, by the aid of light rods, to get to the desired end. He further extended their usefulness by means of the necessary connections, and they are now easily adaptable as supports for lantern screens, and also make an excellent open air studio, with the addition of a few curtains.

Mr. RANSON brought before the members a "New Folding Copying Apparatus," which is adapted for either copying, enlarging, or reduction.

The above business brought the meetings at 76, Peckham Rye, to a termination. The future meetings of the Society will be held at Hanover Hall, Rye Lane, S.E., the first of which will be a lantern night, on Friday, October 3rd. Amateurs wishing to attend can do so by first communicating with the Hon. Sec., S. W. Gardner, 7, Barry Road, East Dulwich, S.E.

PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.

AT a meeting held at 4, Great James Street, Bedford Row, London, on 17th September, Mr. T. E. FRESHWATER in the chair, two applications for assistance were made, and one application was granted, the other being adjourned.

A letter from Mr. W. S. Bird (Chairman of the Executive Committee of the Photographic Section of the London Chamber of Commerce) was read, enclosing 30s., being an outstanding item of the Drapers' Hall Exhibition.

A sub-committee of this Association was appointed to confer with the Photographic Club for carrying out the proposed concert and lantern show to be given by the Club.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES PHOTOGRAPHIC ASSOCIATION.

ON Thursday the 18th, the first and last out-door meeting of the season was held at Gilsland, Lanercost, and Naworth, under very favourable meteorological conditions. Fourteen cameras, ranging from 12 by 10 to stereo and quarter-plate, were in active operation all day, the net result being 113 exposures Driving to Bird Oswald, the Roman camp was the first object to receive attention. The next point of interest was Coombe Crag, a beautifully wooded stretch of the river Irthing, where a couple of hours were spent, numerous exposures made, and considerable amusement created by the misadventures which befel some of the party. Proceeding to Lanercost Priory, a splendid old pile possessing great attractions to those who care for architecture, cameras were soon again in operation, and exterior and interior views obtained in profusion. The beautifully wooded grounds of Naworth followed, and pretty bits were quickly secured, and views of the castle, court-yard, and a fine old tower were obtained. Before starting upon the homeward journey a group of the members was taken by Mr. Auty.

POISONING BY BROMIDE OF ETHYL.—Three cases of poisoning by bromide of ethyl have recently occurred in Berlin, two proving fatal. The dose in each case was only about twenty grammes (310 grains).

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

S. H.—*Reviving Faded Photographs.* A treatment with bichloride of mercury is said to restore the faded impression, but of this we have no experience. The method of development with gallo-nitrate of silver is likewise doubtful. The best plan is to reproduce the faded photographs by the collodio-chloride process, as was done by the late H. Baden Pritchard in the case of the Crimean series in the possession of the War Office authorities. For working details, see the *Photographic Journal* of December, 1870, no camera being required.

OUT OF FOCUS.—*Camera Adjustment.* A bellows camera which has long been kept closed up will often, when first extended, have a tendency to run back again to a shorter focus. To overcome this defect a clamping screw is required, or a wooden wedge may be used, driven just in front of the pinion. High wind from the rear will sometimes push the carrier forward.

T. F.—*Carte Mounts.* Further samples received, which shall have our immediate attention. Meanwhile, the first batch has been returned to us through the post: all shall be examined together.

S. HIGHLEY.—*A Communication.* Duly received, and you shall have an early reply.

AMATEUR.—*Primuline Photographs.* If you refer again to the details printed on page 707 of the NEWS, and the leading article explanatory of the process on page 701, you will see that the treatment with nitrite of soda and acetic acid is necessary to diazotise the primuline before exposure to light. As we stated at the Leeds meeting, the process answers equally well on paper, fabrics, and coloured layers of gelatine.

L. E.—*Bromides in Emulsion.* It is almost a matter of indifference whether the potassium or ammonium bromide is employed, but the first-named salt is generally preferred on account of its more definite constitution. A small addition of iodide has been recommended by Capt. Abney and others, but this will depend on the purpose for which the plates are required.

M. T.—*The Price of Silver.* With the advance in the price of standard silver, the quotation for nitrate must necessarily go up. This ought to be partly compensated by your residues becoming of increased value.

A. S. F.—*Stripping Films.* It is true that with stripping films there is very slight tendency to halation and reversal of image: we have just seen some negatives that had received three or four times the normal exposure, and as regards gradation and brilliancy, leave nothing to be desired.

P. D.—*Sea Gulls.* These birds will often fly in the wake of a ship, expecting to be fed, remaining poised on the wing, and keeping pace with the vessel in such a manner as to be easily photographed.

WIDE-ANGLE.—*Examinations in Photography.* The City and Guilds of London Institute holds annual examinations in May at the Finsbury Technical College and at certain provincial centres, particulars of which can be learned from the secretaries. A small fee is demanded, and certificates and medals are granted for proficiency. It is not necessary to enter for training at the said Institution, and, as it is a written examination, the questions bear upon the scientific side of photography more than the practical.

THE COMING YEAR-BOOK.—We must respectfully request the friends who are thinking of sending us literary contributions for the above, to do so with the least possible delay. We have already stated that it is our wish to place the Annual in the hands of the public at an earlier date, if possible, than has been customary.

VOL. XXXIV. No. 1674.—*October* 3, 1890.

CONTENTS.

POETRY AND ARTISTIC PHOTOGRAPHY.

WITHIN the last two or three years a revival has taken place in that "school" of photography which is largely represented in the present Photographic Exhibition, and which holds that photographs sharp-all-over are inartistic; in addition, it sometimes calls its opponents of another school "sharpists." The latter persons hold that photographs out of focus are bad photographs, that the contemplation of such pictures makes them feel ill-all-over, and that a photograph which gives pain to the observer must be a specimen of bad art. So the war wages, and it wages the more hotly because no universally recognised authorities or rules exist to settle the point at issue, which is one more of individual taste and individual psychical impressions than one which can be decided by any tribunal.

For the representation in artistic form of real and ideal subjects, poetry analogically stands upon much the same foundation as photography and painting. Does the best poetry teem with the rendering of minute detail, or is most of the detail left to the imagination of the observer? Let us, in the first instance, give an example from Congreve:—

ALMERIA.

It was a fancy'd noise; for all is hush'd.

LENORA.

It bore the accent of a human voice.

ALMERIA.

It was thy fear, or else some transient wind
Whistling thro' hollows of this vaulted isle;
We'll listen——

LENORA.

Hark!

ALMERIA.

No, all is hush'd and still as death—'Tis dreadful!
How reverend is the face of this tall pile
Whose ancient pillars rear their marble heads,
To bear aloft its arch'd and ponderous roof,
By its own weight made steadfast and immovable,
Looking tranquility! It strikes an awe
And terror on my aching sight: the tombs
And monumental caves of death look cold,
And shoot a chillness to my trembling heart.
Give me thy hand, and let me hear thy voice;
Nay, quickly speak to me, and let me hear
Thy voice—my own affrights me with its echoes.

Here it is evident that any rendering of minute detail, that any close description of the columns and of the building, would spoil the artistic effect. As the lines stand they excite the imagination, they convey the idea of the presence of some indefinable danger; they work upon that fear of the unknown from which few are free, so that the general effect is impressive.

Here, again, from the Koran is an utterance of Mohammed, truly poetical, and largely so from the play it allows to the imagination because not weighted by petty detail.

As the darkness over a deep sea, billows riding upon billows below, and clouds above; one darkness on another darkness; when a man stretcheth forth his hand he is far from seeing it; he to whom God doth not grant light, no light at all hath he.

Another specimen yet may be given in which great thoughts well up from the depths of man's inner nature, some of them indistinctly, others flashing more clearly, the whole yielding a truly poetical effect:—

An amber heaven fades to faintest grey;
Sky stoops to sea, sea rises grey to sky,
Wave rolls on wave for ever, sigh on sigh—
The death of day.

Art thou, too, dead?
The sea that rolls between, is that Death's sea?
May no hands touch, no solemn echoes fall,
None answering cry if one to other call,
From land or sea?

* * * *

Living or dead
Star-eyed and pale, thy face seems ever near:
Remembering love in life, one hour, one day,
Call once from out the dark, then turn away—
One heart may hear.

Hast thou not heard
Passionate moan of waves that break in tears,
Break on, and die, and still may not forget
The infinite perfection of regret—
These weary years.

Are we, then, to conclude that in all the best poetry much should be left to the imagination of the recipient? Not necessarily. Moreover, some recipients have no imagination. Here is a portion of a poem consisting entirely of clearly cut description of minute details,

yet the general result is artistie and highly impressive :—

"She is dead!" they said to him. "Come away,
Kiss her and leave her, thy love is clay!"
They smoothed her tresses of dark brown hair,
On her forehead of stone they laid it fair;
Over her eyes, which gazed too much,
They drew the lids with a gentle touch;
With a tender touch they closed up well
The sweet thin lips that had secrets to tell:
About her brow and beautiful face,
They tied her veil and her marriage lace;
And drew on her feet her white silk shoes,
Which were the whitest no eye could choose.
Over her bosom they crossed her hands—
"Come away," they said, "God understands!"
And there was silence, and nothing there
But silence and scents of eglantère,
And jessamine, roses, rosemary;
And they said, "As a lady should lie lies she."
And they held their breath as they left the room,
With a shuddering glance at its stillness and gloom.

To attempt to deeide what is the highest form of art in photography is as futile as to attempt to deeide what is the true ereed among those promulgated by different churehes. The eonsideration of ereedal questions sometimes brings to the front magnifieent specimens of intolerance and bigotry who would eonsign all their opponents to fire and faggot if they had the power. In eonnection with sueh subjeets the feelings are aroused, and all ideas of charity or respeet for the opinions of others sometimes thrown to the winds; henee the debates are hot, and eonverts from one side to the other few and far between. The saying that "What is one man's meat is another man's poison," is true also in relation to the appreeiation of alleged artistie productions in photography. Any photographie sehool whieh elaims that it possesses all truth in relation to art, and its opponents none, stands condemned, to a large extent, by its own intoleranee and its elaim to infallibility.

THE OPTICAL LANTERN AS IT WAS.

The approaeh of dark evenings reminds us that the time is at hand when the tourist photographer is thinking of packing up his traps for the winter. But the enthusiast will refuse to remain idle, for he knows that mueh remains for him to do, even at a season when the sun will not give enough of his light and heat to make out-door work either possible or agreeable. Negatives ean be reviewed, arranged, and stored; some ean be set aside for enlarging, aud we may feel certain that a very large proportion of them will be devoted to the making of lantern pictures.

We often hear it stated that the introduetion of the gelatine dry plate has done so much to popularise the art of photography by ereating a new race of amateurs, who could never have existed if the dirty wet plate process had not been dethroned. It is equally true that the popularity of the optieal lantern has inereased to a wonderful degree. By the aid of photography, the lantern had already been ehanged from a mere toy into a most potent aid to education, and few, perhaps, of the younger members of the eraft are aware how mueh the reeent growth and rapid improvement of the instrument are due to the applieation of dry plates to lantern slide making, more espeeially sinee manufacturers have produced a reliable lantern slide plate whieh is easy to use, and most effective when finished.

Under such eonditions, it is not a matter for surprise that the optieal lantern itself should have been the subject of many improvements, but it is diffieult to appreciate their value until we eompare the modern instrument with its predecessor. We have already, in these pages, dealt with the origin and early history of the lantern in the hands of Kircher and others, and we know well enough that these old-time experimenters, groping their way through no end of diffieulties, did wonders eonsidering the times in which they lived. But, in order to appreeiate the marked improvements whieh have taken plaee within the last few deeades, we must go baek not quite so far.

We have before us a book which bears date 1850, and whieh has for its title, "Companion to the Phantasmagorial Lantern." We may point out, in passing, that the "phantasmagorial" lantern differed from the ordinary magie lantern in being movable. It was worked behind a transparent sheet, and gradually approaehed to or reeeded from that sereen, so that the projeeted image —usually a skeleton or terrible monster —became smaller or larger as desired. Considering that the year of publieation was the one before that which saw the opening of the Great Exhibition in Hyde Park, when the wonderful perfection whieh several of the arts had attained was demonstrated, we must eonfess that optical seienee, as evideneed by the lanterns then in use, eould not have formed the subjeet of eareful experiment, or even study. Turning over the pages of this book, we first have an engraving of what is called the "eommon magic lantern," and a single glanee at it is suffieient to comfort us with the reflcetion that it is eommon no longer. Its eondensing lens—a single one—is fashioned after the pattern of the policeman's "bull's-eye," and its objective has the sweet simplicity of the double eonvex lens. Its lamp is an oil one, with a round wiek, the illuminating power of whieh would be far below a standard eandle. As a step forward, we turn to the next pattern shown. In this the eondenser consists of two double eonvex lenses, whilst the objeetive possesses exaetly the same elements, but of smaller size. The latter is set in a sliding foeussing tube, but without the vanity of a raek and pinion adjustment. This seeond lantern is furnished with an argand lamp, so that the projeeted image must have been far better illuminated than in the former case.

But the maker seems to have exhausted all his ingenuity in his "most improved phantasmagorial and mieroseopie lantern." Here we have an instrument that elearly has a double duty, for it can either be moved behind a sereen to produee the wonders of romanee, or it ean be employed to projeet the wonders of nature. There is a slight improvement in the

optical arrangements. The condenser remains the same as in the last case, but the objective consists of a pair of plano-convex lenses with a fixed diaphragm in front of them. The microscope attachment does not, strange to say, screw into the same flange as that provided for the lantern objective—as would be the case in a modern instrument—but projects behind the lantern, so that to use it the operator would have to move the instrument completely round.

Under the best conditions, such apparatus as that described could make but a poor show, and the inflated description of what it could do—quoted in this book from a contemporary journal—is certainly amusing. We read of "a soul-appalling spectacle to those who have hitherto been ignorant of the wonders of light and shade;" of "a ghastly spectre, its eyes moving agonizedly from side to side, or now turned up in the sunken eye-socket, the image of unutterable despair," &c., &c. We much fear that the prosaic boys and girls of the present day would feel more inclined to laugh, and perhaps chaff, at such a "soul-appalling" spectacle, than they would to feel frightened. We must thank photography for conferring upon such exhibitions reality in lieu of romance, and for substituting truth for falsehood.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

The Exhibition of the Photographic Society may be looked upon as a record of the year's progress. One naturally looks round for some novelty, which, though it may not be startling, will yet be significant of original thought and treatment. It does not necessarily follow that the novelty may be a step in advance; if it leads to reflection, and if it be out of the beaten track, it is welcome. There is distinct evidence of a new school of art photography in the present Exhibition, and yet it is not new save in this respect, that the peculiarities in which the late Mrs. Cameron won fame in portraits have been transferred to landscape, plus far greater manipulatory and technical skill. Later on it will be necessary to discuss in detail this revival; it will suffice for the present that the exponents of the new school, Mr. G. Davison and Mr. Lyonel Clark, have the courage of their opinions, and have exhibited pictures which, if they do not call forth universal admiration, will at least stimulate thought and discussion.

After the novelties come the medal pictures. It would be exaggeration to say that the pictures to which medals have been awarded stand out prominently from the rest. This, perhaps, is due to the fact that the Exhibition is of uniform and slightly monotonous excellence. In one point there is an absolute agreement, namely, the entire abandonment of silver printing, with its warm tones, and the adoption of platinotype or bromide prints, more or less cold in hue. It may be that to this fact is due to some extent the apparent lack of superiority in the medal pictures. There was certainly more variety in the old style. Its brilliancy and warmth of colouring in some respects, probably, unconsciously affected the awarding of prizes. Now we get an uniformity of tone, and the judges fall back upon purely artistic qualities. This, no doubt, is as it should be, but on questions of art individual thought steps in, and therefore the unanimous confirmation of the judges' opinion is not to be expected. The peculiar characteristic of the present Exhibition is, that while the medal pictures do not extort the admiration of former years, it would be difficult to say in what respect the judges have erred. Hence the conclusion is confirmed that the general standard of excellence is higher.

Taking the medals in the order of the catalogue, the merits of the new school are recognised by the awarding of a medal to Mr. George Davison for his picture (No. 55), "An Old Farmstead." The effect of this picture is exceedingly pleasing to the eye, and if it be that the quality of a photograph is that it should look as unlike a photograph as possible, then Mr. Davison has succeeded admirably. The composition is well balanced, the light and shade are arranged on what are recognised to be art principles; but the defect—if it be a defect—is that it does not suggest nature. It is not very clear what the mass of growth in the foreground is intended to be. Probably onions run to seed would be the nearest approach to what Mr. Davison has given us in his picture; but it may not matter. The new school possibly goes in for suggestiveness, and if the field of stalks with the knobs at the ends suggests the onion plant, then the object of the picture is answered. It would seem that such photographs as "The Old Farmstead," and others which will be noticed in their turn, can scarcely be criticised on the principles which have hitherto governed photographic art criticism; and it may be necessary to wait until further examples familiarise one with the intentions of the exponents of the new style.

Mr. Lyddell Sawyer is one of the most painstaking and conscientious of modern workers; it is always pleasant to be able to praise him—an opportunity, by-the-way, which one has pretty often. It is, however, by no means so certain that the picture (No. 122) which has gained the medal is the best one he has exhibited. The pictures of shipping on the Tyne will appear, to some tastes, to be more meritorious. However, the judges have decided in favour of his picture entitled "Two's Company," and, as a piece of photographic work, there is nothing to say against their judgment. Mr. Sawyer, however, is apt to fall into the error which mars so many photographs which pretend to tell a story: he essays too much. There is so much which invites criticism when the camera attempts the imaginative, that the simpler the idea, and the less said about it, the better. In Mr. Sawyer's picture, "Two's Company," we get a laughing damsel engaged in a very hot flirtation with a laughing swain, whose pose, by-the-way, is a little bit too energetic to carry out the idea to the best advantage. Further away is a second swain with an intolerable scowl upon his good-looking face. It is not quite clear as to what station of life the three belong—we make bold to say, in itself an oversight—but let this pass; the fault of the picture seems to be the presence of the third party. He occupies the most prominent position in the picture; he attracts the eye, and he is the jarring note, if not in the composition, at least in the idea. Mr. Sawyer, it is to be feared, sacrifices too much to his title. The title of a picture is of not much consequence, providing the story is told with clearness. Having got the idea of "Two's Company," he carries it out to the bitter end; in a word, the picture lacks that which is the aim of the new school—namely, suggestiveness. If a picture leaves nothing to the imagination, then one soon tires of it. Has not Mr. Sawyer made his *de trop* personage far too prominent?

Coming to the next medal picture in the catalogue (No. 165), "The Latest News," by Mr. J. B. B. Wellington, it would be interesting to know what is the special quality the judges have discovered entitling it to distinction. No doubt it fully deserves a medal, but one asks for information. The two girls in the picture, whose heads are in deep shadow, are certainly not prepossessing, and the old man with the stick may be interested about what one of the girls is reading, or may not; it is hard to determine. There is no especial effect as to lighting, nor have there been any extraordinary technical difficulties to over-come. Still, it may be fully entitled to the medal which has been assigned to it.

Mr. Shapoor N. Bhedwar has given us something new in his series of pictures, which are all illustrative of the "Feast of Roses." The medal has been assigned to No. 185, entitled "Hanging the Garland." A few words of explanation, either attached to each picture, or inserted in the catalogue, would make the pictures a little more intelligible to the general public. Mr. Bhedwar's style is that of delicacy and detail. It is to be wished, however, that his models were not so limp and inanimate. The strong point of such subjects as Mr. Bhedwar has chosen should be the arrangement of drapery. It can scarcely be said that Mr. Bhedwar has been altogether successful in this respect. The drapery, it may be said, should follow, or at least suggest, the lines of the human form, but Mr. Bhedwar's drapery will not altogether satisfy the eye nor the taste in this respect. Yet his pictures in many respects are praiseworthy, and as they are by themselves in one particular line, no one will grudge them the medal they have gained.

It is pleasant to come across a photographer who has a distinct style of his own. Most artists of eminence, whether painters or photographers, unconsciously put their individuality into their work, and style—or "mannerism," as some ill-natured people choose to call it—is the outcome. Mr. John E. Austin's work is, in this respect, very strongly marked, and in all his pictures he infuses a tenderness and feeling which are too often absent from photographs. To his photograph, "The Love Letter" (No. 221), a medal has been very properly awarded. It represents a group of three fisher-girls in the shadow of a boat. One is reading the love letter; the other two are listening. The picture is really a very pretty one in general arrangement, in the grouping of the figures, and in its technical qualities. It has also the merit of being unmistakably photographic. Whether a fisher girl is likely to receive a love letter may be doubted, but to object to the picture on this score would be hypercritical, and therefore let it remain.

Mr. Lyonel Clark has been awarded a medal for his picture "Dedham Bridge" (No. 232). How much of the effect is due to the rough grained paper on which it is printed it would be difficult to say. "Dedham Bridge" is an example of the new school, and no doubt an admirable one too. It is, however, a matter of opinion whether it is a school to be encouraged, as imitators are sure to spring up, and it may be in photography, as in painting, that while a Whistler can be tolerated, his imitators are intolerable.

Mr. R. H. Lord's "Study of Two Children" (No. 330), which has gained a medal, is very praiseworthy, but fails to extort enthusiasm. The truth is, the Exhibition is exceedingly weak in the matter of portraiture and figure subjects, and Mr. Lord's work stands out in the absence of competitors.

Mr. Ralph Robinson is as indefatigable as ever, and not a word could be said against his picture of "The Pedlar" (No. 332), if he had only secured models a little more prepossessing. The pedlar himself fulfils his duty admirably, but why is he surrounded by such plain customers? The whole charm of such a picture should consist in girlish beauty, but not a trace of beauty has Mr. Robinson permitted one to have. This a great pity. However, the absence of feminine attraction has not prevented the judges conferring a medal.

Mr. B. Gay Wilkinson, jun., has sent a number of specimens of his very careful work, and to one of these, "Sand Dunes" (No. 365), a medal has been given. It is to be presumed that Mr. Wilkinson's careful manipulation has earned this honour. The picture, which is without fault photographically speaking, is, considered as a picture, somewhat tame and uninteresting.

Mr. Harry Tolley is not quite so happy in the choice of subjects as on previous occasions. Still, it was impossible to overlook the claims of his "Bantry Bay" (No. 399), which, as an example of delicate treatment and distant effect, deserves high praise. Its defect is that it lacks interest. This, perhaps, arises from the subject, rather than from Mr. Tolley's treatment of it.

The most notable picture in the Exhibition is one which, perhaps, will have to be sought out. No. 600 is on one of the screens, and is by Mr. Van der Weyde. It is by no means so certain that its merits will be recognised by the general public, but photographers who know the difficulties of grouping will admire the consummate skill which is apparent in "An Invitation to Supper." The picture is made up of prints from three negatives, and represents a procession of ladies and gentlemen in court costume of the Georgian era. Notwithstanding the fact that the photograph is of a composite nature, the effect is thoroughly harmonious, and the pose of each couple in perfect consonance with the initial idea. There is not a false note struck in the whole composition, and Mr. Van der Wyde is to be congratulated, not only on the subtle skill which has enabled him to produce the picture, but on the fact that the judges have recognised its merits by awarding it a medal.

WIDE-ANGLE.

THE Fry Manufacturing Company offer to send post free to applicants a sample packet of their materials for trial. With each packet is enclosed a pattern negative, as a sample of the results that may be obtained with the plates, as also of bromide print and bromide opal.

ALUMINIUM.—A Chicago chemist, says the *Optical Magic Lantern Journal*—which, by the way, appears this month with an increased number of pages—claims to have discovered a method whereby aluminium may be produced for a few coppers per pound. A company has been formed for supplying various articles, including optical instruments, made of this metal.

CAMERA CLUB NOTICES.—Monday, October 6th, 8 p.m., Opening of the sixth of the series of One Man Exhibitions (pictures by Mr. Lyd. Sawyer); at 8.30 p.m., Smoking Concert. Thursday, October 9th, 8.30 p.m., First technical meeting of the session—Paper by the President, Capt. Abney, C.B., R.E., D.C.L., F.R.S. Thursday, October 16th, 8.30 p.m., Paper by Mr. Lyonel Clark, "Further Notes on Silver Printing." Thursday, October 23rd, 8.30 p.m., Paper by Mr. E. J. Humphrey. Thursday, October 30th, 8.30 p.m., Lantern evening. Monday, November 3rd, 8.30 p.m., Smoking Concert. Thursday, November 6th, 8.30 p.m., Mr. J. Gale, "Country Rambles with a Camera," illustrated.

THE FRENCH METRIC SYSTEM.

BY THE REV. H. GORDON PALMER, B.A.

It can hardly be gainsaid that our most distinguished astronomers and scientists are opposed to our adoption of the pseudo-scientific metre as a standard for weights and measures.

They urge, with convincing arguments, that this outcome of revolutionists of France, legalised in 1802, is not scientific at all; that it is not what their academicians professed it should have been; that, as a standard, it is, by almost impossible conditions of pressure and temperature, rendered practically useless for reference and comparison; that it is unnatural and cumbrous. Fancy a British carpenter or mason going to his work with a rule 39 inches and decimals, in his workmanlike hands, or projecting to the roof out of his trowser pocket! It has been well said, *apropos*, that no power on earth will make the British workman give up his handy two-foot rule.

The adoption of this metric system would involve enormous expense and taxation—on new sacks alone of several millions. Mr. Gladstone warded off this danger in 1853, and because it seems again "within measurable distance," I venture to sound this, my note of warning.

Then, again, a standard measure ought to be secure, fixed, not difficult to recover and compare if lost, as ours was often—as, for instance, in the Great Fire of London.

The standard metre at present in Paris, as history shows, is not exempt from the possibility of destruction, or it may be rendered useless, and if so, it can never be restored. The accuracy of a future metre measured as before will be a doubtful question, seeing that the French Committee in 1799, in place of measuring the arc of their meridian from pole to centre—finding it rather puzzling, and, altogether, like some essays we know, "comical"—were driven to measure the land surface from Dunkirk to Barcelona, over hills and valleys liable to earth movements and changes.

Objectors do more than object; they offer in its stead a far better system, simpler, more scientific, with all the advantages of *the decimal notation*, and one that would cause a mere infinitesimal change in our Anglo-Saxon weights and measures, and none at all, necessarily, in nomenclature. This may be accomplished merely by increasing our inch by its thousandth part, and would make the two-foot rule 25·025 British inches, to read off 25 new inches. And for new weights, five cubic (new) inches of our earth itself of mean density, under mean temperature and pressure, will weigh exactly one pound, or ten cubic inches equal to two pounds. This would be a true cosmic and scientific basis to work upwards and upon; the French using one element, water, as if the solid earth consisted of that only, and their merchants traded in nothing but that one liquid.

It would be more correct to state that five cubic inches (new inches) of matter having the earth's mean density would weigh within $\frac{1}{5}$th part of our avoirdupois pound, and our new pound would be increased so much, of course, to avoid decimals or fractions.

I state above the opinions of such men as Sir J. Herschel, or the Astronomer-Royal of Scotland, founded on the prior researches and opinion of Isaac Newton. Here, for instance, is what the first text-book to hand tells us on this subject. Sir E. Beckett states:—

"The Polar axis is 500 millions of inches one-thousandth part longer than our present inch, which probably only came by accident to be what it was when the standard was taken, and might just as well be that much more; for the other European nations have inches too, some longer than ours.

"The French metre is the worst measure in the world, because it is inconsistent with any natural one; whereas, our yard is the long stride of a man of good height, the natural length of his walking stick, and half his height, or half the stretch of his arms. And the metre is not even what it pretends to be, the four-millionth of a meridian of the earth, for the *measure taken was erroneous;* and if it were so, such a standard is of no more *real value* than the distance of the moon. Yet there are people who have engaged in a crusade to force on us this bad, erroneous, arbitrary, and revolutionary measure of a nation which tried to abolish the week, and make a new one of ten days, and whose language is declining all over the earth, while ours already prevails over more regions of the world than any other, and is evidently destined to advance."

The improved system here suggested by Beckett is such a one as I have described above, and is obtained by taking a millionth part of our semi-axis of revolution of the earth, giving us a new "foot-rule" of 25·025 inches, or 25 new inches, which Sir Isaac Newton calculated to be the measure of the sacred cubit given to the Israelites.

In 1875 a committee was held in London of the Meteorological Congress of Vienna, partaking of an international character, and the views of Professor Piazzi Smyth then applied for his answer, if peculiar, is important, and to the following effect.

"First. The only absolutely unique, straight, true, and characteristic reference for length measure in and for the entire earth and all nations living on it, is its *axis of rotation.*"

The French chose the meridian, but were unable to measure it, except in part, with inaccuracy.

"Second. If the greatest convenience of the greatest number of mankind, and the fact of man living on the earth, are of any importance, &c., the temperature reduction should be made to refer to the mean of all man's experience of that kind on the earth, and not to an extreme ideal point."

The French Committee decreed that their standard should be measured in a vacuum, and a temperature of that of extreme density of water, or 39° F. nearly, which the Astronomer-Royal terms "being so extra and dreadfully pseudo-scientific," no one can use it.

"Third. The true mean reference, or the mean of all man's temperature, is a temperature of one-fifth the distance from freezing to boiling of water—on a thermal scale reading from 0 to + 250.

"Fourth. The weight reference for all nations, if they live on this earth and have intellectual and scientific aspirations, should be founded on and evenly commensurable with the size and weight of this planet, the earth, as a whole; showing a grandly standard pound weight—to be further decimally sub-divided as necessary—equal to the weight of *five cubic pyramid inches of the earth's mean density;* to be taken in air of the standard pyramid's temperature and pressure, or that most suitable to man in his employments, and by no means, as with some modern doctrinaires, *in a freezing vacuum.*"

Leaving out the disputed question of the Pyramid of Ghizeh, we have here outlined a more simple and truer system than that of the academicians, scientific and earth-commensurate, which they failed to advance;

and, taking it all in all, it proves the wisdom of Mr. Bothamley and our Photographic Committee of Weights and Measures; and their refusal to sanction the use of the unscientific metre is shown to be well grounded, cautious, and most sensible.

I conclude by affirming that we should rejoice to adopt decimal notation, adhering to our ancient weight measures as they were probably ages ago; for instance, we have a very old pound in the Exchequer still nearer the weight represented by five cubic inches, as above.

THE NEW PREMISES OF THE PHOTOGRAPHIC SOCIETY.

The following circular has been issued by the Photographic Society:—

The movement initiated by the Council in June last, by commencing a list of subscriptions to a three years' guarantee fund, and appealing to the members for support. has been successful enough to warrant taking practical steps towards providing a "Home" for the Society.

The Guarantee List for three years as published in the June number of the *Journal* amounted to £136 1s. 6d. Since received—H. Bedford-Lemere, £1 1s.; Joseph Elliott, £2 2s.; Andrew Pringle, £3 3s.; Arnold Spiller, £1 1s.; Col. Waterhouse, £2 2s., making a total of £145 10s. 6d.

Probably this matter of a Guarantee Fund has escaped the notice of some of our Members who may desire to contribute, but the list is not closed, and further guarantees will be received by the Treasurer.

The guarantors will be called upon *pro rata* at the end of each year to reimburse the Society any excess of expenditure over income that may be incurred.

In the renewal of the agreement for lease of the Exhibition Gallery, &c., 5A, Pall Mall East, the rent has been increased by £70 per annum, which the usual income of the Society may be expected to bear.

At No. 50, Great Russell Street, directly opposite the British Museum, is a new building of some architectural importance; one of the floors has been engaged for the Society, with possession at Michaelmas. The flat comprises a front room measuring 35 feet by 16½ feet, with five windows looking on to the Museum. At the rear are landing, entry, lavatory, and three rooms respectively 16 feet by 10½ feet, 10 feet by 6 feet, and 14 feet by 9½ feet, which will afford two dark rooms and a library room.

The position of this "Home" is central; its accommodation can be daily at the service of members, with an assistant secretary in attendance. It gives facilities for arrangements that will, as stated in a circular issued to members, "raise the status of the Society, attract new members, and make the Society more useful to those who are already members."

In the agreement for the lease of the new premises, the usual clause as to underletting is modified so that "the tenant may permit the rooms to be used by members of other photographic Societies who may desire to co-operate with the Photographic Society of Great Britain in the interests of the art and science of photography."

For the first year of this experiment the guarantors will certainly have the pleasure of materially forwarding a good work, but an addition of 150 new members would speedily bring the income to the level of expenditure, and in this direction the considerate aid of all our members is invoked.

It may be here stated that, in order to join the Society, it is necessary to be proposed by one of its members "from personal knowledge"; in default of such knowledge, any lady or gentleman, by applying during the Exhibition to the assistant secretary in attendance, could probably arrange an introduction.

A. M. Mantell, *Secretary.*
W. S. Bird, 74, New Oxford Street, *Treasurer.*

THE CONVERSAZIONE OF THE PHOTOGRAPHIC SOCIETY.

Last Saturday, at a *conversazione* of the Photographic Society, held in its Exhibition Rooms at 5A, Pall Mall East, London, the President, Mr. James Glaisher, F.R.S., received the members and the invited guests, among whom were the Lord Mayor, Sir James Douglas, Dr. J. W. L. Glaisher, Dr. Lindsay Johnson, Captain Mantell, Dr. R. H. Lloyd, Mr. Seymour Conway, Mr. J. W. Swan, Mr. Cameron Swan, Mr. and Mrs. William England, Mrs. H. B. Pritchard, Mr. C. F. Pritchard, Mr. John Spiller, Mr. H. P. Robinson, Mr. W. J. Byrne, Mr. Chapman Jones, Dr. W. H. Plaister, Mr. A. Haddon, Dr. Low, Professor Finkelstein, Capt. T. Lamb, Sir H. Trueman Wood, Mr. R. W. Robinson, Mr. F. Wratten, Mr. W. H. Prestwich, Mr. Herbert Fry, the Rev. F. C. Lambert, Mr. H. J. Burton, Mr. W. E. Debenham, Mr. George Davison, Mr. W. S. Bird, Mr. A. G. Green, Mr. Bevan, Mr. W. Ackland, Mr. H. Perigal, Mr. Charles Alfieri, Mr. Edgar Clifton, Mrs. Friese Greene, Mr. J. Traill Taylor, Mr. S. H. Bhedwar, Mr. T. Sebastian Davis, and Mr. E. Cocking.

In the course of the evening, Dr. K. Selle gave his services, and included, by request, in the following programme of the music, two of his recent compositions:—Part 1 (9 o'clock)—"Valse D'Amour," MS., Dr. Selle; "Rêve après le Bal," Mr. C. B. Nash; "Tarentelli," MS., Dr. Selle. Part 2 (9.45 o'clock)—"Then You'll Remember Me," Mr. C. B. Nash; solo violin, "Fantasia on a German Melody," Dr. Selle; "Shells of Ocean," Mr. C. B. Nash.

Particulars about the Photographic Exhibition will be found in other parts of this issue. Suffice it to say that photographs of large size are fewer in number than usual, and that the Exhibition contains a great quantity of small work of good, bad, and indifferent quality. We believe that a difficulty the Society is in, in relation to rejecting a larger proportion of the pictures is, that it does not see its way to the refusal of the photographs of some of its own members. The greatest novelty in the Exhibition consists of a show of photographs by the new primuline process; the pictures attracted much attention throughout the evening. It may here be mentioned that the process is patented.

The attendance of the general public at the Exhibition last Monday was larger than usual, and among the first to enter the doors was Lord Rosse. Sir Francis Galton, of composite photograph celebrity, spent much time in the Exhibition on Tuesday.

Our description of the apparatus at the Exhibition will begin next week.

It is announced that the first meeting of the season of the Lantern Society will take place on the 13th inst., at 20, Hanover Square, when Mr. Andrew Pringle will give a lecture on "Modern Applications and Appliances of the Lantern."

THE EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

[*From* The Times.]

The Exhibition is certainly remarkable for two things. It illustrates very forcibly the distiuct improvement which has recently been effected in photographic printing methods, and it shows a marked advance—consequent to soue extent on that improvement—if not in the artistic capacities of photographers, at all events in their powers of producing the most artistic results with the appliances at their command.

It was, until the last year or two, a common-place among photographers that, while continual progress had been made in the method of producing the negative, no important alteration had been effected in the methods by which the ultimate picture was obtained from the negative. The well-known "silver" process was really only a modification of the earliest device by which a photographic image was produced, and it bid fair, though often threatened, to hold its own as the ouc generally applicable meaus of priuting photographic pictures. Considering how many substances there are which are readily affected by light, and the numerous efforts uiade to utilise them, it is not a little remarkable that for so long no substitute for silver should have been found. The "carbon" process was, iudeed, a dangerous rival, and allied to it are the whole range of processes depending on the same curious property possessed by gelatiue and other like bodies in combination with oue of those chemical salts, of which the bichromate of potass is the best known representative, that of hardeuing and becoming insoluble in the light. None of these gave the best possible results, suitable as they were and are for very many purposes, aud for years the best pictures at Pall Mall were always printed in silver.

Then, some years ago, a new process of printing in platinuum—to be strictly accurate we should speak of this as a process of printing in iron salts, platinum beiug deposited on the faint image thus produced—was brought out. At first it was recoumended for its permanency chiefly, and because for it the glossy albumeuised surface of the silver print was no longer needful. Its tones, however, were somewhat cold, aud, if it was appreciated by the more artistic, the general public would have none of it. In the euergetic hands, however, of the firm which held the patent rights for the process great improvements were uiade, and now a wide range of tone is available, from the coolest pearly grey to the richest sepia brown. Gradually it caue more and more into use. The best workers adopted it. The public gradually got to appreciate it, and it now, except for the most ordinary class of pictures, is rapidly displacing silver.

The powers such a process gives were at once appreciated by the newest school of photographers, those who, not content with the most perfect transcript of nature—the ideal of a few years back—aspire to produce such a renderiug of nature as would be given by a skilled artist in monochrome. There is, indeed, a school, comprising many of the cleverest amateur photographers, who advocate impressionism in photography, and inveigh against the clear, sharp pictures, full of uinute detail, which were once cousidered its *ne plus ultra*. They would represeut, not merely what the ordinary human eye (improved to the perfection of a photographic lens) sees, but the impression made on the artist's miud. Here there are difficulties. The camera cannot select and discriminate; it cannot omit an ugly object, or introduce a beautiful or suitable one; it caunot make those slight adjustmeuts of the landscape which all paiuters do. The artist with a camera can but select his landscape, and choose his point of view, regarding, of course, those conditions of sky, sun, and cloud, light and shade, which make the difference between success and failure. A great deal, indeed, cau be done in the development of the picture, but this power is as nothing compared with that of the man with a brush.

But at all events, they say, we cau consider how a painter would treat this scene. He will indicate with skilful touches what he wishes us to realize, leaving something for the imagination. He will not give us the mean details, the buttons on that distant figure's coat, the texture of brickwork in that far-away cottage, the straw stems of the thatch upon its roof. Let us also avoid miuute detail, let us attempt broad treatment and encourage the imagination. We can at all events put our lenses out of focus and see the result. And, strange to say—in clever hands—the results were in mauy cases admirable. They charmed the artists, those artists, at least, who condescended to admit the existeuce of photography. The artist saw something much more like what he sought in his own work, and admired iu the work of his fellows.

But they scandalized the old school, and they aroused in photographic circles a coutroversy fierce aud loud. As is the wont in all disputes of au artistic nature, this one has been waged with no small decree of acrimony, and with many hard words on both sides. The worst epithet applied to the work of the old school seems to be "topographical," which, while admitting correctness of outline, couveys the covert sneer that the result is not even pictorial, let alone artistic. On the other hand, the impressionist work is "muddy" and "fuzzy," and, indeed, the fact that the chief tenet of the new school is that no object must be in sharp focus, would seem to offer a certain justification for such epithets.

The question is not easy of decision, perhaps will never be decided. Those, however, who care to judge for themselves have an excellent opportunity of doing so now, for on the walls of the gallery are many admirable—and some not particularly admirable—examples of both schools. Prominent among those of the newer style are the works of Mr. Davison, to whom the judges have rightly awarded a medal and the place of honour in the gallery. Perhaps no more beautiful laudscapes have ever been produced by photographic methods than Mr. Davison's "Old Farmstead" and "Breezy Corner," to the former of which a medal has been given. In this one especially atmospheric effect is admirably reudered, and, looked at from a suitable distauce, the picture gives a wonderfully true rendering of the subject, combining in large proportions the broad effect resulting from skilful artistic treatuent with the actual truth in detail of a photograph. A series of smaller pictures by the same artist on the opposite wall are equally worth study. All are printed in a sepia tone on the roughest of rough paper, and some—including, it appears, the large pictures—are done without a lens at all, merely with a pinhole. It is certainly a satire on the labours of the optician that, after the resources of science have been exhausted to produce a perfect lens, the best work cau be produced with no more elaborate optical instrument than a bit of sheet metal with a hole pierced in it.

Work of something of the same character has gained Mr. Lyonel Clark a medal for a small view, "Dedham Bridge," which has the further merit of illustrating a process invented by the exhibitor. Mr. Gay Wilkinson's exquisite little picture, "Sand Dunes," is another instance of the way in which genuine artistic skill can treat a subject simple and commonplace enough.

Mr. H. Tolley takes a medal for a fine view of Bantry Bay, one of an excellent series of which several others are almost equally deserving. Mr. Ralph Robiuson shows a number of clever character groups, one of which has received an award, and Mr. Shapoor N. Bhedwar has been equally fortuuate with one of his careful and well-executed series of views from posed models.

Mr. Lyddell Sawyer shows some fine views of the Tyne, and has received an award for a cleverly-arranged rustic group, "Two's Company," a slighted swain regarding with gloomy brow the dalliauce of his fair one with a more favoured youth. Mr. J. B. Wellington has an award for a study of figures, "The Latest News," aud Mr. J. E. Austin for his "Love Letter."

Two medals are given for portraits. Mr. R. H. Lord takes one for an excellent, if somewhat conventional, "Study of Two Children;" Mr. Byrne the second, for a large-size, full-length portrait. Mr. Van der Weyde's group, "An Invitation to Supper," might perhaps be classed with the portraits. It represents a number of persons in faucy dress, who may be supposed to be passing along a corrider leading from the ball-room to the supper, and its skilful arraugemeut aud admirable workmanship well justify the judges in their award.

Amongst pictures which have not received any award must first be mentioned those shown by two of the judges, Mr. Gale and Mr. H. P. Robinson; these are, of course, *hors concours*. Mr. Gale shows several figure studies and groups, perhaps the best of them "The Ferry." His work, which is all small, and full of the clearest, most delicate detail, may well be compared with that of Mr. Davison, for the two together show the extremes of their respective schools, both as good as they can be. It is as different as possible, occupying, indeed, the other end of the scale, and showing merits of an absolutely opposite character. Mr. Robinson's work also may be taken as a standard of excellence with which to measure the pretensions of the innovators, and he shows some fine, large landscapes with figures which may serve as excellent tests.

Two heads, "Studies from Nature," by the late Robert Faulkner, seem to have been overlooked by the judges, who might also have been almost justified in considering the claims of Mr. Arthur Burchett's "Belle Bretoune." Mr. Wainwright shows some good landscapes—of the sort which took prizes a few years ago—and so does Mr. Bedford. Mr. Dresser's "Corbière Rocks at Half-Tide" is worth notice; so is a photograph by the same gentlemau of boys playing leap-frog, as an illustration of the detail which can now be obtained in very rapid pictures. Messrs. West and Mr. Symonds show some of their well-known yacht pictures—good as ever, but, of course, not presenting auy really novel features. Mr. H. Robiuson, besides his pictures above referred to, sends aa interesting series of portraits of Royal Academicians. Of other portraits there are uot very many. Mr. Mendelssohn sends some of the usual fashionable style, and Mr. Byrne has a good collection. Among other pictures worth notice may be mentioued a frame of small views by Mr. K. Greger, Mr. Gambier Bolton's kittens, Mr. Kimberley's winter scenes, and Mr. Brownrigg's views of the Alhambra. Soue carbon enlargements by Mr. Flather, with what he terms "dry point needle finishing," are extremely good. There are not many lady exhibitors. Among them Miss Florence Harvey is the most successful; her "Dutch Fisher-folk" shows considerable skill in selection and groupiug. Mrs. W. P. Arnot also shows some heads and figure studies.

There are, as usual, some fine examples of photo-gravure, Messrs. Boussod, Valadon and Co. being the principal contributors. Looking at such a picture as the reproduction of Mr. Luke Filde's "Al Fresco Toilet," one cannot help the remark that it is well the length or breadth of the room separates these graceful figures from the self-conscious models appearing in too many of the photographic groups. Too close a comparison would be hardly fair.

Of illustrations of scientific applications of photography there are very few in the Exhibition, a fact all the more remarkable since photography has of late found so many and such important applications. A photograph of the moon, taken without an equatorial movement, is evidence of manipulative skill on the part of the producer, and of the speed of his plate, but it can hardly be considered representative of the work now being done in astronomical photography. Scientifically, the most interesting and the most novel exhibit consists of the illustrations of the photographic application of primuline, a new coal-tar dye. This substance, first brought to public notice at the recent meeting of the British Association at Leeds by Messrs. Green, Cross, aud Bevan, possesses the property of being decomposed by light. In its undecomposed condition it reacts with other coal-tar derivatives to form colouring matters of various shades. When decomposed it loses this power. If, therefore, a fabric dyed with primuline be exposed under a pattern or picture, the pattern or picture is reproduced. When the material has been protected from light it is iu a condition to combine with the other colouring matters; when the light has acted it is not. The picture, therefore, can be brought out in the colour desired by treatment with the proper colouring matter, which attacks the undecomposed portions, leaving the rest, where the light has done its work, unaffected.

The process would appear to be capable of very various uses, and suggests the application of photography in a new direction, thus adding yet one more to the many and diverse purposes for which it can now be applied.

The attention of the amateur—and who is not now-a-days a photographic amateur?—will be attracted by the collection of apparatus ou the table—cameras, slides, shutters, and all the myriad appliances considered necessary now-a-days for the successful prosecution of the art. When we heard of such feats as that recorded by Mr. Frank Stevens, who in his book "Scouting for Stanley," tells how, with his detective camera, he stalked and "took" the wild rhiuoceros at twenty yards distance, we must admit that there is a use for the hand-cameras which appear in such number on the table, even though we doubt if many of the pictures on the surrounding walls were obtained by their aid.

THE PHOTOGRAPHIC MANUFACTURERS' ASSOCIATION.

Recently we published a letter about "The Photographic Manufacturers' and Dealers' Association of the United Kingdom," of which not a few of the large photographic manufacturers are promoters. The following are its objects, as stated in its "Articles of Association:"—

3. The objects for which the Association is founded are:—(1) To promote the interests of the trade generally. (2) To protect, by means of the diffusion of informatiou, members of the Association against persons whoso character or circumstances render them unworthy of mercantile credit, and to promote the prosecution, in cases where the Council of Management of the Association think fit, of fraudulent debtors. (3) To effect the payment of debts due to members of the Association, to facilitate the prompt and economical realisation and distribution of the estates of persons who, being indebted to any of the members of the Association, may become bankrupt, or have their affairs liquidated by arrangement or composition with their creditors, and for this purpose to employ the proper, professional advice, and assistance, and to obtain, whenever circumstances will permit, the appointment of such officer or officers of the Association, or such other fit and proper persons as the Council of Management shall, from time to time, appoint in this behalf, to be receiver or receivers, inspector or inspectors, trustee or trustees, of such estates under the bankruptcy or arrangement by liquidation or composition of such persons respectively. (4) To keep a register of all cases in which persons indebted to any of the members of the Association may become bankrupt, or may have their affairs liquidated by arraugement or composition with their creditors. (5) To effect, as far as possible, the federation of manufacturers of, and dealers in, photographic appliances, for promoting the geueral interests of the photographic trade, and dependent or affiliated industries. (6) To suggest and support measures for the protection of traders and the improvement of commercial law, more particularly having regard to the aforesaid trades, and, with this object, to communicate and co-operate with tradiug companies, chambers of commerce, and other mercantile and public bodies in the United Kingdom, and also with the law officers of the crown, whenever thought desirable. (7) To co-operate or amalgamate with any other association haviug siuilar objects, aud to procure from, and communicate to them, such inforuation as may be considered likely to promote the objects of the Association. (8) To promote the interests of the photographic trade by holding exhibitions of photographic apparatus and allied appliances if thought desirable. (9) To do all other such lawful things as are incidental or conducive to the above objects.

In *Sun Artists* for July, embellished with four plates from medal photographs by Mr. Lyddell Sawyer, is a descriptive essay by the Rev. F. C. Lambert, M.A., in which are quoted the following words by Mr. Sawyer:—"I was born iu photography, uursed in it, and have been continually 'soaked' in it ever since. My father, uncles, brother, and cousins are most of them photographers." "How far," adds the essayist, "the subtle influences of heredity have contributed to the formation of Mr. Sawyer's art perceptions is a consideration of much interest." It will be noted that the sixth of the One Man Exhibitions at the Camera Club, to be opened for press view on the 6th inst., will consist of photographs by Mr. L. Sawyer.

ON THE REVERSAL OF THE NEGATIVE PHOTOGRAPHIC IMAGE BY THIO-CARBAMIDES.*

BY COLONEL J. WATERHOUSE, R.S.C., ASSISTANT SURVEYOR-GENERAL OF INDIA.

Reversal of the image is, as a rule, quite abnormal, and usually occurs from over-exposure or some irregular action of light during development. With dry collodion bromide plates it may be favoured by the presence of certain forms of organic matter, such as some of the aniline dyes, and in the case of gelatine dry plates it may occur by long keeping of the plates before development. Some years ago Captain Abney fully investigated the phenomena, and they have more recently been discussed at length by Professor Meldola in his excellent treatise on the "Chemistry of Photography." Captain Abney attributes reversal to oxidation of the sub-salt of silver, formed by the action of the first impact of light on the exposed salt of silver, the rays of lower refrangibility being powerful accelerators of this oxidation; also to the presence of alkaline haloids or of mineral acids. The presence of a soluble nitrite or sulphite or other reducing agents is also said by Captain Abney to be inimical, while the presence of oxidising agents is favourable.

In the present instance, seeing that an ordinary gelatine dry plate—which, with a normal exposure and developer, will develop a negative—will, with the same exposure, and merely by the addition of a little thio-carbamide to the developer, develop a positive, it is obvious that the reversal is not caused by any abnormal action of light, nor by the action of any special rays of the spectrum, and must be purely due to chemical causes. Over-exposure, as we have already seen, is unfavourable to the reversal, and, although the ultra-violet rays appear most active in producing it, it may be obtained in any part of the spectrum.

Against the theory of oxidation there is also the fact that the thio-carbamides, which undoubtedly are the active agents in producing these reversals, contain no oxygen, and, on the contrary, appear to be powerful sensitisers and reducers. Then, again, the presence of sulphite in the developer does not stop reversal, and even seems to favour it. Pyrogallol with sulphite has produced reversal with thio-sinamine, when with nitric acid and bromide it did not.

Although the action of the thio-carbamides in producing this reversal thus appears to be in direct opposition to the generally accepted theory, as stated above, I think it will be possible to reconcile the facts with the theory, and that these reversals follow the ordinary rules.

With normal exposure and development, a gelatino-bromide dry plate gives a negative image; but if the exposure be prolonged, or if the film has become oxidised from any cause, there is more or less tendency to reversal, and the original action of light, which would produce a normal negative image, is undone, and a positive image is produced. In the present instance, we have in the developer a substance which is capable of liberating halogen without the action of light, and, apparently, of oxidising and hardening the gelatine film. Thus, the film, although it may only have received a normal exposure to light, is really in the same state under the developer as if the exposure to light were being continued, and halogen being liberated all over it, as in the case of over-exposure. The halogen thus set free would appear to attack the parts reduced by the normal action of the developer, while the developer and the alkaline thio-carbamide complete the reduction of the unexposed parts, and thus bring about the reversal. During the process the thio-carbamide probably becomes oxidised, and loses sulphur which would combine with the silver, and, from the appearance of the images, very probably does so. From the experiments described above it would appear that, with thio-sinamine at any rate, a soluble sulphide is formed by the addition of the alkali. In the case of thio-carbamide, or sulph-urea, ammonia is also evolved by the alkali, and this may be the cause of the irregularity of the results obtained with it. The fact of the reversals being most readily obtained with eikonogen would seem to show that it also exerts some chemical influence on the result. Some of the plates produced show a peculiar blue tint very suggestive of *Prussian blue*, but how any such *iron* compound could form it is difficult to see.

The theory I have given above can, however, only be considered a provisional conjecture which requires further investigation before it can be confirmed.

The results obtained seem to warrant the hope that it may be possible to perfect the process for practical use, but a great deal of work has yet to be done before the conditions of successful working can be fully ascertained. As in all these processes of reversal, the balance between reversal and non-reversal is a very delicate one. In any case, an entirely new method of producing reversed images, with so many novel features, must be of interest, and, it is to be hoped, may throw some light upon the still unsolved problems connected with the formation and reversal of the developed photographic image.

Addendum.—Since the above was written, it has been found that, for copying line subjects, it is an improvement to use the eikonogen and phenyl-thio-carbamide developer, and before developing to give the plates a preliminary bath of dilute nitric acid at 5 per cent., or of bichromate of potash solution at about 3 or 4 per cent., the solutions being flowed over the plate in a tray, and washed off quickly. By this means greater density is obtained in the lines, together with cleaner whites. The reversal takes place slowly, but is more complete. The change is quite visible, the lines turning black on a light ground. Greater clearness of the ground may also be obtained by treating the plate, before fixing, with a solution of bromide of copper at 2 or 3 per cent., but care must be taken not to weaken the lines too much.

In working with thio-sinamine, good reversals have been obtained of half-tone subjects by adding about ten drops of bichromate of potash solution at 10 per cent. to the ounce of eikonogen developer.

For copying work the process seems quite practical, as proved by heliogravure plates produced directly from reversed positives taken in the camera, by which one operation (either the taking of a negative or of an intermediate positive) is saved.

* Concluded from page 744.

Adhesive Paste.—A paste which will stick anything is said by Professor Winchell to be made as follows: Take 2 ounces of clear gum arabic, 1½ ounces of fine starch, and half an ounce of white sugar. Dissolve the gum arabic in as much water as the laundress would use for the quantity of starch indicated. Mix the starch and sugar with the mucilage. Then cook the mixture in a vessel suspended in boiling water until the starch becomes clear. The cement should be as thick as tar, and be kept so. It can be kept from spoiling by the addition of camphor or a little oil of cloves.—*Chem. and Drugg.*

Notes.

Last Wednesday several of the members of the Council of the Photographic Society lunched at the Mansion House with the Lord Mayor, Alderman Sir Henry Isaacs. The object of the social meeting was to consider the question whether the time has not come to establish a Photographic Institute which shall teach, examine, and in proper cases give certificates of qualification. The idea is that photo-mechanical and all other branches of photography shall be taught practically, but that no commercial work shall be executed by the Institute. Dr. Lindsay Johnson has been most industrious in his efforts to promote this scheme. In other countries somewhat similar institutions have been established by their respective governments, and a notable instance is the Imperial Institute of Photography of Vienna, under the able direction of Dr. J. M. Eder. Belgium possesses a good institution of the kind in the Old Museum at Brussels, under the direction of a professor appointed by the Government. The chair was long held by the late Professor Rommelaire, who occasionally gave a series of public experimental lectures on photography, to which all interested were invited to be present without charge; all they had to do was to enter their names and addresses in a book. Promising students at this establishment are allowed the use of the laboratory and instruments; some of the latter are of the most costly character, especially one for solar photo-spectroscopy, with a long train of Iceland spar prisms.

In the course of the discussion before the Chemical Section of the British Association about the primuline —or, as its inventors have since christened it, the "diazotype"—process, a speaker whose name was not announced remarked that the browning of the leaves of trees in the autumn is due to the action of light. He said that if the green leaf of a Virginia creeper be taken, and covered with a device cut in black paper, then be exposed to sunlight, the portions of the leaf not covered will turn scarlet, therefore will yield a scarlet image of the design. The red colouring matter is formed as the product of the destruction of chlorophyll by light.

Not so very long ago, the Photographers' Benevolent Association had more money than it knew how to disburse. A member states that such is the case no longer, and that it would be glad of more funds to relieve persons in severe distress, whose circumstances have became known to the managers.

Messrs. Lewis & Co. have sent us some samples of what they call "kallitype" paper for trial. With some negatives we have found it to give good results, and with rather cold tones. The manipulations are no more troublesome than those of bromide paper, and the new paper seems to yield rather better prints from hard and vigorous negatives; the sample sent also acted fairly well with moderately thin negatives. The process has already been fully described in these pages, in one of the patents. At root it is an iron process, but the picture is developed in a silver bath, wherein silver is thrown down upon the image. The name "kallitype" is objectionable, because it is likely to confuse the public mind because of its resemblance in pronunciation to "calotype."

The *Papier Zeitung*, of Berlin, describes an improvement which, it is said, has been introduced in the art of photo-etching. As usual, the zinc plate is backed with asphaltum, and, with its pictured surface uppermost, is placed in a bath of dilute acid. The plate is then put in circuit with a dynamo machine, and when the current passes, the exposed portions of the zinc surface are attacked by the acid with such energy that, in a few minutes, the plate is etched to a sufficient depth. If this process bears out the anticipations of its authors, it will be a boon to the producers of process blocks, especially when time is of importance. The operation of etching generally occupies about two hours, during which time the acid baths have to be kept in continual motion.

Dr. Bullock, of Leamington, recently reported in the *Lancet* a case of poisoning by bichromate of potash, and the account given is worth the attention of workers with the carbon process, who are liable to a similar accident. The patient was employed at a furniture dealer's, where the bichromate was used for staining mahogany previous to French polishing. Having finished his day's work, the man took "a hearty draught" of bichromate solution in mistake for cold tea. He quickly found out his terrible mistake, and started for home, when he was attacked by violent sickness, and quickly exhibited all the symptoms of acute poisoning. The stomach pump was applied, and a mixture of bismuth, magnesia, and chlorodyne was given every two hours, with the result that the man recovered his usual state of health in three hours. This was a marvellous recovery, considering that the patient had actually drank about five ounces of a saturated solution of the poisonous salt. He was lucky in having a medical man at hand who evidently knew well how to treat an unusual case.

The School Board is not a popular institution, either with the scholars or the ratepayers; the first objecting to any kind of control over their sweet wills, and the second looking in vain for any notable improvement in the manners and language of those for whose education they are called upon to pay. We are told that the number of children who play truant from these establishments amounts to 150,000 daily, and a member of the Board has suggested a plan whereby the delinquents might be detected. He proposes to subsidise "a Punch and Judy man to go round the poorer neighbourhoods and give his entertainment, in order to prove how many children of school age and in good health could be collected in a given time." To make

the arrangements complete, we should suggest that the Punch and Judy man should have a camera hidden in the lower part of his stage, so that while the children were looking with rapt attention at the show, their portraits should be taken for future identification. Poor little waifs! Bumble still persecutes them, and would even make their one ray of sunshine a stumbling block to them.

When common-place people go to that uncommon place, Niagara, they often have their photographs taken with the famous falls in the background, thinking, no doubt, that nature is rendered more interesting by their presence. Such a portrait we saw the other day, and the fancy occurred to us that the idea might be greatly extended, and would most surely, in the hands of a careful worker, prove most remunerative. Suppose, for instance, one photographer were to confine his attention to taking the portraits of the clergy. He would have to provide himself with several backgrounds to suit their various views. Some would prefer being taken in front of the Metropolitan Cathedral; others would like Spurgeon's Tabernacle to loom in the distance; not a few would choose St. Peter's at Rome, and so on. The same idea could be extended to musicians, lawyers, statesmen, and all other professions and occupations. We commend it to our readers.

The photographic chart of the heavens, the preparation of which was decided upon at one of the recent International Congresses, is making great progress. The observatories which have got the work in hand include those of Greenwich, Oxford, Paris, Bordeaux, Toulouse, Helsingfors, Catano, Algiers, San Fernando, Rio de Janeiro, Tacubaga, Santiago de Chili, Cape Town, Sydney, Melbourne, La Plata, and the Vatican at Rome. At each of these stations from 600 to 700 diagrams in triplicate will be produced, the complete map being composed of 1,800 to 2,000 sheets. The next Congress, which will assemble in Paris on the 31st of March, 1891, will have an enormous quantity of material to deal with, and its work will be to arrive at a practical settlement of definite results. These world-wide labours will, no doubt, give a great impetus to the study of astronomy, though we are not quite sure that we can endorse the opinion of an enthusiastic evening paper, which says, "at no very distant time, any person having a simple micrometer will be able to produce on plates of cardboard those interesting representations which, until now, have been essentially within the province of the astronomer and the best organised observatories."

The most singular adaptation of photography is that practised in certain "prohibition" towns in America, where there is water, water everywhere, but not a drop of drink! The story is that Kodak cameras have become suddenly very popular, and that quite an epidemic of detective photography has broken out. The camera is thus used: "When a man, armed with one of these instruments, asks a friend if he would like to be taken, he never receives a negative. He simply presses a button, and his friend does the rest." This is a very delicate way of putting the matter. A wag would probably say that the new form of Kodak is utilised for the purpose not of taking portraits, but of taking drinks!

The number of duels of late, we fancy, will probably give a stimulus to the sale of photographs of swordsmen in action. We learn that the renowned Spanish fencer, Baron San Malato, has just returned from America, bringing with him one hundred photographs of positions, defences, and attacks in fencing, for which the Baron has posed. These photographs will doubtless be found very useful for the fire-eaters of the French press, most of whom—so we learn from an article on the subject—are very indifferent swordsmen. It is to be hoped, also, in the interests of the public, that further duels will be photographed. Each man's second should have with him an instantaneous camera, so that the partisans of each of the combatants may be satisfied that the duel was really fought—on which point there is sometimes a little doubt.

Mr. Henry Blackburn, the editor of *Academy Notes*, has started an idea which, we are afraid, will be neither acceptable to authors nor to the general public. He thinks the author should appeal direct to the reader through the agency of his own handwriting. Whatever is depicted in ink upon paper can be photographed, and we take it that Mr. Blackburn proposes that a novel or a poem read through the medium of a photographic reproduction of the author's handwriting should be the book of the future. If this really be his idea, we would humbly suggest, if the public are to read their favourite authors first-hand, as it were, that the favourite author should take lessons in caligraphy, as the vast majority of literary men write villainous hands. When novelists and poets write their "copy" like copper-plate, then it will be time enough to talk about photographic *facsimiles*.

The impression conveyed by the Exhibition in Pall Mall on the minds of those who have not noted the progress of photography of recent years, is very curious. We were in company this week with a man of intelligence, but whose knowledge of photography and photographs was very limited. He admired the pictures on the walls immensely. "But," said he, "these, of course, are not photographed from life, they are copies of pictures, I suppose?" He was much surprised when told that all the pictures, with very few exceptions, were photographed from nature. No doubt the cold tones now in favour, and the almost extinction of albumenised prints, assist the notion. The idea of a photograph years ago was that of a highly-glazed picture very warm in tint. This aspect, of course, has totally disappeared, and the similarity of tone to an engraving might well deceive a superficial observer. Something also is to be said on the ground of a greater knowledge of art which the majority of pictures now-a-days exhibit.

THE BRITISH ASSOCIATION COMMITTEE ON GEOLOGICAL PHOTOGRAPHS.*

Scotland.—Per Alex Ross, Marldon Chambers, Inverness (photographed by D. Whyte, Inverness), size 8½ by 6½ inches:—Registered No. 54, 56, Island of St. Kilda (looking N.W.), 1885—Three views showing weathering and form of gabbros and volcanic rocks. Photographed by R. Mc F. Muir, 35, Underwood, Paisley:—33, 35, Partick, near Glasgow—Three views of fossil trees in coal measures at Whiteinch; 49, Glenffer Braes, Renfrewshire, 1885—Nethercraig's lime quarry, showing master-joints. Per Ed. Ward, 249, Oxford Street, Manchester (photographed by Percy F. Kendall): Island of Mull (series of 17¼ plate views)—Salen shore—Dykes; ditto—Intrusive basalt; ditto—Columnar dyke; Arches, Mull—Columnar with tachylite; ditto—Cave above tide mark; ditto—Spheroidal weathering of basalt; Port, Bean—Faulted dyke; Gribun—Cliffs and talus; Carsaig—Marine denudation; Staffa—Columnar basalt; Staffa—Curved basaltic columns. Photographed by W. Norrie, 28, Cross Street, Fraserburgh, under the direction of Professor Heddle and L. A. Harvie-Brown. Size 5 by 8 inches. [Local numbers in brackets.] Registered No. 60, Island of Rum, 1889 [3]—Stack of Mharagast; 61, Bird's Island, Caithness, 1887 [7]—View of Holboru Head; 62, Holborn Head (E. side) [8]—Flagstone; 63, Ross of Mull [9]—Basaltic colonnade (the last of the twin columns); 64, ditto, Nun's Cave [11]—Basaltic arch; 65, Holborn Head—Rift in rocks; 66, ditto, "Devil's Bridge" [12]—Caithness flagstone; 67, Ross of Mull (looking through Nun's Cave); 68, Gribun, Mull [19]—Clustered basalt; 69, ditto [20]; Basaltic pavement; 70, ditto [21]—Trap dyke in basalt; 71, ditto [22]—Rent in trap dyke; 72, Shiant Island [37]—Basaltic north cliff; 73, Whitenhead Stack [54]—Contorted gneiss; 74, ditto [65]—North end of great fault through Scotland. Photographed by G. W. Wilson and Co., Aberdeen.† Selected list by Professor James Geikie. Large size, 11¼ by 7½ inches. West side of Hauda, Sutherland [2025]—Sea coast section of horizontal Torridon sandstone; Assynt Lodge, Sutherland [2031]—Archæan gneiss in foreground, overlooked by escarpments of Torridon sandstones (so-called Cambrian); Lochnagar [2551]—Corrie with tarn, in granite; The Door Holm, Tangwick, Shetland [2070]—Sea-stack or islet: Old Red sandstone lava-form rocks and agglomerates, showing denudation since period of glaciation: Granite quarries, Aberdeen [4048]—Granite; Buchan Coast, near Stains [4036]—Granite: showing structural features and their influence in marine erosion; Granite quarries, near Bullers-of-Buchan [4038]—Granite: structural features; Cior Mhor from top of Goat Fell [5742]—General views of granite mountains, sharp crests, corries, torrent-courses, and screes; "Cyclopean Walls," Arran [5739]—Granite mountains; knife-edged ridges of granite; weathering and débris; trap dykes cutting granite; Ben Nuish from top of Goat Fell [5743]—Corries, torreut-courses, &c., in granite; Carse of Gowrie from Kinnoul Hill [6601]—Old fluviatile and estuarine flat; Loch Maddy, North Uist [6174]—Characteristic landscape (Archæan rocks); Spiudle Rock, St. Andrews [6269]—Radiating columnar basalt, tuff, &c.; The Old Man of Hoy [128]—Weathering of Upper Old Red sandstone; sea coast; influence of joiuts; The Pot, Bullers-of-Buchau [204]—Sea action on grauite; influence of joints; Dunbay Rock, Buchan Coast [205]—Sea actiou; Duuotter Castle [494]—Sea Cliff—vertical Lower Old Red couglomerate; Gordie Stack and Drongs, Shetland [582]—The old Man, Storr, Skye [873]—Weathering of bedded basalt rocks; The Quiraring, Skye [893, 97]—Weathering of bedded basalt; The Kilt Rock, Skye [898]—Colnmnar basalt resting on Mesozoic strata; The Old Man of Wick [936]—Caithness flags (Old Red); sea coast action; influence of joints in formation of caves and stacks; The Stack of Brough, Wick [939]—Ditto; Clamshell Cave, Staffa [762]—Curved columnar basalt; West side of Staffa [765]—Columnar aud amorphous basalt; Boat Cave, Staffa [766]—Ditto and tuff; Colonnade, Staffa [767]—Ditto; Causeway of bending pillars, Staffa [768]—Amorphons basalt above enrved colnmnar basalt; Island of Staffa [2454]—General view; Colonnade and Boat Cave from the sea [2477A]—Ditto; Fingal's Cave—Three views, showing amorphous and columnar basalt; Parallel Roads in Glenroy [1234]—Glacial lake terraces; North Garlton, Orkney [1450]—Old Red flagstone; influence of joints; Mnchalls, sea cave [1734?]—Granite; Snilven, Assynt, Sntherland [1968]—Torridon sandstone outlier; Archæan rocks; The Maddy's, Loch Maddy [6090]—Characteristic landscape of Archæan gneiss; roches montonnées (weathered); Looking np Loch Eport [6174]—Archæan gneiss; The Grind of the Naver, North Maven [2051]—Structnral features of bedded, lava-form rocks (Old Red) and their influence on marine erosion; Scuir-na-Gillean, Skye [859]—General view of gabbro mountains; moraine in foregrounnd; Smaller size, 8 by 5 inches. The Brig o' Trams, Wick [1567]—Action of sea on old Red sandstone; The Drongs, Shetland [580]—Sea stacks; The Quiraing, Skye [384]—Weathering; The Lion Rock, Cumbrae [1290]—Basalt dyke; Samson's Ribs, Edinburgh [872]—Columnar basalt; East side of Staffa [1464]—Curved basalt; Spindle Rock, St. Andrews [929]—Radiating columnar basalt in tuff; Fiddle Bow Rock, Cullen [6058]—Marine erosion in crystalline schists; The Gloop, Duncansby Head [1586]—Old Red sandstone: Ben Stack, Sutherland [2739]—Archæan gneiss: Stacks of Duncansby [1585]—Marine erosion; Noss Head, near Wick [1576]—Caithness flags; Cliffs on Handa, Sutherland [2735]—Torridon sandstones; Windy Edge Pass. Dollar [2154]—Stream following joint in igneons rock of Old Red sandstone age; Inchnadamph, outflow of nndergrounnd river [2684]—Bared thrnst-plane in limestone; Knrka Stack, Balta, Shetland [2680]—Islet of gabbro; Holm of Noss [568]—Marine action along joints in old Red sandstone; Stack Sheog, Handa [2738]—Marine erosion in Torridon sandstones; The Pot, Bullers-of-Buchan [973]—Marine action in granite. The "Pot" is a "tunnel," the roof of which has fallen in; The Giant's Leg, Bressay [665]; The Needle-Ee Rock, Wick [2613]—Marine erosion in Old Red sandstone; Linn of Dee, Braemar [3657]—River action; cutting in crystalline schists: Staffa: Colonnade and Fingal's Cave [4575]—Columnar basalt; Valley of the Thousand Hills, Glen Torridon [591]—General view of moraines; Inchnadamph and Ben More [2685]—Limestone beds piled up by thrusting from east; Doune of Invernoghty, Strathdon [6890]—Alluvium and relics of old river terrace; The Herdsman Island, Staffa [1460]—Bird's-eye view of columnar basalt; Linn of Gnoich, Braemar [10143]—River cutting through schists along lines of joiuts; "Gulgh" at the Linn—Pot holes in bed of river.

Ireland.—Belfast Natural History and Philosophical Society—per W. Swainston, King Street, Belfast:—Registered No. 52, Whitehead, Belfast, 1889—Columnar basalt resting on eroded snrface of chalk; 53, Whitwell, Belfast, 1889—Amygdaloidal basalt resting on indurated chalk. Photographed by R. Welch, 49, Lonsdale Street, Belfast:—50, Giant's Causeway, Antrim—The "Giant's Fan," showing bases of large hexagonal columns; 51, Ditto—Middle causeway. Photographed by G. W. Wilson and Co., Aberdeen (a selected series of photographs revised by Professor James Geikie).* Giant's Causeway [219]—Columnar basalt; Ditto [225]—Ladies' wishing chair; uearer view of columns; Ditto [226]—The Keystone, showing tops of columns; Ditto [227]—The fan (similar to No. 226); Ditto [229]—The Organ (radiating columnar basalt); Ditto [230]—Pleaskin Head (colnmnar and amorphons basalt).

* Concluded from page 747.

† The Numbers in brackets are those of the photographers, and are inserted for convenience of reference.

* The numbers in brackets are those of Messrs. Wilson and Co., and are given for convenience of reference.

The Photographic Club.—The subject for discussion on October 8th will be "Flash Lamps"; October 15th, "Registratiou as Applied to Photographic Printing."

Photographers' Benevolent Association.—At the meeting held on 26th of September (Mr. Benham chairman), two loans were granted, and Messrs. Sawyer and Jessup elected members.

LANTERN SLIDE MAKING.*

BY C. BEADLE.

I do not think there can be a more interesting branch of our fascinating art than the production of slides for the optical lantern. As to the production of these, I do not pretend to have given any original research in the matter, but, rather, to have followed as carefully as I could the instructions usually issued with the plates by the makers.

In reading articles in the numerous photographic books and journals on the subject, great stress is usually laid upon the necessity for cleanliness of all dishes and measures. This is perfectly correct; at the same time, you will find that the ordinary care which has enabled you to produce a good negative will enable you to obtain a good lantern slide from it.

There are, of course, many means now of arriving at good results. I may say that I do not think anything can surpass, in beauty, those produced by the old collodion process, but, as the dry plates now in the market are so good, and the ease of production so great, I think we amateurs of little leisure hardly need anything better.

It is somewhat of a disputed point as to whether slides obtained by reduction by means of the camera, or those printed by contact, are the better: but, given a good negative, I do not think the effect is materially different, whichever way is tried. My own experience is that those produced by reduction are the sharper of the two, this quality being a great desideratum, for, however much our great artists may differ as to sharpness in positive prints, we all find that, when the subject has to be so many times enlarged upon the screen, the general fuzziness is, as a rule, quite sufficient to satisfy any of us.

With respect to plates, I do not believe there are any in the market but what will produce good results, and the best way of treating them is to work with the formula given. I do not say that at times it may not be necessary to alter it to suit, perhaps, a thin or over-dense negative.

Now we come to the subject of developers. Although I am no lover of hydrokinone as a developing agent for ordinary negative work, owing to the uncertainty of results and tendency to choke up distances, with a slow transparency plate it is different, and I hardly think for this purpose, by reason of its simplicity and cleanliness, it has yet been surpassed.

The developer which I use is as follows:—

Hydrokinone	160 grains
Sodium sulphite	2 ounces
Citric acid	60 grains
Potassium bromide	30 ,,
Water up to	20 ounces

And for the second solution—

Sodium hydrate	160 grains
Water up to	20 ounces

Use equal portions of each for development.

Then we come to the important subject of length of exposure, upon which hinges to the greatest extent the success of the finished picture. In my own practice, I have generally obtained the best results by giving as long a one as the plate will bear, and then developing smartly, when a clean, bright picture should be the result. Should the plate require prolonged development by reason of under-exposure, a yellow stain will frequently result. This may be removed by a solution of—

Cyanide of potassium	2 drachms
Water	20 ounces

But it is better to avoid having to do this, for it has the effect of somewhat reducing the density of the probably already too weak a picture, and, in spite of thorough washing, I have found leaves a granular effect on the film which is somewhat difficult to remove. The alum protosulphate of iron and citric acid clearing bath recommended with most issues of plates works better, but is seldom required if the exposure has been correct. The time of exposure varies according to the density and colour of the negatives. Lately, I have been working from those having a slight brown stain, due to the absence of sodium sulphite from the pyro developer, and find the average time, working with an aperture of *f*/22 in an afternoon light before five o'clock, to be about fifteen minutes. I am, of course, alluding to those slides made by reduction from a half-plate negative. By contact, using a kerosene lamp as illuminant, the flame of which is about 1½ inches wide, holding the printing frame about 12 or 14 inches from the light, the average time has been about forty-five seconds.

I may here remark that, as the result of experimenting with various developers upon the same brand of plates, those developed by the solutions pyro ammonia, ammonia-bromide, and carbonate of ammonia required a longer exposure than those by the hydrokinone formulæ. It should be borne in mind that the distance of the plate from the flame in contact printing influences the result considerably; a dense negative being the better for making the positive from it as near as four inches; on the other hand, a thin one should be held at least eighteen inches to two feet away. These alterations, in my opinion, modify the result in a better way than by varying the time of exposure. This same principle will work well when using bromide paper for prints.

When speaking of transparencies, of course we are not confined to the regulation size of 3¼ inches square, adopted now generally for the lantern. Larger plates can be treated in the same manner, limited only by the size of your negative or the depth of your pocket. It is of course necessary, when making these large window transparencies, and you do not wish the subject to appear reversed, to use those plates sold with a ground glass back, the glass of the front simply acting as a protecting cover, as in a lantern slide. Woodland or river scenes it hardly matters reversing for decorative purposes, in which case the plates with emulsion on plain glass can be used, and a fine ground glass used to diffuse the light. The emulsion on the plates being a slow one, I would remind you, is generally beneficial: certainly so when desiring to screen or locally expose for a longer time any portion of a negative. In this way I found, when making a transparency of an interior of Worcester Cathedral, the east window in the negative of which is partly choked by local over-exposure—which is frequently miscalled halation—the difficulty was overcome by cutting a small hole in a piece of rough card, and using this locally, after having given the requisite exposure to the bulk of the plate.

It will, no doubt, suggest itself to you as well that any portion of the negative being over this can be screened from the light in the same way. Recollect, when using, to keep the card moving, so as to prevent any hard line. In working large plates, should an error occur producing too dark a transparency, it can be reduced by the ferricyanide of potassium and hypo (freshly mixed) in the same way as you would for a negative.

I mentioned just now that I thought a slide made by reduction in the camera the better of the two plans; in

* Abstract of a paper read before the North Middlesex Photographic Club.

fact, in my case, I have few plates that any slide can be made out of except by that means. Sometimes the instructions given for this purpose read a little formidable, more so than there is reason for.

In reductions, the plan I use saves all blocking-out of the bath-room or other windows used as our dark-rooms. It consists of two parts, a platform with an end to hold the negatives of any reasonable size, and a box to put the same in when the camera has been adjusted on it. The platform has a narrow groove down the entire length to enable the camera to pass up and down, and can be fixed in any required position by means of a thumb-screw underneath. At the extreme end is erected a set of frames to hold any negatives from a quarter to whole-plates, these being held in position by small brass buttons. It is probable that most of us desire to reduce from one size; that being so, it a great deal simplifies matters, as when once in sharp focus to the required size, a mark can be put upon the base-board or platform, and another on the camera where racked out to, and in this way all trouble of focussing upon any future occasion is avoided, and the plates can be exposed one after another without fear of varying. The place for negatives is adjusted so that the exact centre comes immediately opposite the centre of lens. The complete action is as follows. The lantern plate being placed in the dark-slide (I use an ordinary quarter-plate carrier with a small strip of wood half-inch wide to keep the plate from shifting out of the centre), the slide is placed in the camera, which, we will suppose, has been adjusted on the platform to the required place; stop the lens down to *f*/16 or *f*/22 (if the light is good, the latter), cap the lens, draw the slide, and place the whole in the box, which has been made with a light-tight fitting cover, and a door at one end where the negative is; place this box now in any position you may find suitable, either pointing to the sky through a window or door, or on its end in the garden, it matters not, so long as it can have the light free of all obstruction. In the event of not being able to get clear of walls or trees, a white cardboard reflector must be used, placing it at an angle of 45° to the negative. In a box such as I have described, the door may be made use of to hold this in position.

I must not forget to mention that in using a box made in this way, it will be necessary to use a lens working at not more than 6-inch focus, as in a longer lens the dimensions of the box would become too great for carrying about. The exposure is made by opening the door of the box (cap taken previously off lens), and the lid shut down when not in use. I have found it, being practically dust-tight, useful to stow away the ever-increasing impedimenta.

Death of Mr. Samuel Fry.—With much regret, though not with surprise, the announcement of the above event will be received by all who were acquainted with the deceased, who was the founder of the firm of Samuel Fry and Co., now the Fry Manufacturing Co. Mr. Fry had for some time been suffering from heart disease, which terminated fatally at Dumpford House, near Petersfield, at the comparatively early age of fifty-six. Mr. Fry was one of the veterans of photography, and his name is closely associated with the dry plate revolution. Prior to the increase of business pressure in the manufacture of dry plates, and failing health, he was a frequent and valued contributor to the Photographic News and Year-Book. The interment took place yesterday at the Friends' Burial Ground, Kingston-on-Thames. Among those present were Mr. Hayman, Mr. Matthew Whiting, and Mr. T. Piper representing this paper.

LANTERN SLIDES AND LANTERN SLIDE MAKING.*

BY F. C. BEACH.

One of the chief requirements of a negative for slide-making is that it shall be very sharp and distinct, with sufficient density in the high-lights to prevent the clouding of the sky portion of the slide. A moderately dense negative, therefore, generally produces a crisp slide, since it enlarges the limits of exposure, and allows more latitude in development. An excellent slide, however, may be made from a very thin, clear negative by careful timing and a proper developer. A foggy negative will produce an unsatisfactory slide. Thus, much depends on the negative; in selecting such for slide work from a summer's collection, reserve only those that are sharp and of good average density.

There are two different ways of making slides; one is the contact method, and the other reduction by the camera. In the contact method, a portion of a large negative is sometimes selected, on which the sensitive plate is laid in contact, film side next to the negative film, in a printing-frame. Over the back of the sensitive plate should be placed a sheet of black or orange paper, to prevent reflection of actinic rays from the back of the sensitive plate against the underside of the sensitive film. Holding the frame towards a screened gas light, or kerosene light, about eighteen inches distant, an average exposure of ten seconds is given by quickly removing and replacing the screen. A thin negative will need but two seconds, a very dense negative from twenty to thirty seconds, and one having a yellow tinge may take a minute.

The different capabilities of different negatives may be quickly learned by a few trial exposures. It is advisable to grade the negatives according to their density, so that a uniform exposure may be given to a certain number, which should result in the production of satisfactory slides. For contact work, many prefer to use 4 by 5 negatives, selecting the centre for the picture, but a better size is the $3\frac{1}{4}$ by $4\frac{1}{4}$ plate, which has margin enough to allow the proper locating of the sensitive plate, and makes a picture better proportional to the lantern size.

As an illuminant, artificial light, diffused daylight, or magnesium flash or ribbon light may be employed. By placing four printing-frames, containing as many negatives and plates, twenty inches equidistant from a central point, one exposure of an inch and a-half of magnesium ribbon burned over the central point, moved about a little, will affect equally the four negatives. The plates thus exposed may all be developed at once in a $6\frac{1}{2}$ by $8\frac{1}{2}$ tray with the probability of securing good slides; so that by the contact method slides may be made very rapidly during the evening.

Reduction by the camera is largely preferred, because the variations in the size of the image to be impressed upon the sensitive plate are so easily and quickly affected. Usually the camera is placed on a long board, holding at one end a frame in which are removable kits or frames to hold different sized negatives. A printing frame with the back removed may be utilized for this purpose. The negative is best illuminated by facing that portion of the sky opposite to the position of the sun, though it is possible to use direct sunlight by interposing a ground glass between

* Read before the Society of Amateur Photographers of New York.

the window and the negative, and giving a shorter exposure. The space between the negative frame and camera should be covered by a light black cloth to exclude extraneous light. I prefer to have a special frame fitted to the back of the camera, with a 3¼ by 4¼ aperture cut in the centre, arranged to support or hold a 3¼ by 4¼ double plate-holder, rather than to employ a kit in a large holder, because it is more convenient and more easily handled. Mr. Chas. Simpson suggested, some time ago, a swinging or pivoted frame for holding the negative, that the picture might be levelled easily in case it was taken at an angle on the plate. He also provided simple means for sliding the frame horizontally and vertically. These movements are very advantageous, and should be provided if one is to work quickly. I generally employ a rapid rectilinear lens, though this is not necessary, as a wide-angle lens will answer just as well. Any lens that will give a sharp picture stopped down to *f*/16 will do.

There have been three favourite kinds of developers for lantern slides—pyro, hydroquinone, and ferrous oxalate. The two latter do not stain the fingers. Pyro should be preserved with sulphite of soda, and combined with such alkalies as soda and potash. Four ounces of sulphite should be mixed with one ounce of pyro. This is undoubtedly the quickest developer, and, when the exposure is nearly correct, imparts a brownish tone to the slide. Not more than two plates should be developed in succession in one solution. A working formula is as follows:—

Pyro	2 grains
Sulphite of soda	4 ,,
Carbonate of potash	3 ,,
Water	1 ounce

If the shadows develop too dense, the amount of pyro should be decreased. A hydroquinone developer contains more hydroquinone in proportion than there is pyro in the pyro developer to obtain the same amount of density, but the difference is made up by the greater number of plates that can be developed with it. The following is used successfully:—

Sodium sulphite	40 grains
Hydroquinone	15 ,,
Water	1 ounce

To this is added fifteen grains of carbonate of potash, which forms the developer, with which from six to eight plates may be developed in succession.

The ferrous oxalate developer, commonly known as the *iron* developer, has for a long time been regarded as the standard for lantern slides on dry plates, and, when properly handled, it does produce exquisite results. But it does not keep well after being mixed, and rapidly deteriorates on exposure to the air. The point most to be feared is the precipitation of the ferric salt by having too much iron in proportion to the oxalate of potash. Two separate saturated solutions of sulphate of iron and of oxalate of potash are made by dissolving each in hot water. The iron is acidified with five drops of sulphuric acid to each pint, while the neutral oxalate may be made acid by adding oxalic acid until blue litmus paper is turned red.

To develop, use—

Oxalate of potash solution	6 ounces
Iron solution	½ to ¼ ounce

When the detail has appeared, if the development is too slow, about 1½ ounces more of the iron solution may be added, which will increase the density. It is advisable, after fixing, to immerse the plate in a clearing bath of alum and citric acid.

We now come to a new developer which will supersede all others for lantern slide making, as it gives to the film a blueish black tone very similar to the palladium or platinum tone usually given to wet-plate slides. I refer to "eikonogen." The proportions recommended are:—

Sulphite of soda	10 grains
Eikonogen...	5 ,,
Carbonate of potash	2 ,,
Water	1 ounce

A developer thus made will develop rapidly from seven to ten slides in succession, each of which will be absolutely clear glass in the high lights, and have in the shadows a density so delicate that the light of the optical lantern will bring out in fine relief all the details. The slides possess a richness in crispness and sparkle that is seldom seen in wet plates. The rapidity of the action of the developer may be retarded by adding a few drops of a ten grains to the ounce solution of bromide of potassium. After fixing, the slides are washed in changing water for half an hour, and they should be rubbed with absorbent cotton to remove any floating particles that may have become attached to the surface, and then set up to dry.

There seem to be several different ways of labelling and marking slides, but the system adopted by the American Lantern Slide Interchange appears to be the simplest.

After the cover glass is put on by the usual gummed strip paper, holding the picture in its natural position, the descriptive label is attached to the right hand side of the cover glass with the reading matter facing inward, while the thumb label is placed on the lower left hand corner. The reason for this is that, as the slide is taken up and held between the thumb and finger with the thumb on the thumb label, the description and name on the label at the other end is very easily seen and read. Still holding the slide with the thumb and finger, it is at once pushed into the slide-carrier of the lantern, and appears correctly on the screen. The cover glass should invariably go towards the condenser of the lantern. If the plan described is used, there need be no mistake in putting through a number of slides.

The utility, benefit, and pleasure to be derived from lantern slides are self-evident to all, and I look for more extended work in this field this winter, and trust many new members will try a hand at it.

The Rights of Photographic Publishers.—The reproduction of photographs in the illustrated press, which most photographic publishers regard as a welcome advertisement, is resented by a few as an infringement of their rights of property. Until last month we have never been refused liberty to reproduce any photograph, the acknowledgment of its source being invariably regarded as an adequate *quid pro quo*. Last month, however, M. Barraud has actually threatened newspapers with legal proceedings for reproducing without his leave a photograph of Cardinal Newman, and the same month brought me a formal complaint from the London agent of the Hanfstaengl Photographic firm of Munich, that I had infringed their copyright in reproducing by a small process block a photograph of Lenbach's painting of Bismarck, which is their property. As I don't wish to infringe anyone's rights, whether they were legally secured or not, I at once stopped the sale of the number containing the picture in question until I could reprint it, which I did at once, omitting the illustration complained of. I naturally regret very much having unwittingly offended the owners of Lenbach's "Bismarck." In the innocence of my heart I thought I was doing them a good turn.—*Review of Reviews.*

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

V.—Action of Light on Sensitive Film.

Our investigations have not only revealed the fact that one single density taken by itself is not characteristic of the exposure which the sensitive film received, since the density may be partially due to "fog," or may not be developed to its extreme limit, but the experiments have also clearly shown that the ratios of two densities, exclusive of fog, is a function of the action of the light on the plate. It will be noticed that in all these experiments the exposures given varied between ten seconds and eighty seconds, and the source of light was always a standard candle placed exactly one metre off the plate. If we tabulate the ratios found between the ten seconds' and eighty seconds' exposures in these experiments, we see at once that the ratio, though constant for one particular plate, is very different for different plates.

Name of Plate.	Ratio of Densities for Exposures $\frac{40''}{10''}=4$	Ratio of Densities for Exposures $\frac{80''}{10''}=8$	Experimental No.
Ilford 'Red Label'	1·53	1·63	13
Wratten 'Drop-shutter'	1·71	1·92	13
'United Kingdom'	3·12	4·27	13
'Manchester Slow'	2·97	3·82	15
Do. Do.	2·85	3·80	16
Do. Do.	2·84	...	14
Own make ..... Batch A. ..... Exposures $\frac{160''}{20''}$			8·00
,, A. ..... ,, $\frac{240''}{30''}$			5·30
,, A. ..... ,, $\frac{1440''}{180''}$			3·00

The ratio is, for the same exposures, smaller for rapid plates than for slow plates, but even with the same plate the ratio between two densities varies for exposures which bear the same ratio to each other, but are different in absolute value, as is seen from the experiments given in the above table, and made with plates prepared by ourselves.

It is certain, therefore, that the ratio between two densities depends not only on the ratio of the exposures, but also on the sensitiveness of the plate and the absolute values of the exposures. The following investigations were made to discover the connection existing between exposure, sensitiveness, and density produced.

Unit of Exposure.—For these investigations it was necessary to adopt a standard unit of exposure. As unit of light we have chosen the intensity of a standard candle at one metre distance, and as unit of time the second, so that our unit of exposure is the product of the intensity of the standard candle at one metre distance and the second, and we call this unit of exposure one candlemeter second. We find for experimental purposes, with plates of average speed it is an excellent unit, easily procured, and of sufficient constancy to permit of satisfactory repetitions of experiments. There are a few precautions necessary to ensure uniform results. The flame of the candle cannot be relied on until it has settled to a height of nearly 45 mm. measured from the top of the spermaceti to the top of the flame, as shown in fig. 4. The candle must be protected against draughts, and this is best done by placing it within a black box having one side open. This also prevents the illumination of bright objects on the working table and consequent reflections. The candle should be extinguished by an extinguisher, and kept covered up while not in use.

As regards measuring time of exposures, we use a chronograph watch, or a metronome for short exposures, but we find that errors of exposures become too great if less than ten seconds are measured. If we wish to give shorter exposure than ten candlemeter seconds (C.M.S.) we place the standard candle two metres off, thus reducing its intensity to one quarter.

It is scarcely necessary to say that we have carefully ascertained that, within such limits of exposures as our experiments embrace, it is immaterial whether an exposure be made with a light of $\frac{1}{4}$ candlemeter for forty seconds, or a light of one candlemetre for ten seconds. We have also proved by experiment that, as far as the ratios of densities are concerned, they remain constant, whether the exposure be made with a candle, with a petroleum lamp, or with daylight, so long as the product of intensity of light and time of exposure be the same. The intensities of such different sources of light cannot, however, for this purpose be compared by the ordinary Bunsen photometer, but must be compared by photographic experiments. But with careful work even single densities can be reproduced with tolerable accuracy. For instance, on three separate days we obtained on three separate plates of the same batch, by carefully measuring the time, both of exposure and of development, densities 0·750, 0·730, and 0·720 respectively. Four different standard candles gave upon one plate in ten seconds the following densities: 0·490, 0·490, 0·500, 0·480.

With the standard candle we investigated, in the first place, the general effect of prolonged exposure on the density, *i.e.*, we ascertained how much silver was reduced by different exposures.

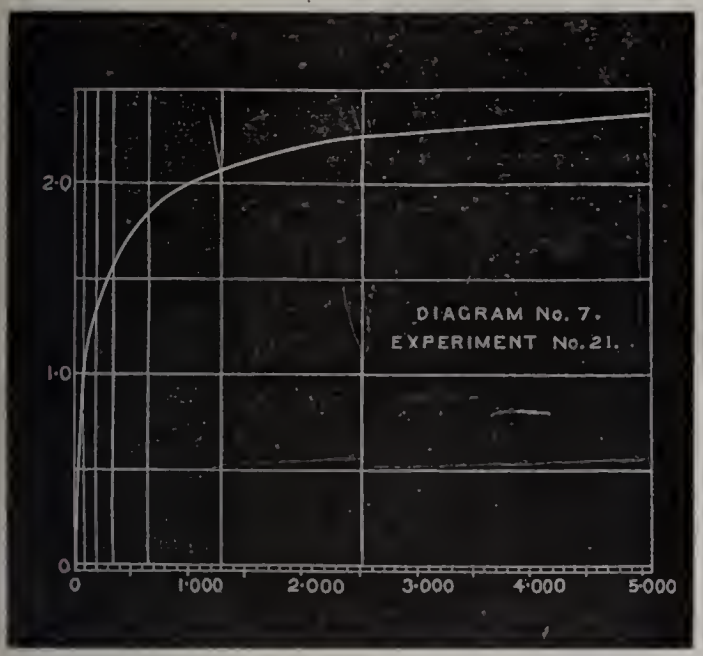
Experiment 21.—A "Manchester Slow" plate exposed, developed with ferrous oxalate, and measured, gave:—

Exposure C.M.S.	Density.	Difference.	Exposure C.M.S.	Density.	Difference.
0·625	·045	...	80	1·010	·255
1·25	·055	·010	160	1·270	·260
2·50	·085	·030	320	1·555	·285
5·00	·175	·090	640	1·885	·330
10·0	·250	·075	1,280	2·088	·203
20	·460	·210	2,560	2·262	·174
40	·755	·295	5,120	2·352	·090

It will be seen that, every time the exposure is doubled, the density increases, at first slowly, then considerably: and (disregarding errors of experiment) from 40 C.M.S. up to 1,280 C.M.S., every time the exposure is doubled, nearly an equal addition to density is the result, the addition to the density being on an average 0·266; but after an exposure of 1,280 C.M.S. further doubling produces less and less increase in density. The first few densities are too small to admit of accurate measuring.

* Continued from page 750.

This series of results is represented graphically on diagram No. 7, the exposures being chosen as abscissæ, the densities as ordinates; from this diagram it will be seen at once how rapidly densities grow at first as exposure is increased, and how slowly at last the densities tend towards a limit.



The following series of exposures is carried still further in order to ascertain the character of the curve representing the action of the light on the silver bromide, and to learn, if possible, something of the limit towards which the curve tends.

Experiment 22 :—

Exposures C.M.S.	Densities.	Difference.	Exposures C.M.S.	Densities.	Difference.
1	·060		1,024	2·985	+ 450
2	·160	+ 100	2,048	3·115	+ 130
4	·340	+ 180	4,096	3·280	+ 165
8	·500	+ 160	8,192	3·405	+ 125
16	·715	+ 215	16,384	3·508	+ 103
32	·940	+ 225	32,768	3·474	— 0·034
64	1·345	+ 405	65,536	3·280	— 0·194
128	1·875	+ 530	131,072	3·128	— 0·162
256	2·290	+ 415	262,144	2·920	— 0·208
512	2·535	+ 245	524,288	2·464	— 0·456

This series of results could not be graphically represented to advantage by choosing exposures as abscissæ since they vary from one candlemeter-second to over half a million. But it is evident that prolonged exposure gradually reduces the density attainable after development.

The graphic representation of experiment 22 on the same scale as experiment 21 would require a diagram about 500 times as long as diagram No. 7, and nothing of any value would be learnt from such a diagram.

What we really wish to ascertain is, whether it is possible to produce a theoretically perfect negative, such as was defined, and what the connection is between the densities and the exposures.

(*To be continued.*)

A correspondent suggests the employment of paper, pressed and chemically prepared, for making lantern bodies, lens tubes, and slide frames, as it would tend considerably towards lightness.—*Optical Magic Lantern Journal.*

Patent Intelligence.

Specifications Published.

18,609. *November 20th*, 1889.—"A Cutting Shape." Benjamin Jumeaux, 11, Brighton Place, Stretford, Lancashire, Artist.

My improvements relate particularly to the thick pieces or sheets of glass which are used when cutting off the edges of photographic prints or pictures to the size of the glass plate.

At the present time the glass sheet is placed upon the surface of the print, picture, or mount to be cut to size, and, owing to the smooth surface of the former, it is apt to slip or move under the pressure of the knife when cutting.

In order to overcome this difficulty, I propose to grind or otherwise form three or more, preferably four, small recesses in the underside of the glass, say near each corner. Into these recesses are secured by any suitable cement small pieces of india-rubber, cork, flannel, or other suitable material, the surfaces of which project slightly beyond the face of the glass : by this means the glass will be prevented from slipping sideways during the operation of cutting or trimming the edges of prints, pictures, or mounts.

The improved appliance for use when cutting prints and the like ; said appliance consists of a sheet of glass provided with recesses in which are secured pieces of india-rubber, cork, or other suitable material substantially as, and for the purposes herein set forth.

19,926. *December 11th*, 1889.—"Dissolving-view Lanterns." Henry Bond, 126, Wilderspool Road, Warrington, Newspaper Manager.

My invention consists of a device for utilising the light derived from an oil lamp, or other suitable illuminant, in two directions, in such a manner as to produce and converge upon the screen two independent and simultaneous discs or fields of view from one light.

The rays utilised are those shining in the directions right and left of the operator standing behind the illuminant, and facing the screen.

Condensers are placed on each side of the illuminant with their edges towards the screen, their axes corresponding with the two lines of light from the central source.

The slides or transparencies to be thrown upon the screen intervene in front of the condensers in the usual way.

Images of the slides are reflected to the objective lenses (placed with their axes at right angles, and in a horizontal plane with the axes of the condensers) by plano-mirrors or specula placed vertically between the slides and the objective lenses, and fixed in regard to the axes of those lenses, and of the condensers at an angle of forty-five degrees.

Means for bringing the two discs of light together, at varying distances of the lantern from the screen, are provided by the movement of one or both optical systems independently on a common pivot under the illuminant, the axis of which pivot lies in a vertical line drawn through the centre of the illuminant.

An alternative method is to preserve the condensers in a fixed position in regard to the source of light, and to adjust one or both mirrors and their associated objectives on separate centres or pivots with vertical axes, which axes lie in the planes of the reflecting surfaces, and cut the horizontal axes of the condensers.

5,227. *April 3rd*, 1890. — "Photographic Cameras." Charles Whitney, Chicago, Manufacturer.

My invention relates to the improvement of photographic cameras and their adjuncts, my improvements being especially designed for the variety which may be termed "pocket" cameras, or those of such diminutive size as to render them conveniently portable in the hand, or by being otherwise carried or stowed away on the person, ready for immediate use whenever desired ; and of the adjuncts referred to, my invention relates, particularly, to the lens-shutter detail for the cameras; to means for controlling a flexible sensitised ribbon for the negative plates, in the form both of a continuous sheet or ribbon, or in separate plates cut to desired size ; to the numbering and construction of the negative ribbon, and to the cutting mechanism

for severing it into plates, and means for permitting observation of the position of any negative plate for its exposure.

The objects of my improvements are, to provide a construction of the instrument whereby it shall be produceable in the various forms, and in the comparatively diminutive dimensions with proportionately large capacity to adapt it to serve the convenience for which it is intended, and the purpose of perfecting and simplifying the operations necessary in making negative plate exposures.

This invention cannot be adequately described without numerous drawings, which will be found in the patent.

12,155. *August 2nd*, 1890.—"Etching upon Glass." Ben Zion Meth, 6, Wollinerstrasse, Glass-Worker, and Hermann Kreitner, 83, Chorinerstrasse, Berlin, Merchant.

This invention relates to a process for etching upon glass, differing from the methods hitherto employed in that the etching is effected by a cold process, and with the aid of an india-rubber stamp, the etching of such articles as bottles, lamp glasses, glass plates, and similar objects being considerably accelerated, and the cost of treatment reduced.

In carrying out our process we use an etching solution prepared in the following manner:—10 grammes of pure fluoride of ammonium, ½ a gramme of common salt, and ½ a gramme of carbonate of sodium are well pounded up in a porcelain mortar, and mixed in a gutta-percha bottle with 4 grammes of highly-concentrated fuming hydrofluoric acid and 2 grammes of concentrated sulphuric acid; the bottle being well shaken. In a separate vessel, made of lead, ½ a gramme of crystallised fluoride of potassium is dissolved in 1 gramme of common muriatic acid heated in a hot water bath. Of the latter mixture 1 gramme is added to the mixture previously prepared; the contents of the bottle being again agitated and mixed with 2 drops of silicate of sodium and 1 drop of spirits of sal-ammoniae.

A small quantity of the etching solution thus formed is dropped upon a sheet of india-rubber covered with a cloth pad, which is rubbed until almost dry; whereupon, by means of an india-rubber stamp, bearing the design to be reproduced, a portion of the liquid previously absorbed by the pad is transferred to the surface to be etched, with the result that the design is eaten out.

Should a deposit be formed in the gutta-percha bottle in consequence of the etching solution not having been used for some time, such deposit may be dissolved by hydrofluoric acid.

Correspondence.

EXHIBITION IN CALCUTTA.

Sir,—With reference to the intimation published in your paper that on application to me particulars can be had regarding the coming photographic exhibition in Calcutta, I shall be glad if you will now add the information that I have returned to India per *Shannon* ss., and, therefore, further letters to my address will not receive reply. John S. Gladstone,
Sec. Phot. Soc. India.

FISHING MATCH AT AMBERLEY.

Sir,—As the photographer at the fishing match at Amberley referred to in your "Notes," I may inform the writer that I am an angler, though I was not fishing in the match, and also that it was impossible to get a photograph of the contest. Three hundred anglers spread along three miles of winding river proved too much for me, though I got some successful views of the river, showing characteristic groups of fishermen.

I must make an objection to the remark that anglers do not care about beauty of scenery. Even the humble East End club men appreciate the beauties of the river and surrounding landscape, and enjoy the outing and fresh air, and the loveliness of nature, even though they may catch no fish.

I am inclined to fancy that the writer must be a bit of a fisherman himself. Whether he be or not, I shall be very pleased to show him a selection of shooting and fishing photographs whenever he likes to make an appointment. I may mention that one of my fishing views is on view now at Pall Mall. Reg. B. Lodge.

1, *Chase Green Villas, Enfield, October 1st.*

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

Sir,—Please insert this corrected list of subjects for discussion, and oblige:—

October 9th.—First lantern night, and demonstration on "Lantern Objectives," by Mr. T. E. Freshwater.

October 16th.—"Pictorial Definition," adjourned discussion resumed by Mr. W. E. Debenham.

October 23rd.—"Preparation of Dry Plates," by Mr. W. H. Prestwich.

October 30th.—"Photography in Colours."

Visitors cordially invited. R. P. Drage, Hon. Soc.

Proceedings of Societies.

Photographic Society of Great Britain.

At the technical meeting of this Society held on the 30th ult., Mr. Friese Greene occupied the chair.

Specimens of a new process of dyeing by a photographically sensitive compound of primuline and nitrite of sodium were shown by Messrs. Green, Cross, and Bevan, and the process—except the exposure to light, which had been given in the daytime—was demonstrated. The effect of light was to render the compound no longer susceptible of development by the various agents used, which were, beta naphthol for red, resorcine for orange, alpha naphtholine hydrochlorate for purple, and alpha naphthol sulphonic acid for crimson. A piece of calico which had received an exposure to light, except where shielded by leaves to form a pattern, was developed by means of brushes with these agents, forming the pattern in the colours mentioned.

In reply to questions Mr. Green, the demonstrator, said that if too long an exposure was given, the resulting image would not be deep enough, whilst with too short an exposure the effect was dauby.

Mr. Arnold Spiller asked whether the effect of light on the compound employed was of a reducing or an oxidising character?

Mr. Green replied that it was neither. Very good gradations were obtainable with proper exposure.

Mr. John Spiller had tested the images produced by this process with all the ordinary reagents of the laboratory, as well as by exposure to direct sunshine, without finding any change in them, from which he augured greatly in favour of their permanence.

Mr. Arnold Spiller enquired whether there was anything of a tanning action in the product of the development? In that case the image might be formed in gelatine, and the light parts could be dissolved out by hot water.

Mr. Greene said that he did not think there would be any tanning action.

Mr. F. Varley showed a stereoscopic camera arranged for the production of successive negatives at a rapid rate. Mr. Friese Greene had with this camera taken a long roll of negatives on stripping film at the rate of from three to five in a second, and so secured various phases of motion. The mechanism of the camera was shown, and Mr. Varley explained that the tendency of a roll to hang loose was overcome by differential speed of the two spools. There was also a small roller, which, being thrown against the film at each movement, both helped in keeping it taut, and prevented it from running to one or the other end of the roller.

It was announced that the next technical meeting of the Society would be held in the Exhibition Gallery on the fourth Tuesday in October, and that on that occasion the apparatus would be shown and explained.

The London and Provincial Photographic Association.

September 25th.—Mr. J. W. Atkins in the chair.

Mr. F. A. Bridge, referring to repeating flash-light lamps, gave particulars of a serious accident that had recently happened to a member of the Photographic Club whilst photographing a party of children assembled at his house. Hibbard's repeating lamp was being used, when an explosion took place, causing considerable damage to the furniture, but fortunately without injury to anyone present. The lamp was blown to pieces, leaving only its nozzle. The powder used was sold with the lamp.

Several members expressed an opinion that a highly explosive ingredient must have been mixed with the compound sold.

An exhibition of prints was given by members who had attended the outing on the previous Saturday at Hampstead Heath, Messrs. E. W. Parfitt, W. E. Debenham, T. E. Freshwater, and the chairman each showing silver prints from negatives taken on that occasion.

Mr. Chang exhibited two albums of instantaneous work, consisting of views in the neighbourhood of Arundel and Hampstead Heath.

The Chairman also showed some photographs taken by him at St. Albans and Church Stretton.

In a short discussion that followed on non-actinic light, it was generally agreed that a plate in course of development would, after the image was out, bear a large amount of light without injury.

Bath Photographic Society.

The eighth and last of this season's excursions took place on Thursday, the 25th ult. The party left Old Bond Sreet by brake shortly after two o'clock, for Newton St. Loe. Newton Bridge, from the city side, was the first subject chosen. The sky was overcast, but some fine effects of light and shade were obtainable. Resuming the journey, Saltford was reached within an hour of the start. Here several plates were exposed in the village and at the landing stage. Crossing by the ferry to the Kelston side of the Avon, a short journey on foot brought them to the lock and weirs facing the boating-station, and here a variety of subjects was presented, including pastoral and woodland as well as aquatic. Nearly two hours elapsed ere the ferry-boat was again called into requisition, so loth were the members to leave this most picturesque neighbourhood. The ferry recrossed, a smart drive was next taken to Swinford Weirs, a little distance up the river in a westerly direction, and here the now declining sun, with its attendant long-cast shadows, produced scenic effects of the most charming description. Before sundown the supply of plates became exhausted, and after the party had refreshed themselves at the Jolly Sailors, Swinford, the journey home was made through scenery which it would be difficult to excel. Mr. H. S. P. Wells acted as leader on this occasion, and it may with confidence be said that amateurs visiting Bath cannot do better than follow the example set by the local society. The indoor meetings will be resumed on the 29th inst.

West London Photographic Society.

A special meeting, convened for the purpose of allowing members to see the new premises of the Society, was held at the Lecture Hall, Broadway, Hammersmith, on Friday, 26th. The president, Mr. Chas. Bilton, occupied the chair. The meeting was of an informal character, there being no special business to transact.

The Secretary then exhibited the fusee repeating flash-light lamp, an ingenious and portable piece of apparatus recently introduced by Messrs. Adams & Co. The "Perpetual" shutter, by the same firm, was also shown. The special features of this shutter are, that it requires no setting, and by an arrangement of a pneumatic cushion it can be fitted to lenses of various sizes without the employment of adapters. Negatives, and prints therefrom, taken during the summer, were then handed round and criticised, after which the proceedings terminated.

The annual general meeting takes place on October 10th, at the Broadway Lecture Hall, where all future meetings will be held. Friday, 24th October, will be a lantern night.

North Middlesex Photographic Club.

Monday, Sept. 22nd.—Mr. Lothbridge in the chair.

Mr. Hiscock exhibited several whole-plate prints in platinum, which were very fine; the negatives had been taken on Edwards's isochromatic plates.

Mr. Paul exhibited one of Chadwick's "Eclipse" lantern slide carriers, by which, upon introducing a new slide, it first cut off the light, after which the fresh slide was pushed into position, when the shutter was again withdrawn, and the fresh slide appeared upon the screen. The simplicity with which it worked was especially spoken upon.

Mr. C. Beadle then gave his paper and demonstration of "Lantern Slide Making" (see page 769). The lecturer exposed and developed a lantern slide, also a half-plate transparency, in which the high lights were remarkably clear for a gelatine slide. The exposure was given by the dark-room lamp, which gave a flame of about $1\frac{1}{4}$ inches, and the time 80 seconds, at 6 inches distance from the burner. One slide (the interior of a cathedral) in which the negative from which it was made was badly fogged by halation, was shown round, in which no trace of this fault was visible; this result had been obtained by masking.

Mr. Marchant wished to know which was the better to use for copying, a rapid rectilinear lens or a wide-angle?

Mr. Beadle: It does not matter which, as among those to whom I have recommended my plan are those who use both.

The Secretary: The results would be equally good, the only difference being in the time taken—the rapid rectilinear working at a larger aperture.

At the next meeting, October 13th, Mr. D. P. Rodgers, who has been photographiug in Egypt this summer, will give a lecture entitled, "Pictures of Egyptian Life," illustrated by lantern slides made by himself, and shown by the optical lantern. Visitors invited to attend.

Cardiff Amateur Photographic Society.

Sept. 26th.—Chairman, Mr. S. W. Allen. The chief topic of interest was an intimation from the Free Library Committee that they would be pleased to offer a gold, silver, and bronze medal in connection with the county survey, the same to be open to all the professionals and amateurs of the county; also a silver medal for competition amongst the members of the Society only.

Mr. W. Booth reported that the survey had made satisfactory progress, notwithstanding the bad season.

Hackney Photographic Society.

A meeting was held on Thursday last, when Mr. Beckett presided.

Messrs. Hensler, Gosling, and Dean passed round views they had taken whilst on their holidays.

The Secretary showed "Le Tison Eclair," a flash-lamp of French make; the flash was brought about by magnesium being blown through an ordinary match flame.

After reminding members that the entry forms for exhibition purposes are now ready, the Chairman called on Mr. W. L. Barker for his paper on "Shutters." There were between twenty and thirty different makes of shutters for the lecturer to comment on, which incidentally he did. After mentioning the various positions in which shutters were used, he proceeded to state his opinion that undoubtedly the most correct position for a shutter was between the lenses, as the illumination was more even and shutter was practically faster. He was, moreover, of the opinion that the centre required less lighting than the margins of a picture. He said that the moving part should be extremely light, so that there should be no "kick" or "jump," thereby causing vibration, and advocated the use of a shutter which had no parts to get out of order. He showed his Newman shutter with a pin attached to the central screw, a contrivance he had constructed to tell at a glance whether

the shutter were set or no. If it were, the pin would rest at a given point (indicated). The best position for a shutter on a hand-camera or studio lens was at the back of a leus, as it was then unobtrusive.

The Chairman preferred the ordinary plain drop-shutter, which, he judged roughly, fell at one-tenth of a second. He generally tested a shutter with the aid of a bicycle wheel.

Mr. Barker said he had done so, with the following result :—Newman's, $\frac{1}{80}$ to $\frac{1}{20}$, and the plaiu drop-shutter, $\frac{1}{10}$ second.

Tooting Camera Club.

The first general meeting was held at the High Schools, Church Lane, on the 23rd inst., Mr. J. H. Beckett in the chair.

The rules as drawn up by the committee were read and approved, and the followiug officers were elected for the ensuing year. *President*—Mr. A. H. Anderson ; *Vice-President*—Mr. J. H. Beckett ; *Hon. Treasurer*—Mr. C. Stowell ; *Hon. Secretary*—Mr. G. H. Dollery ; *Committee*—Messrs. W. Irwin, J. F. Child, S. J. Blazdall, and H. Berger.

It was decided that the name of the Society, viz., Tooting Amateur Photographic Society, should be altered to the Tooting Camera Club.

Those desirous of becoming members are requested to communicate with the hon. secretary, G. H. Dollery, Ivythorpe, Vant Road, Tooting Graveney, S.W.

Birmingham Photographic Society.

A meeting was held on September 25th at the Colonnade Hotel, Mr. W. Jerome Harrison, F.G.S., in the chair.

Mr. Pickard gave a report of the Bristol excursion.

Mr. Longmore exhibited some pictures taken in North Wales, and Mr. Leeson some of North Devon, taken with a haud-camera.

Mr. Sershall then gave a paper on "Art in Drawing—Photography," which was listeued to with attention.

Leicester and Leicestershire Photographic Society.

The last excursion for the present seasou was arranged for Friday the 26th inst., when a few workers met in spite of the unpropitious weather, and journeyed to Ashby Castle. After a time the light improved, and a series of most satisfactory exposures was made on the ruins of the ancient structnre, which shows evident signs of the ravages of time and elements. After the plates had been exhausted, the party drove to Hoo Ash, the residence of Mr. Jas. Jones, Ravenstone, who had invited the Society to accept his hospitality, where a sumptuous repast awaited them. The party then recharged slides, and took a walk to the village, where some pretty bits, and the interior and exterior of the old church, afforded ample scope for the exercise of the art. When the light had so far faded as to render photographic work no longer practicable the members returned to Hoo Ash, where the hostess was awaiting them with a welcome tea table.

The Great Yarmouth and Eastern Counties Photographic Society.—At a meeting held on the 24th September, it was decided that a photographic society under the foregoing name be formed, open to amateurs and professionals of both sexes. The following officers were elected :—*President*—Mr. H. D. Arnott ; *Vice-Presidents*—Messrs. Shuttleworth and Price ; *Treasurer*—Mr. John Taylor (National Provincial Bank) ; *Secretary*—Mr. H. Harvey-George, The Tower, Gorlestou ; *Committee*—Messrs. Rumbold, Pechey, Rudd, Hindle, and Blake. It was decided ou the 1st inst. that an opening meeting be held in the Towu Hall on October 8th, when the Mayor will preside, and lantern views lent by the Liverpool Association be exhibited by Mr. C. Rumbold.

Received.—From Messrs. Hazell, Watson, and Viuey, the second edition of "A Dictionary of Photography for the Amateur and Professional Photographer," by E. J. Wall. The compiler says, in his preface to the preseut issue, that "many additions have been made, new formuke incorporated, and to all have been added the metrical equivalent weights."

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the Photographic News, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the Photographic News, Messrs. Piper & Carter, 5, Furnival Street, London.

Photargus.—*Liquid Water Colours, Photo Stains.* Without actual knowledge of the particular preparatious mentioned in your letter, which you say will *not* mix with varnish, we can only recommend you to try such aniline colours as are soluble in alcohol. For a green varnish use "brilliant green" or "malachite green," dissolved in warm alcohol, and added in requisite quantity to a white lac or suitable spirit varnish. Films coloured in this way would not resist rain or bear long immersion in water, for the aniliue greeus are themselves soluble both in spirit and water. "Iodine green" is not now procurable, and is so easily decomposed by heat, turning over to Hofmaun's violet.

Northern.—*British Association Handbooks.* We do not know whether the "Handbook for Leeds and Airedale," like that of Bath (1888), is procurable by purchase. The printer's name is given, but there is no uientiou of a publisher. It would be well to apply in the first instance to Mr. H. Stewardson, at the office of the Association, 22, Albemarle Street, W.

R. C.—*Sepia Prints on Rough Paper.* Our illustration of last week—"Richmond Bridge," by Mr. Cembrano—is representative of a new style of art treatment which found expression last year in the works of Colonel Noverre and others, and is admirably shown in the medal pictures of Mr. George Davison and Mr. Lyonel Clark in the present exhibition.

A. M. S.—*The Coupon System.* Three cabinets for half-a-crown may appear cheap, and, by a happy chance, prove successful ; but, according to your own admission, you have to wait your turn, and pose yourselves "to look natural."

Tom is thanked for his long explanatory letter. Having got them you must needs prove them. Do this by wrappiug up some of the mounted photos in several folds of damp blotting-paper, and watch the result for a few days or a week to see whether there is any sign of fading.

Received, the prospectus of the Liverpool Photographic Exhibitiou, 1891. Prizes are offered in twenty-seven classes, on the usual conditions as regards entrance fee. The advice note must be received not later than the 20th January, and exhibits sent in between 2nd and 17th February.

R. M.—*Photographers' Benevolent Association.* The subscriptions for the current year should now be sent either to the treasurer, or to Mr. H. J. Beasley, hon. sec., 66, Chancery Lane, W.C. Several sad cases of distress have lately come up for timely assistance, and there is no doubt that contributious are much needed to meet these pressing demands.

L. T. E.—*Fuming Albumenised Paper.* One method is to fumigate with ammonia the felt pads about to be employed iu the printing frames ; another is to hang the dry seusitised paper in a box or closed chamber, with a shallow dish of strong ammonia placed at the bottom.

P. A.—*Original Ross Lenses.* If your lens has "A. Ross" marked upon it there is a probability of its being spurious, for the late Andrew Ross put out a notice warning his friends that he used his surname only—"Ross, London"—to desiguate his own manufacture.

E. Lyell.—*Camera Club.* The works of Mrs. Cameron were long since withdrawn from Bedford Street, and those of Mr. Lyd. Sawyer, of Newcastle-on-Tyne, are about to be shown ; see notice in the News of 12th ult.

M. P.—*Broken Dry Plates.* One in a dozen is a large proportion to meet with, and you ought to get compensation upon returning the unused (fractured) plates. With careful packing the loss should be very small.

Received.—E. and S., F. C., and Enamel.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1675.—*October* 10, 1890.

CONTENTS.

THE DIAZOTYPE OR PRIMULINE PROCESS.

THE chief novelty in the Photographic Exhibition consists of a few specimens of work executed on paper, cotton-cloth, velvet, and other fabrics, by what Messrs. Green, Cross, and Bevan, the inventors, call the diazotype process. Of this process we gave a full description a few weeks ago, and for the first time in photographic journalism, at the close of the meeting of the British Association at Leeds.

There is some possibility of this process becoming for a time a fashionable "craze," because it is easy as well as expeditious, and a lady may take any white fabric and print upon it designs to suit her own taste; pressed leaves would serve instead of a transparency for the production of many an artistic design. By the use of transparencies to print from, it would not take long to produce a curtain covered with the portraits of all the members and the friends of the family; such a curtain, it is true, would be likely to be of interest more from its novelty than its æsthetic merits.

At a meeting of the Photographic Society, Mr. Green recently printed different leaf-patterns upon different parts of a piece of white cotton cloth; next he developed the several patterns with various developers by applying each of the latter locally with a brush; the result was a pretty series of designs in variegated colours upon one piece of cloth. The colours at present obtainable by the use of different developers in the process are red, orange, purple, and maroon; by mixing the purple and orange developers, an unsatisfactory kind of approach to green has been obtained. Developers to yield blues and greens with this process have yet to be discovered.

A story is told that one of the coal-tar greens was first obtained in the following way. A chemist had discovered a new red coal-tar dye, but it was fugitive. He asked a local photographer if he could suggest a way to fix it, and the latter replied that, so far as his experience went, "hypo" would fix anything. The chemist tried it and found that it produced a beautiful green dye. May Messrs. Green, Cross, and Bevan be equally happy in their experiments.

All the diazotype prints have at present a yellow ground. Mr. Green holds the idea that the way to avoid this is to try to prevent its formation, not to produce it first and try to discharge it from the fabric afterwards. His efforts have been partially successful, for he exhibited a piece of silk with coloured designs photographed upon it, and the ground was nearly white; it was of about the colour of cream.

In the diazotype process, what is called "developing" might almost as well be called "colouration," for the image is previously visible nearly, if not quite, to its full extent. Assuming a really invisible image to be impressed in the first instance on the sensitive compound, the discovery of a suitable developer therefor would quicken the present process, and render the camera more available; it might also form the foundation of a new branch of camera photography with organic salts free from silver.

The inventors describe diazotype printing as a "positive" process based upon the fact that the diazo derivatives of a newly-discovered group of coal-tar colouring matters, known under the name of primuline, are extremely sensitive to light, and therefore rapidly decompose on exposure. They say that the diazo compounds react with a variety of coal-tar derivatives—phenols and amines—to form colouring matters of very rich shades; when decomposed by light, this property is entirely lost in the product of decomposition, which is an inert substance. After exposing a surface sensitive with the diazo compound to the graduated action of light, such as results from the varying tones of a positive, the destruction of the diazo compound is found to have taken place in exact proportion, and the subsequent development produces a coloured picture with an accurate reproduction of the details of the original. In the fully discharged portions, the high lights, the colour is the neutral tint of the product of decomposition of the diazo compound.

Papers on this subject, with demonstrations, are to be read hereafter before the Society of Arts and the Camera Club. A medal for photographs produced by this process has just been awarded by the Photographic Society of Great Britain.

AN AID TO DAYLIGHT.

The time of year is now approaching when every photographer, be he professional or amateur, will be greedily crying out for "more light," for the days are darkening, and studios are beginning to look dull and gloomy in spite of their transparent walls and roofs. The average sitter has heard and read so much about instantaneous photographs, and has probably seen so many pictures of express trains, seagulls, and lightning, that, as he enters the photographer's premises, he is apt to expect a little too much in the way of instantaneity. "If," he perhaps argues to himself, "an express train a couple of hundred yards long can be taken in the two-hundred-and-fortieth part of a second, in how much less time should a comparatively small object, such as myself, be photographed?" The question looks almost like one of those arithmetical problems which are invented to tease and worry students at competitive examinations, and bears still further resemblance to them in its utter absence of common sense and probability. But it is put forward here as the kind of argument which would be used by one who was quite ignorant of the part which light plays in the production of a picture. To the untrained eye, the sunlight of autumn is as bright as that of early summer, and it is only the man who has to deal with it, and coax it into doing certain work, who knows how much its brightness diminishes as the year grows old. It is therefore necessary to take advantage of any means which presents itself of adding to the amount of light available, and there is no doubt that this can be done by the judicious use of magnesium powder.

The quantity of this metal sold in winter time by the photographic dealers alone must be enormous, and it is principally used by amateurs for photographing at night. But we would now advocate its use by professional workers, not only as their sheet anchor for evening photography, but as an auxiliary for daylight operations with the camera. No such help is, of course, needed by those who have their studios fitted with the electric light, and who habitually shut out daylight from their premises as a thing which is far too fickle to be regarded as a reliable assistant. But to those who depend on daylight—and more especially those whose studios are so situated that, although they have enough light early in the year, they suffer for want of it in the autumn—magnesium offers a ready means of overcoming their difficulties.

If all the sitters were of that cast-iron type familiar to photographers—we mean the man who will sit down, fix his head against the rest, and remain immovable for any time required—everything would be easy for the proprietor, and work would go on from morning to night with the sweetest regularity. But, unfortunately, the majority of people are differently constituted, the adults possessing *nerves* which prevent them keeping quiet for more than two or three seconds at a stretch, and the infants possessing tempers and other infirmities which prevent them ever keeping quiet at all. It is for the treatment of this class of patients that the metal magnesium is so valuable when used as an adjunct to daylight in shortening the necessary exposure. A few photographers have adopted the plan, and have spoken in high terms regarding its advantages, some going so far as to say that they have taken certain large negatives of babies which would have been simply impossible without such aid.

We believe that many photographers have been prejudiced against the use of the flash-light from having seen some of the pictures taken by its aid, and it must be confessed that a great many of these are of the most ghastly description. The fault is, in most cases, due to dependence being placed on one flash-lamp only, by which all the shadows are exaggerated, and the lights made painfully dense. The best results are obtained when three or four lamps are included in one circuit, that circuit not being a metallic conductor, as in the case of electric illumination, but an air-tube which will operate the lamps instantaneously by the pressure of one large pneumatic ball. Such lamps and fittings are now obtainable at a very low price, with movable stands upon which the lamps can be placed to the best advantage.

With regard to the best form of lamp for burning the metal, we should choose one of those in which the pure powder is driven through a spirit flame, in preference to the use of any pyrotechnic mixture of which the powdered metal forms only a part. Used in this way, by itself, it is safe, but when we begin to experiment with powders of unknown composition, and probably containing such quarrelsome ingredients as sulphur preparations and chlorate of potash, we are on dangerous ground. Besides, these mixtures are apt to deteriorate with keeping, and become inefficient in their action. The use of the magnesium flash in daylight does not startle the sitter as a flash of similar intensity will do at night, and therefore the daylight worker need not fear that his sitters will have that unnatural appearance so often seen in flash-light pictures.

*** *Those friends who have not yet sent in their* Year-Book *articles, are respectfully requested to send them without delay.*

Advice to Amateurs.—In every photographic operation care and deliberation are above all things necessary. The beginner should confine himself to one branch at a time, and, until he has learned by experience what deviations can be made from them with safety, should adhere absolutely to the instructions given. As he advances he is sure—and it ought to be so—to deviate in small matters from any written instructions which can be given him; but he will always find that careful and cleanly working is a necessity if good results are required. Above all, let him endeavour to avoid making the mere technicalities of his photographic work an object, instead of letting them be but a means to an end. Let him try at all times to produce pictures which will be a credit not only to himself, but to the art by which they are produced, bearing in mind that if photography is not ranked by all as one of the fine arts, it is rather because it is practised by so many who have not any artistic feeling, or will not take the trouble to acquire any artistic knowledge, than because it is incapable of producing true works of art.—*Marion's Guide to Photography.*

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

No mention was made last week of the medal awarded to Mr. W. J. Byrne, as it seemed to be more convenient to deal with the matter in connection with other examples of portraiture in the gallery. Portraiture has, year by year, been occupying a minor position in comparison with landscape work. This year there are less examples than usual, and it cannot be said that any single specimen shows a distinct advance. The fact is, photographers have gained a mastery over their materials in respect to portraiture, and as the professional photographer has of late depended so much upon the retoucher's "artful aid," one can well understand his reluctance to exhibit his productions. The exhibits in the direction of portraiture must mainly depend upon the professional. He has all the appliances in the way of apparatus; he has a perfectly lighted studio, and really, there is no world left for him to conquer. Mr. Byrne, who figures as the most important exhibitor of portraits, depends for attraction upon the fact that the pictures shown are not taken at his studio. I am not sure that they are any more interesting on this account, because it is now fully recognised that an ordinary room, in skilful hands, will give even better results than the studio, simply for the reason that they are not quite so conventional. "Dr. W. K. Selle" (No. 441) figures as the medal picture. He also appears in a series of pictures on the screen. There is little in the medal picture calling for comment. It "presents no mark to the foeman." Its manipulation is perfect, as it always is in Mr. Byrne's work, and that is the most which can be said for it. We have now grown out of mere admiration for a portrait because of the skill of the photographer; we look, rather, to the model, and desire to forget the manipulation.

In Mr. Mendelssohn's pictures there is much to admire, because he has been so very fortunate in his sitters. Some of them might really be taken as types of English beauty. Apart from this, his work is orthodox in treatment, and perhaps the captious critic might say a little akin to the show-case picture, but this quality is difficult for the professional photographer to avoid, and I find no fault with Mr. Mendelssohn's work on this account.

Some of the so-called studies in the Exhibition might almost rank as portraits; indeed, it is often difficult to determine where the portrait ends and the study begins. The distinction sometimes seems to be the insertion of the name in the first case, and the putting on of a fancy costume in the second. Mrs. W. P. Arnot shows some very excellent work, evincing much taste in the arrangement of drapery. If "a study" means something which is somewhat cold and academic, then Mrs. Arnot is to be highly praised, as all her pictures are well thought out, if somewhat unimpressive.

Mr. H. Stevens, I do not think, is up to his usual standard. It is difficult to understand why he chose such an unprepossessing model as No. 172. The misfortune is that she has irregular teeth, and Mr. Stevens has elected to take her with her mouth expanded into a smile. The same face appears in No. 305, with all her defects intensified. I am afraid that tiresome person to please, the general public, will see little to admire in Mr. Stevens' pictures this year. He affects a monotonous, out-of-focus aspect, and the prints are of a corpse-like hue. The tone of a photograph, and probably a type of beauty, are matters of taste, and I may be totally wrong.

Mr E. Resta shows some admirable portraits of children, as he has done on former occasions; but, skilful as he is, he is far distanced by Mr. Robert Faulkner's exquisite work—work which will be looked at with a melancholy interest. Both Nos. 156 and 408 show all the old feeling, tenderness, grace, and delicacy. So far as one's knowledge goes, there is no one to take Mr. Faulkner's place.

Mr. Harold Baker shows some careful pictures, but his work, on the whole, is not so notable as in former exhibitions. One of the best subjects, on the borderland between a study and a portrait, is Mr. Arthur Burchett's "La Belle Bretonne" (No. 279). It is simple in pose and pleasing in expression. It nowhere oversteps the modesty of nature, and fairly accurately gnages the photographic limit in regard to what used to be called "fancy" pictures. The stumbling block in the way of imagination, when a photograph which is supposed to tell a story is presented to you, is that you cannot get rid of the means by which the picture is produced. The posing of the model, the building up of the accessories, even the manipulation of the dark room, are too obtrusive. When a photographer makes one forget these things, he has accomplished much. Hence, in regard to this class of photograph, one might adapt a well-known saying, and exclaim, "Simplicity, simplicity, always simplicity!" Mr. Burchett is, clearly, convinced of this.

I cannot say I care much for Mr. Walter R. Cassell's portrait studies. His "Three Heads" (No. 12) are not beautiful, nor does Miss Calhoun as "Vashté Dethie" (No. 280) extort admiration. The somewhat repellant aspect of the pictures as a whole is assisted by the unbroken background which Mr. Cassell has chosen.

It is not quite certain whether Mr. Byrne intends No. 317 to represent Moses as a child, or a child as Moses; but the public can take their choice. Of course the photography is perfect.

Mr. Ralph Robinson gives us a second series of the admirable portraits of the Royal Academicians which gained a medal last year. They are all intensely interesting, and are really of national value. Mr. Robinson is to be congratulated on the uniform success which has attended what must have been a very trying undertaking.

Mr. Barry's portraits (Nos. 351 and 352) suffer from a sombreness of effect; while his picture of the "Misses Hamilton" (No. 429) is somewhat diffused in the composition; otherwise there is much in his work that is meritorious. Miss Florence Harvey's "Dutch Fishing Folk" (No. 436) is an excellent piece of work. It is out of the beaten track, and keeps well within the range of the possible. Mr. John Collier exhibits an admirable portrait of Cardinal Newman, and Messrs. Window and Grove show some portraits distinguished for delicacy of detail, a portrait of a nobleman being particularly good.

Mr. Lyonel Clark's portrait studies will inevitably excite considerable comment. I should be inclined to regard them as experiments, rather than as exemplifying Mr. Clark's ideal. Nos. 460 and 462 are the best; No. 461 is distinctly ugly. It may have its value as a specimen of equality of focus—or, to speak properly, equality of no focus—but as a counterfeit presentment of the human face divine, one would rather not look at it. It is instructive to stand by the pictures and listen to the comments of the spectators. Mr. Lyonel Clark fairly puzzles them. Sometimes it is said, "These are copies of paintings"; one critic hazarding the suggestion that the original must have

been in process of restoration. Mr. Clark, of course, expects to be keenly criticised over his new departure. What is to be feared is the risk of imitators. The out-of-focus picture *does* offer such an excuse for careless work.

Mr. Henry Stevens' photographs of well-known models (Nos. 470 and 482) are in some respects superior to his other pictures, but suffer from their inkiness of tone. On the screen are some portrait exhibits by Mr. Alfred Warner and Mr. Edgar Scammell, which, however, do not call for any particular comment. WIDE-ANGLE.

THE CAMERA CLUB NEW SESSION.

THE new session of the Camera Club began last Monday night, when Mr. Francis Cobb, who presided, said that they had met that evening to inaugurate another session, and that they were doing it with another "one-man exhibition." On that occasion the "man" was Mr. Lyddell Sawyer, who, he regretted to say, was unable to be present that evening. The photographs upon the walls, especially the views of Newcastle to the left upon entering the room, were samples of works of art. Some of his pictures had also been taken in the style of Mr. H. P. Robinson. The room in which they had assembled that evening was small as compared with that which they hoped to use hereafter, for they would occupy their new building as soon as possible, and the Furniture Committee was busy with its preparations. Their contractor, although he had not been able to carry out all he promised, had been doing his best. The County Council had caused trouble and delay. Although the Club had once hoped to be in its new premises by Christmas, he was afraid it could not do that; the noble British workman, in fact, was master of the situation. The contractor said that if he "cut up rough" with his men and tried to make them go on faster, they might "cut up rough" with him, and do no work at all. He hoped that the Club would get into its new premises by January or February next. Meanwhile, the workmen might be allowed to go on in their quiet, sedate way, in order that the building may get dry before it is required for use. When they saw the new concert room, they would say that it was better than the one in which they were then listening to him. The Club itself was getting on well, and the proportion of town to country members was growing larger than ever before; the proportion now on the notice board stands at eight to one.

A smoking concert followed the above remarks.

NEWCASTLE ON TYNE AND NORTHERN COUNTIES PHOTOGRAPHIC ASSOCIATION.—The next meeting will be held in the Mosley Street Café, Newcastle, on Tuesday, the 14th inst., at 7.30 p.m.

LECTURES ON PHOTOGRAPHY.—Mr. T. C. Hepworth, F.C.S., commences a course of practical lectures on photography at the Birkbeck Institution on Saturday next. The lectures take place weekly at six o'clock, and are sure to attract many beginners, as well as those who wish to perfect themselves in different branches of photography.

IT is often required to obtain a good grey tone for bromide prints, and M. Senior, in the *Photographische Mittheilungen*, recommends for this purpose that the bromide be altered to chloride by the employment of a solution of chlorine (chlorine water), which should be followed by redevelopment of the print. This redevelopment should be with either pyro or oxalate restrained with a goodly amount of bromide. If a red tone is desired it may be obtained by the addition of potassium bromide in the proportion of 4 parts to 100 parts of the developer.

ON SULPHITES, THEIR STABILITY AND PRESERVATION.*

BY JOSEPH C. BELCHER.

WHEN we burn a piece of sulphur in air or oxygen, there is formed a suffocating gas of a sharp, penetrating odour; freely soluble when brought in contact with water, producing what is known to chemists as a solution of sulphur*ous* acid, according to the following equation:—

$$\underbrace{S}_{\text{Sulphur}} + \underbrace{O_2}_{\text{Oxygen}} + \underbrace{H_2O}_{\text{Water}} = \underbrace{H_2SO_3}_{\text{Sulphurous Acid.}}$$

Now, although sulphurous acid (H_2SO_3) is the principal body formed, yet some is carried a stage further in oxidation, resulting in the production of traces of sulphur*ic* acid (H_2SO_4) which always accompany sulphurous acid prepared by burning sulphur in air or oxygen, and dissolving the resultant products in water. This aqueous solution of sulphurous acid is very unstable, and, when exposed to free access of air, is gradually converted into the more stable and permanent body, sulphur*ic* acid, or what is commonly known as oil of vitriol.

The facility with which sulphurous acid combines with an additional atom of oxygen is a property also true to a greater or less extent of its salts (sulphites). [Here sulphur was burnt in a bottle containing air, and the gaseous product shaken with water.] The presence of sulphur*ic* acid was clearly demonstrated by the following experiments:—

1. With a little of the water from the bottle in which the sulphur had been burnt, the formula "H_2SO_4" was written on a piece of blotting-paper, and warmed over a spirit lamp, when the presence of sulphuric acid was rendered evident by the formula being charred upon the paper.

2. It was shown that a precipitate of sulph*ite* of barium was soluble in a solution acidified with hydrochloric acid, but sulph*ate* of barium was not. The presence of sulphuric acid in the liquid, from the bottle in which the sulphur had been burnt, was then demonstrated by acidifying a portion of the latter with hydrochloric acid, and adding barium chloride, when a precipitate of barium sulphate was produced.

When sulphur dioxide (SO_2) is brought in contact with nascent hydrogen, this latter body is oxidised with formation of water, by combining with the oxygen of the first-mentioned body, whilst the sulphur combines with hydrogen, forming sulphuretted hydrogen, thus:—

$$\underbrace{SO_2}_{\text{Sulphur Dioxide}} + \underbrace{3H_2}_{\text{Hydrogen}} = \underbrace{H_2S}_{\text{Sulphurett d Hydrogen}} + \underbrace{2H_2O}_{\text{Water.}}$$

This is an instance of a reducing agent becoming an oxidizing one. All bodies capable of evolving SO_2 under the circumstances stated (hyposulphites, &c.) give this reaction, but we are at present only considering sulph*ites* which are detected by this reaction, even if present in very minute quantities; for if we allow the sulphuretted hydrogen produced to impinge on a piece of filter paper soaked in lead acetate, it is immediately turned brownish-black or black, from the formation of lead sulphide. Sulph*ates* do *not* give this reaction. [Here the experiment was shown by adding a little sodium sulph*ite* to a test tube in which hydrogen was evolved from pure zinc and hydrochloric acid.] A solution of iodine is decolourised by sulphur dioxide, a reaction which also enables us to detect minute quantities of the latter.

Sulphurous acid is a bi-basic acid—*i.e.*, it contains two

* Lecture delivered before the London and Provincial Photographic Association.

atoms of replaceable hydrogen; when one atom is displaced by a monad element we have a *hydrogen* or acid salt produced; when two atoms are displaced we have a normal, or what is commonly called neutral salt. Of those salts of sulphurous acid which are soluble in water, we have the acid sulphites of barium, strontium, calcium, and magnesium, and the neutral and acid sulphites of lithium, sodium, potassium, and ammonium. Most other sulphites are insoluble.

The sulphites of sodium and potassium are mostly used by photographers, especially the former, of which there are four in number: (1) normal or neutral sulphite, Na_2SO_3+7Aq; (2) the acid or bi-sulphite, $NaHSO_3$; (3) meta-sulphite, $Na_2S_2O_5$, or $Na_2SO_3.SO_2$; (4) sesqui-sulphite, $Na_2SO_32NaHSO_3+nAq$; this latter discovered by Mr. J. B. Giles, F.I.C.

The neutral sulphite of sodium of commerce is prepared by saturating the carbonate in solution with sulphurous acid, and adding to it, while warm, as much sodium carbonate as it originally contained; consequently, through carelessness in manufacture, many samples show a large excess of the latter, and although the sulphite crystallises better from a solution containing a small quantity of sodium carbonate, still, in a carefully manufactured sample, this should never exceed 1 or 2 per cent. A pure salt of this description is manufactured by Messrs. A. Boake, Roberts, and Company, of Stratford, E.; also a "special photographic salt" and alkaline meta-sulphites. I am requested to mention that these sulphites are patent articles, and can only be obtained from or through this firm. By their kindness I am able to show you these fine specimens of sulphite and meta-sulphite. [Here the specimens were exhibited, the lecturer dilating upon their great purity, and recommending them as standard articles in preference to making allowances in the commercially impure samples.]

The presence of an excess of sodium carbonate in the sulphite causes great annoyance to photographers, as, by its varying amount, they are unable to make any allowance in their formula, which demands an addition of a definite amount of the former in conjunction with the latter for developing. The presence of carbonate in sulphite of sodium is easily detected. The method depends upon the fact that carbonic acid gives a beautiful red colour with an alcoholic solution of phenolphthalein, whilst sulphurous acid produces no action in this respect. [Here the experiment was shown.]

If, then, we dissolve some of the sulphite above referred to containing only 1 or 2 per cent. of carbonate, add a little alcoholic phenolphthalein, we have a red colour developed due to the carbonic acid, and, on adding carefully a solution of the meta-sulphite—preferably potassium meta-sulphite, as this crystallises much more freely than the sodium salt, and is more stable—till the colour just disappears, the result is a pure solution of neutral or normal sodium (potassium) sulphite, the SO_2 radical combining with the sodium which was previously combined with the CO_2 radical. The question, therefore, of obtaining a pure solution of normal or neutral sulphite of sodium need no longer perplex photographers.

I pointed out in the first part of my lecture that sulphurous acid gradually became oxidised to sulphu*ric* acid, and that sulph*ites* oxidised more or less rapidly to sulphates, which latter, of course, affects the purity of the salts when stored; and I suggest, as a means of preservation, that a pure sample, such as that referred to, and manufactured by Messrs. A. Boake, Roberts, & Co., should be kept in well-stoppered bottles with the crystals covered with pure ether, which procedure, I am of opinion, would prevent oxidation; the ether being very volatile, when the crystals were wanted they could be removed from the bottle and placed upon blotting-paper till they became dry preparatory to dissolving. [Here crystals were shown in support of this, which had been kept under ether for six months.]

To summarise: I have pointed out (1) that the sulphites oxidise more or less rapidly, forming sulphates, and (2) have suggested a means of preserving by keeping the crystals below the surface of ether; (3) I have mentioned and demonstrated simple tests within the capability of any photographer to perform for recognising the presence of sulphates and sulphites, and the detection of carbonate in the latter; and, lastly, by the use of the meta-sulphite, how to obtain a pure solution of the neutral or normal sulphite.

In conclusion, I desire to acknowledge my thanks to Professor Lewes, Royal Naval College, for the loan of his apparatus, which has enabled me to illustrate these experiments, and to sincerely thank my friend, Mr. Haddon, for suggesting the subject of this lecture, which has given me such pleasure to deliver to you this evening, and your very kind attention and manner in which you have received me. I particularly wish to acknowledge my indebtedness and thanks to Mr. J. B. Giles, F.I.C., for much information given me concerning the sulphites manufactured by Messrs. A. Boake, Roberts, & Co., whom I have also to thank for their courtesy and kindness in supplying the two specimens of sulphites.

PHOTOGRAPHY IN GERMANY.

BY HERMANN E. GUNTHER.

CONVENTION OF GERMAN AMATEUR PHOTOGRAPHERS—GOOD NEWS ABOUT EIKONOGEN—THE "THULA" DIRECT PRINTING PAPER—DEVELOPING ENLARGEMENTS ON BROMIDE PAPER.

Convention of German Amateur Photographers at Berlin.—Last week a Convention of Amateur Photographers was held at Berlin. At the official welcome, which took place in the large hall of the Zoological Garden, amateurs from all parts of Germany were present. The *Correspondenz Verein* was represented by its chairman, Mr. M. Allihn, of Athenstedt; the Amateur Photographic Society of Kiel by Dr. Karsten and Dr. Spener; the Dresden Amateur Photographic Association by Messrs. Ernemann, Rauscher, and Bernhart; the Breslau Photographic Society by Dr. Kunisch, and so on. The opening address was delivered by Prof. H. W. Vogel. With the Convention, an exhibition of photographs and photographic instruments was combined, which was also accessible to the public. Many of the photographs exhibited were of high perfection. The well-known traveller, Dr. Paul Ehrenreich, showed a series of highly interesting views; E. Vogel, jun., instantaneous photographs taken in Italy; Captain von Westernhagen contributed a number of portrait studies; A. Halwas, a series of photographs showing scenes of the last large military manœuvres; O. Marquardt showed animal studies executed at the Berlin Zoological Garden, and views of the sea-shore at Ostend. J. Standigl, an amateur photographer of high ability, and formerly an opera-singer, exhibited a series of beautiful collotypes, printed by himself on the hand-press. An interior of

great merit was shown by M. Trene, member of the German Society of Amateur Photographers, who carried off the first prize offered by this society for the best interior. The second prize had been offered to Dr. Witt, for a beautifully lighted photograph of the hall of the University of Marburg; this picture was also exhibited. Among cameras, there were instruments of the detective type by Dirschau and Co., and C. P. Goerz, of Thöneberg, which firm had also a good selection of its wares, including the "Anschütz" instantaneous camera, of which it is the sole maker. Many other specimens of excellent apparatus were shown in this department of the exhibition, which was much frequented. On Monday morning, September 29th, the members of the Convention met at the Photochemical Laboratory of the Technical High School of Charlottenburgh. Prof. Vogel and Dr. Schultz-Henecke received the members, showing them first the exhibits of the various photographic and photo-mechanical processes, which had been arranged in the large corridor, then leading them to the auditory, where a paper was read by Prof. Vogel, on "The Action of Coloured Light on the Eye, and on the Sensitive Film," which was illustrated by many interesting experiments. Various photographic processes—as, for instance, the carbon process, platinotype, and collotype—were then demonstrated practically. At the evening meeting Captain Mensing took the chair, and after an opening address, which was delivered by the Chairman, Mr. M. Allihn, of Athenstedt, read a paper on "Tourists' Cameras and their Construction." Papers were then read by Dr. Miethe on "Photographic Optics," by M. Gaedicke on "A New Flash-light Lamp," and by Dr. Jeserich on "Juridical Photography," illustrated by a large number of highly interesting lantern slides. On Tuesday evening the Convention met at the Hall of the Zoological Garden. Business matters were first discussed. By a number of amateur photographic societies the wish for a closer mutual relation was mentioned. Besides the societies which were represented at the Convention—namely, the Postal Photographic Club, *Correspondenz Verein*, and the societies of Kiel, Breslau, Brunswick, and Dresden—the Amateur Photographic Societies of Munich and Königsberg also declared for the union. The elected committee was charged to take the required additional measures for the foundation of the new Association; the members of this committee are Prof. Vogel, Dr. Jeserich, Dr. Schultz-Henecke, Dr. Miethe, Prof. Roese, and M. Kirchner. After some further discussion, a paper was read by Dr. Dubois-Reymond on "An Air-tight Developing Vessel," and another by Dr. Witt, on "An Actinometer with Pendulum and Blue-Sensitive Bromide Paper." On Wednesday, September 30th, an excursion was made to the Havel Seas and Potsdam, and a large number of negatives was taken on this occasion. In the evening the Convention closed with a banquet.

Good News about Eikonogen.—A circular has just been sent round by Dr. Krügener, of Bockenheim, by which it is announced that the manufacturers of eikonogen have succeeded in finding a means of entirely preventing this substance from becoming brown and decomposed. The body by the aid of which the eikonogen is rendered permanent is as yet kept secret; it is only stated in the circular that a small quantity of a preserving substance is added, and that the eikonogen will in future be manufactured in the form of a white, absolutely permanent powder, for the use of which as a developing agent the formulæ remain the same as hitherto. This improvement will no doubt be welcomed by all those who have tried the eikonogen developer, and appreciate its valuable qualities.

The "Thula" Direct Printing Paper.—I have been favoured by the firm of Dr. Adolf Hesekiel and Co., of Berlin, with a sample of its new direct printing paper. It is generally known that the price of platinum is still advancing, and that in all probability it will continue to do so. With regard to this fact, Dr. Hesekiel tries to make the platinum process cheaper by using the platinum salt only as a toning agent—*i.e.*, by printing on his specially prepared ready-sensitized paper, and toning it with a solution of potassium chloroplatinite. The silver picture is thereby transformed into a platinum print by substitution. The process is the same as in silver printing. The prepared paper is with its slightly yellowish surface placed against the negative, and is printed deeper than is required when the picture is finished. It is then thoroughly washed, and toned in the platinum toning bath until the print shows, if examined by transmitted light, the well-known greyish-black, copper engraving tone. The print is then well rinsed, and fixed in the same way as ordinary silver prints. The prints obtained are, provided that a good negative was used, of beautiful tones, and of great detail and depth. As will be known, the ordinary silvered albumen paper, if treated with the platinum toning bath, gives with difficulty agreeable tones; the new paper prepared by Dr. Hesekiel will therefore prove useful, inasmuch as its treatment differs in no way from that of the ordinary silvered albumen paper.*

Developing Enlargements on Bromide Paper.—Dr. Miethe, in one of the recent numbers of his journal, gives an extensive and excellent description of the enlarging process with bromide papers. In order to obtain a purely black tone, he recommends a ferrous oxalate developer of the following composition:—

Solution A.

Sulphate of iron	100 grammes
Water	350 to 400 c.c.
Tartaric acid...	3 grammes

Solution B.

Potassium oxalate	300 grammes
Water	1200 c.c.

Just before use are mixed—

Solution B	100 c.c.
Solution A	25 ,,
Old developing solution	20 to 60 ,,

If the print comes out rapidly the solution should always be diluted with old developer, never with water, the latter tending to produce greenish flat prints. Dr. Witt recommends for the same purpose the following eikonogen developer:—

Solution A.

Eikonogen	8 grammes
Bisulphite lye	10 c.c.
Sodium sulphite	10 grammes
Water	400 c.c.

Solution B.

Potassium carbonate	35 grammes
Water	400 c.c.

Solutions A and B are mixed in equal parts.

*We know of no tabulated experimental evidence that silver prints toned with platinum are more permanent than those toned with gold. In both cases it seems to be largely an action upon the surface of the silver only. Mr. Lyonel Clark long since used chloroplatinite of potassium for toning.—Ed.

MR. LYDDELL SAWYER'S PICTURES AT THE CAMERA CLUB.

However premature from an art point of view a system of one-man exhibitions in photography may be held to be, it cannot be said that Mr. Lyddell Sawyer's collection is the least interesting of the series that has been given at the Camera Club. If some may consider it the most unequal, this may be traced to the presence of some very early work and portraiture in which Mr. Sawyer has shown his whole hand and the history of his development. There are very few photographers who could make a "one-man" exhibition of more than twenty prints which should, in any critical sense, pass as works of art. Mr. Sawyer is not an exception, and it would be largely stretching a severe test if that number were selected from this exhibition to be included in such a category. The tendency in such exhibitions is to show too many photographs, some, possibly, in every department of work that has been touched. This, from the point of view of the aim of these exhibitions, is a mistake, and one which is unpleasantly paid for by the artist being subjected to a frequent and irritating expression of criticism from "candid friends." There are hardships for any exhibitor in making a "one-man" exhibition of himself. The general defects of style or treatment, and any looseness of artistic principle which may be present, are shown prominently when a photographer lays bare his whole portfolio. He must be prepared, amidst some appreciative but indiscriminating criticism, to have all these little crudities and greater shortcomings laid bare unfeelingly. Every defect thus picked out by smart young investigators with microscopes or with naturalistic spectacles, is freely fathered by the larger body of geniuses whose talent is latent, and who dearly love a ready-made opinion with which to impress others and pose as *connoisseurs*. Such an exhibition invites criticism, and certainly gets it. This is as it should be in a series which purports to show the best that has, up to the present, been done by photography. As a rule, however, it is only the pleasant things which command publication.

Looking at the exhibition as it stands, it might have been fairer to the exhibitor if all which are clearly juvenile productions had been arranged in one dark corner by themselves. However, these are easily singled out, showing, as they might be expected to do, the most rudimentary crudities, and all in that class of story-telling work in which Mr. Sawyer has been least happy. He would, perhaps, have been better advised to have left out all these early attempts, and in addition all his portraiture, and have confined himself to that excellent vein of work of an original character which he has struck occasionally in the course of his practice during the last two or three years. As it is, it must be confessed the exhibition is made up of very unequal material, and it is very doubtful whether the artistic character of the exhibition should have been sacrificed to the idea of showing the gradual growth and progress of the artist. However, this arrangement, whilst it detracts from the show as an art exhibition, adds considerably to its personal interest. Here development can be traced from early efforts, devoid of any style, when the mere processes were all the pleasure and the difficulty. Then we have a series of heavy silver prints, some of them badly painted on, in which there has been a struggle to find expression rather by the aid of some one else's ideas, for these particular photographs are in somewhat feeble imitation of Mr. H. P. Robinson, and consist of crude, lumpy prints in which small figures are doing funny things unnaturally in largish, uninteresting landscapes. Amongst these are "Come Along, Grandad!" "The Good Samaritan," "The Sisters"—a production almost offensive in its crudity and bad mimicry of a pathetic incident—and several others of the same class. It would, perhaps, have been hardly fair to refer to these defective early studies, but that very much the same mistakes have been continued in one class of Mr. Sawyer's work right down to the present time. In the present Pall Mall Exhibition, the picture entitled "Two's Company," upon which a medal appears to have accidentally fallen, is simply a travesty of human nature as unnatural as it is possible to be. It is, of course, only a piece of comic fooling to which any of us, with nothing better to do, might lend ourselves for the amusement of a pretty cousin. The subject itself is not one for any serious art, but, even taking it as it stands, the details are of the most incongruous and imperfect kind.

Of the same kind are "In the Moonlight," a painted photograph, one of the results of the painter's art being to give the figures unpleasantly distorted features, and others not quite so objectionable in treatment, are "In the Twilight" (called last year "Dangerous Company)," "Love's Young Dream," and "How Happy could I be with Either." There is yet another class of subject treated by Mr. Sawyer, in which he has with great pains, as far as can be seen, arranged his studio for certain figure and group studies, such as "She Stoops to Conquer," "The Amateurs," "At Home," "Time to get up," "Bachelors' Quarters," and the like, some of them intentionally amusing, but all weak and unprofitable from an artistic point of view. Mr. Sawyer has evidently yet to learn fully what naturalness means, and that this quality is essential to any picture to be accepted as good art. He would be well advised to abstain from these made-up subjects, leaving this class of things to illustrations for popular magazines. If he *must* depict human nature, let him take it as it is found in its proper habitat. It is a mistake to publicly exhibit bits of badly done theatrical tomfoolery. He should rather seek to express something of the life of the class or individual he is depicting which may be of interest beyond to-day, as he has sought to do in the excellent subjects gathered from the dark ways of Newcastle-on-Tyne.

It is a relief to pass from the photographs we have named to the pictures he has given us, such as "In the Castle Garth," "Rare old Gossips," "Waiting for the Boats," and some of the Tyne River series. The beauty of these lies in the selection of strongly characteristic subjects, which he has rendered with broad treatment, and one is disposed to overlook in them certain defects of the figures and accessories. In "Waiting for the Boats," the figures tell somewhat unnaturally hard against the distant water, and in "On their own Hooks," "Rare old Gossips," and "A Motley Crowd," the composition is somewhat weak. In fact, where there has been much meddling with the figures, unnaturalness has generally resulted, and the moving of accessories has occasionally introduced artificiality and mistaken intention. All these pictures, as well as some of the Tyne and Wear series, are, however, strong and æsthetically pleasing in comparison with the niggling, narrow character, both in subject and treatment, of those previously referred to. If Mr. Sawyer's own observation has led him to these greater studies, all credit is due to him for his originality and insight, and he may be left safely to work out his own salvation. It is to be hoped he will

continue in that strain, somewhat alter his views in regard to pictorial portraiture, and avoid hybrid products, the result of painting and photography combined.

In addition to what have been mentioned, there are in the exhibition a large number of well-executed local views, some very large conventional portraits, very largely painted, and two or three curious but unnatural effects of artificial lighting, all of which may prove attractive to the public. X.

ACID SULPHITE OF SODA IN PHOTOGRAPHY.

Since the introduction of acid sulphite of sodium as an article of commerce, we have frequently been asked what is the relative value of it compared with the regular crystallised neutral sulphite hitherto used? As this is a very reasonable question, and one that is of especial importance in connection with the making up of developers from the formulæ given by the dry plate makers, we have taken the trouble to make some experiments in this direction, and thus give our readers some definite information on the subject.

Taking a good sample of the acid sulphite as it comes to us in commerce, one of the best that we could obtain, as supplied by our publishers, we found that 100 cubic centimetres of the acid sulphite solution requires 27 grains of dry sodium carbonate to neutralise the excess of sulphurous acid in it, and have it just alkaline to test paper. To put this into the ordinary weights and measures used by the photographer, 1 fluid ounce of the acid sulphite solution will require 123 grains of dry sodium carbonate to make it just alkaline.

As we have stated on a former occasion, the acid sulphite of soda is twice as strong in sulphurous acid as the neutral sulphite crystals. To put this a little more definitely, 1 fluid ounce of the acid sulphite is equal to 2 ounces by weight of the ordinary sulphite; but in using the acid sulphite, more alkali will be required to secure the same quality of developer. This additional alkali must be added in the proportion given above.

If we use crystallised sodium carbonate (soda crystals), the proportion must be increased two and two-thirds times, and the figures become 332 grains of soda crystals to neutralise 1 fluid ounce of acid sulphite solution.

Since the acid sulphite is twice as strong, practically, as the neutral sulphite generally used, it is only necessary to divide the figures given in any of the ordinary formulas by two, use this amount of sulphite, and add sodium carbonate slowly until the fluid is just alkaline, to obtain the same proportion as that given for the ordinary sulphite. The great advantage of this method of procedure is, that you can regulate the proportion of alkali in the developer much much carefully than when you use ordinary sulphite of sodium; this latter material containing variable quantities of sodium carbonate in excess, according to the care with which it is made. But, in our own practice, we find it much better to mix the acid sulphite with the eikonogen or pyrogallol at once, and use it as a preservative alone, not attempting to neutralise it until needed for developing. In this way we have preserved solutions of eikonogen and pyrogallol for months, and in a condition which we have never seen equalled by any other method of procedure. When about to develop, we add a little more of the alkali than is usually applied, and in the proportion given above.

In order to give some guide to those who prefer to use potassium carbonate as a developing agent instead of sodium carbonate, the proportions become as follows:—

One hundred cubic centimetres of the acid sulphite require 35 grains of dry potassium carbonate to make it just alkaline. In English measures, this becomes 1 fluid ounce of acid sulphite requires 160 grains of dry potassium carbonate to neutralise it. Of course, in using potassium carbonate with the acid sulphite of sodium, the resulting mixture contains both sodium and potassium sulphites, and since potassium sulphite is not as soluble in water as sodium sulphite, the potassium carbonate should not be added to the acid sulphite in the concentrated form, but only after diluting, as in the developer. If carbonate of potassium is added to the acid sulphite direct, after a while potassium sulphite will separate as a white powder that is difficult to get into solution again without heating the mixture. The best way to manage is to add the acid sulphite to the eikonogen or pyrogallol, as stated above, and use the extra potassium carbonate in the alkaline part of the developer.

The use of acid sulphite in the hypo bath is now a well-established practice, and we need not say anything here about it. With us stained negatives are a thing of the past, and we heartily recommend this new material to all who wish to obtain clean work in photography.—*Anthony's Photographic Bulletin.*

Literary Notices.

Ausfuhrliches Handbuch der Photographie. Dr. J. M. Eder. First part. (*Knapp, Halle.*)

The important hand-book of photography by Dr. Eder, which appeared in ten or a dozen parts, was commenced some eight years since, and was, undoubtedly, the most comprehensive and complete work in photographic literature. It is not so very long since the completion of this encyclopædic work, but we find that a second edition has already been commenced. We speak of it as a second edition, and the plan of the original publication will, no doubt, be observed; but, in the first part, which is now to hand, there is so much fresh matter, that the labour of collecting the material and arranging it must be nearly equal to writing an entirely fresh work.

The early history of photography has never before been dealt with in so complete a manner as in the opening part of Dr. Eder's work. "From Aristotle to the Alchemists" occupies nearly a dozen pages; then about ten more bring us to the period of "Gyphantia," a work which we have recently referred to. Passing on through the time occupied by Scheele, Priestley, and others, we come to Senebier, an experimentalist of whom more deserves to be generally known. A table is given which he had compiled, showing the comparative activity of various portions of the solar spectrum upon chloride of silver, the period of darkening ranging from fifteen seconds in the violet to twenty minutes at the red end. The work of many subsequent experimentalists, including Davy and Wedgwood, is quoted, but we close the "part" with regret at finding we must wait for the next one to come to that all important period of the work of Daguerre and Fox Talbot.

The present work is to be completed in about forty parts, and will probably include more than double the matter contained in the original edition. A work so encyclopædic in its character, and so conscientiously careful in its composition, should be in the library of all photographers whose acquaintance with the German language enables them to profit by it.

AN EXPERIMENT IN BOOK ILLUSTRATION.

Piazzi Smyth's "Teneriffe."

BY WM. LANG, JUN., F.C.S.

In 1858, now more than thirty years ago, a somewhat notable work was published, having for its title "Teneriffe, an Astronomer's Experiment; or Specialities of a Residence above the Clouds." The ordinary book collector, meeting with the volume on the shelves of some second-hand bookseller, would, in all probability, after taking a hurried glance at the illustrations, and seeing the somewhat yellow appearance of many of them, simply pass on, replacing the work on the shelf where he originally found it. Were our book-hunter, however, one interested in affairs astronomical, the faded appearance of the plates would not prejudice the book in his eyes; he would look rather to the matter contained therein, the record of a scientific enterprise nobly conceived, and no less nobly carried out. To the individual interested in photographic endeavour, the work appeals as strongly as to the student of astronomy. The author of "Teneriffe," C. Piazzi Smyth, Astronomer-Royal of Scotland, was, in his time, an ardent photographer. The conditions of working in the "fifties" were very different from what we now are accustomed to. No plate could then be obtained ready to receive its destined image, and capable of being put away for development at some convenient season—it may be weeks, months, or even years afterwards. The work done in the way of preparing the sensitive surface had, in the days of the wet plate, to be performed by the artist himself. Surely enthusiasm was the *sine qua non* required when collodion reigned supreme: that our author had this in no ordinary degree the present volume sufficiently bears out. His labours at the Great Pyramid in 1865, when he photographed its dark recesses by means of burning magnesium, were well known at the time not only to the photographic, but to the whole world. Events march so quickly with us now, it seems to me, that many grand achievements such as those accomplished in the past are quite unknown to the present generation. Knowing, therefore, the difficulties, we surely can all the more appreciate the results obtained—we may safely say single-handed—in the volume we are considering. Although it may now be truly said that the silver print for book illustration has been weighed in the balance and found wanting, still the early attempts to press it into this particular service must—or should, at all events—possess for us now a more than passing interest.

In the preface to "Teneriffe" we find our author paying this tribute to photography:—"By its necessary faithfulness a photograph of any sort must keep a salutary check on the pencil or long bow of the traveller." Piazzi Smyth was not content, however, to give to the reader a bald photograph of the scene portrayed; he wanted to go a step farther; he desired, if possible, to bring it before him in a manner still more realistic. This he attempted to do by means of the stereoscope, and herein consists the unique character of the illustrations accompanying the letter-press of "Teneriffe." We hear a good deal just now regarding the revival of stereoscopic work; it will, therefore, not be considered superfluous to quote still farther from the preface, bearing out, as it does, the importance attached by the author to this mode of representing the scenes he deems worthy of notice. Referring to the ordinary photograph he remarks: "It is not perfect; it may be tampered with, and may suffer from accidental faults of the material. These, which might sometimes produce a great alteration of meaning in important parts of a view, may, however, be eliminated when, as here, we have two distinct portraits of each object. Correctness is thus secured, and then if we wish to enjoy the effects either of solidity or of distance—effects which are the cynosure of all the great painters, we have only to combine the two photographs stereoscopically, and these bewitching qualities are produced."

It goes without saying that the stereoscope, to view pictures bound up in a volume, must be one which will be open at the bottom, and, from the advertisements connected with the publication when it appeared, such an instrument was supplied by Messrs. Negretti and Zambra; it folded up into small compass in a case, and was called the "Book Stereoscope." The term applied to the double picture was "Stereograph;" it sounds somewhat strangely to us now-a-days, but it nevertheless has the merit of being concise and appropriate.

Regarding the literary part of the work, it is not our intention to discuss this; but it may be simply stated that the contents are grouped under four headings: The Voyage and the Climb; On the Crater of Elevation; On the Crater of Eruption; and the Lowlands of Teneriffe. The number of photo-stereographs is twenty, and each one is fully described in the letterpress adjoining. Every effort had apparently been made to render the prints lasting. The printing was entrusted to Mr. Melhuish, of Blackheath, and the whole was under the superintendence of the worthy president of the British Photographic Society, Mr. James Glaisher, F.R.S. While we may take it for granted that every effort would be made to secure uniformity, it is very instructive, albeit somewhat sad, to note how scarcely two pictures are to be found presenting an identical appearance. The book was published by Lovell Reeve; from an outside source we learn that the edition was one of 2,000 copies, and the price it was issued at was one guinea. There is no occasion to enlarge further; the whole interest of the book to us lies in the fact that we have in it one of the first attempts to bring before the reader by means of photography those very scenes which the author himself has witnessed. Subsequent writers have followed in Piazzi Smyth's footsteps, and by improved processes of reproduction travellers have presented us with the very effigies of the people they may have visited, or given us facsimiles of the countries they may have passed through; but I am not aware that the stereoscopic picture has elsewhere been utilised in the manner indicated in the volume we have been considering. In naming his book "Teneriffe, an Astronomer's Experiment," he could, with an equal regard to the fitness of things, have likewise added "A Photographer's Experiment."

It would be instructive to have the idea once more carried out with our improved methods of reproduction—collotype, for instance. We recommend, therefore, to our publishing photographic friends a trial of the stereoscopic picture by way of illustration.

University College, Liverpool.—Mr. Charles A. Kohn, B.Sc., Ph.D., is about to give a course of evening lectures at this College on "Photographic Chemistry," commencing October 14th. The course will consist of ten lectures, illustrated by experiments and lantern slides, and will treat of the fundamental principles of chemistry in their relation to the various photographic processes.

Notes.

Some items relating to the Daguerre Memorial at Washington have not been pleasing to its promoters. In the first place, the monument itself has been almost unanimously condemned by the photographic press for its ugliness and want of taste. In the second place, the committee connected with the memorial has just had to report a deficit of five thousand dollars. The *American Amateur Photographer* holds that one reason for this may be that the project was started by one of the American photographic journals, and that rival journals therefore gave it but lukewarm support. It says: "There is a possibility, also, that not a few dollars failed to be forthcoming because their possessors, knowing something of photographic history, cared very little about helping to erect a memorial to the very clever scene-painter who had the wit to turn the discoveries of another to his own profit, and to claim as his that which, in part, rightfully belonged to another. But, whatever the cause, the fact remains sadly true that there is a deficit of five thousand dollars which must be met." It seems to be probable that all sections of photographers in the United States will now join to pay off the debt.

The Photographic Society of France has opened a subscription for the restoration of the tomb of Daguerre at Cormeilles, and the question has been raised why the same should not be done to restore the tomb of Nicéphore Niepce at Saint-Loup-de-Varennes, near Châlon-sur-Soane, for the tomb is in a complete state of dilapidation. Critical historical research has proved that Daguerre does not come out of his dealings with the Niepce family with clean hands, and that, all things considered, Nicéphore Niepce has probably a greater claim than Daguerre to be considered the founder of photography. To Daguerre, however, appertains the honour of accidentally discovering mercurial development.

Occasionally a tendency to originality is discernible in the devising of picture frames. At an exhibition in Milan we have seen some large, dark wooden frames, with broad patches of paint upon them, of subdued and unobtrusive colours, so selected and placed that, by contrast, they should heighten the effect of the adjoining portion of the picture. An exhibition was recently held in Washington, at which the designs upon some of the frames bore relation to the subject of the picture; for instance, one painting, "Fortune Telling," had on one corner of its frame some painted playing cards. On one corner of the frame of "The Startled Miser," money was represented. Another painting, "A Man's a Man for a' that," represented a sturdy blacksmith, and on the corner of the frame was a horse-shoe.

Next year the American Photographic Convention will be held in Buffalo. This year it was held in the National Museum at Washington, and, according to Mr. F. C. Beach, the exhibits were small, the space at disposal not well utilised, and it was more a Daguerre Memorial Convention than one likely to yield results of practical value to photography. One of the most curious facts revealed by photography, and brought under the notice of the public at the meetings, was stated by Mr. Thomas Wilson, Professor of Prehistoric Anthropology, in his address on "Types of Beauty." He said that, in determining the characteristics of the various types of mankind, it becomes necessary to have living specimens, and here it is that photography can aid anthropology. One of the great anthropologists of this century, in Paris, has been making a collection of the various types of mankind, and he does it by means of photographs. He has discovered, or thinks he has, that the type of origin—the race to which the party originally belonged—is better preserved among women than among men, at least, that the evidences and characteristics are better preserved among women than among men. So he has made his collection from among women, and, to make it more attractive and worthy, he declared it to be his intention to choose only the beautiful women for his types. Therefore, his is a collection of types or standards of beauty, and these are made by a series of photographs.

Among the amusements at those places of public resort at which merry-go-rounds, swings, and cocoanuts abound, a species of rifle gallery has lately come into vogue in which, in lieu of a target, sundry glass bottles are suspended from the roof for cockney sportsmen to aim at. There is possibly an additional charm in being able to smash something—if you hit it—which is extremely pleasing to the vulgar mind, and which accounts for the amount of patronage which these pseudo galleries receive. The bottles are of all shapes and sizes, from the humble pickle receptacle, to that which has held the vintage of champagne. Pausing before one of these establishments the other day, we saw mingled with these vessels of sacrifice several bearing the well-known pyro brand, and while we reflected upon this evidence of the ubiquitous photographer, we could not help quoting the well-known line, "To what base uses, &c., &c.," which was written some time since by the immortal William.

Ready sensitised silk is, perhaps, the most recent printing material which has been placed on the market, and we should think that it will be welcomed by many amateurs as something "new" upon which to try their skill. Printing on textile fabrics has engaged the attention of many, but hitherto such experimenters have had to prepare their own material before its exposure under the negative. In these days manufacturers are so anxious to meet a want half-way, that the worker is saved all trouble of preparation, and finds everything ready to his hand. There are many applications for this silk, and new ones will probably soon arise now that the material can be bought ready

prepared. Among those which occur to us are book-markers, banner screens, as well as d'oyleys for the dinner table.

The ready-sensitised silk will naturally commend itself to the attention of lady photographers who know how, by a few pretty knick-knacks, to make a boudoir look pleasant and home-like. The material is a thick, ribbed, white silk, and has that roughness of texture which, like rough drawing paper, and by a strange contradiction of terms, gives such exquisite softness to a picture. After exposure under a suitable negative, the silk is toned with gold and bicarbonate of soda, fixed, and washed in the ordinary manner. When nearly dry, a warm iron is passed over its surface, and, if desired, the picture can be tinted with water-colours. Besides the applications already named, the new material will doubtless be enlisted in the service of Christmas cards.

A case recently came under our notice which shows the value which is attached to a photograph compared with that of a drawing. Usually the case is reversed, and the drawing, if done by a skilled hand, ranks far higher than a photograph; but in this instance nothing but a photograph would do. The member of a provincial archæological association had taken the trouble to trace the history of an architectural relic of some interest about which very little was known, and when his work was completed he brought the matter before the society in question, and sent in with his manuscript a careful drawing of the object. He was informed, in answer to his communication, that the matter could not be accepted by the society unless the drawing were replaced by a photograph. This condition was ultimately complied with, but not without extreme difficulty, for the original was half way up the side of a steep hill.

The present fine weather is rather against the Photographic Exhibition. As a rule, Londoners by this time have finished their holidays; but there are hosts who have been tempted to stay a week or two longer at the sea-side, and, in consequence, all London exhibitions suffer more or less. Apart from this special cause, a less number of visitors may be expected in fine weather than when it is dull or rainy. People like sunlighted streets in preference to picture-galleries, and the experience of past years shows that cold and almost inclement days are more favourable to the Photographic Society's Exhibition than when the weather is warm and bright; but the Exhibition has almost a month to run, and there may be yet a chance for a few rainy and foggy days of the good old-fashioned style.

Reading between the lines of his speech at the first meeting of the International Literary and Artistic Congress at the Mansion House, it would almost seem as if Mr. John Leighton, F.S.A., regarded an Artistic Copyright Act as one which should protect not only artists and engravers, but the whole world, from what he calls "chemical operators"—in other words, photographers. Mr. Leighton referred to the fact that he was the only member present of the Art Copyright Committee who, about thirty years ago, codified the Acts relating to painting, engraving, and photography. Whatever these Acts may have done for painting and engraving, they certainly did little for photography. The copyright questions involved in photographs are hopelessly vague, and every attempt to legislate afresh has, up to the present, had a singular run of ill-luck. Thirty years ago the marvellous reproductive powers of photography were undreamt of. Photogravure had no existence, photographs in carbon were almost unknown, and the scores of photo-mechanical printing processes now in use were in their infancy. Could Mr. Leighton have foreseen these developments of the art, possibly the codification of the copyright would have embodied something which would have checked photographic progress. For it is from the engravers' point of view that he speaks, and engravers—the majority, at least—are no friends of photographic reproductions. Mr. Leighton, however, has been the victim of American "process" piracy, and much may be forgiven him on this score.

But did Mr. Leighton make himself quite clear when he said: "At present no one had a copyright in his own face, and great had been the violations perpetrated and the troubles inflicted alike on authors, artists, and publishers by the means of chemical operators who had the same protection as a Meissonier or a Millais." What can this mean? Is it a protest against the use of the instantaneous secret camera? If so, why should a photographer who uses a camera to take the portrait of a person unknown to the latter be more guilty than the artist who makes a positive sketch under the cover of a newspaper? But perhaps those points were elucidated on Wednesday, when the whole subject of photographic copyright came up for discussion, and we shall look for a full report of the proceedings with much interest.

How much of the artificial look which most miniatures of the old school have is due to the smooth locks and little curls primly plastered on the forehead it is difficult to say. Miniatures are often contrasted with photographs to show that the latter are very much better and much more artistic, but we are afraid the argument is pushed a good deal too far. Fashion has the power to make one blind to defects. The photographs of the crinoline, chignon, and pork-pie hat period are now detestable to one's eyes, and beside them the miniatures, wherein every lady is represented with a simpering smile, look beautiful. If rumour be true, the photographer will shortly have an opportunity of pitting his skill against the miniature painter of half a century ago, for it is said fashion has ordained that wavy and curly hair is to be discouraged, and that the hair is to be arranged in loops down the back, the miniature fringe on the forehead being flat as a postage stamp, and as well stuck down.

PHOTOGRAPHY AND BUSINESS.

BY ELLERSLIE WALLACE.

It is a very pleasing and encouraging thing to hear as old and experienced a member of the craft as Mr. Rockwood, of New York, say that he has been in active business for four and thirty years, and has never felt sorry at his choice of the art of photography as a calling.

In these days of plentiful, not to say superabundant, photographic literature, we find the two philosophical extremes of the optimists and the pessimists fully represented in our journals and annuals, and we regret to say that there are not wanting those whose views upon photography, particularly in its financial aspects, are directly the reverse of those expressed by Mr. Rockwood.

We are by no means disposed to take part in the discussion whether or no photography is a good means of earning a livelihood. We might as well waste time in inquiring whether it were worth while to raise cattle or vegetables as a means of making a living. We may dismiss this matter by simply saying that, having done our best to support our calling, we have found it to support us in return. If we were asked whether our business life had been free from trials, perplexities, and sometimes bitter discouragements, we should plainly answer, No! and then ask our questioner what calling he could recommend that was thus free from all vexations. We can occupy space and time to better advantage here by pausing, as it were, for a little, and looking about us at the present condition of the photographic world, particularly here in America

The first thing we notice, and greatly do we congratulate our fellow-members of the craft upon it, is the vast increase in the number of applied uses of photography. Aside from the well-worn ruts of portrait-making under the skylight, and ordinary landscape photography, we find new fields of industry in literally every direction we turn to. Interiors—easy, pleasant, and profitable work; portraits and interiors at night, either in public or private, also pleasant and profitable, if not quite so easy. Printing, either by the old or by any of the numerous new methods—profitable and easy. Lantern slide making, perhaps the most fascinating branch of practical photography, and one that is increasing in importance every day in the year. General business photography, including the photographing of real estate for advertisement, of samples of goods of every possible description for commercial houses, of enormous numbers of small portraits of celebrities for increasing the ready sale of various articles, such as cigarettes; photography in conjunction with the microscope, and the incessant calls upon the art made by scientific students and professors of all grades. We merely mention these few of the multitudinous uses of photography, so that if anyone should be a little discontented with the art as being narrowing and cramping in its tendencies, he may be set to thinking of the matter, and see that the fault lies in himself and not in photography; and farther, that if one kind of photographic business does not suit him, there are plenty of others for him to select from and pursue.

The question has frequently been raised whether the money-making side of photography was not seriously affected by amateurs and amateurism. Now we have always held to the opinion that the greater the number of amateurs, the greater the benefit to the profession. We know very well of the bitter complaints from certain quarters, that the local amateurs take away the business from professional men. But we are glad to see that these complaints grow fewer in number and less loud every year. Besides this, there is one point that these grumblers always lose sight of—namely, that immediately upon an amateur's receiving pay for his work, he ceases to be an amateur, and enrols himself amongst the professional members of the craft. We can, indeed, recall certain instances in which so-called amateurs had the effrontery to take pay for their work, and print their names and addresses, with the title "amateur," on their card mounts, like any regular member of the calling. This might be taken as conclusive proof of the gross ignorance both of the "amateur" and of the public he attempted to cater to, for everybody has always known, or been supposed to know, that an amateur in any science or art is one who follows it for amusement only, and receives no pay for his work. This, at least, is the conventional or commonly accepted sense of the word "amateur"; but we are afraid that the more elevated, as well as the more literal, meaning of the word is too often overlooked entirely. Properly rendered, "amateur" means one who loves (Latin, *amo*, I love), and one who thus really loves his art does not disgrace it and himself by such shabby tricks as we have referred to. If he does these mean things, and tries to call himself an amateur, he should be told that his receiving money has effectually banished him from the ranks of true amateurs, and that he is deserving of such treatment as the members of liberal callings visit upon the heads of those scab members who attempt to debase the same. The extent to which photography is indebted to the *real amateur* is a matter so well known that we need hardly mention it.

Out of the large number of amateurs now practising photography, there are many who are already, or who may in time become, of money value to the professional man. Men of business well enough off to make frequent trips to Europe and less known portions of the earth, generally find it all that they can do to make the exposures while *en route*, and will not require much persuasion to leave the routine laborious work of printing and mounting to the professional photographer. In most cases, if lantern slides or enlargements of any kind be required, the same plan will be pursued, and a very fair profit made. Scientific men of all sorts, physicians, astronomers, and others, are paying more and more attention to photography, but it generally amounts to their making the negatives only, and leaving the printing to the professional man, as well as the developing also sometimes. All of this, of course, benefits the photographer, and he would be a more than commonly stupid person who would not endeavour to extend and increase any opportunities of the kind that might offer. When we get into the "upper ten" among amateurs, we shall frequently find wealthy would-be æsthetes who prate learnedly about lighting, Rembrandt effects, and "Truth in Art," and consider the manual labour of printing from their negatives quite beneath them. We should not at all object to receive profitable work from such people, and in many cases might look forward to regularly instructing them, after a time, in the art of how to make a negative, for let us here remark that, as a general rule, the louder the art-talk of an amateur, the more detestable is his work photographically, and often artistically as well.

From our point of view, then, which in photographic matters is always that of the optimist, we regard amateurs as valuable to the profession in the strictly business sense.

Efficient assistance in the working of a photographic business is a necessity, and here the question will arise how and what to teach growing lads who have entered our employ with the *bonâ fide* intention of making photography the business of their lives. For our own part, we should prefer the assistance of any ordinary steady person, after a reasonable time of instruction under ourselves, than that of a stranger appearing with highly worded testimonials, and who was obstinately set in his own formulæ and ways of manipulating. A boy starting out to learn the business should be made familiar with the processes step by step, and gradually advanced to such difficult portions as developing and toning, and during this time of instruction we should keep his interest alive by allowing him to assist, now and then, during the posing and lighting; if he manifests any of the ideas which might in time make him a good person to handle sitters, train him for this also by sending him to art exhibitions, or, in default of these, set him on a regular course of art study from first-rate photographs and illustrated books. At the end of a year or eighteen months we should expect a very fair assistant from a young man whom we had thus taught, so far as the mechanical parts of the business are concerned, and one in whose hands a large portion of the business could safely be left in the event of our own absence. In regard to the salary paid, we may call to mind that while the heavier parts of the work are best done by men, the operations of trimming and mounting prints and binding lantern slides is quite as well, if not better, done by women and girls, who would probably consent to work for smaller compensation. Indeed, the neatness of handling required in printing renders it a peculiarly fit employment for women.

Amongst others things that are in favour of the photographer from the business standpoint, are the lower insurance rates charged, and the lower price of apparatus. If those who quarrel with the insurance rates had been in active business a few years ago, when ether and gun-cotton had to be kept on hand in comparative large quantities—and risks paid accordingly—the would see how vastly things have changed for the better since the introduction of gelatine plates. The lower prices of apparatus, even in spite of the high wages demanded by skilled labour, show that there has been improvement in making the apparatus of a solid, practical character without unnecessary outlay of the skilled labour in excessive finishing. so that the camera (or whatever else it might be) was made to resemble a piece of ornamental bric-a-brac.

In concluding, we can truthfully express our feelings as being, on the whole, well satisfied with matters in general, and can thankfully say, in the words of a well-known volume, "Godliness with contentment is great gain."—*American Journal of Photography.*

Light.—If we study the action of light as exhibited in photography, we shall enjoy hours of amusement and instruction watching the action of such light on a variety of chemical substances. This investigation would well repay any earnest student.—F. W. Sutcliffe, in *The Journal of Microscopy.*

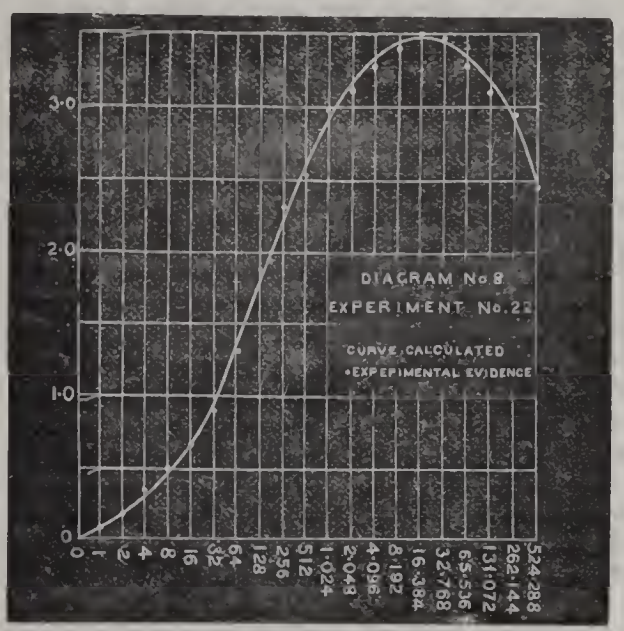
A photometric balance has been invented by M. Lion, who uses for this purpose the dangerous explosive substance iodide of nitrogen. If this is obtained, he says, by allowing ammonia at 22° to act upon iodine, it may be managed without danger if kept in the liquid. It yields a supply of nitrogen which is proportional to the intensity of the light which falls upon it. The evolution of the gas begins and ceases instantly with the luminous impression.—*Monthly Magazine.*

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

V.—Action of Light on Sensitive Film.

IE in any part of the curve of densities, as represented in diagram No. 7, the densities were proportional to the logarithm of the exposures, we should discover that portion of the curve if, instead of choosing the exposures as abscissæ, we used the logarithms of the exposures as abscissæ. This is easily done when the exposures progress, as they always do in our experiments, in a geometric series. We have only to mark every new exposure equidistant from the previous one as abscissæ. In this manner the results of experiment 22 are plotted in diagram No. 8.



It will be perceived that the curve now consists of four distinct branches. It proceeds from exposure 1 in almost horizontal direction, ascends slowly to exposure 16; from thence it proceeds almost in a straight line to exposure 2,048, when the growth of densities becomes slow. The densities reach their maximum at exposure 16,384, and from thence the curve returns, the densities diminishing slowly with increased exposures.

We accordingly distinguish four different periods of exposures. The first period we term the period of "under-exposure;" it is comprised in the first curved portion. The second period, that during which the curve is almost a straight line, we call the "period of correct representation." The third period is that during which the curve is again strongly bent as far as its maximum; this is the period of "over-exposure," and the last portion of the curve we term the period of "reversal."

1. *Period of Under-exposure.*—During this period the ratios between two densities are at first accurately equal to the ratio of the corresponding exposures. It is very difficult to study this portion of the curve accurately, owing to the short exposures which it demands, but still more owing to the small densities which this period yields, and which are difficult to measure. By making very slow emulsions we have, however, succeeded in showing clearly that at first the amount of silver reduced is proportional simply to the exposure. Thus, a plate

* Continued from page 773.

made by ourselves, with pure bromide of silver, gave the following results:—

Exposure, 20 C.M.S. Density, ·125 or 1
,, 160 ,, ,, 1·055 or 8·4.

The ratio between the densities being very nearly 8 the ratio of exposures.

Again, a "United Kingdom" plate gave the following results:—

Exposure, 2·5 C.M.S. 0·160. Ratio, 1.
5·0 C.M.S. 0·313. 1·95.

A very slow "Manchester" plate gave the following results:—

1 C.M.S. 0·260. Ratio, 1.
2 C.M.S. 0·550. 2·1.

But of course there is no definite point which marks the end of this period and the beginning of the next. But it is from this period that we learn that, for short exposures, the *amount of silver reduced is directly proportional to the exposure.*

2. *Period of Correct Representation.*—The second period of exposures we have thus named because during this period a plate is capable of giving a negative differing as little as possible from that which, at the beginning, we defined as theoretically perfect. That definition demanded that the densities of the negative should be proportional to the logarithms of the exposures which produced them. It is characteristic of this period that the *densities are proportional to the logarithms of the exposures.* This is shown on diagram No. 8, where the densities are the ordinates, the logarithms of exposures are abscissæ, and the period of correct representation a straight line. We have measured densities of dozens of plates falling within this period, and we find them all to conform to this very simple linear equation—

$$D = \gamma [\log. I.t + C],$$

D being the density, γ a constant depending on time of development, I.t the product of intensity of light and time —*i.e.*, the "exposure"—and C a constant depending upon the speed of the plate. As we shall give further detailed proof of this, we will here merely insert one example of a plate, the constant C of which is zero; it is Plate 2 of experiment No. 13. That plate gives the following results with equation:—

$$D = ·175 \times \log. \text{exposure}.$$

Exposure.	Density found by Experiment.	Density Calculated.
10	1·74	1·75
20	2·37	2·27
40	2·91	2·75
80	3·33	3·30

Many similar examples will be quoted presently.

We have thus arrived at the answer to the question, Can negatives be produced such as we defined to be theoretically perfect? And this answer is, they *can* be produced, but only by so carefully adjusting the time to the intensity of the light, that the exposures may fall within that period of correct representation. No variations whatever in development will correct an under- or over-exposure.

3. *Period of Over-exposure.*—Little need be said about this period. As the curve tends to become parallel to the axis of abscissæ it is clear that when exposures fall within this period, shadows and high lights will all be represented by densities which are almost equal. There will be no contrasts. In the first period of under-exposure the contrasts are too great; here they are too small.

4. *Period of Reversal.*—This period we have named the period of reversal because within this period happens that peculiar phenomenon, the transformation of the negative, into the positive the "solarisation," reversal, &c. It is easy to understand how the negative becomes a positive. Whilst the deep shadows still act upon the plate, increasing the density, the high lights have passed their maximum, and their densities grow less and less. The more the exposure is prolonged, the less dense the high lights become, the shadows exceeding them in density. It is quite easy to observe this phenomenon of reversal with a powerful petroleum lamp or gas burner, or to produce by direct contact printing a secondary negative, instead of a positive, from the original negative, by about fifteen to twenty minutes exposure at six inches distance from the light. When, in the camera, exposure is prolonged, it is well-known that a positive is obtained instead of a negative. It has been stated by Jaunsen that a secondary negative and a secondary positive can be obtained by prolonging the exposure still further. We have not, however, been able to verify this statement, and we believe it to be erroneous. Our investigations show that the density tends to a limit, and a picture produced by prolonged exposure in the camera is gradually lost in a uniform veil of fog, though it is still visible even after a three days' exposure.

A "United Kingdom" plate received various prolonged exposures, with the following results:—

		Difference.
75,000 C.MS. gave density ...	1·415	
		·304
150,000 ,, ,, ...	1·111	
		·141
300,000 ,, ,, ...	·970	
		·045
600,000 ,, ,, ...	·925	

A piece of the same plate exposed to direct daylight for ninety minutes (about six million C.M.S.) gave a density 1·200. From this it appears to us that there is an equilibrium established between the action of the refrangible and less refrangible rays.

The period of reversal is, theoretically, exceedingly interesting, and deserves further careful study, but the reversing action is so slow, and requires such enormous exposures, that it does not need to be considered from a practical point of view, and we shall disregard it entirely for the present. The three first periods—that of under-exposure, that of correct representations, and that of over-exposure—are the only practically interesting portions of the curve. We have already stated that, during the first period, the ratio of densities is equal to the ratio of exposures, *i.e.*, the amount of bromide of silver reduced is proportional to the exposure, whilst, during the second period, the density only grows in proportion to the logarithm of the exposure. It almost ceases to grow during the third. Of course, these assertions are only two approximate statements of one single law connecting the densities with the exposures.

(To be continued.)

Edinburgh Photographic Exhibition.—The space at disposal is, it is stated, well taken up, and the Exhibition promises to be a very successful one, many of the principal photographers in the Kingdom having intimated their intention of exhibiting. The Lord Provost of Edinburgh has consented to perform the opening ceremony on the 14th prox.

AN AMATEUR AT THE LAST WASHINGTON CONVENTION.

BY CATHARINE WEED BARNES.

It was suggested to me late last spring that it would be well to enter the professional competition at Washington, in August, for the "Enoch Arden" prize. Finding that amateurs who paid their dues to the National Photographic Association of America could compete with their professional brethren, I entered the Association, and received the circular of regulations. As expressed in my July editorial, the subject of illustrating poems has a wonderful fascination for me. I began the preliminary study of the poem with an earnest zeal which led me to write the above-named article. It seems to me, now the victory has been decided, that it may be of interest to other amateurs to learn how one of their number prepared for such a contest. It was more through a hope of gaining valuable help in an advanced department of the school of experience, than from any idea of eventual success in winning the prize, that the work was undertaken. These were gained, as they could not fail to be, but the prize, as is known, went elsewhere.

Many hours of thoughtful study were spent in selecting the lines which, it seemed, might best express the poet's ideas to one who, perhaps, might not have read the poem, or scarcely remembered it. Passing over the child-life of Annie, Enoch, and Philip, which I did not think could be used when only three pictures were allowed, I decided on the early married life of Annie and Enoch for the first picture. It did not seem correct to take fragmentary scenes without proper connection, and then, to be consistent, I was obliged to include only such lines as required little, if any, out-door scenery. Much searching of books of travel, magazines, and art works aided me in designing the scenery and costumes, and then the sitters had to be carefully chosen. Believing that in what artists call a "picture" painted or simulated effects should, if possible, be avoided, I got a carpenter to make me a wooden framework covered with painted boards, such as would naturally form the walls of an English sailor's cottage. Everything was to be extremely plain, from the rag carpet to the old-fashioned table and dishes, while the bird-cage hung in the passage-way, and Enoch mended his nets over the half-open door, watched by Annie inside the room as she mended her husband's socks.

A sailor's costume was easily planned, but Annie's must be of some soft, clinging material, inexpensive, and made in the style of a century ago. Ordinary sateen and home sewing accomplished this, and all of the other accessories were meant to express the surroundings of a happy, simple married life.

The day set for the sittings proved stormy, but by 6 a.m. I was out in the studio putting the last touches to the scenery, and thinking of different poses. After breakfast posing began, and before noon eighteen exposures had been made without any help to fill plates, adjust the heavy camera-stand, and generally make life easier. After development with pyro and soda, which in this, as in the subsequent work, was slowly and carefully done, the negatives were all laid aside for future selection. None of them were in any way retouched, and the average exposure was ten seconds.

The second picture was the hardest of all to conceive and execute. The scene selected was where Enoch, returned, sees, through the window of Philip's home, his beloved Annie watching her babe on its father's knee, while his own children stand looking on, a happy family circle. The light from the room into which he gazes shines on Enoch's weary, sad face, and that which would have fallen on the ivy-covered wall and crouching figure was curtained off, confining all but a few rays of light to the interior of the room shown through the half-open window, it being night when Enoch sought Philip's home. After careful consultation with Mr. L. W. Seavey, he made me the wall and window, but the ivy and branches that nearly covered it were natural growths, and the turf and gravel in the foreground came from the garden about my studio, the former being laid on zinc to protect the floor from dampness. Great care was needed to properly place the little furniture the room could hold, and in arranging the group of several grown people and a five-months' old baby. It was not easy to procure proper subjects, devise costumes, or manage to focus on sitters placed in anything but a straight line, and have everyone and everything in proportion. It was another struggle to have the inside group just enough visible to appear natural, but Enoch, as the important fact of the picture, required the greatest care in treatment. Of the two dozen exposures made that hot day, all but one were rejected for some slight defect. It was necessary several times, in making this and the other pictures, to pose myself in the required attitude before the sitter caught the idea I wished to convey. The studio is nearly twenty-three feet long, but so much was taken up by the scenery that I had to build out a platform from the front door, and a framework covered with non-actinic cloth, so as to run my camera-stand several feet outside the building. In this and the last picture I had someone to change plates and help with the heavy work, but not with the arranging or posing.

The last picture was the first taken, and the wall of Enoch's room was made of rough boards stained and defaced by age and hard usage, while the doorway partly revealed an old staircase. Everything was intended to sharply contrast with the comfort and abundance of Philip's home. Overhead, shutting out the top-light of the studio, was a timbered ceiling made under my directions by a carpenter so as to make the room appear as it naturally would—dim and shabby, with all the light coming from the side. This scene also required several exposures.

Then came the work of final selection of the negatives for the three best ones. I took the latter to the gallery of a professional friend, my own not having conveniences for such large work, the negatives being 11 by 14. There I spent a day in printing and toning the selected pictures. He then mounted, framed, and sent them to Washington.

It is needless to say that the benefit of comparing one's efforts with the work of those who are supposed to be thoroughly proficient is worth much to those who sincerely desire to improve their work, and I, personally, feel confirmed and strengthened, if that were needed, in my love and interest in camera work by my Washington experiences. They also taught me, and I wish to impress this strongly on all camerists, that while, with expensive accessories and a large studio, one can most easily do fine work, it is possible in a smaller room, with considerable exercise, it may be, of brain and body, to bring about results of which one need not necessarily feel ashamed. Of course a good lens and plates are absolutely necessary. Mine was a

Voigtlander W. A. euryscope, and I used for two of my negatives Newcomb and Owen's plates, and for the other Allen and Rowell's. Both were sent me especially for this purpose, and were equally good. A quick, inventive brain can supply more of the other requisites than would be believed possible by those who think that such things can always be purchased; but it means hard labour every time, and a willingness to put one's own hands to every detail of the work. With every obstacle or troublesome difficulty, I was continually told it was *impossible* to do thus or so, to which my reply was, "I don't like that word: very few things are really impossible." "Well, I don't see how you are going to manage," would be the comment on this, to which I would say, "Neither do I at this moment, but I mean to *find* a way." The portrait studio is an excellent place for patience to have her perfect work, and the Christian graces find plenty of unconscious teachers through which to impress themselves on many a pupil. But it is a curious fact that the more one does the more one can do, as long as strength lasts, and if women could always systematise their work as men can, the results would startle them. The manifold cares of a household with its incidental "werryments" make regular work of any kind difficult, if not impossible, for many of them, but determination works wonders, and I wish to urge on all, women and men, who find in camera work a vital source of interest and benefit, do not play with the work, but make it a real, genuine part of yourself, and you will be doubly, trebly rewarded. In its far-reaching, ever-extending field of exploration you will gain a broader, wider, deeper culture than you dreamed might be possible, and, deeply as I revere and honour the work of brush and palette, I shall never regret my transferred allegiance to the camera.—*The American Amateur Photographer.*

APPARATUS AT THE PHOTOGRAPHIC EXHIBITION.

I.

AMONG the specimens of apparatus on view at the Photographic Exhibition is Mr. T. Samuels' arrangement in which a leather case is fixed to the camera legs, as shown in fig. 1, so that the case cannot be lost. The same cut shows that the camera case can also be used on the top of the stand, so that the camera can be covered promptly while it is on the top of the stand, and thus be protected at once from any sudden shower of rain, yet be in readiness for the taking of the next view required. The legs and camera can be carried over the shoulder while the camera is in its case. In stormy weather the case thus in position increases the area presented to the wind while the exposure is being made, which seems to be a drawback.

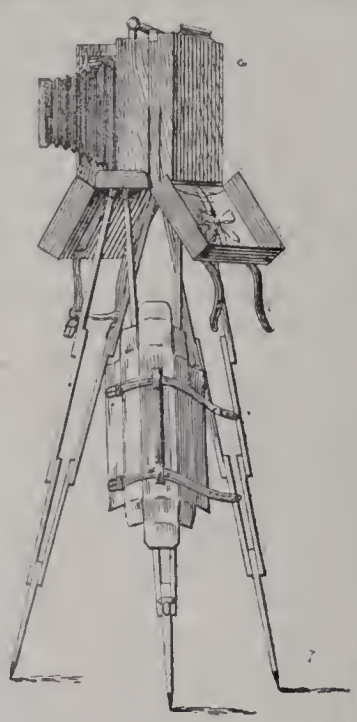


Fig. 1.

Fig. 2 represents the camera itself, as devised by Mr. Samuels. It is one of that class which, when closed,

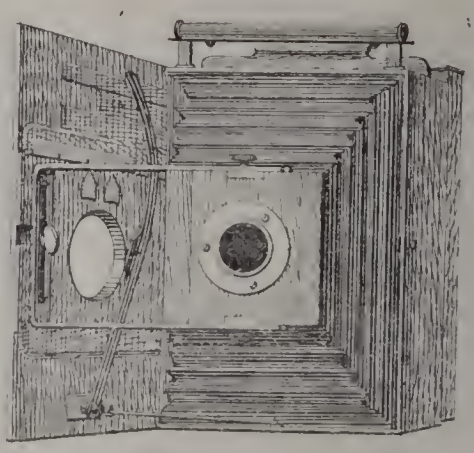

Fig. 2.

forms a rectangular box, exposing little which might be liable to breakage by an accidental blow. The focussing is done quickly by a lever arrangement; the long lever, of bent form, is represented in the cut. By means of two thumb-screws and a brass support, represented in the engraving, the front of the camera can be fixed in any position, and the focussing can be done by measurement by means of scales and pointers. A flexible transparent screen can also be used for focussing; it winds upon and unwinds from a roller, represented on the top of the camera. This screen, when extended, did not lie very flat, perhaps because visitors to the Exhibition had been pulling it about. When closed, the camera presents no screws or projecting parts. The dark slides of this arrangement are furnished with a special device for locking the shutters. Mr. Samuels has also introduced some minor improvements into this camera.

Fig. 3 represents a studio stand exhibited by Messrs. Marion & Co., in which the camera slides up and down a substantial iron tube, and can be clamped thereupon at any level. A counterbalancing weight is in the inside of the tube, and is connected with the baseboard of the camera by means of a rope passing over a pulley wheel. The two hind feet of the stand are longer than the two fore feet, and the former are connected with the top of the stand by means of two iron tie-rods.

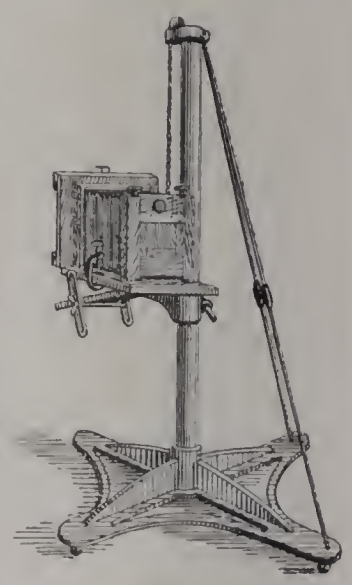

Fig. 3.

Fig. 4 represents one of that class of shutters in which a time arrangement is attached to the roller-blind shutter of Kershaw. Shutters of this class are among the best and most useful in the market for use in front of the lens; they are rapid, light, and give no vibration. In Messrs. Marion's shutter, represented in the engraving, the shutter is set by means of a small brass lever; it is released by a piston connected with the usual pneumatic flexible tube-and-ball arrangement. Other of

the exhibits of Messrs. Marion & Co. we shall describe hereafter.

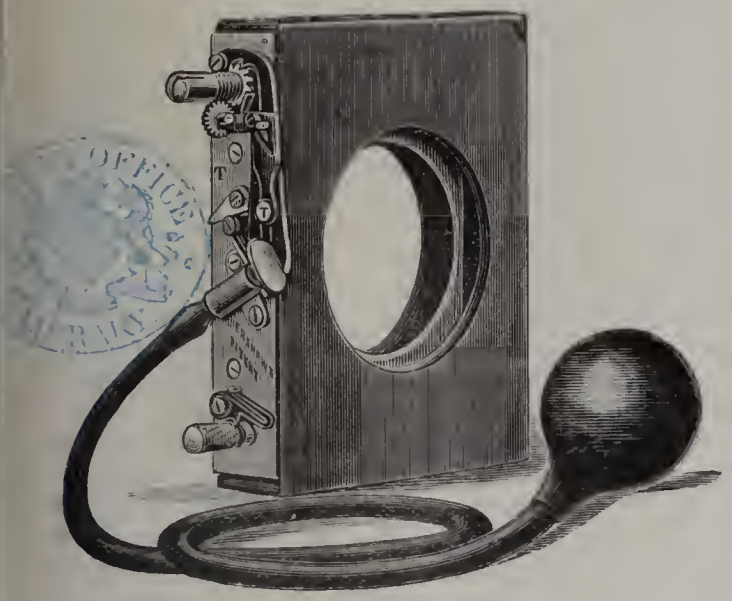

Fig. 4.

Sir David Salomons exhibits a rocking-table for use in the development of plates. It is represented in fig. 5, in which K N is a glass rocking-platform connected with the iron rocker shown "on the swing" near the bottom of the cut. A H is a sheet of looking-glass to reflect the ruby or yellow light from a developing-room lamp upwards through the glass table and the glass bottom of the dish holding the negative. In front of the apparatus two wooden handles and two long spiral springs are represented; these are for raising or lowering the two front legs of the table, so that the developer can be made to act more upon one part of the negative—say the foreground—than upon the other part. A merit of this arrangement consists in the neat way in which the iron weight of the rocker is got out of the way of the operator; it is a horizontal cylinder vibrating under the table, and connected with the glass platform K N by two iron rods.

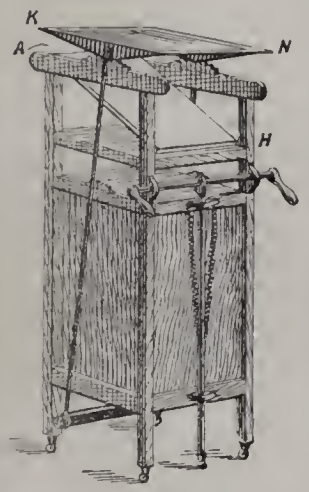

Fig. 5.

Mr. Morley exhibits a simple shutter, which both at the Exhibition at Pall Mall, and the Photographic Exhibition at Geneva, where it is now also on view, attracts some attention from the visitors. It is always set: it gives time and instantaneous exposures, regulated by the projecting head represented to the left of the cut; by means of an india-rubber ring it will fit on to hoods of different diameters, within a narrow range. Extremely rapid exposures can be made by pinching the india-rubber tube and squeezing the ball at the same time, then suddenly releasing the pressure on the tube.

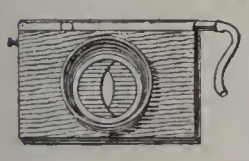

Fig. 6.

The Photographic Club.—Subject for discussion on Wednesday, October 15th, "Registration as Applied to Photographic Printing"; October 22nd, "Photographic Copyright."

OPERATING NOTES.*

BY L. J. ULLMAN.

I will begin with the curtaining of the light. Nearly twenty years ago, I advocated a system in which the curtains of the skylight were divided into six sections. The curtains were run on wires *parallel* with the side light. I believe this method gives better control of the light than by the usual way of curtains on rollers running from the lower to the upper side of the light; at least, such is my experience. The side light for bust work should not be open except above five feet from the floor. In groups and full figures the light may be used much lower. We should always keep in mind that the general direction of the light falling on the subject should be about an angle of forty-five degrees. This is, of course, varied for certain picturesque effects which the taste of the operator may devise.

I prefer ordinary white sheeting for the material for curtains; on a north exposure one set is sufficient, but where much sunlight has to be shut out two sets are found desirable. It is my custom to place the subject for ordinary portrait lighting a very little back of the centre of the light, and for Rembrandt and shadow-effects slightly forward of the centre. The usual position for the Rembrandt light is to work diagonally toward the side light, but if brought forward as suggested it will be found that the finest results may be obtained working parallel with the light. An important factor in the production of fine portraits, and one often overlooked, is the distance between the subject and background. If you wish atmosphere and apparent space or perspective to relieve the image, you *must have* it; the lens cannot produce it. Let plenty of light fall between the subject and ground, and there will be a feeling of fine relief that is not otherwise obtained.

I am a great believer in the value of the head screen. Used in connection with a screen frame about 6 feet high by 3 feet broad, in which are hung two smaller frames supported horizontally at each end by pivots which allow them to be inclined to any angle, and then covered with *thin* muslin, you will have in this combination the means of obtaining any desired lighting *without* the use of curtains to the light. The reflecting screen should be in two sections, adjustable like the screen above described. One side should be covered with white muslin, the other side coloured a light drab tint. A reflector is a necessary article, but its injudicious use damages a great many negatives otherwise good. The chief reason for sectional curtains, as described, is that light may be admitted from any direction and in any quantity desired, making the use of a reflector seldom necessary. Now, if anyone will try covering the entire light with white curtains, and will then take a negative; afterward put back every curtain and flood the room with light, and then take another negative, giving the same time as before; develop them together; the result will be a lesson in lighting which will be of great value. The result will be that one negative will be soft and full of subdued detail, the other hard and lacking in full shadows. The other, taken with the east light, has the best time. You all know that a sunlit landscape requires more exposure to produce a soft negative than when the sun is veiled with light clouds. It is the same in studio exposures. Hence use only a small opening of direct light, only enough slightly to accent the high-lights.

* Read at the American Convention.

The result is perfect in modelling, and every way more satisfactory. Another way is to use the light uncurtained, then control the light with the screens before mentioned. In all bust-work for large sizes I use the latter method. The idea I wish to convey is: *Use a soft, well-diffused light.* It is more agreeable to the sitter, secures good modelling with short exposures, and saves greatly in the retouching.

I notice of late a great stride in the right direction, and that is in the adoption of more simple designs for backgrounds. In many instances it has been a little difficult to tell which was the subject and which the accessory. In every detail of the business of the best galleries there is a decided improvement in an artistic sense. The new order of things proves one thing pleasant to contemplate, and that is, the beneficial influence exerted by the Photographers' Association of America.

I cannot forbear in this connection to mention another element which is contributing to the dissemination of knowledge among us, and that is "The Photographers' Free School." Now, I don't think any of you have ever heard of it before, but many of us have partaken of its advantages. The professors are paid by such liberal men as Cramer, Seed, and Carbutt, and by the Eagle and Phœnix Companies.

I allude to the demonstrators. These men are selected as the best qualified to be had, to show the respective merits of their plates, and are usually capable and willing to impart their knowledge to any who ask.

A photographer who was called upon one day by a demonstrator, said to him, "I will not buy of you; yesterday you spent some time instructing Mr. ——; he is my competitor, and you have no business to do so." The demonstrator replied, "Does not the golden rule apply to photographers? *You* are a man who has grown grey in the business; he is almost a boy, and is working earnestly, if not for fame, at least to support a mother and young sister. If you feel like that, I don't think the house I represent would care whether you use their plates or not."

Now, as a rule, I think photographers are nice men, but you all know the old saying about the black sheep.

Photographs almost always lack the quality of breadth. There is too much *prominent* detail to satisfy the artistic taste. Greater breadth is imparted by softening the light and using large diaphragms in the lens. A picture requires breadth because it then appeals to the *imagination* of the beholder. The richer the picture is in its *suggestions*, the greater its merits as an artistic production.

I may illustrate by describing a painting representing a storm on the sea-coast: As I gazed on the sky with its dark, flying clouds, and on the waves dashed into showers of spray against the rocky shore, it seemed that I could *hear* the whistling of the wind and the thunder of the surf. The sea-line was scarcely visible, and in the breakers was the piece of a spar bearing a few broken strands of the rigging; all suggesting that the angry waters might conceal the story of a wreck with its attendant horrors. Now, on examining the painting closely, it looked as if it might have been done with the refuse of a house-painter's dried up pots, and *any* kind of brushes from shoes to brooms. As for detail there was none; and yet, when viewed from the proper distance, the power of the scene thrilled one indescribably.

Now, although we are hedged about and limited by the powers of our lenses, yet we have the greatest things necessary—light and dry plates—and by their intelligent use we shall yet do far greater things than has yet been accomplished, and I believe the next exhibit of this Association will prove it. We have, all our lives, been trying to see who should make the *sharpest* picture, and the lens makers have helped us. This is all right, for *we* have demanded it. It is in this way we have discarded our best friend—*breadth*. Petty detail and breadth are mortal enemies, and the sooner we acknowledge the fact, the quicker shall we see the artistic excellence of our work improve. Well, says someone, how can I get it? I say *cut loose* from *small diaphragms*, and even then take a turn out of focus; study the effect. Give soft, rich lighting, simplicity in posing, and make your draperies fall in broad folds. Keep out of your pictures all *big* patches of white. Remember that flesh is never white under any circumstances, and neither is white to be represented white if in shadow. A very small space of white is a sufficient key for a large picture.

In the works of Adam Salomon we have the nearest realisation of what I have attempted to describe. With the increase of knowledge and new appliances, may we not hope for great things?

Specifications Published.

15,163. *September 26th*, 1889.—"Photographic Cameras." Abraham Dirk Loman, 361, N. Z. Voorburgwal, Amsterdam, Manufacturer.

The object of my invention is so to construct and fit with such appliances photographic cameras, and especially hand or portable cameras, that the object can very easily be exactly

focussed that the longest or the shortest desired exposure can be given to the sensitive plate therein, and that no vibration will be given to the camera by such exposure, or, that is to say, by such movements of those parts in this camera that allow the exposure, and I realise all these advantages in a very simple and effective manner.

To carry out this object, the camera forms or is placed in a preferably rectangular casing of the desired size, one end whereof, or part of the same, may be open or capable of being opened, and the lens is placed at or near this opening, preferably being mounted, as is usual, in a tube, and when the lens is behind the opening this tube can be secured in and to a partition placed transversely in the casing, and a rack and pinion movement is provided which can be operated from outside the casing, and by which this partition may be moved, or the tube may be elongated or shortened to bring the object into focus, and suitable stops, preferably diaphragmatic, may be fitted to the lens or to the lens tube. When the partition is to be so moved, suitable opaque bellows can very conveniently be fitted between and to the opening of the casing and the partition round the lens tube to make this partition light-tight. The proper distance behind the lens is horizontally and transversely pivoted in the casing, and near the upper part of the same by its upper and further edge, a mirror corresponding wherewith a piece of ground glass is inserted into the top of the casing, and this mirror, when inclined downwards at the proper angle, receives the image through and from the lens and transmits it to the ground glass. The mirror and the ground glass are suitably surrounded by opaque bellows, and when the same are extended an opening made in the front part thereof corresponds with the lens. Below the mirror is fitted in the casing an india-rubber pocket or other pneumatic bellows, which can be operated from outside the casing by a collapsible ball, and is connected by a link or otherwise with the mirror in such wise that when and as the same is distended, the mirror is folded up against and parallel or thereabouts with the ground glass. Behind the mirror is inserted in the casing the dark slide that holds the sensitive plate or plates. All these parts are so arranged that when the image has been focussed on the ground glass it will also be exactly in focus on the sensitive plate, or a certain predetermined movement must be given as aforesaid to the lens whereby it is known this exact focussing will be effected. Any suitable shutter may be used in and with this camera that will give a timed or an instantaneous exposure, as may be desired, and I preferably use what is known as a blind shutter, placed behind the mirror and immediately before the sensitive plate, and more especially the blind shutter that is described in the provisional specification accompanying another application for a patent which I have made this day.

The method of using this camera is as follows. When the image has been duly focussed on the ground glass, and the known correction (if any) has been duly applied to such focussing, and the sensitive plate has been placed in position and uncovered, if a timed exposure is required the shutter is properly arranged therefor, and then, by the pneumatic bellows, the mirror is raised and the required exposure is given to the sensitive plate, when the pressure is removed and the mirror is allowed to regain its normal position, being assisted therein, if desired, by a spring; but if an instantaneous exposure is required the shutter also is properly arranged therefor, and then in the same manner the mirror is raised until it comes in contact with a spring, or catch, or other appliance which, when pressed, will allow or cause the shutter to act and give the required exposure.

Instead of inserting the ground glass, as aforesaid, into the top of the casing, I may, when I so desire, insert the same into one of the sides of the casing, moving the other parts of this camera, where necessary, into the proper corresponding relative positions.

18,062. *November 12th*, 1889.—"Purifying Compounds of Alumiuium." Hamilton Young Castner, 115, Cannon Street, London, Managing Director of The Alumiuium Company, Limited.

Traces of iron in aluminium give it a yellow colour, and with the difficult task of removing the iron this patent deals.

The object of this invention is to purify the anhydrous double chloride compounds of aluminium, such as the double chloride of aluminium and sodium and others.

In the production of metallic aluminium from the double chloride by the action of sodium or otherwise, it is of great importance that this compound should be pure. It is, however, ordinarily contaminated with iron, which renders the aluminium also impure.

My present invention relates to a method of purifying these double chlorides by decomposing the chlorides of iron which they contain by the use of the electric current, the apparatus and the quantity of current used being so arranged as to decompose the ferrous and ferric chlorides, and to deposit the iron in the form of metallic iron, leaving the double chloride pure.

To do this by my invention, it is necessary to melt the impure anhydrous double chloride of aluminium, and pass through it an electric current of proper magnitude, taking care that the molten crude chloride is kept in motion between the electrodes, and further, that the current which operates on the double chloride is diminished from time to time, so that it may just be sufficient to cause the iron to be deposited, but not to deposit any substantial portion of aluminium with it. This may be effected in a single bath if the current be diminished from time to time, or it may be carried out by causing the molten crude chloride to pass through a series of baths in which it is exposed to a series of electric currents of decreasing quantity suitable to produce the above effect, it being kept in motion throughout the process. In this arrangement it is not necessary to vary the quantity of the current in each bath, as the required object is attained by using a series of baths.

The quantity of the current at each stage will depend upon the amount of iron remaining to be deposited.

Correspondence.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

Sir,—Please insert corrected list of subjects as under:—

October 16th.—"Stereoscopic Photography."

October 23rd.—"Preparation of Dry Plates," Mr. Prestwich.

October 30th.—"Pictorial Definition," paper by Mr. W. E. Debenham.

PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

Sir,—I am requested to state that the judges have awarded a medal to Green, Cross, and Bevan, for their exhibits of Diazotype Printing; also to Andrew Pringle, for Photo Enlargements.

Edwin Cocking, *Assistant Secretary.*

5A, *Pall Mall East, S. W., October 7th.*

"A WARNING!"

Sir,—It is my unpleasant duty to call your attention to a theft of lenses which has just been perpetrated at my establishment, and I trust that my mentioning the case may serve as a protection to some of my photographic brethren. At the same time it may, perhaps, lead to the recovery of the missing articles.

A few days ago I took pity upon an individual who called in answer to an advertisement for a printer, answering my question regarding references with the plausible story of his having had a quarrel with his family, who were in business as photographers in Huddersfield and elsewhere. He said that he thought to find it easy to obtain work in London, but had been unsuccessful during a search of several weeks. This morning he rewarded my confidence by depriving me of his services and a couple of large portrait lenses, one of which was stamped Lerebour and Secretan (half-plate), and the other a rather larger-sized *whole-plate lens*, cone-shaped and wider at one end. The man was rather good-looking, of respectable appearance, and good address. His face and neck were very florid; his hair and moustaches red. He had evasive habits. The police have been communicated with.

J. Hubert.

238, *Mare Street, Hackney, London.*

Proceedings of Societies.

THE LONDON AND PROVINCIAL PHOTOGRAPHIC ASSOCIATION.

October 2nd.—Mr. A. HADDON in the chair.

The subject for discussion was "The Keeping and Testing of Sulphite of Soda."

The CHAIRMAN said every photographer must be interested in the subject. It was only by having a knowledge of the chemicals they were using that photographers could contend successfully with any difficulties that might arise. He introduced to the members Mr. J. C. Belcher, M.S.C.I., who read a paper on the subject (see p. 780).

The Lecturer illustrated his paper by various experiments, commencing with sulphurous and sulphuric acids. A piece of sulphur was burnt over a solution of sulphite of soda in a bottle—to which barium chloride had been added—afterwards using the solution to write on a piece of paper. The paper being held over a spirit lamp, the sulphurous acid was driven off, leaving sulphuric, which proved its presence by the charring of the letters on the paper. Several experiments were then made in testing sulphite and sulphate of soda, by adding hydrochloric acid to a solution of sulphite of soda and barium chloride, sulphite being soluble in hydrochloric acid, but not sulphate. A delicate test was shown for the detection of the presence of carbonate, by adding to a solution of sulphite phenol phthaleine. The solution would change to a bright pink colour if only a trace of carbonate were present. The preservation of sulphite was next dealt with. This was effected by keeping the crystals of sulphite in ether. The Lecturer showed a sample of sulphite in ether that had been kept in the bottle six months; sulphite in solution could be kept by floating rectified benzoline on the top.

Mr. A. COWAN asked whether, in testing a solution of sulphite with phenol phthaleine, the depth of colour of the solution would indicate, to some extent, the quantity of carbonate present.

Mr. J. C. BELCHER thought not. He showed a sample of sulphite which contained 2 per cent. only of carbonate; the usual quantity generally present in sulphite was from 5 to 6 per cent.

The CHAIRMAN spoke of the value of the hints that had been given in the paper that had been read before the meeting, especially with regard to the preservation of sulphite, expressing a hope that Mr. Belcher would favour the members with a further contribution on the chemical side of photography at an early date.

This Mr. BELCHER promised he would do.

M. ROBERT showed a new developer; it was in one solution. He claimed for it that it was a very energetic developer. M. Robert subsequently took some photographs of the members present, for the purpose of demonstrating the power and efficiency of his flash-light apparatus.

Mr. T. E. FRESHWATER passed round an album of prints from negatives taken at his various outings during the summer.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THIS Society met for the first time at Hanover Hall, Rye Lane, S.E., on Friday, October 3rd. Five members were elected and three proposed, after which an excellent series of slides (the work of Messrs. Boydell, Esler, Collins, and other members) was shown. Amongst them was a series taken with the "Ideal" hand-camera, which created much amusement. Some well-executed microscopical slides were also exhibited.

The lantern was lent and worked by Mr. Bauks, the treasurer.

ENFIELD CAMERA CLUB.

A MEETING was held at the Lancaster Coffee Tavern, Silver Street, Enfield, on the 1st inst., Mr. PINKNEY in the chair.

The photographs of the monthly competition were exhibited.

It was resolved that the next field day be held on Saturday, 11th inst.; members to start from the Lancaster Coffee Tavern at 9.30 a.m., and proceed to Nether Hall, near Broxbourne.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

ENAMEL.—Your's is hardly a photographic question. We have no technical knowledge of the materials employed in glazing enamelled iron plates, beyond the fact that powdered felspar is a chief ingredient, and that the enamel coatings differ greatly in their power of resisting acids and corrosive chemicals, according to the nature of the fusible composition and perfection of its attachment.

E. and S.—*Photographs of Samoa and Fiji, Animal Studies, &c.* We have not seen the new series of Samoan photographs mentioned in your second letter. With regard to Mr. Gambier Bolton's animal studies, besides the horse and lion of last year you will find a dog and three kittens now in the Pall Mall Exhibition—catalogue Nos. 347 and 389.

A. C.—*Retouching by Night.* The best hint we have to give you is a recommendation to employ a pale blue glass to counteract the yellow tinge of artificial light by which you propose to work; this makes it less trying to the eyes. The use of ground glass or rice paper is unnecessary unless you are working upon very thin negatives.

MEDALLIST.—*Further Awards at the Exhibition.* In the scientific department two medals have been given; one to Messrs. Green, Cross, and Bevan, for their Diazo-Primuline process, and the other goes to Mr. Andrew Pringle for his micro-photographs of bacteria. These will be notified in the corrected edition of the catalogue.

A. W.—*Primuline Materials.* The new dye, primuline, together with the developers, red, purple, orange, yellow, and brown, also nitrite of soda and acetic acid, are procurable from Messrs. Brooke, Simpson, and Co., Atlas Works, Hackney Wick, N.E. The process is not a difficult one; on the contrary, quite simple, and easy of execution.

W. L. (Bandoeng, Java).—*Watkins' Exposure Meter.* This instrument is figured on page iv. of last week's NEWS, and is now being shown as one of the novelties in the Pall Mall Exhibition. It will come in for notice amongst the apparatus, and so far as the nitrite paper is reliable, it promises to be the best in the market. Can you stimulate the action of your instantaneous shutter by an additional elastic band, as is possible with Sands and Hunter's? See report on page 775, and reference to the fact that twenty or thirty different forms are now before the public, making it a very difficult task to say which is best! Kershaw's has been recently improved. On other points we will make further enquiries, and communicate again next week.

A. M. M.—*Graphic Inks.* We are sending you two samples of permanent black for trial, and shall be glad to know whether either of them answers your purpose. If so, we will give you fuller particulars.

LUX MINOR—*The Weather.* The month of September, indeed the last six weeks, may be said to have redeemed the character of the past summer; warm and genial, with glorious sunshine, and less rain than for many years (only about one inch), photographic operations must have been very greatly facilitated, and out-door exposures rendered almost a matter of certainty. We never remember a better season for photography, and let us hope it will result in much good work having been accomplished within this later period.

F. C.—*Mounting in Albums.* It is often difficult to ensure flat mounting of photographs in albums. Before laying down the pasted photo you ought to pass a moistened sponge over the face of the paper or card upon which it will be in contact. Lay a sheet of blotting paper between each page, and allow to dry slowly under pressure.

ALBUMEN.—Received, and will be answered in our next. For private address, see head of this column.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1676.—*October* 17, 1890.

CONTENTS.

IS ALBUMEN PAPER DOOMED?

In spite of the oft-repeated and, unfortunately, true charge of want of permanence, the silver picture on albumenised paper still represents the most common method of printing from a photographic negative. We need not seek far to trace the reason for this apparent recklessness in employing a servant of such treacherous disposition. The process of printing on albumenised paper is so easy that a mere child can be taught to look after the printing-frames, besides which it has the still more laudable quality of cheapness. Since manufacturers have turned out ready-sensitised paper of good quality at a price at which it could hardly be prepared by the worker himself, the method of printing on albumenised paper has had an astonishing impetus given to it, and other methods of printing have naturally been neglected.

This last statement may be questioned by those who only judge of the relative popularity of different processes by the pictures seen at our exhibitions. They look around the walls of such an exhibition, and remark at once that the familiar warm tones of the silver print are all but absent, and that they are replaced by the greys and blacks due to bromide paper and to platinum. Even the silver prints themselves are under a disguise since it became the fashion to tone them with platinum instead of gold. Other strange processes are also represented by a few experimental photographers, but the general conclusion arrived at is, that the silver print on albumenised paper is fast being relegated to obscurity.

But the exhibition gallery is not the place to form a correct judgment regarding such a reformation. We should get far more reliable information by seeking it from those who prepare or who sell sensitised paper; and they would probably tell us that, in spite of bromide, platinum, and all the other new-fangled things, silver prints are still as common as daisies. If they are as ephemeral as those flowers of the field, it matters not to either the producers or the public. The first have their living to make, and competition has so cut down prices that they cannot pause to enquire whether the pictures which they issue to a confiding public will be as lasting as the pyramids, or whether they will fade before another year has passed away. They do their best by copious washing and by choice of good materials to ensure permanence, and they can do no more. Of course these men are the struggling members of the photographic fraternity, for we know well that those who have deservedly won first places in the race for existence will, by careful experiment, be careful to leave no stone unturned to render that which comes from their studios as permanent as possible.

The public cares little to enquire whether a picture will be permanent or not, for few of them look beyond the present. They like the portraits to look well, and expect them to last for a reasonable time, and, provided that they do this, satisfaction is secured. Now and then a case occurs where death comes in suddenly, and then the fading of a particular portrait is deplored, but, as a rule, the fading of pictures, possibly long after the course of events or lapse of time has engendered or lessened interest in the original, is taken with equanimity.

Those photographers who compete for prizes at our exhibitions are somewhat differently placed to those whose circumstances confine them to the same well-worn ruts year after year. They mostly wish to show prints from pet negatives which have been taken expressly for exhibition purposes. They know that prints in platinum are permanent, and they are aware that the matt surface of such pictures, if not fully appreciated by the general public, commends itself to artists, and at least one artist is sure to be on the list of judges; so that the proportion of platinum prints at an exhibition is not a fair guage of the general adoption of platinum in lieu of silver printing. We would that it were otherwise, but we fear that the use of the more permanent metal will be checked, instead of increased, by the recent extraordinary rise in price of the raw material.

The old question of £ s. d., indeed, must, for a long time, determine this matter, as it rules most other things where advance and improvement are called for. The public are, at the present time, mad on the subject

of cheapness; the store system has demoralised them. Quality, permanence, and everything else must give way to that fixed idea, except among the few who are educated up to higher considerations. So that, in spite of fresh processes, some of which are most promising in the results which they afford, the silver print holds its own, and simply because it is the cheapest to work.

We have, perhaps, been unfair to the old process in writing of it as if it were bound, in time, to give pictures which are evanescent; but our readers will know that we do not wish to convey this idea. We have silver prints—some, too, with obscure names printed on their backs—which are beautifully fresh in appearance, although taken twenty-five years ago. Others, with well-known names, not so old, are dying fast of yellow fever. No one yet has satisfactorily solved the riddle represented by these vagaries of silver prints, but all agree that they are most uncertain in their behaviour.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

In endeavouring to arrive at a clear idea of the value of the Photographic Exhibition as a record of progress, one naturally seeks to make some sort of classification. But this is difficult to do. There are portraits at the one end of the scale and landscapes at the other. Between these two extremes any number of variations exist. When Mr. A. Keighley, for instance, calls his capital little picture "Who's Coming" (No. 5), does he mean it to be judged as a landscape, as a group of figures, or as an attempt at telling a story? Mr. Ralph Robinson frequently is puzzling in this way, while the portrait men, with in-door effects, are fond of suggesting the same uncertainty. The point is not important, save that it renders arrangement into classes almost impossible, and one is perforce obliged to take the pictures in the order of the catalogue as the simplest way of proceeding.

There is, however, no need for hesitation in deciding what Mr. J. Gale means. He is a landscape man of a thorough type. A flock of sheep is the most prominent object in "Through the Driftway to the Fold" (No. 18), but sheep and cattle may almost be considered as component parts of a landscape, and in this case the sheep certainly add to its charm. The same remark may be applied to "The Ferry" (No. 32). Here are two figures, but they are admirably in keeping with the scene, and subordinate to the general effect. The composition of the picture as a landscape is what Mr. Gale aims at, and he succeeds. All his work is marked by the taste, refinement, and delicacy of workmanship to which Mr. Gale has so long accustomed us, though it may be said that this year he has not been quite so happy in the choice of subjects. One pauses before differing from so skilful an artist, but I am tempted to ask whether his skies are not sometimes too heavy and pronounced. They have a way of suggesting an impending storm, all very well when this idea is intended, but rather confusing when not.

One of the most striking features of the present Exhibition is the fact that, despite the number of artist photographers who have grown up in recent years, Mr. H. P. Robinson more than holds his own with the best. Indeed, in some respects he has excelled himself, and rarely has he shown to such advantage as in the present Exhibition. In "A Strange Fish" (No. 26), representing an old fisherman on the seashore showing to a couple of wondering children some uncanny occupant of the deep which has found its way by chance into his net, Mr. Robinson displays his old skill in telling a story effectively. "Against the Wind—a Race with Grandad" (No. 109) is also a scene on the seashore. I am not certain, however, whether the picture would not have been improved by the excision of the girl in the distance whose skirts cling to her in rather ungainly fashion. The two principal figures are full of life and "go," and withal natural. Mr. Robinson has done nothing better in the way of landscape work than in the series Nos. 358 to 363. His ripened experience has enabled him to guage accurately what a photographer may attempt with success. He wisely contents himself with more simple materials than in years past, and to the greater advantage of his work, and the greater pleasure of his critics. It is needless to say that Mr. Robinson, officiating as one of the judges, is precluded from obtaining that recognition to which his pictures are emphatically entitled.

Mr. H. F. Knight gives us some charming examples of pure landscape in his "Views in Switzerland" (No. 27). Mr. H. Tolley shows a fine work in Lake Killarney (No. 30), and in a series (Nos. 396 to 403), in which his medal picture figures. Mr. Tolley is one of the few men who can deal satisfactorily with large masses of sea and sky. The subjects he chooses are those which the ordinary photographer fights shy of, as "bits" are so much easier than panoramic expanses; hence Mr. Tolley's success is all the more praiseworthy. A view of the street in Zaandam, where Peter the Great lived as a shipwright (No. 36), by Dr. Lindsay Johnson, is extremely interesting, and a capital piece of photography in addition.

Mr. Lyddell Sawyer is irritatingly unequal in his work. His "The Smoky Tyne" (No. 324), so suggestive of Mr. Wyllie's studies of shipping, is as fine as anything in the gallery. His "Crewell Work" could not easily be matched for badness; it is neither interesting nor intelligible, and the weak pun in the title does not make up for its deficiencies. He is fairly successful in his pictures of Newcastle street life; but a little of this goes a long way. As an example of clever grouping, his "Rare Old Gossips" may be commended; but no one can feel much interested in such deplorably ugly women. Is his "In the Prime of Summer Time" (No. 186) a challenge to William Collins' well-known picture, "As Happy as a King"? The photograph is marked by much cleverness, but what should be an important focus of attention—namely, the figure of the child who has fallen—is only to be discovered by accident. Mr. Sawyer shows no less than twenty pictures of large size, and one can only regret that he did not exercise a little judicious thinning out. The demon of fatal facility seems to beset Mr. Sawyer; he is so clever, it is no trouble for him to make a score of pictures of fair merit; but more is expected of Mr. Sawyer than this. Like Mr. Ralph Robinson, he exhibits too much.

Mr. W. T. Kimberly shows some clever examples of winter scenery in Nos. 41 and 273, and Mr. T. M. Brownrigg's pictures of the Spanish Alhambra and of the Alcazar, Seville, should be looked at with great interest. Most of Mr. Brownrigg's work, however, lacks vigour, due, probably, to the printing rather than to the negative. Mr. William Bedford always maintains a standard level of excellence. His "The Mirror of the Woods" (No. 52),

"Dowu Dale" (No. 92), "Stream and Woodland" (No. 93), and "Amongst the Woods aud Waters" (No. 304), are all admirable examples of his paiustaking if undemonstrative style. Mr. W. Bedford is emphatically a "safe man," and oue does not look for startling innovations from him.

Mr. G. Davison's medal picture has already been mentioned. He shows a nnmber of other pictures which also exemplify what has been called the "new school." I am inclined to think that, taken as a whole, they will excite more controversy than unanimous admiration. One would like to know whether the title of "A Breezy Coruer" was bestowed upon the picture because the wind was blowing at the time when the photograph was taken, or whether the woolly effect produced by the want of sharpness and the drawing paper combined suggested it to Mr. Davison. One little fact may be noted: the boat in the centre of the picture is quite as breezy as the trees. How comes this about?

Cattle are well represented in the Exhibition; indeed, most of the landscape photographers have availed themselves of these extremely useful sitters. Miss Florence Harvey, who seems to have bovine tastes, shows a good series of studies, of which No. 11 strikes me as the best. In her study of "Highland Sheep" (Nos. 127, 128, aud 129) is a somewhat mixed effect, especially in No. 128, the large stones being themselves so much like sheep.

Mr. A. B. Hepburn deserves commeudation for his picture, "On the Tramp" (No. 82), which, however, lacks feeling, as the tramp is obviously standing to be photographed.

"A Harvest by the Sea" and "St. Margaret's Bay" (Nos. 112 and 113), by Mr. Francis Cobb, are well selected views of well-known spots, of which, to my thinking, the first is the best. Messrs. West and Sons continue in the path in which they have gained so many laurels. They are less prolific than of yore, but their pictures are quite as good. Mr. H. Symonds is also represented by work about which nothing new can be said.

The clever series by Mr. Shapur N. Bhedwar, illustrating the Feast of Roses, has already been noticed in speaking of the medal awarded to No. 185. Mr. Bhedwar's careful, delicate style is also seen in a picture to which he has given the title of "Granny's Comforts" (No. 168), and more especially in "La Tambourine" (No. 463). Mr. Bhedwar shows a degree of individuality which promises much for the future, and his progress will be watched with much interest.

Some clever pictures of Jersey scenery (Nos. 143 and 144) are exhibited by Mr. A. R. Dresser, but Mr. Dresser's most striking contribution is seen in some instantaneous pictures of leap-frog. The odd peculiarity of instantaneous work is well shown in these pictures. Although we know that the boy in the act of leaping is moving rapidly through the air, yet the effect is not that of motion. It only shows what has been said over and over again, that instantaneous photographs, whether of human beings or animals in motion, are altogether unnatural, and are really of little use to artists, who want to suggest a combination of movements, rather than one movement petrefied, so to speak. This, however, does not take away from the merit of Mr. Dresser's dexterity. Mr. Robert Slingsby is not quite so happy in his "Idle Hours" (No. 159) as in some of his former efforts. The figure seems swamped by the surrouudings. Were the picture cut down to about a third of its present size it would gain much in effect. Mr. Slingsby has been so successful in flash-light photographs that one naturally looks for something from him in this direction; but he exhibits no pictures of this, the latest curiosity in portrait photography. There are one or two examples of flash-light work which it may be convenient to mention here, but they are not remarkable. One is by Mr. F. Downer, described as "Flash-Light Group of Young Ladies at a Ball" (No. 4). Whether it is the fault of the flash-light or not I cannot say, but all the young ladies look exactly the same in figure and feature. Their unanimity is wonderful. It cannot be described as a pleasing picture. Mr. Downer also shows other examples in No. 486.

IODIDE OF NITROGEN.

BY F. H. VARLEY, F.R.A.S., M.I.E.E.

I am induced to write upon this compound, being stimulated by an article in a daily journal in reference to its employment as a measurer of the actinic values of light. The paragraph which I here append concludes with the sentence, "Precautious are taken to prevent heat effects."

With the increase in the means of obtaining artificial light, the need for an improved means of comparing their various intensities has increased also. The common photometer, with its fixed "standard candle" and its sheet of paper with a centred disc, depends much on the care and skill of the observer for its practical value. A new form is announced, in which the readings can be taken as readily as comparing two thermometers. It is based on the decomposition of iodide of nitrogen by light. There are two vessels with glass bottoms, close side by side, equal in size. Iodine and ammonia solution are put in each, forming the iodide of nitrogen, which remains unaltered so long as it is in the dark. The two lights to be compared shine by a mirror each up into one of the vessels. The amount of nitrogen gas given off each is collected in a tube above in ammonia water, and the relative height shows the relative activity set up by the light. Precautions are taken to avoid heat effects.

It is this last remark which tickles my fancy, and causes me to write my experience. I prepared a few grains of the iodide in the usual way by placing some iodine flakes in ammonia, and, after the reaction, poured off the excess of ammonia. Attending to other things, I forgot for the moment that I had made the preparation. I came again into the room, and started pounding up some calcined caustic soda, when one of the fragments knocked off by the pestle lodged in the beaker containing the iodide of nitrogen. The sudden heat set up was sufficient to cause an explosion. The beaker and its contents went "scat!" The zone of bombardment was directed toward the end wall, which, not being at right angles to the front of the building, but inclined at an angle of 25° to 30°, focalised the zone of explosion. The floor was literally strewn with separated particles of the unexploded iodide of nitrogen, and a few minutes after this catastrophe it was impossible to walk about without producing a minor explosion for every step that was taken. These explosions, though not very pronounced, were sufficiently startling, and might be compared to treading upon the head of an ordinary lucifer match. I took the precaution of sprinkling sand over the floor, and, by sweeping it to and fro across the boards, succeeded in discharging the remaining particles, when all was apparently quiet. I considered that no farther explosions were possible, but the next day the foreman went to the pigeon holes fixed against the end wall to take out some brass castings. He took one weighing about three-

quarters of a pound; in so doing, he rubbed an unexploded portion of iodide which had lodged on the castings, with the result that a fresh explosion ensued, as startling as it was unexpected. He looked at the casting with blank astonishment for a second or two, and then, by muscular action set up by the reflex action of the brain, he jerked it upwards, striking his face and causing the blood to flow. When I asked him what he did it for, he maintained that it was shot up by the explosion. He was evidently too startled to to be aware of the fact that immediately after the detonation the casting was resting quietly in his hands. For some days afterwards, upon removing sheets of drawings, it was impossible to dust them without setting free detonating particles, although the iodide had been exposed to the action of full daylight during that time. Now, should it be found that iodide of nitrogen liberates gas by the action of light, and that nitrogen thus set free is a true measure of light values, it is well to bear in mind, to prevent *contretemps*, that, although iodide of nitrogen is not so powerful an explosive as the chloride of nitrogen or fulminate of silver, it is, nevertheless, most distinctly explosive, and in quantities would prove highly destructive; it therefore requires careful handling. Should, however, the reader try these experiments, I would advise his making the preparation out of doors, and, if mischievously inclined, to spread it, while wet, upon a wall, and allow it to dry, where cats do mostly pass, where it will cause some astonishment to the feline species, as the softest touch of a feather, or the pressure of grimalkin's paw, will produce a real good, startling explosion not calculated to do the animal any grievous bodily harm, but quite sufficient to scare the poor creature and upset its imperturbable equanimity.

THE OPTICAL ASPECT OF "NATURALISTIC" DEFINITION.

BY W. E. DEBENHAM.

When writing* on some criticisms originated by Mr. W. K. Burton's article, "Sharp All Over," in the Year-Book of 1890, the question of submitting one's own judgment to that of artists, even against all arguments that could be advanced, was left for future consideration.

The reason that artists often condemn sharpness whilst, as Mr. Burton says, no satisfactory argument can be adduced against it, is probably to be found in the fact that the word sharp, as applied to pictures, is used with very different significations by artists—by which term it is intended to refer to painters and draughtsmen—and by photographers. I have heard a painter condemn a photograph as too sharp that, in reality, was not what a photographer understands as sharp at all. The photograph in question was an under-exposed portrait with sudden lighting, and the effect was to render the shadows crude, and what is called cutting, both against the background and against what should have been the half-tones of the face. The fine definition which is what a photographer recognises as sharpness, and which was absent, partly owing to movement or defective focus, and partly to the forcing of such definition as was in half-tone either into the heavy shadows or chalky lights would, if present, have actually prevented or reduced the harshness that was condemned by the painter as sharpness: harshness, in fact, and not fine definition, was the quality which was referred to as unpleasant sharpness.

Without now going into the question as to whether, in some cases, a more agreeable picture may be produced by losing detail, I propose to deal with the statement that an effect more accordant with what is produced upon the human eye by the natural objects represented in the picture, is obtained by the use of such large diaphragms as to throw part of the picture decidedly out of focus. One answer that is frequently given to this proposition is, that the eye has power of adjustment, and can see any portion of the subject it looks at in focus, and that if we do not obtain the best focus upon the photographic plate, we are robbing the eye of the privilege which it possesses when looking at the original subject. If, for the moment, this reply be waived, and it is admitted that we ought only to represent in the picture what the eye sees at any given fraction of a second, the question arises, what is the sort of diaphragm that ought to be used in order to render objects in different planes, when one plane is sharply defined, with the same amount of distinctness that belongs to them when they are seen by the normal human eye without allowance for power of adjustment?

If the answer to this question could have been foreseen by those who support the statement that, for the effect referred to, the small stops ordinarily in use amongst photographers should be replaced by larger ones, it is probable that they would never have ventured upon such a proposition. The matter is an optical one, and depends upon a law which I have found to be received by most photographers with surprise, and even incredulity. The law is, that the definition of the out-of-focus planes depends, not upon the proportion of the diaphragm or aperture to the focal length, but upon the absolute size of the aperture itself independent of the focal length. By equality of definition of out-of-focus planes, it is meant that the indistinctness or circle of confusion of any point in the subject will reach as far as the same adjacent point in the cases to be compared. This will give, when the photographs are looked at at a distance equal to the focal length of the lens, or are enlarged or diminished to any fixed proportion to the original, pictures identical in the amount of indistinctness.

When this optical law is understood, it is seen that we need not go into the question of the focal length of the human eye, or of the lens to be used. We have only to ascertain the size of the aperture of the eye (which is estimated to be, out of doors in a good light, about one-eighth of an inch), to find that that is the size of the diaphragm with a lens of any focus that will give, when one plane is sharply focussed, the out-of-focus planes with as much indistinctness as they possess to the human eye, deprived, to suit the "naturalist" contention, of the power of adjustment. If, therefore, the argument is admitted that the lens ought not to define out-of-focus planes more sharply than the eye sees them, that argument would only apply to those cases where diaphragms are used smaller than that of the eye. Thus, so far from having to use larger stops than those commonly employed by photographers, it is evident that, to represent the limited amount of want of definition in the out-of-focus planes, as impressed on the retina, it will be necessary to use such small stops as with long, or even medium focus lenses, necessitate a length of exposure that would, in many cases, be found impracticable.

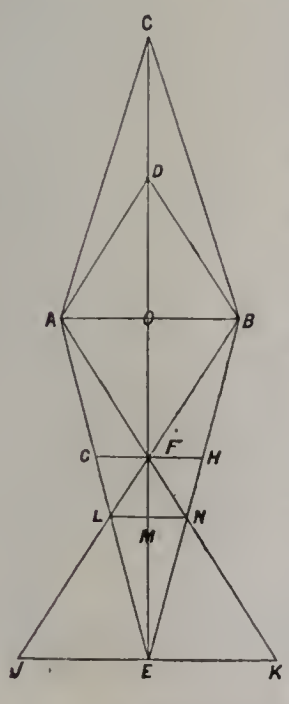
* "Spherical Aberration and the Treatment of Subjects by Focus."—Photographic News, August 22nd, 1890, p. 646.

It was not intended, in the present article, to do more than show the hollowness of the contention—founded upon a want of recognition of the optical laws governing the amount of indistinctness of out-of-focus planes—that large stops give definition more nearly representing that amount than do small ones. It may, however, be mentioned, for the comfort of those who have been aiming to produce the most perfect photographic work in their power, but have been discouraged by being told that what they aim at is artistically condemned, that the *practice* of artists is in favour of finer definition in the various planes than it is easy to obtain by photographic means in any but planes in the focus or closely adjacent to it. As instances readiest to the hand of photographers at this season, may be mentioned the reproductions of paintings in the present Exhibition at Pall Mall. Probably that of the painting by Edwin Long, R.A., "Diana or Christ?" will be recognised as the most important. Here the definition of several figures in different planes, behind the leading female figure, is in each as fine as it would be in a photograph if they were taken separately. Note the man holding the Act of Accusation, and the parchment that he is holding: also the hand on his shoulder, and the faces, two or three of them, behind. See also the face of the seated figure on the left, the statue of Diana behind him, and the face behind that. Observe, indeed, all the faces that are large enough to be seen with any distinctness, and then say whether, if they had been arranged for a photograph, it would have been practicable to get them focussed as sharply as they here appear, without the use of such a small diaphragm as to be out of the question. Similar observations may be made with respect to the "*Al Fresco* Toilet," by Luke Fildes, and many others. The pure landscape (No. 501) by R. W. Leader, A.R.A., might, no doubt, be rendered similarly well defined in a photograph, but only by the use of a very small diaphragm.

ON THE DIFFUSION OF FOCUS.

BY N. E. DUNER.

The question about the depth and diffusion of focus has been treated of in different manners. The following generalisation of the problem might perhaps be of some interest.



Let C and D be luminous mathematical points, and A B a stop in the centre of a photographic lens; let F and E be the points into which the rays starting from C and D respectively are collected by the lens, and put:—

$$CO = D_1;\ DO = D;\ AB = d;\ OF = F;\ OE = p_1.$$

It is now evident that one can choose different positions of the photographic plate. Let

(1st.) This position be in G H. In this case, C will be represented by the point F; cut D by a circle, whose diameter is G H. Put G H $= x$, then

$$x : d = p - F : p;\quad x = d\left(1 - \frac{F}{p}\right)$$

But if f is the focal length of the lens, we have

$$\frac{1}{f} = \frac{1}{D} + \frac{1}{p} = \frac{1}{D_1} + \frac{1}{F}$$

whence,

$$p = \frac{FDD_1}{DD_1 + DF - D_1F}\qquad F = \frac{D_1 f}{D_1 - f}$$

Introducing these values in the expression for x, one obtains readily—

$$\left.\begin{aligned} x &= d \cdot \frac{f}{D} \cdot \frac{1 - \frac{D}{D_1}}{1 - \frac{f}{D_1}} \\ d &= x \cdot \frac{D}{f} \cdot \frac{1 - \frac{f}{D_1}}{1 - \frac{D}{D_1}} \end{aligned}\right\} \quad \ldots \quad \ldots \quad \ldots \text{ (I.)}$$

(2nd.) One can place the plate in J K, whence the point D will be represented by the point E. Cut the point C by a circle whose diameter is J K $= y$. But

$$y : d = p - F : F,$$

whence, by introducing the above values of p and F,

$$\left.\begin{aligned} y &= d \cdot \frac{f}{D - f} \cdot \left(1 - \frac{D}{D_1}\right) \\ d &= y \cdot \frac{(D - f)}{f} \cdot \frac{1}{1 - \frac{D}{D_1}} \end{aligned}\right\} \quad \ldots \quad \ldots \text{ (II.)}$$

But it is evident that neither G H nor T K will be the most favourable position, but that one will have the least possible diffusion by

(3rd.) Placing the plate at L N. In this case neither C nor D will be represented by a point, but both by a circle, whose diameter is L N. Put: L N $= z$; M F $= s$. Then we have—

$$\left.\begin{aligned} s &: p = z : y \\ p - s &: p = z : x \end{aligned}\right\} \text{ whence}$$

$$z = \frac{1}{\frac{1}{x} + \frac{1}{y}}$$

and by (1) and (2)

$$\left.\begin{aligned} z &= d \cdot \frac{f}{2D - f} \cdot \frac{1 - \frac{D}{D_1}}{1 - \frac{f}{(2D - f)} \cdot \frac{D}{D_1}} \\ d &= z \cdot \frac{2D - f}{f} \cdot \frac{1 - \frac{f}{(2D - f)} \cdot \frac{D}{D_1}}{1 - \frac{D}{D_1}} \end{aligned}\right\} \quad \ldots \text{ (III.)}$$

It is evident that z is smaller than x and y. Putting in the expressions (1), (2), and (3), D_1 infinitely great, one will have—from (1):

$$d = x \cdot \frac{D}{f} \quad : \quad D = \frac{f\,d}{x} \quad \ldots \quad \ldots \quad \ldots \text{ (IV.)}$$

which are the formulæ published, for instance, in the "Hand-book" of Pizzighelli, Part I., page 141. From (2) we find—

$$d = y \cdot \frac{D - f}{f} \quad : \quad D = \frac{f(d+1)}{y} \quad \ldots \quad \ldots \text{ (V.)}$$

which are the formulæ given by Mr. Burton in the PHOTOGRAPHIC NEWS, No. 1659, p. 473, where, however, the ex-

pression for d is vitiated by a misprint, as one will find, by deducing d from the expression for D. Finally, the equation (3) gives—

$$d = z \cdot \frac{2D - f}{f} \quad ; \quad D = \frac{f}{2}\left[\frac{d}{z} + 1\right] \qquad \text{(VI.)}$$

The formula (3) being evidently the most advantageous. I have also deduced the value of the distance, $F + s = \Delta$, between the plate and the stop by means of this equation, and I have found

$$\Delta = f\left[1 + \frac{f\left(1 + \frac{D}{D_1}\right)}{2D - f\left(1 + \frac{D}{D_1}\right)}\right] \quad \ldots \quad \text{(VII.)}$$

By means of this equation, one can deduce the distance from the stop in which the plate must be placed in a camera without focussing adjustment, in order to have the greatest possible distinctness for all objects between the distances D and D_1. Putting D_1 infinitely great, one will have—

$$\Delta = f\left[1 + \frac{f}{2D - f}\right] \ldots \quad \ldots \quad \ldots \quad \text{(VIII.)}$$

(*To be continued.*)

LUNAR PHOTOGRAPHY.

IN last week's *Nature*, Mr. R. A. Gregory gives a concise history of lunar photography, and makes the following remarks about recent results:—

"In a recently published paper on 'Astronomical Photography at the Lick Observatory' ('Publications of the Astronomical Society of the Pacific,' vol. ii., No. 9), Prof. Holden gives a detailed account of the photographic apparatus of the great equatorial, and the work done with it. The image of the moon in the first focus of this instrument is nearly five and a quarter inches in diameter, and the negatives bear easily an enlargement of 570 diameters, and even double this amount. In the production of these negatives the aperture of the object-glass was reduced to 12 inches. From an examination of the best pictures yet taken at the Lick Observatory, Prof. Holden finds that parallel walls on the moon whose tops are no more than 200 yards or so in width, and which are not more than 1,000 or 1,200 yards apart, are plainly visible. A series of copies from the negatives obtained at Lick Observatory has been published.

"Some photographs of the moon taken in March last, by the Brothers Henry, at the Paris Observatory, appear to eclipse all previous ones. The instrument used was the 13-inch photographic equatorial, and an examination of the plate which accompanies this note will show that real progress has been made. The superiority of the results is due not only to the perfection of the object-glass, but to the use of a secondary magnifier, by means of which the size of the image at the first focus was increased fifteen times. It is manifest that this method of direct enlargement possesses many advantages over that ordinarily used, and its further development will be awaited with considerable interest."

THE Catford Cycling Club announces a grand "camera" concert to be held at the Bridge House Hotel, London Bridge, on November 4th, at which the exhibition of lantern slides will comprise a selection of cycling scenes, under the headings of "Road Riding," "Racing," "Touring," "Goodfellowship." The lantern entertainment will be under the superintendence of Mr. Herbert Smith. The chairman and lecturer will be Mr. C. W. Nairn.

APPARATUS AT THE PHOTOGRAPHIC EXHIBITION.

II.

FIG. 7 represents a developing-dish rocker exhibited by Messrs. Lewis and Co.; it is driven by clockwork, and its motive power is a coiled spring. When weighted with a small developing dish and plate, it will run for about half-an hour, and not with an objectionable amount of noise, such as is sometimes given by instruments of this class. The table on which the dish rests might conveniently be made larger and fitted with a cover of little weight, so that light can be excluded from the dish and its contents. The motion, especially at first, is somewhat more rapid than is theoretically necessary or desirable; it is regulated by a fan governor. Rocking tables like that of Sir David Salomons run noiselessly and for a much longer time. For purposes of experimental research, a clockwork rocking table which would run for twenty-four hours without attention, and include the power of excluding light from the sensitive salt, would sometimes be of considerable utility. The advantages derivable from clockwork mechanism in the driving of rocking-tables, come in at their best when motion is required extending over long periods of time; such tables would sometimes be exceedingly valuable for purposes of original research.

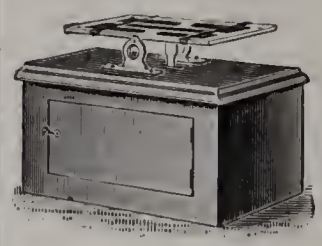


Fig. 7.

Messrs. Lewis & Co. also exhibit a simple device, fig. 8, to prevent tripod legs sliding on slippery floors. A cord can be affixed to each leg by a clamp, and under the centre of the head of the stand the three cords hold in suspension a light piece of brasswork, so pierced with suitable holes that the operator can make it grip and hold each cord where he pleases.

Fig. 8.

Fig. 9 represents one of Messrs. Marion & Co.'s new tripod photograph stands with a triangular glass and frame. This simple device may possibly please the public, and if so it will come into general use.

Fig. 10 represents a shutter exhibited by the same firm, and invented by Mr. Bain. It works between the lenses, and is actuated by strong springs, which cause two suitably shaped "jaws" to cross each other, and, in so doing, to make the exposure. The springs can be tightened for more or less rapid exposures by means of the lever arms A A, which, near their upper ends, can be placed in different

Fig. 9.

indentations in two curved strips of brass, shown in the cut. The shutter is set by drawing down the

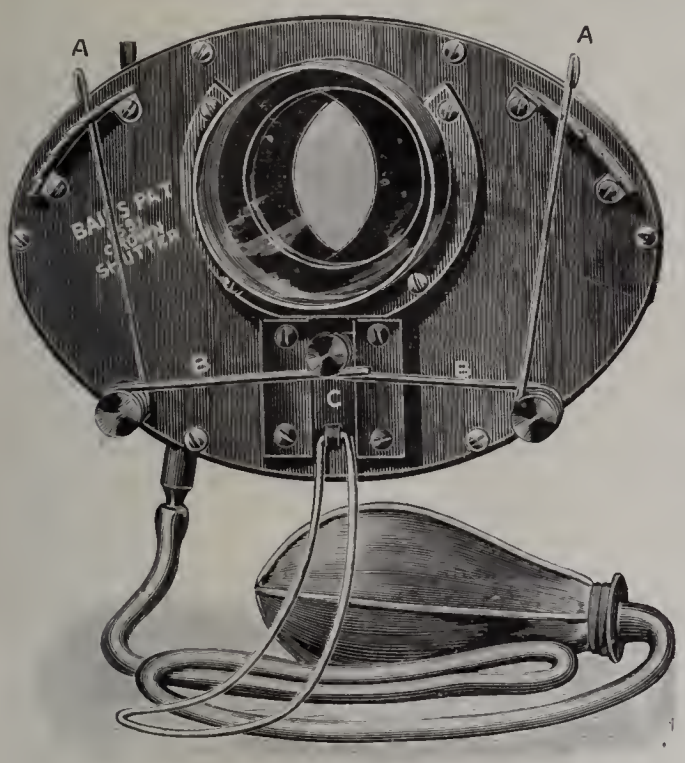

Fig. 10.

string loop below C. The arms by which the actuating pin is driven up in its slot are represented by B B. It has an arrangement for giving time exposures at will. The pneumatic release is of the ordinary kind, as depicted in the cut. When high tension is put upon the springs the action of this shutter is extremely rapid.

*** *Those friends who have not yet sent in their* Year-Book *articles, are requested to let them reach us on or before Tuesday next.*

Osmium Toning Baths.—Herr Liesegang has been making some remarks concerning the osmium toning bath recommended by M. Mercier, and of which we gave an account some weeks ago. This is what he says:—"The toningsalt consists essentially of ammonium-osmium, chloride, and acetic acid, and is fit for use on simple solution in water. On immersing in the bath a washed-out silver print, it first assumes a brown tinge, after which the half-lights tone a deep azure blue. Aristo paper tones deep blue-black when acted on sufficiently long, which gives a very beautiful effect, considerably superior to that of platinum prints. The prints ought not to be washed out between toning and fixing."—*Invention.*

Photographing Stars in the Daytime.—In the *Astronomical Journal* for September 16, 1889, Prof. Holden gave an elementary theory of the subject of photographing stars projected against a bright background. He showed that, if the intrinsic brilliancy of a star be ten times as great as its background, the photographic image in the Lick telescope was 4,124 times brighter than that of the sky. It was also proved that small photographic contrasts of this charcter could be increased with a given telescope by simply cutting down the aperture. Recently, Prof. Holden writes (*Astr. Journ.*, September 19, 1890), "The question has been examined experimentally by Mr. W. W. Campell and myself, using the great telescope (focus, 570 inches, and apertures of 33, 15, 8, and 4 inches). Photographs of Venus, Mercury, the moon, and of Alpha Lyræ have been taken in broad daylight (2 to 5 p.m.) with the apertures named, with a constant exposure of 0·13s., and on Seed 26 plates. In general, the smallest apertures used have given the darkest images, as demanded by the theory.

NOTES FROM INDIA.

BY COLONEL J. WATERHOUSE, B.SC., ASSISTANT SURVEYOR-GENERAL OF INDIA.

New Gelatino-Chloride of Silver Paper for Printing-Out.—Trials lately made with the new "Delta" paper manufactured by Romain Talbot, in Berlin, would seem to show that the death-knell of silver printing has by no means sounded yet, and that, though long threatened with extinction, the old process may well take a new lease of life.

The paper is prepared with a gelatino-chloride emulsion, like Liesegang's "Aristo." and the Obernetter printing-out papers, and has a thick, glossy surface of gelatine. It is exposed to light under the negative, just in the same way as the ordinary albumenised paper; the exposure is, however, less. As the picture is printed out, all the ordinary silver printing dodges of vignetting and shading can be carried out on the prints with the same ease and certainty as with ordinary silver prints. This, in itself, is a great advantage over the developing and other processes, in which the image is invisible, or only faint.

After exposure, the prints can be toned at once in a gold toning bath containing sulphocyanide of ammonium and some alum, but it seems an advantage in this country at this time of year to soak the prints for a few minutes in a bath of chrome alum at one or two per cent., and then, after a short washing in water, to tone them. They tone very quickly and readily, and are then washed and fixed as usual. After fixing, a hardening bath of alum is desirable. The coating of gelatine is fairly thick, consequently the prints are very much more delicate, and require more careful treatment throughout than ordinary albumenised paper prints; and there is a great tendency for the film to break away from the paper round the edges. The prints ought, as far as possible, to be kept apart in all the operations, and washed, after fixing, in an apparatus in which each print may hang vertically by itself in the washing water.

The finished prints are certainly the perfection of silver printing in their fine, rich tones and the delicate transparency and detail of the shadows. Full justice seems to be done to all parts of the negative. All kinds of negatives have been printed from, and the best possible results seem to be obtained, even from hopeless-looking ones; certainly better than can be obtained from the ordinary ready-sensitised papers usually obtainable in this country, or imported. The prints are more glossy than is, perhaps, altogether desirable, especially for those who detest a "vulgar glaze," but a matt surface can be given to them by drying them on a piece of finely-ground glass, or a celluloid film (?) previously greased to prevent their adherence.

The keeping qualities of the paper have not been tested. It came out by post in very good condition, but after a few weeks it showed a tendency to discolour slightly, and was used up. It is said to keep good from six to nine months, but in this damp climate it would require to be carefully kept dry in a calcium box, or by being well wrapped up in paraffined paper, especially as it appears to have a tendency to attract moisture. It is much more expensive than ordinary ready-sensitised albumenised paper, but probably contains more silver. However, if—as seems likely—the prints are more permanent than albumen prints, while certainly better results can be more easily obtained, the extra expense will not be of much

consequence. It is only very little more than for bromide prints by development.

Similar papers were recommended by Captain Abney, and the process of preparing and using gelatino-chloride emulsions for printing-out on glass and paper was very fully described by Messrs. Ashman and Offord some four or five years ago, but English manufactnrers do not appear to have taken up the preparation of these papers, and have left it in the hands of German makers.

Acid Fixing Bath.—The acid fixing bath recommended for nse with the eikonogen developer seems to be an improvement over some of the others that have been bronght forward. It keeps clear, and retains its fixing powers for a considerable time. It is composed as follows:—

Hyposulphite of soda	...	...	200 grammes
Sulphite of soda	...	...	50 ,,
Water	...	...	... 1,000 c.c.

when dissolved, add slowly—

Sulphuric acid	...	...	6 c.c.

But it seems to work better with more hyposulphite.

Reversed Positives with Thio-Carbamides.—During the past month farther experience has been gained in obtaining reversed positives with thio-carbamides in the developer, and some improvements have been effected, though the method seems too uncertain to be considered thoroughly practical. As the phenyl-thio-carbamide appeared to be more regular in its working than the others, the experiments have been almost entirely with it.

It has been found that at present temperatures (about 80° F.) 1,000 parts of distilled water take up about 1 part of phenyl-thio-carbamide. Also that it is advantageous to nse a smaller qnantity of this thio-carbamide in the developer than was first recommended, and that from 12 to 15 parts of the saturated solution as above in 100 parts of the eikonogen developer are quite sufficient. By using more the ground becomes darkened, and it is difficult to get clear lights.

The preliminary oxidising bath of dilute nitric acid at five per cent. is decidedly useful in copying work, and it is also advisable to use the bromide of copper bath at two to three per cent. before fixing. It may be noted that a preliminary treatment with the bromide of copper solution before development destroys the image. For landscape and half-tone work the nitric acid treatment is also an improvement, but the best working conditions have not yet been ascertained.

Bichromate of potash does not seem to answer so well as a preliminary oxidiser with phenyl-thio-carbamide as nitric acid, and does not give good results when added to the developer. It seems to work better with thio-sinamine.

Ferridcyanide of potassium, added to the developer in the proportion of 2 to 4 parts of a ten per cent. solution to 100 parts of eikonogen developer, containing the usnal proportion of phenyl-thio-carbamide, acted as a strong restrainer, and thongh it gave complete reversals, it did not seem to exert the clearing and intensifying action of the nitric acid. The images obtained with it have been weak and of a chocolate-brown colour. Further trials are, however, requisite.

Thio-sinamine and thio-carbamide in the eikonogen and hydroquinone developers, with preliminary treatment with nitric acid or bichromate of potash, have not given good results for copying line work, and phenyl-thio-carbamide seems best suited for this purpose.

With the hydroxylamine developer neither phenyl-thio-carbamide, thio-sinamine, or thio-carbamide show any reversal, but it may be noted that thio-sinamine seemed to stop the evolution of gas in the film, but the image was not very strong. Glucose also is useful in this respect; it acts as a restrainer, and gives a very fine deposit of good colour, but rather wanting in density. Manna also reduces the blistering, and does not restrain development so much as glucose, giving a dense image.

Under favourable circumstances the process with phenyl-thio-carbamide seems likely to be usefnl for line-work. In half-tone work, either copying or landscape, it is much more uncertain, and a great deal more work will be necessary to ascertain the best working conditions for ensnring certainty, if, indeed, it is possible to do so.

At present these conditions seem to be to use as little as possible of the reversing agent with the minimum of exposure necessary; not to use more added bromide than is necessary, a fairly strong eikonogen developer, and a preliminary treatment with a suitable oxidising agent; the proper proportion of sulphite has yet to be determined.

The weather during the month has been hotter and damper than before, and very much against work with dry plates, and, under present circumstances, it is difficult to get definite results. Only one brand of plates will stand the treatment with acids.

Reversing Action of Sodium Thio-sulphate in the Ferrous Oxalate Developer.—In my paper last month, the reversing action of hyposulphite of soda, when added to excess to the ferrous oxalate developer, noticed by Prof. Eder, was alluded to as the solitary instance of a substance added to the developer causing reversal. It was forgotten at the time, however, that some very clearly reversed positive images had been obtained last year on "Ilford" plates developed with a ferrous oxalate developer containing a fairly large proportion of hyposnlphite, after an exposure of thirty minntes on a view. On again repeating the experiment, similar results were obtained, but, on fnrther investigation, it has been found that the thio-sulphate plays no active part in the reversals, and, indeed, they are, in some respects, better without it, the fixing salt having a weakening action on the image. With "Ilford" plates exposed on a view about thirty minutes, sufficient to show a faint but qnite visible image, ferrons oxalate has given very perfect reversals, in some respects even better than those obtained with the thio-carbamides. Though not so bright, and of a blacker and less agreeable colour, there is more perfect gradation, the lights are generally clearer, and there is no solarisation about the skyline. A lightning conductor comes out sharp and clearly reversed against the sky, which has seldom been the case with the thio-carbamide reversals, unless the plates have been much under-exposed.

Similar reversals have been obtained with pyrogallol and eikonogen developers with about the same exposure, but not so clear in the lights.

It may be noted that, on developing one of these over-exposed plates with an eikonogen developer coutaining phenyl-thio-carbamide, the same reversal took place, and the further action of the thio-carbamide did not change it into a negative, thongh it fogged over. The long exposures necessary for obtaining perfect reversals in this way render the method almost useless for practical purposes, unless means can be found for accelerating the action. If reversals obtained with short exposures by means of the thio-carbamides were as perfect as those produced by long exposure, the problem would be almost solved.

LIGHTING.*

BY E. P. KING.

This paper is not written with the idea of giving any of the older heads anything new, but as a starter, in hopes that we may hear from some of them, and get more practical ideas than I am able to give.

I was somewhat surprised at receiving a request from our worthy president, calling for a paper on lighting, and, no doubt, you will all be glad to learn it was to be a short one.

The question is, "What is lighting, and is it best to know it on *scientific principles*, or to train the eye to know *when* the lighting is correct?"

Did you ever stop to think, while lighting a subject, why you move the curtain a trifle higher, or the side curtain a trifle lower, and see how long it would take to give a more satisfactory answer than that it did not suit your eye as it was, but by that movement it was satisfied?

Now, how can the eyes be trained? Of course, we must know the principles of light and shade first. These I do not propose to speak on, as it would take too much time, there being so many books published on this subject; so I will only give my own experience in study, and there may be a good point in it all somewhere, I hope.

After working at the business some time, I found the only practical way to study lighting was when someone was paying for what they thought a graduate's work (not a student's), and while making my sitting, my thoughts were so busy on all details that I had no chance to give my eyes the necessary training, so I made and placed at a window a light about three feet long, in the same proportion to the one I was then working with, and used as my subjects small dolls; and at my leisure, with my little dumb subjects, experimented with light, and in that way spent many a happy and profitable hour, and became quite in love with my models, because they never dictated to me, and not one of them ever said they would as soon have a tooth pulled as sit for a picture.

On the floor of my model light I made a large circle, and found by placing my subjects on and moving them around the circle I had produced almost every light that is needed in portrait work. When tired of portrait work, I then tried fancy lighting and groups, trying to reproduce a light I saw in "so-and-so's" photo., or in a painting, or a lighting in a street car.

Did any of you ever notice the number of different lightings you may see in a car? There are more chances to study good lightings there than many are aware of.

If I had an appointment with a subject where there was a chance to make something nice, I would get my little models, and have a practice before the subject came, thereby ascertaining exactly what I wanted, and where to place my subject.

After learning by my model light, I always seemed to have an imaginary circle in my operating room, and knew where to place a subject for any light I might want.

There is fully as much in lighting a face as in expression. If you take a subject with a drooping of the mouth on one side, or strong lines about the nose and mouth, and make what some call a "shadow lighting"—why they call it so I have never been able to find out—you will make the lines very prominent, causing more work in retouching, and not as satisfactory a finished print as if a plain, soft lighting had been used.

In lighting white drapery, I advocate posing the figure well under the light, and, with the use of the head screen and reflector, soften the lights on the face *only*, leaving the drapery strong and bold. Some operators object to the use of the screen or reflector. I have worked under lights where I found it unnecessary to use either, the light being ground glass, and always soft. I have also worked under a clear glass light and used no screen, because my customers did not see the difference between a black-and-white picture and one full of gradation, and I did not know the difference. So we were both happy, and our eyes satisfied, but, as my eyes received more training, I found I had to improve my work or close my eyes.

I once worked for a gentleman who posed a subject in a white dress about four feet back of the open light, and got a pretty light on the face by turning it from the light. But the drapery! Well, when I had developed the plate it was condemned, because I had not made good in the dark room what he had ruined under the light.

Now, my brothers in the profession, if you find anything in my paper that is weak, and needs intensifying, do your intensifying.

* Read at the Washington Convention.

Lantern Slides.—Lantern slides will, 'ere long, be in favour again, as the dull weather approaches, and it may be well to point out a few facts that are too often overlooked in connection with the production of this class of pictures. A perfect slide has been defined as having its highest lights clear, its secondary lights with a full range of gradation, and its shadows transparent and full of details without opacity anywhere. In proportion as a slide fails in any one of these points, it departs from the standard of excellence. It will be evident that there are two great factors which prevent so many slides from reaching the standard. They are, first, the deficiencies of negatives worked from, and second, the absence—in too many cases—of reasonable discretion in the pains taken to correct, as far as may be, those deficiencies. Whatever care may have been used in obtaining the negative, it is, in the great proportion of cases, impossible *to be certain* that the requisite qualities will be obtained. We do not mean to insinuate that a special class of negative is wanted to produce a good slide, for we hold that a negative possessing the characteristics requisite to give a good print by almost any process will produce an equally good slide with the same amount of care. We only want to lay stress on the fact that negatives have an unfortunate habit of being far short of perfection, but that being so, we want to point out that it is too often forgotten that the defects in negatives can, in the making of slides, be to a very great extent corrected and modified by exposure or development. Having a negative with the shadows thin and high-lights dense, we know, or ought to know, that we must over-expose somewhat, and use a developer rather weak, with rather less than the normal quantity of bromide (restrainer). We write, naturally, of alpha lantern plates, with which we are best acquainted. On the other hand, a weak negative will want less exposure, and more bromide, with the normal alkali. Such a negative will also be best printed from with a less intense light than usual; or, in other words, the printing-frame should be held a little further away from source of light. *Au contraire*, a hard negative, as first mentioned, should be placed nearer the light. Of course, we are presuming that both class of negatives we mention are full of detail, but have either too great or too little contrast. Negatives which have either of these defects, and in addition have not detail, can never be made to give the requisite gradation by any modification, and it is useless to waste time trying to make a good slide from that which is a bad negative.—*Scraps.*

Notes.

Once we published, as a supplement to this journal, a photograph by Colonel Noverre reproduced by the collotype process upon exceedingly rough paper, a paper rougher than ever issued—in this country, at least—in connection with a newspaper supplement by that process. The growing public taste for prints upon rough paper was so met, not without difficulty. Such prints can only be obtained in collotype by machining with extra heavy pressure, combined with slow speed; other unusual conditions also require attention. With this rough-paper collotype printing, the plates require frequent renewal. In a recent supplement of a picture by Mr. Cembrano, several practical difficulties cropped up, so that the prints turned out were of unequal quality, and some of them did not give an idea of the beauty of the original negative, the chief feature of which was a delicate play of light and shade in the sky and water. A trace too much or too little pressure, the amount of absorption of the ink by the paper, and variations in other delicate conditions, perceptibly affected the result. It was one of the most difficult subjects for reproduction on rough paper that the printers ever took in hand. In fact, collotype printing on excessively rough paper is, at present, in this country, as much in the experimental as it is in the practical stage for certain classes of subjects.

Mr. Cecil Carns-Wilson writes to *Nature* that he has invented a luminous crayon for drawing on the blackboard while other illustrations of the remarks of the lecturer are being given by means of the magic lantern. Why should not the lecturer also have a bottle of phosphoric oil, and rub some of it over his face, that those present may see the play of his features? The sight of such play of features being a means of giving emphasis to remarks, and imprinting them more firmly on the memory, is a means of enforcing attention which should not be overlooked. The lecturer is encouraged when he knows that the listeners are interested, so their features might be rubbed with phosphoric oil likewise, and the whole proceedings could close with the burning of coloured fires by way of applause. Could not the light of the glow-worm be utilised? Mr. Gerald Massey once told us that he wrote one of his poems by means of the light emitted by a glow-worm crawling over the page. South American fireflies are giddy, frivolous young things, not sedate enough for utilisation by the scientific lecturer.

On Thursday last, passing through the City, and during one of those temporary blocks in Cheapside which give omnibus conductors and cabbies opportunities for badinage and repartee of forcible, if not always polite, tendency, we heard one of these men ask another whether the fire at Christs' 'Orspital was still alight. The answer came quickly, "No, its hout, and none o' the blue-coat boys is roasted!" The incident passed from our memory until the next morning we took up our copy of the *Daily Graphic*, and then learnt that a fire had actually occurred at the famous school. But what interested us more than the fire was the sketch of the event which appeared in the paper, and which was taken, we read, from an excellent instantaneous photograph by Mr. W. S. Bradshaw, of the London School of Photography. Bravo! Mr. Bradshaw, and bravo! *Daily Graphic* too—for pictures from photographs "up to date" like this are indeed valuable.

In an article entitled "Shop Window Celebrities," which last week appeared in the *Evening News*, it is stated that the sale of photographs of prominent personages is on the decline, and this is attributed to the large number of engravings and sketch portraits which have appeared in the newspaper press since the discovery of the photo-etching process. We also learn some interesting particulars with regard to the selling value of the portraits of different celebrities. The Archbishop of Canterbury and the Bishop of London head the list among the clergy; Tennyson takes the lead among literary men, and Tyndall has first place in science. The two political leaders, Gladstone and Salisbury, naturally come first among politicians, but Balfour and Churchill run very closely at their heels. Lastly come the prize-fighters, among whom, we learn, that the veteran Jem Mace holds his own very well against such new comers as Slavin, Jackson, and Sullivan. It would be interesting to know the market value of a Bishop's negative compared with that of a pugilist, but on this point the deponent is silent.

Before the snow makes its appearance, let us say one word about the opportunities which the present fine weather affords for autumnal landscape photography. Mr. Millais has shown us the poetry and beauty to be coaxed out of simple materials even in "chill October," and although the photographer does not work with colours, there are many scenes of a similar nature which lend themselves remarkably well to studies in monochrome. The lace-work formed by the shrivelled leaves which yet remain upon the branches of the trees has a beauty of its own, and this effect can often form the principal feature of an autumn photograph. The blue mist which hangs about the country at this time of year at one time presented a difficulty to the photographer, but it is obviated by the use of a yellow screen and a colour-sensitive plate.

Judges and magistrates are very chary of admitting photographs as legal evidence. No doubt there is some justification in regard to the photograph of a person, as cases of mistaken identity are not uncommon in the flesh, and might well occur in the photograph; but it is difficult to see where the objection comes in with regard to the photograph of a scene in the street. The Tipperary magistrates, however, hold this view, and so the photographs taken by Mr. P. O'Brien, M.P., of the struggle in front of the Court-House were rejected. This is a pity, as it is a check upon enterprise

in this direction. Supposing an amateur with his detective camera photographs the picking of a pocket by a thief, we suppose the thief would have the right to object to the production of such a picture, and, possibly, the objection would be upheld. In America, as in England, photographs are rejected as proofs of identity. The latest example occurred in a case before Judge Cullen, of Brooklyn, who said, when a photograph of the defendant in a divorce case was produced, that it would be necessary for the witness to personally identify the person in his presence.

The International Literary and Artistic Congress, which concluded its sittings on Friday last, had a good deal of novelty about it. One especial feature of singularity was that, although it was held in the metropolis, at the residence and under the immediate patronage of the Lord Mayor, and although, so far as photography is concerned, the subject discussed was of pressing importance, yet not a single English photographer of eminence, so far as we have been able to gather, was present. It seems difficult to understand why the Congress was held at all, and certainly why it was called "International," but probably we shall learn the reason in time. The discussion in connection with the photographic section was commenced on Wednesday, when the old vexed question as to whether a photograph is a work of art or not was entered upon. The main point was, should a photograph be protected under a special law, or under that of art and literature? and out of this point, of course, arose the discussion we have mentioned.

The general opinion was that a photograph was an artistic production, and should as such be protected; but one speaker argued against this view. While he allowed that the rights of photographers should be rigorously protected, he was not quite so sure about the artistic worth of photography. "Would you," said he, "consider those wretched little pictures of sixpence each, sold in the Boulevards, works of art?" He was inclined to think the photographers should claim a copyright under the heading of an "industry." The succeeding speaker did not mince the matter when he gently insinuated that the gentleman who had argued against art and photography did not understand what he was talking about. This speaker contended very fairly that a photograph should be protected in company with lithographs, engravings, and etchings. A photograph, he said, could be lithographed, and the lithograph could be protected; why, then, should the photograph itself not have this right? The discussion was adjourned till Friday, when the conclusion of the report of Dr. Vannois was adopted, with amendments suggested by the President (M. Bulloz) and M. Davanne. The effect will be to give to photographs the status of works of the graphic artist, the Congress protesting against any attempt that may be made by nations who have not accepted the Convention of Berne to introduce into new legislation any provisions of a retrograde character.

The modern photographer and his *fidus achates*—the retoucher—have introduced a new embarrassment into society. The embarrassment arises when a lady shows a portrait of herself very much beautified to a friend, and the latter exclaims, in natural surprise, "What, that is not you, surely!" Directly the words are uttered, the unfortunate friend feels guilty of having perpetrated a thing which one would rather not have said. What *is* one to do when asked to give an opinion on a photograph which is grossly unlike the original, and which the original is, secretly, very proud of? Is good taste to be sacrificed to truth, or is truth to be kept in the background? Perhaps the safest plan is the middle course, adopted by Sir Joshua Reynolds whenever an effort of juvenile genius was shown to him by parents. "Yes," he would say, "it is very pretty." This is the criticism which exactly fits a touched-up photograph, and we think anyone would be perfectly safe in using the formula.

Special privileges are certainly accorded to the amateur photographer. The professional man may not carry on his business in the parks under the jurisdiction of the County Council, but the amateur may easily get permission to work there. Cricket matches are constantly being interrupted so that the teams may be photographed, and now comes the story that the commanders of two opposing armies kindly stopped the progress of a battle for a brief space, so that a couple of English tourists might use their cameras. The battle took place during the revolution at Buenos Ayres. The two armies were drawn up in a public place, and were firing briskly at each other, when out came an English lady and gentleman armed with camp-stools, opera-glasses, and a detective camera. They seated themselves between the opposing forces, and, with charming impartiality, proceeded to photograph both, while the leaders, with true politeness, ordered the troops to cease firing while the operation was performed. If this story be true, it opens up quite a new era for the "special correspondent." He must never go to the scene of battle without a camera, when every facility will be afforded him. If we recollect rightly, Mr. W. S. Bird, in his genial speech at the last dinner of the Photographic Society, alluded playfully to the possibility of something of this kind happening in the future. And now, judging from what took place at Buenos Ayres, the prediction has been fulfilled.

A curious application of the electric light and photography is recorded. A West-end wall-paper manufacturer, having noticed the curious effect of the dark, clear-cut shadows caused by the play of the electric light among the foliage of trees, has conceived the idea of applying these forms, so clearly defined, to wall-paper patterns. He has been for some time making, by means of photography, a series of records of these beautiful effects, which he intends to use in connection with his business. Some of the designs which have already been made are, it is said, of exceptional merit.

MY EXPERIENCE WITH HYDROQUINONE.

BY J. C. HEGARTY.

My attention was first called to hydroquinone about the time of its introduction by reading several articles setting forth its merits as a developer in the various photographic journals. During the summer of 1888 I saw some plates developed with this new reducer by a photographer in Philadelphia I was pleased with its action, and secured a supply for the purpose of experiment. After my return home I gave the hydroquinone developer a trial, and have been using it in my photographic work ever since. I have found it superior to pyro in every way except in rapidity, and this objection of slowness in working can be removed by using caustic potash as an accelerator. But hydroquinone does not owe its claim to superiority to rapidity of working, but to other points—the fine negatives it produces, the beautiful detail, even in the deep shadows, and entire absence of stain.

Another advantage which should be noted is the great latitude of exposure, and the fact that every effect of exposure appears to be grasped by it. I have exposed plates on scenes with heavy foliage, dimly lighted, and views in shady dells, giving a very liberal exposure, and developed with hydroquinone, getting full detail in the shadows and fine half-tones, without the high lights being opaque or too thin. Had the same plate been developed with pyro it would have resulted in a flat negative, with the high lights very much over-timed. The absence of fog or stain is one of its chief merits. The development of a plate can be prolonged to almost any extent without danger of fog, and the shadows always remain clear and transparent. Its pleasant and agreeable method of working, and the sureness of results with hydroquinone developer, make developing a pleasure, and relieve the amateur of many disappointments.

Some operators are not successful in working hydroquinone; but doubtless most of the complaints are from persons who do not properly use it, or work with a solution not properly prepared. They may have under-exposed their plates, or lacked the patience necessary to develop a short exposure.

I tried several formulæ, most of which were good, and, being an advocate of simple formulæ, I chose the following, which has proved very satisfactory. The ease of working, and certainty of results with it, have led me to recommend it to others.

A.—Sulphite of soda crystals...	...	...	2	ounces
Ice or distilled water ...	...	...	16	,,

Dissolve and filter; then add—

Hydroquinone ...	...	...	120	grains
B.—Carbonate of potash ...	...	...	1½	ounces
Ice or distilled water ...	...	...	16	,,

Normal developer: One ounce of A, one ounce of B, and one ounce of water. If pure water be used, the amount of sulphite used in A solution is sufficient to ensure its keeping; if more should be added, or any acid used, it retards its action. I find no difficulty in keeping it in good order for weeks. Nothing is added to the carbonate of potash solution.

Now as to the method of developing. First notice the temperature of your dark room, which should be 70 or 75 degrees Fahrenheit. I find that a difference in the temperature makes a marked difference in the time it takes to develop.

If I have a batch of 6½ by 8½ plates to develop which I think have had about the correct exposure, I mix five ounces of solution with a little less than the normal quantity of alkali, and, if my note-book leads me to believe that any are over-exposed, I reserve them for the last, using the weakened developer on them. Put a plate in the tray and flow with the solution: if it has been correctly exposed, and the solution is freshly mixed, traces of the image will begin to appear in one and one-half or two minutes, and grow steadily with good contrasts and infinite detail. Do not hurry the development by adding alkali, for the finest tone graduations are built up slowly. The development is completed when the shadows show no white on the surface. The high lights usually show on the back of the plate. Wash and fix as usual, leaving the negative in the hypo a few minutes after it is clear to insure thorough fixing. You will then have a crisp, brilliant negative, full of detail in the shadows, and of fine printing quality, the film being pure in colour through all the range from black to transparency.

If a plate is known to have been over-exposed, or if you are doubtful as to the exposure, the solution should be prepared with not quite the normal amount of A solution and about one-fourth of potash solution. The image will then appear very slowly, giving the person time to modify the developer to suit the exposure, cautiously adding alkali or hydroquinone as the plate requires. It should then build up in fine form. Some may become impatient at the time required; but the amateur who works for results will not object to the time, and who would not rather have one good negative than a dozen poor or indifferent ones?

In regard to exposure, I am apt to over-expose a trifle and develop slowly, and by that means secure brilliant negatives with plenty of detail in the shadows.

I will not say that hydroquinone will take the place of all other developers, for during the great advancements in photography other reducers may be discovered, and the possibilities of eikonogen are not yet fully known: but I do think that a developer superior to hydroquinone would be a perfect universal developer, and I venture to say that, if hydroquinone development be once mastered, but few will return to pyro.—*The American Amateur Photographer.*

A general meeting of the directors of the eighteen chief observatories in the world will meet in Paris on the 30th of March next, to make their final arrangements before commencing the great photographic atlas of the heavens, divided into numerous zones. The atlas will consist of from 1,800 to 2,000 leaves, representing 12,080 large squares, comprehending the superficies of the celestial sphere.

A Photographic Amateur.—A phase of the matter of asking questions is that of enquirers who, knowing nothing of photography, will not even take the trouble to read the directions given with any articles they are using. For example, a gentleman wrote to us a short time ago saying he wanted to know the reason for using of the alum bath with Ilford plates. This desire to know the why and the wherefore is most admirable in its way, but, as we pointed out to him, if he had read the instruction issued with each box of plates with ordinary attention, he would have found this phrase, "acid added to the alum bath entirely destroys its property of hardening the film." This same person owned that he did not know of the existence of any photographic publication except *Scraps*, and naturally applied to us. Therefore we forgave him, and wrote him a long letter of instructions, and recommended him to buy a text-book and study it carefully.—*Scraps.*

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

All photo-chemical investigations which have hitherto been made have proved that the amount of chemical action is proportional to the "exposure"—*i.e.*, the product of intensity of light and time. The sensitive film of the photographic plate forms no exception to this general law, and we take it as a fundamental truth that the amount of action upon the plate is, at any moment of the exposure, proportional to the energy which the plate receives at that moment. During the first period, when the surface—or chiefly the surface—of the film is acted upon, the results of the investigations have shown this to be true accurately; but when the action of the light upon particles of bromide of silver below the surface has to be considered, the question arises, how much of the light which impinges on the surface really reaches those particles?

Of the rays of light which impinge upon the surface of the sensitive plate, some are reflected and some pass right through the plate. If one sensitive plate be exposed to light behind another, it will be found that it also is affected.

The energy of the reflected and transmitted light cannot, obviously, play any part in the molecular work to be done in the film. It is useless photographically.

The light absorbed in the film is the only light which contributes towards the formation of the "latent image," but not even the whole of the light which is absorbed does useful work. It can be proved experimentally that a plate which has received such an exposure as to yield maximum density on development, absorbs exactly as much light as a plate which has not been exposed at all, yet the light absorbed by a plate already so exposed obviously contributes nothing towards increase of density.

From this it is clear that the light absorbed by a particle of silver bromide which has already received sufficient energy to bring it into that condition in which it is capable of development, is useless.

It will, therefore, be evident that, of the light impinging upon the plate, there is only one portion useful, viz., that which is absorbed by unaltered silver bromide, the light reflected, the light transmitted, and the light absorbed by particles of silver bromide already changed, being altogether useless.

The amount of work done at any moment of the exposure is, therefore, proportional to the amount of energy received by the unaltered silver bromide only.

It is very easy to state this proposition mathematically, and thus find the law which connects the densities with the exposures.

If the intensity of the light—with respect to chemically active rays—is I, and the fraction of the light reflected from the surface of the film is a, then the amount $(1-a)$ I enters the film. If the film contains, at the moment we are considering, x particles of silver bromide per unit area, which are already changed, then the transparency of the plate with respect to the changed particles is E^{-kx}, *i.e.*, this is the amount of light which passes the particles already changed. If from this amount we deduct the amount of light which passes *all* the particles of silver, changed or unchanged, the difference represents the amount of light absorbed by the silver bromide not yet affected. Now, the light which passes all the particles of silver, if there are a of them per unit area, will be measured by the transparency of the plate, viz., E^{-ka}. Deducting this from E^{-kx}, and multiplying the difference with the total amount of light entering the film, will give the mathematical expression for the amount of light which, at the moment we are considering, can do useful work; this amount is $(1-a)$ I $(E^{-kx} - E^{-ka})$. If this expression is multiplied by the short time of exposure dt, it will represent the amount of useful energy conveyed to the plate during that time.

Suppose it requires an amount of energy e to change one particle of silver bromide into the condition capable of development, then the number of particles dx so changed during the time dt will be

$$(1.)\quad dx = \frac{T}{e}\ (1-a)\ [E^{-kx} - E^{-ka}]\ dt.$$

This is the complete mathematical expression of the idea that it is only that portion of the light which is absorbed by unchanged silver bromide which contributes to the growth of density.

By integration of equation (1), and by substitution of the symbol 0 for E^{+ka}, we find that the density of the "latent image" (before development) is

$$D = \log_{\epsilon} [0 - (0 - 1)\ \beta^{k\,(1-a)\frac{It}{e}}]$$

where β is a fraction, the hyperbolic logarithm of which is $-\frac{1}{0}$, 0 is simply the opacity of the plate to the chemically active rays before exposure.

In this derivation of the connection between the density D and the exposure It, two assumptions have been silently made which need explanation. The coefficient of absorption, k, has been assumed to have the same value both for the altered and the unaltered silver bromide. We have, however, experimentally ascertained that this is a fact. It can be easily proved photographically. If, behind a plate, one portion of which has been already exposed so as to yield maximum density, the other portion having received no exposure at all, a very sensitive plate is placed, and if now a suitable exposure be given, it will, on development, be found that the shielded plate has uniform density all over. This proves that k is the same as regards blue light both for the altered and for the unaltered silver bromide.

The second assumption is that the sensitive film obeys the laws of absorption, as explained at the beginning of this paper. It would prolong this paper very much if we had to furnish here the proof that, as far as the chemically active rays are concerned, and as far as the light *not reflected* is concerned, the law of absorption does hold good. Suffice it to state that, to the more refraugible portion of the spectrum, the sensitive film is as black as Indian ink is to white light.

To recur to our formula, it requires still more alteration to complete it. The density as given by the formula is the maximum density, and expressed as regards the behaviour of white altered silver bromide towards the blue rays of the spectrum. As we know already, we can develop of that maximum density as much as we please, and the change from white to black during development makes the density more or less equal for all rays of the spectrum. We therefore simply multiply the equation by a constant to express this change, and we call this the development constant. The formula then stands—

$$D = \gamma \log_{\epsilon} [0 - (0 - 1)\ \beta^{k\,(1-a)\ \frac{It}{e}}]$$

k, a, and e represent physical and chemical properties of

* Continued from page 790.

the bromide or silver, which together constitute its sensitiveness to light. We combine them into one single symbol, and write $i = \frac{c}{k\,(1-\alpha)}$, so that we have finally—

$$(2.)\ D = \gamma \log_{\epsilon} [0 - (0-1)\,\beta^{\frac{It}{i}}].$$

This formula represents the density of development as a function of the opacity of the unexposed plate, of the exposure, and of the symbol i, which is a measure of the slowness of the silver bromide, and which symbol we shall call the "inertia" of the silver bromide.

To show the approximation of densities calculated by this formula to those obtained in experiments 21 and 22, we append here the calculated and the observed densities. For this purpose the plates used for experiments No. 21 and 22 were investigated for their opacity to the rays of the spectrum from F to H, and this opacity was found to be 332.

Experiment 21 compared with theory.

Exposure, C.M.S.	Density Found	Density Calculated.	Exposure, C.M.S.	Density Found.	Density Calculated.
0·625	·045	·035	80	1·010	·992
1·25	·055	·065	160	1·270	1·272
2·5	·085	·121	320	1·555	1·531
5	·175	·214	640	1·885	1·780
10	·250	·339	1,280	2·088	2·022
20	·460	·520	2,560	2·262	2·218
40	·755	·743	5,120	2·352	2·352

Experiment 22 compared with theory.

Exposure, C.M.S	Density Found.	Density Calculated.	Exposure, C.M.S.	Density Found.	Density Calculated.
1	·060	·092	128	1·875	1·800
2	·160	·172	256	2·290	2·165
4	·340	·302	512	2·535	2·518
8	·500	·482	1,024	2·985	2·860
16	·715	·735	2,048	3·115	3·138
32	·940	1·050	4,096	3·280	3·328
64	1·345	1·405	8,192	3·405	3·405

On examining the "calculated" series of results, it will be found that they have exactly the same characteristic properties as those we pointed out as appertaining to the three periods. For the short exposures the calculated densities are nearly proportional to the exposures, whilst from 16 C.M.S. to 1,200 C.M.S. the densities increase by nearly equal amounts for every successive double exposure, and differ very little from densities calculated by the simple formula—

$$D = \gamma\,[\log It - C].$$

In order that this may be very clearly seen, we append another table, comparing in column 1 the densities obtained by the correct formula (2), with densities in column 2 calculated by the approximate formula—

$$D = 1{\cdot}176\,[\log It - 0{\cdot}579].$$

Exposure, C.M.S.	(1.) Density by Correct Formula.	(2.) Density by Approximation.	Exposure, C.M.S.	(1.) Density by Correct Formula.	(2.) Density by Approximation.
16	·735	·735	256	2·165	2·151
32	1·050	1·089	512	2·518	2·505
64	1·405	1·443	1024	2·860	2·859
128	1·800	1·797	2048	3·138	3·213

We think it necessary to draw attention to this agreement, because the approximate formula is extremely easily applied, whilst the correct formula requires very tedious calculations, and we shall make a very important practical application of such calculations.

(To be continued.)

PHOTOGRAPHY IN GERMANY.

BY DR. H. W. VOGEL.

Restoring Exposed Plates — Warnerke's Luminous Table—Films in a Tropical Atmosphere—The Value of Decoudin's Photometer—New Magnesium Powder for Enlargements—Stereoscopic Effect in Lantern Pictures.

There are certain photographic tales which pass from mouth to mouth and find a good many believers, and to these belongs the assertion that we are able to restore an already exposed plate so that the image impression disappears completely from the sensitive film, by placing the plate in a weakly acidified bath and sending an electric current through the latter for a prolonged time.

The Paris *Figaro* mentions still another process by which one should likewise be able to restore an already exposed plate. This matter has, undoubtedly, its significance. It will happen to the best photographer, when he is in a great hurry, that he may get two pictures on the same plate, whereby the latter, of course, becomes useless. On the other hand, when travelling, two negatives are oftentimes made of the same subject on account of the uncertainty in the time of exposure, which changes according to the height of the sun or cloudiness. If the first of these plates is developed and proves to be good, the second is considered unnecessary and is laid aside; it becomes, therefore, a useless sacrifice. The process mentioned in *Figaro*, to treat plates of this kind so that the image impression disappears, the plate therefore being restored for a new view, consists in bathing the plate for two to three minutes in a three per cent. solution of bichromate of potassium, after which it is well washed and dried.

Dr. Riesenfeld has made a test of both manipulations. The electric current, in gradation from the bare immersion of an element to the full immersion of six large Bunsen cells at a duration of from two minutes to half an hour, gave completely negative results. Bichromate of potassium gave also no satisfactory results. In a few cases the picture disappeared completely; but as a general thing the picture would appear in the development, even if very faint. Additional bromide in the bichromate bath had no influence.

My views are that all experiments to restore a plate are not worth more than that to restore a cartridge which has been shot off once. The labour is more expensive than the value of the results.

Lately the usefulness of the Warnerke sensitometer has been more closely investigated. This little instrument is spread over the whole world, and I find the scale of the same to be very good. I only am not favourable to the luminous table, particularly because it emits blue light, and because its brightness is not constant; but to determine definitely its usefulness I handed the table to Professor Leonhard Weber, who is considered first authority with regard to photometry. He has made experiments with the luminous table, and in consequence thereof he declares that the table loses its brightness very quickly after exposure. In the critical half-minute during which the exposure takes place the brightness sinks on the average from 100 to 65. The absolute brightness is also strongly influenced by the manner in which the exposure takes place. The table can, therefore, not be considered as a normal light-source. A normal lamp of Hefner, filled with amyl-acetate, is much more suitable for this. According to the most exact

investigations, this is considered the best light-unit at present existing.

The film question is now discussed here pretty vigorously, particularly since film manufacture in Germany by Perutz in Munich. They are colour-sensitive. A holder has now been constructed which will hold twenty-four 6½ by 8½ films, making the long rolls superfluous. About the usefulness of this instrument I will report at some later time, after I have been able to give the same a thorough test.

The durability of films in a tropical climate was the subject of discussion here recently. To determine the same in the interest of a Brazilian expedition, a Stegemann holder, filled with a sample of two colour-sensitive Perutz films (with glass-backing), was put in the conservatory of the Imperial Technical High School at a temperature of 28° C. on the 28th June, and left there until the 12th of July, therefore eighteen days. After this time the slide moved less freely than ordinarily. The films appeared partly matt, but were just as smooth as before. Being put into the holder without any support, they stuck somewhat to the wood of the holder, but could easily be detached from the same. They were developed with hydroquinone, and gave faultless pictures without the least trace of a black edge. As a consequence of this successful test the expedition provided itself with films.

Dr. Michalke, one of the most eminent young professors of physics, has made some experiments lately about the usefulness of the Decoudin photometer. The following doubts have been raised against its reliability:—

1. The eye, dazzled by the daylight, cannot correctly estimate.

2. The graduation of the apparatus is incorrect.

3. The apparatus gives the optical, but not the actinic lightness.

Considering the first reproach, we can protect ourselves against this by prolonged practice, and locating the apparatus immediately after putting the ground glass in proper focus under the focussing cloth. The apparatus should be placed as close as possible to the ground glass.

The amateur can make the graduation himself. One exposes at a certain height of the sun (about forty-five degrees when the object and its shadow are of equal size) with a certain diaphragm upon a line drawing, newspaper, or something similar, and the position is marked at which the transparent points of the photometer just disappear. On the slide of the plate-holder marks are made at about a centimetre apart each, and after the plate-holder has been put in its proper place the slide is drawn at certain intervals, centimetre by centimetre, so that one obtains upon the plates stripes of different times of exposure. The latter is chosen so that the middle stripe will show the estimated time of exposure, and that the first stripe is surely under, and the latter surely over, exposed. If, for instance, 30 seconds are estimated, the different times of exposure taken should be 5, 8, 13, 20, 30, 45, 67, 100, and 150 seconds, so that each following time of exposure is fifty per cent. higher than the preceding one. The slide is hereby opened at 150—100=50 seconds, at further drawing out of the same, 100—67=33 seconds, &c. When developing, one stripe will give the correct time of exposure, which is marked in the location of the photometer previously marked. It is sufficient to put marks on the photometer for three to four different brightnesses. For the intermediate brightnesses the marks on the photometer can be determined by producing different brightnesses upon the ground glass by changing the diaphragm, the relation being inversely proportional to the diaphragm openings.

(To be continued.)

REPORT OF THE PROGRESS OF PHOTOGRAPHY DURING THE YEAR CLOSING AUGUST, 1890.*

BY W. H. H. CLARK.

Were I permitted in this report to a reminiscence of but ten years, and had before me an audience ignorant of what has been accomplished by the aid of our art during the interim, this report could be made to sparkle like the diamond in crowning the progress of photography; but, alas! I have but twelve short months from which to formulate this report, and an intelligent and progressive audience to sit in judgment.

Photography is ever progressive, and ever will be, and although that progress may be rapid, comparatively speaking, the world probably never will be so overwhelmingly astonished by any announcement of the progress of our art as it was when Daguerre's discovery was first made public. Now and again a slight ripple across the photographic horizon is occasioned by the announcement that photography in natural colours is an assured success.

Recently an Austrian, Herr Verescz, announced that he had made a decided advance towards the solution of photography in colours. His operations, however, are based upon the researches of Mr. Carey Lea, on the photo-compounds of silver salts. It remains to be seen whether any decided advance over the latter has really been made.

Pigment Printing in one or several colours has long been successfully accomplished, and I am reliably informed that Mr. H. H. Snelling, in his early days, was a practical experimentalist in this direction, and is to-day in possession of practical formulæ for producing the colours by pigment printing; but owing to reverses in fortune and long continued sickness, and now almost totally blind and broken down with age, he has been unable to successfully bring before the fraternity his invention. It will be remembered by the older members of this association that Mr. Snelling for a number of years successfully edited and published *Snelling's Photographic and Fine Art Journal*. If it would not be considered out of order in this report, I would suggest to the members present they should appoint a committee of as many or few as is deemed advisable to investigate the claims of Mr. Snelling, and, if found of sufficient value, to purchase the same in the name of the Photographers' Association of America, to be published for the benefit of all.

The invention of Frederick Eugene Ives, of Philadelphia, which was patented the 22nd of last month, is undoubtedly a step in advance in photographically rendering the colours, and, possibly, may prove a great one. The invention consists in a method of producing a set of three photographs of an object or landscape, which can be subsequently used for the production of a heliochromic picture. The Ives patent consists of an apparatus or camera whereby three negatives of the same subject can be taken simultaneously, the light passing at the same time through three different colour screens or media, a full description of which cannot be rendered in this report. While this invention of Mr. Ives may become of

* Read before the American Convention.

great value and use, it is hardly to be expected that it will be of general practical utility in the hands of every photographer.

Orthochromatic photography has not made the advance that was hoped for it, and no marked improvement has been accomplished since last year. Much, however, is hoped for in this direction.

Photography an Art.—Whether or not we can rightfully call photography an art, it is, nevertheless, the hand-maid of art, and, in the hands of an artist photographer, fine art pictures can be produced; but your committee cannot report the progress in this direction that some of us had hoped for. The insane practice of rate cutting has reduced many bright lights in the photographic world to nearly the level of a common "shyster," and, with prices insufficient for a decent living, the quality of the work delivered to their patrons is anything but promising. I have visited a good many of the first-class galleries of the land, and the work there seen palmed off on the public as first-class was really shocking. In a great measure photography is superseding drawing with the pencil, and artists are making more use of the camera as an aid in producing the outlines of their sketches and models.

Specifications Published.

18,547. *November 20th*, 1889.—"A Photographic Developer." BENJAMIN JUMEAUX, at present of 11, Brighton Place, Stretford, Lancashire, Artist.

My invention relates to a new or improved compound for use in photography as a developer. This compound consists of eikonogen, chlorate of potash, and sulphite of soda, used in the form of a solution. These ingredients may be used in the following proportions, namely—

Eikonogen (powdered) ...	...	... 2 drachms
Chlorate of potash (powdered)...	...	1½ ,,
Sulphite of soda (powdered) ...	...	3 ounces

which are slightly damped and mixed together, and then dissolved in one pint of hot water.

The above proportions are those which I consider give the best results but they may be varied or modified, more or less, without departing from my invention. For example, the quantities of the chlorate of potash and the sulphite of soda might be either slightly diminished or increased with the same weight of eikonogen.

Other suitable salts of potash, such as a bromide, and other suitable salts of soda, such as a carbonate, might be employed in combination with corresponding proportions of the chlorate of potash and sulphite of soda and eikonogen as herein described. Glycerine also might be added to the solution if desired.

The chief advantages obtained by my new or improved compound are, that it is self-contained—that is to say, it requires no accelerator; it will develop well with negatives of all makes, opals, lantern slides, and bromide papers, and does not stain either the hands of the operator or the plate, except after repeated use, when it will slightly stain paper or opal.

What I claim is:—

1. The new or improved developer consisting of a solution containing eikonogen, chlorate of potash, and sulphite of soda substantially as herein set forth.

2. The new or improved developer, consisting of a solution containing eikonogen, and salts of potash, and soda as described.

Correspondence.

AN EXHIBITION IN NEW YORK OF MODERN PHOTO-MECHANICAL WORK.

Nothing in the wonderful history of photographic progress, which has been so strikingly rapid during the past few years, has been of greater importance than the development of what may be called, for want of a better term, the photo-mechanical processes, which are so largely superseding wood engraving, steel engraving, and other pictorial methods. This subject is of great interest to the whole public, but particularly to all persons in any way interested in the production or use of pictorial illustrations, such as artists, authors, publishers of books, magazines, and newspapers, printers and manufacturers whose products require illustration. For the past few years these processes have multiplied in number, have improved greatly in their results, and are every day assuming greater importance in both artistic and economical directions; yet it is a remarkable fact that in no exhibition have they been brought together for comparison and study.

During the week beginning November 3, 1890, the New York Camera Club will give an exhibition in its Rooms, 314, Fifth Avenue, of the work of the various establishments producing all classes of photogravure, photo-engraving, photo-lithographic, and other mechanical photographic illustrations.

Admission will be by cards of invitation, which will be sent as generally as possible to photographers, artists, authors, publishers, printers, manufacturers using illustrations, and in general to all persons likely to be interested in the subject.

A pamphlet will be distributed at the exhibition containing an essay giving a sketch, historical and descriptive, of the different methods. A space, probably a page, will be set apart for each exhibitor, in which, on his own responsibility, he will be allowed to describe or recommend his process in his own way. No charge will be made for such insertion, and the pamphlets will be distributed free. Exhibits suitably framed and of proper character, subject to the approval of the committee in charge of the exhibition, will be hung upon the walls. Other exhibits, whether in books, albums, or on cards, will be displayed upon tables for the examination of visitors. All frames must bear a neat label, which will be furnished by the Club, giving the name of the exhibitor, the process by which made, and the title or explanation of the pictures. All other exhibits must be properly marked for identification. There will be no charge whatever to exhibitors.

DAVID WILLIAMS, *President.*
H. T. DUFFIELD, *Secretary.*
New York Camera Club, 314, *Fifth Avenue.*

MR. LYDDELL SAWYER'S PICTURES AT THE CAMERA CLUB.

SIR,—I do not take any particular exception to your review in last week's NEWS of my pictures at present on view at the Camera Club; many of its statements are correct, and as to its peculiarities, they will perhaps be sufficiently understood

and qualified in the minds of your readers when you let me tell them that the paper is from the pen of a red-hot naturalist.

I should feel myself holding a very precarious position if I could not withstand such an onslaught from a "candid friend;" and in this light I should not reply so far as it touches my individual pictures, but I am reminded by it of a matter of more general principles, and which I wish to object to with all my might. It is that of the-perhaps unconsciously-ungenerous and oft-times false objections raised against all posed pictures by a certain class, more or less proportionate to their imaginary or real sympathy with the narrow "naturalistic" school.

Taking any picture where the figures or accessories are arranged to tell a story, express a sentiment, or indeed create any effect, and however successful and natural the result may be, it must not be allowed, because *photography* has produced it, and the same old inconsistent sing-song is chanted forth about artificiality, straining, untruth, and so forth. The critic may not know "B from a bull's foot" in matters artistic, still he feels quite safe to launch forth this tirade, however unjust, because he knows the picture is not natural, insomuch that it is arranged for, and not accidentally formed.

Presuming that it could be always uncertain which pictures were posed, and which were simply mechanically obtained (for this is the *real* distinction), I wonder how many of these ultra-æsthetical gentlemen would be able to dispense their subtle sentiments! I am afraid there would be a large addition to the ranks of the unemployed.

As an instance in point, I have been very much amused at the eulogies bestowed on my two pictures, "Waiting for the Boats" and "On their own Hooks," by these "purists." Both pictures having a large number of figures included in them, appear to suggest to the superficial eye that they might have been groups accidentally alighted upon and taken, although I should have thought it would take a very small combination of pictorial and photographic knowledge to recognise that there is about the same possibility of accidentally finding and taking a group posed on these lines as there is of getting the whole thirteen trumps in one hand of whist.

As a matter of fact, with both of these groups I started by selecting a perfectly clear piece of quay, brought every figure and accessory on to it, and posed each as I wanted. They are the most entirely built up and posed pictures of my collection, yet the "naturalists," who do not admit arranging and posing, have declared these two pictures to be "masterpieces!" I leave your readers to digest these facts for themselves.

The pictures of my own which I am *nearest* to being satisfied with are those most created and posed. Spite of the many faults which I am quite cognizant of their possessing, and the "naturalistic" objections to this class of picture, I can still feel with some *true* sentiment that what *is* good in them is more honestly my own. "'Tis better to have loved and lost than never to have loved at all," and on the same principle it is more worthy to struggle straight forward, with, doubtless, stumbling steps, into the rough-pathed realms of art, than-from perversity, or ignorance of the road, or any other cause, to go nervously around its borders, making water into wool, chaotic blurs where detail should exist, cornfields into conundrums, and generally torturing nature until she must in many cases cry out with pain at the unnaturalness of "naturalism."

Photographers of legitimate art convictions are sufficiently open in mind to concede that with certain stretching of the artist's licence some naturalistic productions are of pleasing effect. This amenability to conviction is evidenced by the judges at Pall Mall this year having medalled pictures of this description. In return it might not be too much to expect that naturalists should be sensible enough, if not possessing sufficient innate "clannishness," to avoid obscuring photography in the eyes of the outside press and public, and endeavouring to snuff out its all too feeble higher art light.

I must repeat that, apart from the inconsisteney of the objection, when viewed beside many of their own mechanical and unnatural operations, the "naturalists" yield to a greater amount of narrow-minded injustice than, I trust, they are fully cognizant of in peeping behind the scenes, and from this point of view declaring all posed studies unnatural, not because any artificiality is manifest in them, but it is enough that they have discovered the original *modus operandi*, and that the photographer has dared to show he had courage enough to clothe the picture with his own ideas, instead of being content with the comparatively insignificant proceeding of pilfering pictures of nature's sole production, and palming them off as his own.

Please remember that what I have here stated is again connected with general naturalistic principles, rather than directly replying to your review of my work and its writer individually. In one direction at least my remarks would not apply, inasmuch that, however limited and inconsistent I may consider the judgment of the writer in this direction, I know he has only expressed his honest opinions; and as regards my pictures, they have received so much more kindly recognition than they can ever deserve on every side, from naturalists included, that I feel I have been too much indulged, and it would be very churlish to resent the first bit of adverse criticism which appears, even if it is on the wrong lines.

And now I am finished. Your reviewer, or any one else, can throw brickbats at either my pictures or me, if they like—while expressing a desire that the former might preferably receive these favours if their bestowal is absolutely necessary. I shall yet either way not trot out again for some time. We—again my pictures and I—have been too much in evidence lately, so I shall, with necessary modifications, follow the example of the young lady mentioned by Shakespeare, and "let concealment, like a worm i' the bud," have a meal or two off whichever cheek nearest approaches the apparently necessary damask tint.

By-the-way, I have another "candid friend," who suggests that if a real genuine damask colour is a necessity to suit concealment's digestion, he or she—as the case may be—is likely to preferably settle and grow fat on my ornamental proboscis. That's the worst of candid friends.

Newcastle-on-Tyne, October 13th. Lyddell Sawyer.

THE EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

Sir,—It has been pointed out that a medal has been awarded in error to photograph No. 600, in the Exhibition of this Society: "An Invitation to Supper," by Mr. Van der Weyde.

It was not noticed at first that this picture had already been publicly exhibited within the London Postal district, and should, therefore, have been disqualified.

The medal has been withdrawn.

It is greatly regretted that the mistake occurred. The exhibitor, through some misunderstanding, was led to suppose that the rules of the Exhibition did not exclude the photograph in question. A. M. Mantell, Capt. R.E.

(Hon. Sec. Photographic Society of Great Britain.)

8, *Mansion Row, Chatham, Oct. 15th.*

Proceedings of Societies.

The Camera Club.

On Thursday evening last week, at a meeting of the Camera Club, Mr. Francis Cobb presided.

Captain W. de W. Abney, F.R.S., read a paper on "The Density of Negatives," in the course of which he stated that a little controversy had been going on between himself and Messrs. Hurter and Driffield about the accuracy of the instruments used for the purpose of measuring the density of the said negatives. Messrs. Hurter and Driffield used a grease-spot photometer of small dimensions, 12 inches by 4 inches by 5 inches, and he maintained that this was not the best apparatus which could be used for the purpose. He then threw upon the screen a small disc of light by means of the optical lantern, and pointed out that when a negative was suitably interposed some of the light was scattered, and feebly illuminated the screen for some distance outside the disc proper. The light which is scattered in passing through a negative causes the chief difficulty in measuring the intensity of the

latter; it amounts to more thau 5 per cent. of the whole light, and of this scattered light the grease-spot photometer measures very little. Lantern slides sometimes give darker images than are expected, simply because much of this scattered light does not reach the screen; he thought collodion slides likely to give the better results, because they scatter the light less. By the plau of Messrs. Hurter aud Driffield more of the scattered light was measured than should be the case, and they measured the scattered light where it was most intense. As for the grease-spot photometer, he asserted that whether they took their measuremeuts from the position of equal illumination, or from the vanishing position, the results were the same, and this they denied; if they obtained a difference there was something wroug in their method of uneasuremeut. He maintained that his own method of measurement, by meaus of a dise with sectors, gave absolutely trustworthy results, and that the hundred per cent. of error which Messrs. Hurter and Driffield asserted it to yield was, in reality, in their own method of measuring. His own instrument was as perfect as human hands could make it, and he had tested it by differeut lights; the rotating sectors cut off exactly the amount of light they should do, and any error due to scattered light was a constant, running through all the experiments alike. He theu described apparatus and a method of measuring the amount of the scattered light. Next he dealt with the problem whether the time of exposure and the intensity of the light are equal, and said that, so far as his experimeuts had gone, the answer must be "Yes," when the time of exposure is measured by seconds. Whether the law holds good with very short exposures is a question; he was disposed to imagine that it does not hold good. Questions as to the viscosity of the ether aud the energy of the light then come in. Astrouomers believe that they have evidence that such viscosity exists, and that it quenches some of the light from the heavenly bodies which otherwise would reach the earth. Experiments on the lines he had just laid down might, he said, perhaps give the means of measuring absolutely the resistance of the ether, thus enabling the problem to be attacked from an entirely new direction.

In reply to various questions, Captain Abney said that he thought that in taking pin-hole photographs, the operator was beginning to feel the practical effects of the viscosity of the ether. He said that when his rotating disc apparatus was driven with great velocity by means of a whirling-table, white light passing through the sectors appears violet, but that this is a physiological and not a physical phenomenon. Paraffin lights do for use with his apparatus; they are uniform enough after they have been burning a quarter of an hour.

The London and Provincial Photographic Association.

October 9th.—Mr. A. L. Henderson in the chair.

Mr. F. A. Bridge showed two prints from negatives taken at the previous meetiug by Mr. Roberts with his flash-light apparatus; one of the negatives was developed at the time by Mr. Roberts, the other Mr. Bridge had developed in his own dark-room. A print from the former took two days to print; the latter negative required only ten minutes.

The subject for discussiou for the evening was as to the advantage of the use of large objectives in optical lantern work.

Mr. Freshwater said: Time has not not allowed me to put my remarks down in the form of a paper, but I hope I shall be able to show that all this talk about large objectives for the lantern is not of value, except, perhaps, as regards appearance and outward show, which, by-the-bye, go a very long way with some people. I was once in a hall getting ready for the show, when a lady came up; she looked at the lantern very studiously, as if she knew all about it, aud turniug to me, said, "What a beautiful lantern! It seems quite a pity to use such an instrument." On another occasion I had a small tin lantern on the table, when soue noble "swell" remarked, "You are not going to show that thing?" I said indeed I was. After the exhibition I did not see him. But enough of this. First, perhaps, I should show you the cone of light as it passes from the condenser to the front lens. Now, if you are using a short-focus condenser, one that is usually supplied with a lantern for limelight, you will find the cone comes down to a point at about nine inches, and then it crosses; now, if you place a six-inch lens in this cone at its right place—that is, at its focus with the picture in the lautern—you will see that the diameter of the spot of light is about oue and a-half inches in diameter, so you see a two-iuch lens is quite large enough to pick up all the rays from a four-inch condenser, and carry them to the front combination; but if you place an eight-inch lens, this same cone of light has come down very much, and is almost ou the cross, so that there is not enough light to fill the lens so as to illuminate the whole of the disc, as I shall presently show. I intend to put on lenses of different forms—the old meniscus pair, single achromatic, using in front of both of these a stop about one-third of the diameter of the lens. This stop is necessary to cut off the outer peucils of light, and give a flatter field and better definition. The other lens is a combination of the portrait form, but altered in the curves to give a flatter image on the screen. Now, if you use a large lens of this form of about eight inches iu focus with the same condenser, you will undoubtedly gain some considerable advantage. It will pick up the rays better than the small lens, and cover the disc much better, but you increase the size of all your fittings, and the weight of the lantern you have to carry. Some will say that is of no consequence; you must have a cab; a pound or two is of little moment. That is all very well, but a set of such lenses is rather a serious matter. Now, if you alter the condenser in such a way that the cone of light is longer, you will then illuminate the smaller lens, as I will show, and get as good a picture as with the large objective. Then comes the questiou of definition. It does not matter for long-focus lenses what form is used. A siugle lens will give just as flat a field as a compound lens, and pass more light. This will apply to lenses of above ten inches in focus.

Mr. Baker said that the marginal rays were cut off by the mat of the transparency, otherwise a 4-inch condenser could not be worked up to its full liuit: he would prefer $4\frac{1}{4}$. At one tiue he was in favour of small lenses, but he was quite converted into using lenses of large diameter, especially for long distance work. He considered the gain in illumination was worth the extra weight. Condensers that answered well for a three or four wick oil lamp were too short in focus for the lime-light. He cousidered the best form of condenser to be one composed of a meniscus and a double convex lens.

Mr. Freshwater thought this form of condenser had no advantage over the two plano-convex lenses, especially for long distance work.

Mr. J. Traill Taylor said that it was quite possible for a large condenser to focus to a small point. Mr. Grubb had projected the whole of the light of a condenser through a quarter-inch microscopic objective; therefore, assuming other conditions to be perfect, there could be no advantage in increasing the diameter of the object glass. A condenser to be perfect required three lenses. Mr. Taylor gave an illustration on the blackboard of a lens he had devised some time ago, showing the advantage of separating the lenses, by which a flatter field was obtained. The position of the luminant with regard to the condenser was important, the effect of increasiug the distance being to shorten the coujugate foci, and thereby to allow a large object glass to be used close to the condenser.

Mr. T. E. Freshwater contended that, using a 6-inch front lens, a 4-inch condenser was quite sufficient.

This being the opening night of the lautern season, a number of transparencies was projected on the screen, contributed by Messrs. A. L. Henderson, Cembrano, Medland, Wollaston, and Chang.

Hackney Photographic Society.

A private auctiou was held last Thursday, under the directorship of Mr. Henry J. Beasley (a member). The idea was that many amateurs bought apparatus which was found useless to them, but might be useful to others; little, if any, reserve was placed on them. Mr. Beasley gave a humorous description of the various articles.

Mr. Wm. Smith showed a new repeatiug flash-lamp, which

was handed round. The repeating action was brought about by a spring, which caused a box full of powder to discharge a given quantity into a small chamber, and on releasing the spring the box went back. The flash was caused by magnesium being blown upwards through a spirit stove.

The Fry Manufacturing Company sent samples of their various specialities, which were duly distributed; the members were requested to report the result of their trials.

Messrs. Mawson and Swan sent copies of "How to Make Lantern Slides," also some enlargements.

West London Photographic Society.

The annual general meeting took place on the 10th inst. at the Lecture Hall, Broadway, Hammersmith, Mr. C. Bilton, president, in the chair.

Mr. Whiting moved that Rule 5 be amended by striking out the clause which provided that the president be not eligible for re-election. He thought it undesirable, speaking generally, if a society possessed a good president, not to give the members an opportunity of re-electing him. They could not do better than follow the example of the parent society, which had not changed its president for many years.

Dr. Low, while admitting that there was something in favour of Mr. Whiting's argument, pointed out that the converse was equally applicable: an unsuitable president might be elected, and if the motion were carried the opportunity for selecting a subsitute would to some extent be lost. The alteration was made in order that every member should, like the French soldier, have the marshal's bâton in his knapsack, or, in other words, stand an equal chance of occupying the presidential chair.

Mr. Winter thought, putting both arguments in the scale, that the unpleasantness which might arise if the rule were rescinded would quite counteract any possible benefit from the change, and therefore hoped the meeting would allow the rule to stand.

Mr. Hodges had always looked upon the rule as being contrary to the interests of the Society; it was, moreover, contrary to the original constitution, and he should like to see its abolition. He hoped that his remarks would not be construed in a personal sense.

Mr. Whiting, in reply, thought that in the election of officers it should not be supposed that the person voting entertained an unfriendly feeling for the person for whom he did not vote. They would not be doing justice to the Society if they did not act independently.

The President said, as the proposer of the resolution last year, he should be sorry to see it rescinded, he having suggested it mainly upon the ground that an annual change in leadership would be beneficial to the Society, and would give every member the opportunity of so studying the interests of the Society that he might be elected to the chair.

The motion having been put to the meeting, was negatived by a majority of one. A discussion then ensued on the financial statement, and resulted in the adoption of the following resolution: "That all subscriptions become payable on the 1st of October; old members whose subscriptions are paid to the 1st of January to pay three-fourths of the full amount."

Further revisions in the rules having been made, the election of officers was proceeded with, but owing to the lateness of the hour the meeting was adjourned to the 17th inst., when, bearing in mind the importance of the business, it is earnestly hope that all members will make a special effort to attend.

Sheffield Photographic Society.

The annual meeting was held at the Masonic Hall, Surrey Street, on Tuesday evening, Mr. B. J. Taylor in the chair.

The Treasurer's statement of accounts for the year showed a good balance in hand.

The Secretary's general report stated that some good work had been done by the members, several having gained prizes at the photographic exhibitions in different parts of the country, notably Mr. Ernest Beck.

The election of officers for the ensuing year resulted as follows:—*President*—Mr. B. J. Taylor, for the second time; *Vice-Presidents*—Mr. A. Davy and Mr. G. Bromley; *Council*—Messrs. A. Reynolds, A. J. Brown, T. Furniss, Thos. Firth, and W. Spencer; *Secretary*—Mr. Ernest Beck; *Treasurer*—Mr. Bradley Nowill; *Reporter*—Mr. E. H. Pearce.

The President's prizes are again offered for competition.

Yarmouth and Eastern Counties Photographic Society.

On Wednesday evening, the inaugural meeting and entertainment in connection with the above Society was held in the Supper-room at the Town Hall. Invitations were sent out to a number of ladies and gentlemen, and so many responded that by the time the proceedings commenced the room was full to overflowing, and many had to stand, while others could not even obtain admission to the room. Round the walls of the room, and also outside on the landing, were a quantity of very fine photographs of Yarmouth and places in the vicinity, which clearly demonstrated that the work of the amateur photographers of Yarmouth is indeed of an excellent description, two cases of scenes on the beach and river, by Mr. C. Rumbold being much admired. The Mayor (Mr. J. W. B. Johnson) occupied the chair, and among others present were the Rev W. T. Goodrich, Col. Dixon, Mr. H. D. Arnott (president), and Mr. Harvey-George (hon. secretary).

The Mayor, in opening the proceedings, expressed the pleasure he felt at seeing so many present at the inaugural meeting of what he thought would prove to be a very important society in the town. He had no doubt that in a few months it would become a great and important body.

Mr. Harvey-George remarked that he was very pleased to see such a large attendance, and thought it bid fair for the prosperity of the Society.

Mr. Arnott, as president of the Society, also addressed the meeting, remarking that it was evident great benefit was derived from those societies by the constant demand for others. All liked to have sympathy and help in their work, and their needs were met by assembling together to relate successes and help one another in doubts and difficulties. Photography had gained such a hold upon the town and locality that they felt justified in establishing a camera club, which was sure to be of great assistance in forwarding and developing all matters connected with photography. He hoped no exclusiveness would be shown; the Society was open to amateurs, professionals, and ladies, and he hoped they would help each other, and not encroach on the trade of the profession. Rivalry was a good thing when carried out in a friendly spirit. No bitter jealousies must creep into the Society, but each must try to out-do the other in thoroughness of work. At the monthly meetings the practical working, different methods of printing and toning, would be dealt with, and papers read by the members. He hoped before the end of the year the Yarmouth Society would be reckoned among the most important, not only in respect of numbers, but of good work.

Several songs were well rendered and appreciated at intervals during the evening by Dr. Tipple, Messrs. C. Paucheu, and W. D. Tonkins.

The evening concluded with a lantern entertainment illustrating Boston, U.S. The lantern was lent by Mr. C. Rumbold, who also exhibited the slides, which were lent for the occasion by the Liverpool Amateur Photographic Society. A descriptive lecture, read by Mr. Harvey-George, added to the interest of the evening.

Croydon Camera Club.

A meeting was held on October 9th, with Mr. H. Maclean, F.C.S., in the chair.

The result of the competition for prize given by the President for "Views on the Wandle" was announced, the prize being awarded to "The Wandle at Beddington," by Mr. H. E. Lewis.

Some excellent work was sent in, and a large number of instantaneous views and animal subjects was exhibited.

A letter was read from Mr. L. De Clercy resigning his ap-

pointment as hon. secretary, and Mr. G. R. White was elected his successor.

A social meeting will be held every Wednesday, when visitors are cordially invited.

Photographic Society of Ireland.

The first meeting for the session was held at 15, Dawson Street, Dubliu, on the 10th inst. The chair was takeu by vice-president Dr. J. A. Scott, who regretted that the president (Mr. George Mansfield) was uot able to be preseut, owing to a family bereavement, to deliver the address anuounced, but that Mr. Greenwood Pim had undertaken to say a few words.

Mr. Greenwood Pim, in the course of his address, said that that meeting was the second of what might be called a public character in those rooms. Nearly twelve months before the rooms had been acquired by the Society, and at that time the number of members was about eighty ; since theu they had uo less than sixty new members, and he thought that fact afforded no doubt whatever of the propriety and advautage of having taken those rooms. By death and resiguatiou they had lost three members, and the total number was now 137. Their expenses were much larger thau they had been in oldeu times, aud the life of a society was to keep a constant influx of new members. He suggested that if a member were uot prepared to write a paper himself he might suggest a subject on which a paper might be desirable, and they would eudeavour to get some one to take up the subject so suggested. He also announced that arrangements were being made to obtaiu loans of the American sets of lauteru slides, aud in addition that the Society was about to organise a loan collectiou of its own. Mr. Pim concluded by hoping that the dark room would be largely utilised, aud that the members, especially the younger oues, would take advantage of the "Questiou Box."

The meeting was brought to a close by the exhibition of a number of the Society's lautern slides, the work of the older members of the Society, most of them having been taken on wet plates aud in the early days of the gelatine dry plates. The lantern was worked by Messrs. J. H. Hargrave and M. Hedley.

Dundee and East of Scotland Photographic Association.

October 9.—General meetiug.

Mr. Andrew Stewart, Editor of *The People's Friend*, gave a lecture on "How Our Morning Paper is Laid on Our Breakfast Table." The lecturer described the various details in connection with the production of a daily paper, from the receiving of "copy" to the despatching of the papers to the railway station. A series of lantern slides illustrating the different processes carried on in a newspaper office was thrown upon the screen, which gave the members a realistic view of the working of a newspaper establishment.

Mr. V. C. Baird exhibited a number of prints on Fallowfield's aristotype, toned iu the ordinary borax touiug bath.

The Photographic Club.—The subject for discussion on October 22nd will be "Photographic Copyright ;" October 29th, First Lanteru Night of the seasou—Slide Competition ; November 5th, Annual general meeting.

Nature says that at the British Association, Mr. F. H. Varley exhibited and explained the action of a new direct-reading photometer— au ingenious and compact instrument, iu which intermittent illumination is employed for equalising the intensity of illumination from two sources of light.

Spectacle Glasses.—Making glasses for spectacles is work requiring great care. The grinding of lenses is accomplished by placing them on an oval form embedded in a cement-like substance, which, as the operation proceeds, hardens, and thus holds the lens in position. Over the form is placed a bowl, and this moves upon the lenses in a manner closely resembling that produced by moving the palm of one hand in that of the other. The material used for grinding is vermilion. The glass for the lenses is imported, chiefly from Germauy and France, and colourless crystal glass makes the best lens, better, indeed, than Brazilian pebbles or rock crystal.—*Detroit Free Press.*

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the Photographic News, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the Photographic News, Messrs. Piper & Carter, 5, Furnival Street, London.

Professor Silvanus Thompson, of the Finsbury Technical College, invites his Manchester friends to search for the portrait of William Sturgeon (inventor of the electro-magnet, &c.), which is known to have been in the possession of his only daughter, until lately residiug in that town. Should auy of our correspondents know of its existence and whereabouts, they are informed that a photographic reproduction of the said painting is much desired. See refereuce made to it iu last week's *Journal of the Society of Arts.*

Sept.—*Punch's Illustration.* Harry Furniss' cartoon descriptive of the ubiquitous amateur photographer, on page 166 of the 4th inst., is a humorous bit of criticism. We think with you that the word "pest" is not very complimentary, but *Punch* will always take full license, and we must not look for exceptional treatmeut.

A. E.—*Slow Toning.* It may happen that your ready-made toning bath is suffering from the cold at nights ; try the effect of warming it, and if this does not prove successful, stimulate it by adding some freshly mixed gold solutiou.

P. L.—*Chronological Record.* The twenty-four pages in Mr. J. Werge's book, "The Evolution of Photography," devoted to historical record gives the best account we have seeu of the successive steps of photographic progress, since Robert Hunt's general summary, published iu the first volume of the *Photographic Journal*, and Mr. Jerome Harrison's later epitome.

Albumen.—*Sensitised Paper and its Faults.* 1. If you use a 70-grain solutiou of silver nitrate to make good the diminution of bulk, the strength of the bath would be kept pretty uniformly to 60-grains. 2. The perfectly straight lines in the sample sent lead one to suspect that they are either pencil marks or an original fault in the paper. 3. Mr. England makes his own. 4. The causes of fading are numerous and diverse ; one cannot specify without seeing a sample. Were the prints mounted ?

G. C.—The address of Dr. R. L. Maddox is Greenbank, Park Road, Perlswood, Southampton.

M. E.—*Measuring Pyrogallic Acid.* The oft-repeated weighing out of small quantities is inconvenient, and measuring unsatisfactory. Perhaps the best plan is to dissolve up the whole ounce iu a measured quantity of water, adding a few drops of nitric acid or other preservative, and make up to the bulk of fifteen fluid ounces. Call this a thirty-grain stock solution, aud dilute it according to the strength required for use. The bromide ought to go in with the ammonia rather than into the pyrogallic solution, although some formulæ prescribe the latter course.

W. S.—*Half-Tone Zinc Blocks.* You will find fifty pages devoted to the preparation of zinc plates iu Mr. W. T. Wilkinson's new edition of "Photo-Engraving" (Hampton, Judd, & Co.). We cannot attempt to supply working details in this column.

B. N.—*Kallitype Developer.* Prints taken to about one-sixth silver exposure, are floated face downwards for ten seconds on

Nitrate of silver...	... ...	50 grains.
Citrate of soda ...	... ...	800 ,,
Bichromate of potash	...	...1 to 2 ,,
Water	... ...	10 ounces

To which solution add 1 drm. of ammonia (which should just re-dissolve the precipitate first formed); then add 35 drops of nitric acid.

R. L., A. M. M., J. W., Experimenter, and A. G. G.—Received.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1677.—*October* 24, 1890.

CONTENTS.

THE PERMANENCY OF PHOTOGRAPHIC PRINTS.

THE powers possessed by photographers of obtaining prints of various desired tones at will are now large, so that when any new method of toning is brought before the public, a chief point of interest is the amount of permanence of the results, and to leave the problem to be settled by lapse of time alone is neither altogether necessary nor desirable.

When Mr. Lyonel Clark, last week, was expressing confidence at the Camera Club that some of the results he had obtained were more permanent than if he had used ordinary albumenised paper, it seemed to us to be a pity that a store of chemical solutions for testing prints was not upon the premises, and strips of some of the prints immersed in them while the speaker was addressing the meeting. A little diluted sulphide of ammonium, for instance, with one of the prints soaking in it, would have given emphasis in the one way or in the other to the remarks. Why should not some photographic organisation appoint a committee to consider the best series of chemicals and proportions thereof to be used in testing prints of any kind, and, after coming to a decision, recommend that such test solutions should be kept always on hand by every photographic society throughout the world? Experiments conducted anywhere with these solutions at the same temperature, and with the same times of immersion, would then be comparable with each other wherever performed.

When certain liquids ruin a particular photographic image, evidence is not thereby necessarily obtained that time will do the same, but information is thereby given sufficient to form a basis for argument, and sometimes for tolerably correct predictions as to the stability of the prints in the future. For instance, blue ferro-prussiate prints are attacked with the greatest ease by alkaline solutions, but as they are not likely to be so attacked in pure air, the prints are tolerably stable, as engineers know. If some of Mr. Lyonel Clark's heavily toned prints had been immersed the other evening in various standard test solutions side by side with some prints heavily toned by gold, like those recently produced by Mr. Scholzig, much more would have been known than at present as to the probable relative durability of the two classes of pictures.

Over certain photographers the word "platinum" has as sacred an influence as the word "Mesopotamia" had over the old Scotchwoman after she had heard it used in a sermon. Gold is an excessively permanent metal under atmospheric influences, and toning either by gold or by platinum seems to be but a surface action, so that at present there is no evidence before the public, so far as we know, that prints toned with the one metal are, in average batches, more permanent than those toned with the other.

The faded monstrosities in family albums, kept constantly before the eyes of visitors because of the interest in them due to the personality of the sitter, have done much to lessen public respect for photographic work, and to give rise to the expression, "only a photograph." Such influences have tended to give rise to a partial revival of the old art of miniature painting in cultured society, and it will be good for the photographic profession if, as soon as possible, it begins to turn out nothing but stable work.

Mr. Clark ascribed the yellowing of the whites of some of his prints to the palladium salt. Has anyone tried whether, like platinum, it enters into combination with gelatine? Mr. Willis avoids gelatine in platinotype papers because of the consequent yellowing of the whites under adverse influences. The old silver-pyrogallol intensifier used by Mr. Clark on paper prints might be expected to degrade the whites, though, perhaps, in the presence of plenty of acetic acid this defect may be avoided. At such meetings as that now under notice, not alone should test solutions be at hand, but a magnesium lamp, by the aid of which to examine the quality of the whites of the prints. It is desirable that at the end of any meeting of a photographic organisation, those who attend shall feel that the time they have given has been fully utilised, and it is easy enough, by means of testing solutions, to get some idea of the probable durability of any class of photographic prints.

GELATINO-CHLORIDE PAPER.

Last week we had occasion to allude to the fact that there were certain printing processes which give extremely promising results, and which present some advantages when compared with the ordinary albumenised paper. These processes are mostly of foreign origin, or perhaps it would be more correct to say that the prepared papers for practising them are not of English make, but are due to the enterprise of Continental neighbours. The papers have fanciful names, but they mostly bear a coating of silver chloride in gelatine.

It is difficult to understand why our own manufacturers have allowed this branch of photographic industry to remain in the hands of foreigners. Bromide paper was conceived, and its manufacture carried out in England long before it could be obtained elsewhere, and chloride paper would seem to be a natural outcome of that enterprise. Why it should chiefly be made abroad is a problem most difficult to solve, for we have had no strikes among photographic employées to drive away trade, and it is not pleasant to English workers to see that constantly recurring and exasperating label on all kinds of goods, "Made in Germany." But this is the case now-a-days with most things, and certainly it is with gelatino-chloride paper, although it may be called by some other name.

This process for printing photographs takes two distinct forms. First, we have a paper which is exposed to artificial light, and is afterwards subjected to a developing process. We first heard of this under the name of alpha paper, five years ago, when its introduction by Messrs. Marion was signalised by a long descriptive article in the *Times*. This paper, it will perhaps be remembered, was used in conjunction with a clever automatic printing machine invented by Mr. John Urie, of Glasgow. A negative was placed in the upper part of a box-like structure, and above it was a crown of gas burners. These burners were turned on at short intervals for a given time, and a strip of paper running over drums actuated by clockwork passed beneath the negative for the necessary exposure to gaslight. The unbroken strip of paper was then developed, and a dozen or more pictures, side by side, and all of the same tone and density, were the result of the operation. This was an extremely valuable process to any photographer in a large way of business where quick results were necessary, for a dozen prints could be delivered, mounted, and finished a few hours after the negative was received, and quite independently of the vagaries of daylight.

The other form in which the gelatino-chloride process is presented to us is a printing-out method, and it is this process to which we must look for the finest results and the widest adoption. Let us enumerate some of its best points. It is far more sensitive to light than ordinary albumenised paper, as anyone may prove by exposing a strip of each to daylight side by side. Long after the gelatine paper has assumed its darkest tone the other is struggling through its usual course from pink to brick red. Next, it is easier to tone than its older rival, and, what is more important, will yield a variety of colours which are impossible with any other medium; indeed, the wonderful colour scale which is possible on lantern-slide plates coated with gelatino-chloride emulsion, and which can be coaxed from them by making slight variations in the composition of the developing fluid, are naturally possible with paper which has been treated with an emulsion of the same composition. The next advantage which may be credited to this kind of paper is the marvellous richness of detail and brilliancy which distinguishes the prints made by its aid, by the side of which prints on albumenised paper appear dull and flat. Nor are these results only achievable from a first-class negative, for one which is thin, and which would yield but a ghostly image by other processes, will give fine results on this gelatine paper. At will, we can produce a matt surface on the finished print, or one with a high gloss, and this is a distinct advantage, for both have their admirers. Lastly, the paper does not quickly deteriorate, but, with ordinary care, will keep good for many months. There is also good reason to believe that the pictures printed upon it are permanent in character.

Most of us have been deploring the great rise in the price of platinum, which is now very nearly that of gold, for it cannot but adversely affect the employment of the salts of that metal in photography; but this ill wind will blow for some good if it only should turn renewed attention to the neglected printing process to which we have adverted. We use the words "renewed attention," for our readers must not forget that between four or five years ago we devoted a good deal of space to the consideration of this subject, and published a series of articles which gave information concerning the methods of compounding the emulsion, and applying it to paper and other supports for positive printing. "Life is too short," many will say, "for us to attempt to make emulsion, or to coat paper for ourselves," and we are inclined to agree with them. Still, it is right that every photographer should know as much as possible about the composition and manufacture of the agents which he uses, and, with this view, his attention was called to the subject. Let us hope that those who have not yet seen how their pictures look when printed on gelatino-chloride paper will try the experiment.

How Will You Take Me?—"I think photography is very interesting," she said to a young man who is in that line. "Yes, it is." "I should like to have you make a picture of me." "With pleasure." "How would you prefer to take me?" He looked at her with a face that showed deep thought, and then replied, slowly, but in a firm voice: "For better or for worse, by all means."—*Washington Post.*

A Wonderful Invention.—Mr. Edison has, say the newspapers, made another wonderful invention. He attaches an instantaneous photographic camera to his phonograph, plants his two lethal instruments right in front of the orator, and sets them to work. The phonograph records every syllable that falls from his lips, every 'hem and er,' and mispronunciation, while the lightning camera simultaneously photographs eight or twenty times every second the movements of the speakers. Then the photographs are projected by a magic lantern the size of life, the phonograph is set going, and the oration can be delivered *ad infinitum.*—*American Journal of Photography.*

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

Considering the enormous number of amateurs at work all over the United Kingdom, and the devotion they show towards "instantaneous" work with "detective" cameras of every conceivable design more or less complex, it is curious that so small a result is seen in the Exhibition. In fact, it may be said with truth that there is no result at all. The reason of this disappointing outcome can only be conjectured. Instantaneous photography, in appearance so simple, is, in the reality, surrounded by difficulties. What can be easier (in theory) than pointing a camera and pulling a trigger? Hundreds of amateurs have started full of enthusiasm to point and pull, and peradventure to develop, and have ended in disgust with their plates, their apparatus, and themselves. The most experienced of instantaneous workers cannot guarantee success, and frankly own that their best pictures are "flukes;" and if this be so, what must be the lot of the hapless amateurs who take up photography—as most of them do—in the firm belief that they have only to point and pull. The number of spoilt plates and ruined films representing the great bulk of amateur efforts must be perfectly appalling. No doubt failures make good for trade, but is there not a risk of a reaction setting in? The craze for speed is fatal to art. The proportion of artists among amateur photographers may fairly be estimated as very small, and if the sole attraction to the average amateur be the possibility of taking an instantaneous picture, as it is to be feared it is, we may be sure that his taste for photography will not be lasting. One does not like to be a prophet of evil, but, judging by the present Exhibition, there is nothing to encourage a belief that photographers are enlarging their ranks.

To deal with this subject in all its aspects would, however, occupy too much space, and I leave it at this point and return to the more immediate matter in hand. Close to Mr. Dresser's instantaneous pictures already mentioned is a clever seascape by Mr. Ernest A. Shipton, "The Return of the Smack" (No. 161), the only defect of which is the unfortunate perpendicular shadow thrown by the mast. Mr. Shipton also sends an effort in another direction, a picture of an old woman who is, to quote the title, "Dreaming the dreams of long ago." There is a superabundance of old women's pictures in the exhibition, and I do not know that Mr. Shipton's dreaming old lady is any better than the rest. Mr. J. E. Austin, besides his medal picture, has a number of others, all marked by the same care and taste, No. 178, entitled "Chaff," being particularly meritorious. Work such as Mr. Austin shows is always welcome; it is unpretentious, and thoroughly conveys the meaning intended. Mr. S. Bourne, in his series 190 to 201, is as neat in his manipulation as of old. Mr. W. Wainwright deserves a passing mention for his English landscapes (Nos. 223 and 228), and Mr. William Atkinson has been very happy in his selection of a view on St. Paul's Cray Common (No. 237). Mr. Frank M. Sutcliffe is too skilful and experienced a photographer to show anything which is not thoroughly good, and his series (No. 251 to 257) has all the qualities with which his work is identified.

Mr. L. E. Westropp exhibits an excellent series of Elmley Castle Church in Nos. 265 to 267, and is equally successful in a view of York Minster (No. 264). Mr. R. S. Redfield deserves commendation for his three pictures, "A Berkshire Hillside," "Wending their Way," and "Hesitation;" but the appropriateness of the two last titles is not quite evident.

Mr. G. Davison's series of pictures (Nos. 289 to 298) does not challenge criticism, as do his more ambitious attempts which have already been mentioned. Yet they are out of the beaten track, and for this reason alone they are acceptable. But they have distinct merits of their own, and will certainly find many admirers.

In No. 310 Mr. Karl Greger gives us some admirable examples of what may be called the old school. After all there is a distinct charm in the delicacy and sparkle which belong to what may be called a purely photographic effect. Extreme sharpness may be offensive to some eyes, but it certainly conveys the effect of sunlight, and this, in these days of sombre tones, is something to be grateful for.

Mr. Matthew Whiting has well utilised his time in his "Country Rambles" (Nos. 313 to 315), but has come slightly to grief in the grouping of the children in No. 313. Children in photographs fully answer the description of a certain young lady who, "when she was good, was very good indeed; but when she was bad, she was horrid." Mr. Whiting's children approach the horrid stage. There they are, all of a row, and all staring at the camera. I dare say it was not Mr. Whiting's fault, for the "cussedness" of children when you want them to do the thing they will not, is too well known.

Mr. J. M. Nisbett has, in his time, done so much good work that, judged by his own standard, his "No Tidings" (No. 323) is disappointing. The figures on the cliff are well enough in pose, but their faces do not invite sympathy, and they appear to be enveloped in a fog appertaining to a "London particular." It may be supposed that Mr. Nisbett intends to represent the dusk of evening; but this is not certain.

Not far from Mr. Nisbett's picture Mr. Ralph W. Robinson's work appears in full force. Farm scenery and life have an irresistible attraction for Mr. Robinson, and he cannot tear himself away from them. What a man chooses to photograph is a matter which concerns himself, and, doubtless, Mr. Robinson finds variety in bucolic subjects; but it may be doubted whether the spectator derives similar pleasure. The models of the fields, whether men or women, are usually stolid persons, in whom it is difficult to infuse anything like expression, and that Mr. Robinson has succeeded so well is to his credit; but is the game worth the candle? Take "Home to Dinner" (No. 331), for instance. The group of figures is arranged with exceeding cleverness, the picture is a well-balanced one, the surroundings are in keeping; but can anyone get up more than a languid interest in the picture? This seems to be the fault of most of Mr. Robinson's work. He fails to fascinate, and lacks that indescribable quality which causes the spectator to linger in front of a picture and return to it again and again. "A Helping Hand" (No. 25) is an example of what may be called missing the point. The keynote of the picture is surely a sad one. An old woodcutter and his wife, bent double with rheumatism and monotonous toil, trudging along under the weight of their burdens, if suggestive of Millet, would at least have been in harmony with the scene; but Mr. Robinson's woodcutter, though supposed to be in need of a helping hand, is neither old nor feeble, while his theatrical attitude is one which it is extremely doubtful a woodcutter ever assumed. If Mr. Robinson bestowed as much care upon the selection of his models as he evidently does upon his photography, how much his pictures would gain. Wide-Angle.

STEREOSCOPIC PHOTOGRAPHY *

BY G. W. WATKINS.

The stereoscope is an instrument by means of which the pictures are presented to the eyes under practically the same conditions as those which obtain when we look upon the natural scene with binocular vision. That the instrument itself is not necessary to enable many to combine the views is a well-known fact, the conditions being that the optic axes shall be so directed that the right eye sees the right-hand picture on the mount, and the left eye the left picture.

It is an unfortunate fact that the stereoscope has fallen away so much in popular estimation. Many attempts have been made to resuscitate it, but so far, I do not see anything like a permanent revival; and it is very rarely indeed that one sees a pair of lenses in use by an amateur. This leads me to ask how it is that, with all the advantages which the gelatine plate offers, this beautiful department of photography is so neglected? To the modern form of camera with its tapering bellows must be attributed a share of the blame, inasmuch as a pair of lenses cannot be mounted upon the front board of such a one. To the possessor of a camera of square form of half-plate or larger size, the only addition necessary is a central division to prevent the fields of the two lenses interfering with each other. I have mentioned a "pair of lenses" above as being the usual method of working, and show such a pair of the single meniscus form of four and a-quarter inches focus which I generally use; but when I started to take stereoscopic views I employed the one-lens arrangement, which I will now describe, as it is quite as efficient as the first-mentioned plan. The sliding cross front carrying the lens is first pushed to one of its extreme positions, the view focussed, then going through the usual routine.

After exposure and re-capping the lens, all that you have to do is to pass the lens over to the other extreme position and again expose. This system of working has the advantage over the special pair of lenses, inasmuch as any lens already in your possession from, say, four inches to seven or eight inches focus may be used. Of course, there is the drawback that objects may have moved during the time between the exposures, but many subjects may be taken by this method when other means are not available; indeed, the movement of small objects, such as persons walking about in a street scene, is not of the importance that might be supposed, many of the older slides being taken by the one-lens arrangement as above, examples of which I produce.

Premising that a half-plate camera will be the size most used at the present time to produce stereoscopes, it becomes a matter of importance to determine the best separation of the lenses (and consequent distance, centre to centre, of the pictures on the negative), because a very small margin exists in the length of 6½ inches (that of a half-plate) from which to cut two pictures, each 2¾ inches wide, after making allowance for the rebate of the slide at each end and the division in the middle. I find that 3⅛ inches is about right; with any material departure from this distance there will be a difficulty in getting the same subject on each side, and still keeping the right width of picture.

As to the matter of exposure, it goes without saying that it must be equal for each lens, and the diaphragms rigidly exact in size. The older stereoscopic pairs were frequently furnished with a double flap-shutter, opened and closed by hand, and this, no doubt, was efficient. Personally, I prefer the double cap for time exposures (and I have attempted none others), and experience no difficulty in removing and replacing it without shaking the camera.

Those possessing a 5 by 4 or quarter-plate camera and outfit can practise stereoscopy without any addition at all to their ordinary appliances, the only departure in working being to take one view as usual, then to move the camera legs, one at a time, to the new position of three inches or more to the right or left, and make the other exposure, taking care that the camera is maintained fairly level and pointed to the object. The development of both plates should take place in the same dish.

My remark, as above, concerning the lateral movement of three inches *or more* reminds me that in a class of views in which there is no immediate foreground, such as one finds in mountainous localities, and where the main objects are at a considerable distance, the points of sight for the two halves may be at a distance many multiples of three inches without producing exaggerated effects, which would certainly result if the same distance were used when objects are close at hand. If this were attempted in the latter case, everything in front would appear more or less drawn out in depth; that is, a tree stem, instead of being round, would assume an oval form, with the longer axis pointing towards the spectator.

I now wish to draw your attention to the reason why it is necessary to have the two halves as they appear on the negative reversed in mounting the prints. This point has often been explained, but many do not seem to master the cause for it. It is found to be necessary on account of the inverted projection of the lens upon the focussing screen, and consequently upon the plate. The lenses invert their images in each half of the camera, *i.e.*, each picture makes a half revolution *around its own centre*: consequently, when the print comes from the negative, and is then held right way up, the half which was exposed in the right side of the camera will be found upon the left side of the print, and *vice versa*, thus necessitating either the cutting of the negative or the print, the latter being usually the more convenient. There is an old method of printing by which neither negative nor print need be divided. The cause which originally obliges us to reverse the prints when printing by contact is ingeniously taken advantage of when copying with lenses in the camera in making transparencies, when, by a second optical inversion, the original positions came back again correctly without further manipulation.

In order to show distinctly the difference between a reversed and a non-reversed print, I have made (for the purpose of this paper) a wire model of a pentagonal prism, photographed it as usual, and mounted the prints—one reversed, and the other not—when the different appearance in the stereoscope is most marked, the unchanged one appearing as if turned inside out, as it were—an effect which has received the name "pseudoscopic," or false sight. The same thing takes place in an uncut print, but the eye is deceived by the physical impossibility of certain objects in the view which we know to be behind, something else appearing in front of them.

In the early days of the stereoscope, before the advent of practical photography, the objects principally in use were figures, such as can be projected in the ordinary way

* Abstract of a paper read at a meeting of the London and Provincial Photographic Association.

from two views of an object in geometrical drawing, a difference being made in the two figures by slightly altering the angle of projection, their appearance being somewhat similar to the slide of the prism already shown you; but you will understand they were not photographs, but printed as white lines on a black ground.

When photography came to the front, it was very soon seen that pictures for the stereoscope were now possible which before could not be produced, or, at least, only done in a very imperfect manner, owing to the minute difference existing in the two halves, and which it was well-nigh impossible to imitate by hand engraving. The result of this popularity was that the stereoscope was rapidly vulgarised, all sorts of objectionable slides were introduced, and this, coupled with bad mounting, either through carelessness or ignorance—the two halves in some cases possibly having been printed from the same negatives, when, of course, no proper effect could be obtained—all these combined to bring into discredit a most charming optical instrument.

I will conclude my paper by saying a few words upon the subject of mounting the prints. Although not absolutely necessary, still it is advisable to so cut them that a trifling amount more of the subject appears on the two middle margins than on the outermost ones, as mounted on the cards—about one-sixteenth of an inch is sufficient. The reason for so doing is that the picture will seem, when viewed stereoscopically, to recede behind the mount in much the same manner as if it were looked at through a window or similar aperture. The height of the prints may be left without limit when using the open instrument, but must be of such height for the old box form as will pass through it.

Levelling the camera in the cross direction when focussing will be found of great advantage when cutting the prints (before separation), because if the base and sky lines are made to pass through the same object in each of the prints, we then know that they are each in a vertical position.

PHOTOGRAPHY IN VIENNA.

The Vienna Photographic Society began its winter session with a meeting held on the 7th of October. The beautiful heliogravures on the walls by Haufstaengel, and the instantaneous photographs by V. Angerer, met with general approval; they showed up well when Professor Luckhart operated with one of Hacke and Alber's magnesium flash apparatus. Professor Luckhart mentioned the forthcoming International Photographic Exhibition of the Club of Amateur Photographers of Vienna, and took the opportunity afforded by the great part that English exhibitors are expected to take in it, to pay English amateurs and professionals the compliment of describing them as the vanguard of the great army of photographers. Dr. J. M. Eder spoke of the great gain to photographic optics by the use of the new Jena baryta glass. Mr. Einsle described his method of equalizing the intensity of negatives under development, by painting with solutions which promote the intensification or reduction of certain parts as required.

The best "kodaker" in America to-day is Miss Alice Longfellow, daughter of the poet. The finest views of the Massachusetts coast are touched off by her in the stormiest and windiest weather. Her illustrated storms are at present gracing the title-pages of a book of sea songs.—*New York Truth.*

THE PHOTOGRAPHIC TOUT.

BY JAMES MEW.

The origin of the word "touter" or "tout" is not devoid of interest. Lexicographers generally derive it from the Icelandic verb *tota*, which means to stand out, to be prominent, an etymology which would well suit that species of the genus tout which is connected with photography. But both the Icelandic *tota* and the Anglo-Saxon *totian* are chiefly used of the prominent position of the lips, whence is formed the Scotch expression "tout", for a pet, or fit of ill humour, with which Scotch word the English "pout" seems closely allied.

The general signification of tout—that is to say, one who plies for customers—may, however, be akin to that of *toot*, or the noise made by a horn. It is possible that the tout originally made his presence known by the blowing of some wind instrument, as at the present time is the case with those uneasy young gentlemen who, arrayed in a consequential demeanour and a red coat, yearn to attract the admiration, or the attention, or the custom of the public by disturbing the thoroughfares with uncanny howls and screeches of various degrees of dissonance. It is a most fortunate thing for the present generation of men that this custom of soliciting notice, which may be classed with the ringing of the muffin and, if it may be said without irreverence, the church bell, is applied to few other trades, and is gradually falling into desuetude.

The photographic tout to be considered in the present paper is himself a photographer—a photographer who proceeds on the time-honoured principle that the man who wants a thing well done must do it himself; a photographer, who stands at his own door, partly, perhaps, from a love of contemplating human nature, and partly from a disposition to philosophical reflection. But probably his main reason is that he cannot afford to pay anyone else to stand there in his stead.

Sundays and Bank Holidays are the harvest times of this photographic tout; the days on which his seeds of eloquence—unless, indeed, they be cast on very stony ground—spring up with more than the suddenness of Jonah's gourd, and bear fruit some twenty-fold and some a hundred. A paper might be written about the seductive arts which this gentleman employs to induce the public to become his customers. Conviction, we are told, affects the understanding, while persuasion subjugates the will. The photographic tout seldom meddles with the former, possibly because of an opinion, derived from a wide experience, that the generality of his customers have little understanding to be affected, but with the latter he is engaged from dewy morn to dusky eve. The end of his eloquence is to induce people to have their portraits taken, and to this end all his arguments are adapted. Now he will assure the lingering wayfarer that he will not detain him a minute, and now he will descant on the cheapness of his work. Now he will assure him—or rather her—that her face would make a most charming photograph, and now he will declare his own theoretical knowledge and practical skill. In a word, he will employ the necessary photographic patter.

But what, the reader may enquire, is the meaning of patter? Dr. Pusey, in a letter to the Bishop of London, in explanation of some statements contained in a letter by the Rev. W. Dodsworth, published at Oxford in 1851, quoting Tyndall's complaint of those who "patter all day with lips only that which the heart understandeth not,"

and his wonder at the blindness of the persons who think "prayers to be the pattering of many words," explains patter as the saying of Paternosters. This, however, is clearly not the meaning of patter as it is conceived by the tout. In the technical language of our own time, patter is the repetition of certain formulæ of persuasion, which are supposed to have the effect of inducing, or, rather, helping to induce, a person in doubt whether he will become a customer to purchase those articles about which the patter is used. Examples of patter are common enough in most trades, but patter is most frequently, and most copiously, and most effectively used where ignorance is supreme, and conceit holds high holiday. Hence, among what are called the "lower orders"—a term only justifiable, not, as it is commonly understood, in consideration of their wealth, but in consideration of their morality or intelligence, and hardly even then consonant with courtesy or with charity—specimens of patter may be heard on Saturday nights in connection with many articles of humble trade, from a "chaney" tea-service to a mouse-trap, from a pair of real coral earrings to a carpet broom. These rhetorical harangues, which constitute the gifted orators who use them the aristocracy of the sellers of the streets, open with the commencement and never end, save with the conclusion of the business on hand; and so it is with the speech of the photographic tout. He must continue his patter with the persistency of rain drops on a very rainy day, or all his labour will be ineffectual. Not till the customer is fairly posed opposite his camera must his well-spring of talk be dried up; and even then it is to his interest to add a few words for the benefit of possible profit out of his customer's friends and relations.

The photographic tout has been much abused. It has been cruelly said of him, when he appears at the sea-side, that he is worse than sharks. But, on the whole, the photographic tout has an honest and a busy—and, doubtless, a profitable—time of it. However, a thorn sprung up long ago in the flesh of this Sunday artist which has not yet altogether ceased to trouble him. As long ago as a quarter of a century of our swiftly passing years, a cry was raised against him for his naughtiness. The good people of that time were scandalised at what they considered his overt acts of impiety and profanation. Rival photographers who indulged themselves with Sunday holidays were especially grieved and loud in their outcries against his open indecorum. They objected to the photographic tout on grounds perhaps a little mixed, like those urged by Mr. Bung, the pious landlord of the "Pig and Whistle," in *Punch* of a few weeks ago. That severe and strict Sabbatarian is represented turning his back with extreme disgust on a band playing upon a fine Sunday afternoon in one of the parks of London to the harmless delight of some hundreds of men, women, and children, and inveighing in good set terms against the Sunday League, whose members have provided this great gratification for the people. "Sunday League, indeed," we hear him saying, "I'd Sunday League them if I'd a chance, a breaking the Lord's day and a hinterfering with my tryde!" But whether the grounds of objection were mixed or simple, it is an historic fact that other members of the photographic trade emitted shrill voices of objection, and many ideas, as their owners called them, were in their own language thrown out, which, perhaps, was the best thing, so far as their owners were concerned, that could have been done with them. One gentleman suggested the imposition of a license on all photographic professional practice; another thought a monster petitition ought to be signed against all Sunday trading; another said that the clergy and the most respectable class—a division of terms which bore rather hardly on the cloth—should take the matter in hand, but what they were to do with the matter after they had got it in hand was left as doubtful as the particular rat who was to bell the common enemy in La Fontaine's fable. Yet another respectable photographer and most honourable householder was of opinion that nothing could close these vile dens, as the premises of the Sunday artist were called in those days, but a thorough education of the general public in art; for, as he lucidly argued, though without any considerable novelty, the demand creates the supply, and if 'Arry and Sairey Jane were taught to distinguish between the artistic high-priced design and the cheap daub, they would infallibly prefer the former, a conclusion to which the adhesion of 'Arry or of his beloved is extremely doubtful, if they reflected, as they certainly would reflect, that the difference between the two prices might be more satisfactorily spent on a treat of tea and shrimps.

(To be concluded.)

PHOTOGRAPHY IN GERMANY.*

BY DR. H. W. VOGEL.

THIS graduation of the apparatus would be good for a certain height of the sun. If the height is changed, the actinic action changes to a considerably higher degree than the optical one. About the absorption power of the air for actinic rays a very few measurements have been made, so far. At vertical incidence of the sun the atmosphere will absorb about 0·20 of the red rays, 0·22 of the yellow rays, 0·30 of the green, 0·36 of the blue, and 0·45 of the ultra-violet rays.

From this, the action of the sun's rays for the several colours at different positions of the sun can be calculated:

Height of the sun.	Red.	Yellow.	Green.	Blue.	Violet.	Ultra-violet.
10 Degrees.	1·	1·	1·	1·	1.	1.
20 ,,	1·88	2·02	2·75	3·80	4·26	5·44
30 ,,	2·31	2·54	3·82	5·73	6·82	9·14
40 ,,	2·55	2·84	4·39	6·99	8·55	12·33
50 ,,	2·70	3·02	4·90	7·82	9·73	14·33
60 ,,	2·80	3·14	5·17	8·46	10·51	15·68
70 ,,	2·85	3·21	5·33	8·70	11·00	16·59
80 ,,	2·88	3·25	5·53	8·90	11·28	17·00
90 ,,	2·89	3·26	5·45	8·96	11·37	17·19

In this table the action of the sun's rays for the several sun elevations are calculated by giving the action at 10 degrees the figure 1†. One sees that while the yellow radiation increases about three times at a sun elevation of 60 degrees, the ultra-violet radiation increases about sixteen times. As the yellow radiations essentially determine the optical, and the ultra-violet particularly the actinic, brightness, the actinic action of the sunlight is five times larger in proportion to the optical action at 60 degrees. If, therefore, the optical brightness were chosen as a measure to judge the time of exposure (by estimating the brightness of the picture upon the ground glass, or

* Continued from page 811.

† That the time of exposure at less brightness must be larger, as the calculation shows, is of not so much consideration, the question being only the insertion of intermediate members.

focussing with a Decoudin photometer), we would expose five times too much at 60, if the time of exposure at 60 is correct.

These proportions are for a bright day. On dark, cloudy days, with increasing cloudiness, the condition of the actinic to the optical action increases, so that on such days the time of exposure can be taken relatively much shorter than shown by the Decoudin photometer. On high mountains the light is also proportionally more actinic than in the valley below. The colouration of the object is also to be considered, green-coloured objects requiring, for instance, a shorter time of exposure than red-coloured ones. The circumstance is still of not so much importance that the law is not so strictly adhered to, whereby at only half the brightness it requires double the time of exposure. The latter has to be increased when the brightness is reduced. This defect can be removed by the above-described graduation.

According to this, it seems, therefore, as if Decoudin's photometer were useless for photographic purposes. With consideration of the above circumstances this simple and handy apparatus should be capable of protecting against under or over-exposure. In the table which accompanies the apparatus, it has been tried to remedy the above defects by noting an unproportionally long time of exposure for only moderate brightness, to which Professor Weber has already called attention some time ago. The supposition was perhaps here, principally, that a reduction of the brightness was mostly caused by a low position of the sun, whereby the time of exposure has to be increased on account of the relatively less active action. One point seems to have been overlooked here, and that is the artistic. This is simply a matter of feeling, and cannot be replaced by any instrument.

The greatest exertion is made now to simplify photography. Boxes are made for the amateur like the kodak, requiring nothing but to turn the roller and to pull the shutter. Whether the object has got the correct illumination or not is, of course, not marked on the kodak, not to mention the artistic impression. The intelligent operator will therefore have enough yet to do. It is the same as with the hunter. A gun is easily loaded and fired off, but it is more difficult to hit the mark. The smart hunter shoots the deer; the incapable and awkward ones will spend their powder on sparrows and cats.

The magnesium flash-light still occupies the minds of practitioners and scientists. Until recently the ordinary magnesium light was considered satisfactory, which, as is well known, is poor for yellow and red rays. Attempts are now being made to relieve this defect, and thereby magnesium light has become an important factor for micro-photography. According to Dr. Röhmann and Dr. Galewsky, in Breslau, two powders proved to be particularly suitable for micro-photography. They are made in the following manner:—

Powder I. These mixtures are made (*a*) of perchlorate of potassium and magnesium in proportion of 138 : 96; (*b*) of perchlorate of potassium and acetate of copper in proportion of 1108 : 724; (*c*) of perchlorate of potassium and sugar-of-milk in proportion of 831 : 342. *a*, *b*, and *c* are mixed together in the proportion of 6 : 1·4.

Powder II.—Seven parts of perchlorate of potassium, 7 parts of neutral tartrate of barium, dried at 100-110° C., 3 parts magnesium, and 0·5 parts of chloride of sodium, are mixed.

For the ignition of both powders a salt is used consisting of 1 part of sugar-of-milk, and 2 parts of chlorate of potassium.

Powders I. and II. are completely harmless, and they explode neither by the hammer nor by slowing heating. Powder II. is used in all such cases where the application of a yellow light filter would otherwise be appropriate.

A microscopic object is taken in the following way: For focussing the object a lamp serves as light-source (albocarbon flame), which is at the end of the optical table. By means of the condensing lens the picture of the flame is thrown upon the ground glass in the well-known manner, and by application of a Zeiss apparatus, and moving the achromatic condenser, it is projected into the flame of the object. The illuminating lens is now covered with a black cloth, and the powder-carrier is pushed to exactly the spot where the ground glass was previously. The carrier consists of an ordinary stand, which carries in a muffle a strong iron wire, at whose one end is fastened a 10 c.m. long and 4 c.m. wide piece of sheet iron with bent edges in rigid connection. Upon this sheet iron a suitable quantity of the powder is placed, and on the small side a small quantity of the igniting salt of the size of a pea is put. The focussing glass is now replaced by the plate-holder, the slide is drawn, and the salt is ignited with a match. In one to two seconds the colourless flash-powder is consumed; the baryta powder burns a few seconds longer. Dr. Galewsky has shown a number of faultless negatives which were taken after this method with a Zeiss apochromatic of 2 mm. and angular aperture 4. They represent to some extent preparations of bacteria coloured with fuchsin and methyl-violet, and partly coloured and uncoloured pieces of woven fabric.

According to the latest communications from Dr. Rohmann, the strength of the above-described powder, consisting of magnesium, perchlorate of potassium, acetate of copper, and sugar-of-milk, is not fully sufficient for thousand times enlargements. In tests to obtain a greater light intensity I found that the simple mixture of equivalent quantities of magnesium (96 parts) and perchlorate of potassium (138 parts) is consumed, with development of only a moderate smoke, and produces a light of quite extraordinary strength when ignited by the before-mentioned ignition salt of 1 part sugar-of-milk, sugar, and 2 parts of chlorate of potassium. Equivalent to this "white flash-light" a "barium-chloride of sodium light" is obtained by mixing 10 parts of flash-powder with 0·5 parts of chloride of sodium, and 1 part of a mixture of 285 parts of dry tartrate of barium and 138 parts of perchlorate of potassium. Both mixtures produced, at a thousand-times enlargement and a small diaphragm, very handsome, strong negatives upon colour-sensitive Obernetter plates.

Dr. Galewsky applied the white flash-light for portraits, and obtained satisfactory results. There is no doubt that this light is also suitable for ordinary enlargements, and it may find yet a more general application.

It has oftentimes been believed that it is possible to obtain a picture with stereoscopic effect if, by means of two lanterns, both halves of a glass stereoscopic picture are projected upon the same spot, so that the pictures cover each other. Such pictures were called photo-binographs. Some asserted that they could actually see the photographic effect; others, again, denied it. Schober, in Antwerp, has now tried the matter in a more successful way. He puts into the one lantern a green, and into the other a red glass, and lets the

spectator look through a green glass with the right eye, and through a red glass with the left eye. In this manner the right eye will perceive only the right half of the stereo picture projected through green, and the left eye only the left half projected through red. The experiments which Schober demonstrated before the Antwerp Photographic Society are said to have been surprising.—*Anthony's Photographic Bulletin.*

APPARATUS AT THE PHOTOGRAPHIC EXHIBITION.

III.

Mr. Fox Shew has on view at the Photographic Exhibition a shutter to work on the hood of the lens, which deserves attention; it is small in size, is always set, renders a lens-cap unnecessary, and gives any kind of exposure at the will of the operator. It is a go-and-return shutter, and Mr. Shew states that it gives no shake. For half-plate size its weight is 6¼ ounces. This shutter, which is shown in fig. 11, is the invention of Signor G. Mattioli. There is an arrangement by which it will remain fully open to permit focussing, and, when fully open, its aperture is almost as large as the lens tube. It is furnished with an india-rubber circular air-cushion, that it may fit upon hoods of different sizes within a limited range, and means exist to tighten the pressure of the cushion by means of a screw. The shutter is made of thin steel. An improvement would be to make as much as possible of it of aluminium, to lighten its weight, which, however, is not heavy as metal shutters go. The leaves of the shutter are represented in the cut as slightly open. The pneumatic pressure for releasing the shutter has to directly overcome the resistance of the spring which works it, so more force is necessary than with some shutters, but not to an objectionable or inconvenient extent. How the shutter will work in continuous use we do not know, but it appears to be a promising instrument.

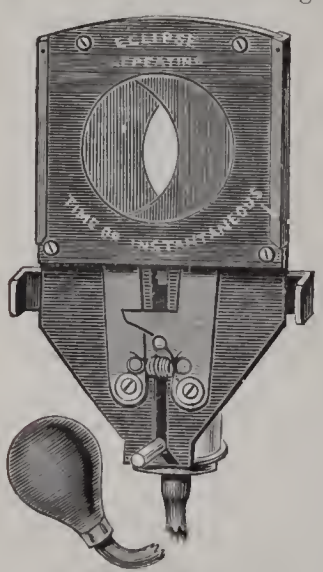

Fig. 11.

Messrs. Sands and Hunter have on view at the Exhibition a camera which they call "The Cranbourn." It is of light make, has a central swing, and the whole camera can be fixed an any part of the base-board. Automatic

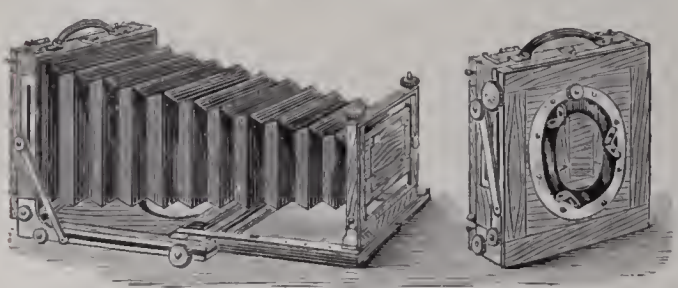

Fig. 12.

spring catches hold the focussing glass in position, and there is an improved arrangement for clamping the rising and falling front of the camera in any position. When closing the camera, the front falls into place without removing it from the runners of the base-board.

The business of the much-respected and old-established firm of Messrs. Sands and Hunter has just been purchased by Mr. J. J. Foster.

THE CHEAPENING OF ALUMINIUM.

The best aluminium combined with a small proportion of silver, seems to be one of the best alloys which can be used in the manufacture of photographic apparatus and lens-mounts.

Some of the cleverest chemists and metallurgists in this country—both with and without the aid of capitalists—are experimenting continually in the endeavour to discover a cheaper way of making aluminium; for when once the metal can be produced cheaply, one of the greatest industries of modern times will have been founded. Vague rumours from Chicago are agitating the minds of these workers to some extent, but the amount of truth in the rumours has yet to be determined: it has been said that an inventor there has found out how to produce the metal at 7½d. per pound.

Invention of last week announces that—

The new Chicago aluminium manufactory is assuming a tangible shape, says *The Chicago Journal of Commerce*. This company, which was recently organised in Chicago for the reduction of aluminium from native clay by Professor J. M. Hirsh's process, is composed of men of means and enterprise, and, it is understood, will soon be ready to enter upon the work for which it was formed. "I will manufacture the metal myself," said the Professor to a *News* reporter; "I can separate it from common clay at a cost of a few cents a pound, by a process entirely different from any now in use." Of course the process is a secret, but evidently one worth knowing, and, besides, a very profitable one. Two five-storey buildings have been leased at the corner of West Twelfth and Rockwell streets, and works on a productive scale, to the amount of about 2,000 lbs. per week, will soon be in operation. A New York mining journal, which attacked the professor's process as a borrowed one, will probably recall its uncalled-for and harsh criticism as soon as the public learns to appreciate the results of his original methods of reducing this remarkable metal, and of cheapening its cost to a degree that will bring it into more general use.

The same journal says that—

The Cowles Electric Smelting and Aluminium Company, of Cleveland, has, according to *The Chicago Journal of Commerce*, announced that they have reduced the price of aluminium to 1 dol. per lb. Heretofore the lowest price of this metal, as a public quotation, has been 2.50 dols. per lb. in small lots. Five years ago, when the Cowles aluminium was first offered for sale, the current price of the metal was 20 dols. per lb., and little, if any, was obtainable even at that figure, and this without any guarantee of chemical purity. The first price made on the Cowles aluminium was 5 dols. per lb. as against the above figure. At 1 dol. per lb. aluminium will become a sharp competitor with both nickel and tin. At 50 cents pure aluminium would become a formidable competitor with copper. The Cowles Company are amongst the largest manufacturers of aluminium in the world—if, indeed, they are not the very largest—and to their success is due the gradual reduction of its cost. The possibilities of the metal have frequently been discussed, and its high price will not, evidently, be an impediment to its general use much longer.

Business Tact.—Unprepossessing female (to photographer): "How much would you take me for?" Photographer: "About sixteen, madam." He got the job.—*Texas Siftings.*

CLOUDS IN BROMIDE PICTURES.

BY GEORGE WHEELER.

An old saw says, "For want of a shoe the horse was lost." We may supplement this by saying, "For want of a sky the picture was lost." Without any sky, or an atmosphere, or something to indicate that the space above the horizon is not an empty void, the representation of a landscape is only half a picture, and therefore incomplete. Unfortunately, this condition applies to many of our photographic productions.

It is comparatively easy to print clouds in silver prints, and Mr. Wade has already dealt with the subject in a masterly style in his paper on "Combination Printing;" but to adapt the same method to bromide printing entails considerable trouble, waste of time, and an abundance of spoiled prints before a satisfactory result is obtained. To overcome the difficulty, I have adopted the plan of painting a sky on the back of the negative, and find that a good variety of effects can be obtained, and in a very short space of time. The examples which I have placed before you will give some idea of the improvement over blank or white-washed skies which has been effected.

Negatives, to be suitable for bromide printing, should be developed with rather thin skies, so that when the exposure is made the light will penetrate the film, and produce a tone in the sky. To obtain a thin sky on a negative, use less pyro and bromide than usual in the developer, and let the fixing be thorough.

Natural skies, taken at the same time as the views, must, of necessity, be preferable to painted or any other skies. These true copies of nature should be made to reveal themselves, if possible, either by an extra exposure to that part of the negative containing them, or by strengthening with paint.

To paint clouds is not a difficult operation, but it needs to be done judiciously, and with some idea of representing natural appearances; it will not be sufficient to put a few dabs of colour here and there. Observation of the forms which the sky assumes, supported by experiment and perseverance, will soon overcome any difficulty.

Paint the clouds on the back of the negative, which, along with the brush, should be held upside down while the operation is being performed. This will cause the colour to flow towards the top of the clouds, where the highest lights are required, and the point of the brush will form the sharpest edges where they should appear. The unusual position of holding the brush will be soon acquired.

Use "Payne's grey" colour, which can be got from almost any artists' colourman. It is a natural, semi-transparent water-colour, and only obstructs the light by its density, and not by its colour. Do not use reds or other non-actinic colours, as they tend to a crude result. Take very little water in the brush, with a small quantity of colour, and apply it with a free touch, always commencing at the bottom and working upwards towards the landscape. Do not cover the sky with a mass of forms; a few outlines, top and side of clouds only, carefully introduced, will prove the most effective in first attempts. When the colour has dried, breathe upon it, and, with the ball of the second finger, go over the irregular lines of colour along the edges nearest the picture, patting and shaping it so as to soften it away to nothing. The finger end will be found to be an admirable working tool. When necessary, additional colour may be added, but, as has been already hinted, do not overwhelm the sky, or the effect may be unreal; rather aim at a suggestion or indication as a relief from the flat tone which would otherwise appear.

The aerial perspective must be preserved, or, in other words, the clouds must not appear as a map or a wall in front of the eye. The perspective formed by the objects on the land demands its counterpart above, and, just as foreground objects are treated by the artist in a bold style, with strong contrasts, so the highest clouds, which are always nearest to us, and stand in the same relation as a foreground, must be made the most prominent. As the clouds approach the horizon, little more than the lower edges are seen, and these gradually assume streaky horizontal lines, with the darkest shades at their base, and fade away in the distance.

The well-defined masses of cumulus clouds usually have their highest lights at the top and on the sides facing the sun. Sometimes they are simply margin-lit—a form which readily adapts itself to pictures, and is easily introduced.

The side lighting must be correct with the lighting of the view. It would never do to have the landscape lit up from one side and the clouds from the other.

Nimbus, cirrus, and other forms and effects may be afterwards attempted, but should be left until experience has been gained.

To obtain soft edges to the clouds, the negative must be held diagonally to the light, and kept revolving during the exposure.—*The Photographic Record*, Manchester.

Wood-Engraving. — Wood-engraving is no longer to be taught in the Art Schools of the Cooper Union, of New York. The authorities base their decision in this matter upon the fact that, except for such as have special genius, wood-cutting is no longer a remunerative profession, on account of the universal introduction of photo-engraving and kindred processes. Although warm advocates of process-work in general, we are inclined to think the authorities in this case are a little premature. Wood-engraving has a field of its own, and skilled workers will be able to find work for some years to come, unless we are greatly mistaken.—*Wilson's Photographic Magazine.*

Gum Arabic.—Professor Leo Liebermann communicates to *The Chemiker Zeitung* a paper on the examination of gum arabic, in the course of which he states that both Senegal and Cordofan gums should dissolve completely in luke-warm water, whereas cherry-gum only partially dissolves, or, at the best, swells up in the water. When the solution is treated with large excess of potash solution and copper sulphate, warmed slightly (not boiled) and filtered, the filtrate and the precipitate may be reserved for examination. The filtrate will contain dextrine if any has been present in the sample, and, on boiling it, the characteristic brick red precipitate of cuprous oxide will be formed should that be so. The precipitate formed by the Fehling's solution, in the first instance, gives the data for conclusions regarding the nature of the gum proper. After washing with distilled water, dissolve in dilute hydrochloric acid, and precipitate with a large excess of alcohol. Allow the precipitate half a day or day to settle, collect it, dissolve in water, and again precipitate with alkali and copper, purifying with hydrochloric acid and water as before. If the sample is pure gum arabic, it is noticed that the precipitate thrown down by alcohol gathers into one lump, and a little of it dissolved in water and boiled with solution of potash gives an amber-coloured solution. The gum senegal precipitates, and it gives no colour, or only a straw colour, when boiled with alkali; but if the precipitate does not agglomerate, and gives an amber colour with alkali, the sample is a mixture of gum arabic and gum senegal. It is also noticeable that the blue copper precipitate formed on adding alkali and copper to the watery solutions of the gums, is more abundant in the case of tree gum arabic than in the case of gum senegal—indeed, in the latter case the precipitate is not at all abundant.

Notes.

The great rise in the price of platinum is likely enough to check the rate of increase of the production of photographs in platinum. Nearly the whole supply of the metal comes from Russia, in which country the Government takes possession of all the platinum found within its dominions, and afterwards sells it to the world at what price it pleases. The original source of supply was the Brazils, but little comes now from South America. Before its value was known, natives and others, while prospecting the banks of rivers for gold and silver, were disgusted when they found pieces of platinum in place of the latter metal, and when they found them would usually throw them into the river. The first workers of platinum were South American Indians; they hammered some of the rarer large pieces into sacred vessels which were used in their temples. Search should be made for platinum in Australia, South Africa, and other English colonies, for it is a metal likely to be overlooked by first explorers, who are not always the most educated class of men. Photographers in the colonies might do well to get their various daily newspapers to draw attention to the existing demand for platinum and its abnormally high price.

At the close of the season just over, the returning travelling public felt the benefit of the removal of the severe system of Custom House examination of baggage, which had been in vogue in Great Britain for several years previously, because of the dynamite scare. For some weeks past passengers with hand-baggage only have been allowed to land at Dover without much notice being taken of themselves and their belongings by the revenue officers. Between Brussels and Dover there are two competing routes, one *via* Ostend, and the other *via* France through Calais. The effect of this is, that the French Custom House officers at the Belgian frontier near Tournai pay little attention to the baggage of passengers coming to England, provided they show their through tickets on demand.

Several inventors are in the field attempting to increase the rapidity by which photographs printed by light can be turned out by the supplementary aid of suitable machinery. The Donaldson Rapid Photographic Co., of 12, Vesey Street, New York, is said to be printing photographs at the rate of about five hundred copies per hour each machine, from a roll of endless paper. Sunlight or a strong arc lamp is used for printing, and the photographs come out at the end of the machine, cut, dried, and ready for mounting. The method is stated to be entirely automatic from first to last.

In *Le Moniteur de la Photographie*, Dr. T. L. Phipson calls the attention of French readers to the out-of-focus "school" of photographers of this country. He says that its advocates want to do for landscape photography what Mrs. Cameron has done for portrait photography, that is to say, to produce pleasing and artistic pictures something like those produced by the crayon of an accomplished draughtsman. Dr. Phipson says that the *Moniteur de la Photographie* was the first to applaud the efforts of Mrs. Cameron and the Viscountess Hawarden, "whose happy essays have never been surpassed in artistic taste, and very rarely equalled."

The lantern season now commencing is sure to see a greatly extended use of compressed gas. Setting aside the time occupied, and the trouble and risk in making oxygen, which it obviates, it insures to the user a pure gas—free, that is, from chlorine—which plays such tricks with the brass fittings of both lantern and bag. This admixture of chlorine is a fruitful source of annoyance when home-made gas is employed. The smell, too, of the impurity is far too pungent to be agreeable, and sticks to the india-rubber bag with marvellous persistency. We have had such a bag (empty, of course) with us on more than one occasion in a railway carriage, not having been disposed to consign it to the tender mercies of a porter, and each traveller, on entering that carriage, has looked round, and given an audible sniff. It is very difficult, under such circumstances, to sit still and look as if you knew nothing about it. The remedy—a bit of caustic soda put into the wash-bottle—is obvious, but caustic soda is not always at hand when wanted.

There is no doubt that the use of a couple of cylinders—one for oxygen, and the other for hydrogen—presents other advantages in saving bulk and weight, for neither bags, pressure-boards, nor weights are needed. But there are some people who will do what they can to put difficulties in their own way. We heard of an amateur lanternist the other day who had purchased two cylinders, which, in order to ensure safety, were painted the one red, and the other black. This, we need hardly point out, is now the universal rule. But our amateur friend could not get over the fancied incongruity of the different tints, so he carefully painted both cylinders sky blue. He then wrote to the makers to ask them how he was to distinguish "t'other from which." The best answer to his question would perhaps be that which is recorded of an eminent chemist with reference to the best way of detecting ammonia: "The best test," said he, "is the *nose*."

The metal aluminum is now becoming common for lens mounts and camera fittings, and, as it daily gets cheaper in price, its use will most surely extend. Perhaps the best and most extensive application of the metal is to be seen in the fittings of the famous hot baths at Bath. In each bath-room here the pipes, nozzles, jets, and other arrangements are all of silvery aluminum, and these fittings are all exposed to view as if the metal were far too precious to be hidden in the walls. And it was precious at the time these works were carried out—now about ten years ago—for improved methods of manufacture had not then cheapened it. Its price was then as stiff as the clay from which it is popularly supposed that the metal is won.

It seems a pity that no agreement is come to as to the way in which this metal is named. Our American cousins invariably spell it *aluminium*, but in this country we generally drop the second *i*. There is not much difference in the appearance of the two words when printed, but a great difference in their sound. We notice that "Chambers' Etymological Dictionary" gives both words, but places the one with the extra letter in a secondary place. Of course, if the word alum had not already been appropriated, it would do well for the metal. Aluminum is better, we think, than aluminium, which seems to have first grown into use as a trade-mark for certain imitation gold articles. Its adaptation to the purpose is probably the result of accident or ignorance, for the snowy white metal is as different from gold in appearance as is chalk from cheese.

Enthusiasm in a photographer is a desirable and commendable thing, but it is only right it should be tempered by discretion. For the lack of the last-named virtue Mr. John Davies, a builder's foreman, has been fined £18 2s. 6d. It happened in this wise. He was anxious to get a good photograph of a certain public house in Kingston, for reasons which, we may suppose, were not wholly unconnected with the licensing sessions, but found that a satisfactory view of the premises was rendered difficult, if not impossible, because of a certain tree which stood in front. It was nothing to Mr. Davies that the tree was considered an ornament to the locality. He attacked it with all the ardour of Mr. Gladstone himself, and lopped off as many of the obnoxious branches as interposed between the house and the camera. Unfortunately, the magistrates could not see the matter in the same light as Mr. Davies, and the result was that they imposed the fine mentioned above. We should like to sympathise with Mr. Davies, but we must confess we are inclined to side with the magistrates.

The movements of the runner, the boxer, the fencer, are of great interest to the physiologist. In this respect instantaneous photography fulfils a distinct mission, as not only the play of the muscles, but even the working of the nervous system, so far as concerns the period of time between volition and action, can, by its assistance, be watched. Some interesting studies have been made recently by M. Marey of the attitudes of fencing, and the rapid changes from one position to the other have been the subject of a series of photographs. The straight thrust of the fencer is deemed the most important. It is executed with such rapidity that neither the one who gives it nor the one who receives it can define either its exact passage through space, or the length of time taken. Here, however, comes in the value of M. Marey's photo-chronographic apparatus. The fencer is placed before the black screen, and his foil whitened with chalk and wax applied to the point. The apparatus, with its rotatory disc, is set in motion, the fencer makes the thrust, and an image of the sword in its passage is secured. As two successive pictures are separated by a period represented by the fiftieth part of a second, the time occupied by the thrust can be easily calculated. In the reproduction of the photograph given in *La Nature*, nineteen separate movements or pictures can be counted; it follows that the thrust occupied $\frac{1}{50}$ of a second.

The photograph which illustrates this curious calculation not only indicates the speed and the sinuosity of the passage taken by the thrust, but shows the simultaneous movements of the extension of the right arm and left leg. M. Georges Demeny, Preparateur de la Station Physiologique, who writes the paper on this interesting subject, says that two fencers may thus be compared in relation to their speed, and the most adroit be awarded the palm. As this is a record-breaking age, we may expect fencers to enter the lists, and vie with each other as to who can make the swiftest sword thrust. The minute fractions involved are, perhaps, a drawback; nor does it sound well, as has been suggested, if the novelist of the future who wishes to be accurate writes, "Our hero's sword flashed, and to thrust it into his antagonist's breast was but the work of four-tenths of a second." But we may get used to these things.

The copyright question is just now occupying a good deal of attention on the Continent, and, from the activity displayed, we may expect before long to see some definite propositions put before the various governments for acceptance. We learn that the French Minister for Foreign Affairs, acting on a desire expressed by the Russian Government, has asked the Syndicate in France for the Protection of Literary and Artistic Rights for any details which it may be able to furnish of infringements of authors' or artists' rights which have taken place since 1861, when a convention was concluded between the two countries. The Syndicate has, in consequence, addressed itself to authors, painters, sculptors, engravers, and photographers, and requested their assistance to enable it to satisfy this demand. A similar request has also been made to the various societies which the Syndicate represents.

The fog of Tuesday week must have been a sore disappointment to hosts of photographers. They had come out, professional and amateur, almost in their thousands, to secure mementoes of the funeral cortege of the Salvation Army, but we are afraid that the results were failures. One enterprising photographer erected a stand in the cemetery with the idea of obtaining a picture of the funeral service, and we read that "through the mist the cameras of photographers could be made out on all hands. The photographers were on house tops and peeping over walls, and most of them commanded a good view of the temporary platform upon which the service was to be held." This seems very suggestive of photographic energy; the odd thing is that rarely is any result evident. Who are these active photographers, and what do they do with the pictures which, we may presume, they take?

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

ALTHOUGH there is a close general agreement between the experimental results and the numbers calculated by means of the equations, yet in individual cases there are discrepancies. Diagram No. 9 shows the theoretical curves in full lines, the actual observations being indicated by dots. This diagram leaves little doubt that the action of the light on the sensitive film is fairly represented by our equation, and, consequently, it may be assumed as proved that the action of the light at any moment is proportional to the amount of light absorbed by unaltered silver bromide.

Nevertheless, we felt that more experimental proof was wanted to support our equation, which represents the resulting density as a function of the opacity of the unexposed plate to blue light. When it is remembered that the density of the unexposed plate is proportional to the silver bromide spread over its area, it will be perceived that this statement means, in fact, that the density of the

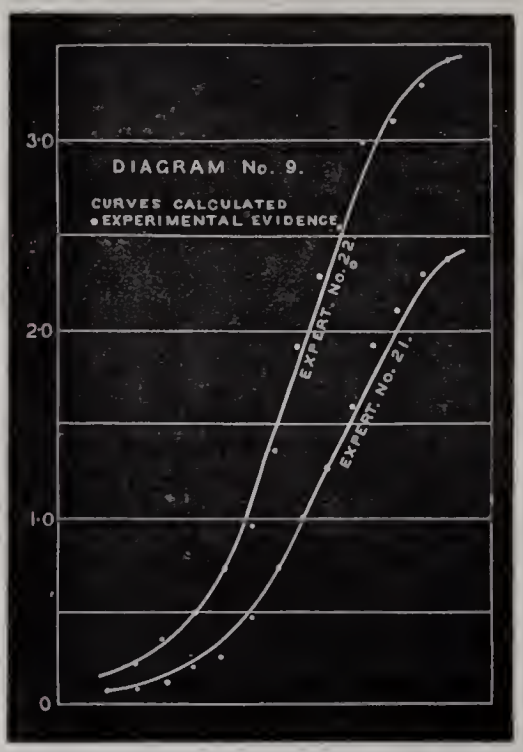

image depends upon the amount of silver on the plate in some way, and this is almost a self-evident proposition.

We prepared sensitive plates of different opacities by spreading on equal areas different amounts of silver bromide. These plates were measured to ascertain their opacity to blue light, and the following results obtained:—

Plates No. I.	Amount of Silver Bromide per 100 Sq. C.M.	Opacity to Blue Light.
	Grms.	
1	0·016	1·738
2	0·031	3·00
3	0·062	10·0
4	0·124	83·0

By means of these opacities four curves were calculated, which are represented in diagram No. 10. To ascertain whether the relative distances between those curves were true, points in each curve belonging to the same exposure (or abscissa) had to be determined in at least two different positions. For this purpose four plates, one of each opacity, were simultaneously exposed, and two different exposures were given of 30 and 240 C.M.S. respectively. The plates were then developed, and the ratios of the densities were taken alone for comparison.

The following results were thus obtained:—

Exposure.	Plate I.	Plate II.	Plate III.	Plate IV.
	Density.	Density.	Density.	Density.
30 C.M.S.	·065	·095	·260	·272
240 C.M.S.	·120	·275	·700	·852
Ratio	1·84	2·89	2·69	3·31

The ratios which are obtained for the theoretical densities, calculated by the equation (2), are the following ones:—

—	Plate I.	Plate II.	Plate III.	Plate IV.
Ratio	1·70	2·50	2·83	3·22

It will be seen that the theoretical ratios agree as well with the observed ratios as could possibly be expected from so difficult an experiment. In diagram No. 10 the relative distances of the curves, as calculated from the ratios obtained by the experiment, are marked by dots.

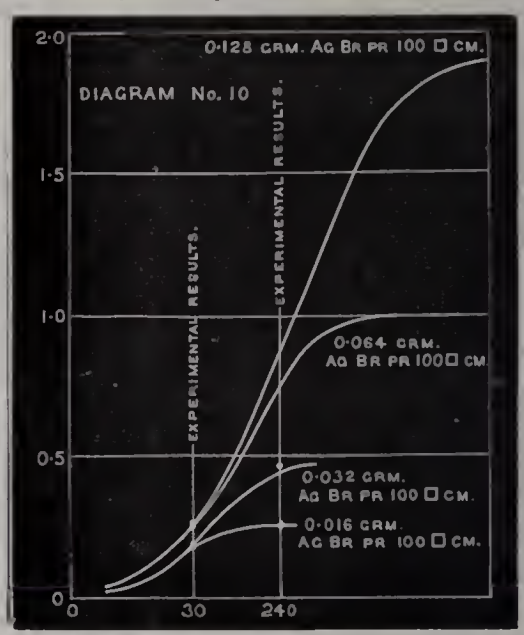

Diagram No. 10 is worthy of some remarks. It will be at once perceived that the more thinly the plates are coated, the shorter is that portion of the curve which is a straight line. This means that the period of correct representation is very short, and great contrasts cannot be truly rendered by a thinly-coated plate. It will also be found, on closer inspection, that the centre of the straight portion is, in each curve, in a different place, and that the thinner the plate, the shorter is the exposure necessary to reach the centre portion. This means that a thinly-coated plate is somewhat faster than a thickly-coated one, though they are made of the same emulsion. A thinly-covered plate, however, appears very much faster than it is in reality. It is incapable of rendering wide contrasts, and hence the negative always looks flat, and thereby gives to the eye the impression of over-exposure.

We have now learnt the great influence which the opacity of the unexposed plate has on the density of the resultant image, and we must now point out a most important source of error in photographic experiments such as we have described. If a plate be not perfectly evenly

* Continued from page 810.

coated, the densities, after development, arising from equal exposures will be different on different parts of that plate. We give here an example of a plate, not a bad one either, on which, in different parts, different exposures were given. The table shows the densities which the same exposure produced on the one half and on the other half of the plate:—

Exposure.	I.	II.	Ratio.
	Density.	Density.	
10	·275	·240	1·14
20	·535	·480	1·12
40	·825	·775	1·06
80	1·185	1·080	1·10

The errors on this plate amount to from 6 to 14 per cent., owing to unequal thickness of the film. It is needless to say that in the dark room, in ruby light, such differences in the thickness of the film cannot be observed. The only remedy for this is to use only very thickly coated plates. We may here say that for our most important experimental work we used slow plates specially prepared for us by Mr. Chapman, of Manchester, every care being taken to secure a thick and even film.

Thickly-coated plates give also very much greater latitude in exposure. The plates used in experiments 21 and 22 would have given good pictures of subjects with contrasts varying from 1:80, though the exposures had varied from 1:2, so that an exposure of ten seconds or one of twenty would have resulted in but little difference in the negatives, excepting that the one would have been much slower in printing, because generally denser. Thinly-coated plates, on the other hand, need very accurately-timed exposures.

(To be continued.)

ON THE DIFFUSION OF FOCUS.*

BY N. E. DUNER.

The distance of the luminous point, between C and D, which is represented by a point, and consequently unaffected by diffusion, is—

$$D = \frac{2D}{1 + \frac{D}{D_1}} \quad \ldots \quad \ldots \quad \ldots \quad \text{(IX.)}$$

or, putting D_1 infinitely great,

$$D = 2D \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \text{(X.)}$$

$$x : d = p - F : p\,;\; x = \frac{d\,(p - F)}{p} = d\left(1 - \frac{F}{p}\right)$$

$$\frac{1}{f} = \frac{1}{D} + \frac{1}{p} = \frac{1}{D_1} + \frac{1}{F} \quad \text{whence}$$

$$\frac{1}{p} = \frac{1}{D_1} - \frac{1}{D} + \frac{1}{F} = \frac{DF - D_1F + DD_1}{FDD_1}$$

$$p = \frac{FDD_1}{DD_1 + DF - D_1F}$$

$$\frac{1}{F} = \frac{1}{f} - \frac{1}{D_1} = \frac{D_1 - f}{D_1 f}\,;\; F = \frac{D_1 f}{D_1 - f}$$

Introducing the value of p in the expression for x.

$$x = d\left(1 - \frac{DF - D_1F + DD_1}{DD_1}\right) =$$

$$d\left(\frac{DD_1 - DF + D_1F - DD_1}{DD_1}\right)$$

$$x = \frac{d\,F}{DD_1} \cdot (D_1 - D) \quad \text{Introduce the value of F.}$$

$$x = \frac{d\,(D_1 - D)}{DD_1} \cdot \frac{D_1 f}{D_1 - f} = \frac{df}{D} \cdot \frac{D_1 - D}{D_1 - f}$$

$$\left.\begin{aligned} x &= \frac{df}{D} \cdot \frac{1 - \frac{D}{D_1}}{1 - \frac{f}{D_1}} \\ d &= x \cdot \frac{D}{f} \cdot \frac{1 - \frac{f}{D_1}}{1 - \frac{D}{D_1}} \end{aligned}\right\} \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \text{(I.)}$$

$$y : d = p - F : F\,;\; y = d\left(\frac{p}{F} - 1\right)$$

$$y = d\left(\frac{DD_1}{DD_1 + DF - D_1F} - 1\right) = \frac{d\,F\,(D_1 - D)}{DD_1 - F\,(D_1 - D)}$$

$$y = d \cdot \frac{D_1 F}{D_1 - F\,(D_1 - D)} = \frac{df(D_1 - D)}{DD_1 - Df - D_1 f + Df} = \frac{df(D_1 - D)}{(D - f)\,D_1}$$

$$\left.\begin{aligned} y &= d \cdot \frac{f}{D - f} \cdot \left(1 - \frac{D}{D_1}\right) \\ d &= y \cdot \frac{D - f}{f} \cdot \frac{1}{1 - \frac{D}{D_1}} \end{aligned}\right\} \quad \ldots \quad \ldots \quad \ldots \quad \text{(II.)}$$

$s : p = 2 : y\,;\; p - s : p = 2 : x$ Consequently,

$$sy = xp - xs \qquad s = p \cdot \frac{x}{x + y} \quad \text{But we have also,}$$

$$z = y \cdot \frac{s}{p} \quad \text{then} \quad z = \frac{xy}{x + y} = \frac{1}{\frac{1}{x} + \frac{1}{y}}$$

$$z = \frac{\frac{1}{f}}{\frac{D}{df} \cdot \frac{1 - \frac{D_1}{D}}{1 - \frac{D}{D_1}} + \frac{D - f}{df} \cdot \frac{1}{1 - \frac{D}{D_1}}} = \frac{df\left(1 - \frac{D}{D_1}\right)}{D - \frac{Df}{D_1} + D - f} =$$

$$\frac{df\left(1 - \frac{D}{D_1}\right)}{2D - f\left(1 + \frac{D}{D_1}\right)}$$

$$s = \frac{df}{2D - f} \cdot \frac{1 - \frac{D}{D_1}}{1 - \frac{f}{2D - f} \cdot \frac{D}{D_1}}\,;$$

$$d = z \cdot \frac{2D - f}{f} \cdot \frac{1 - \frac{Df}{D_1(2D - f)}}{1 - \frac{D}{D_1}} \quad \ldots \quad \ldots \quad \ldots \quad \text{(III.)}$$

$$s : F = z : d \qquad s = F\,\frac{z}{d}$$

$$\Delta = F + s = F\left(1 + \frac{z}{d}\right) = \frac{D_1 f}{D_1 - f}$$

$$\left[1 + \frac{f}{2D - f} \cdot \frac{1 - \frac{D}{D_1}}{1 - \frac{Df}{D_1(2D - f)}}\right]$$

$$\Delta = \frac{D_1 f}{D_1 - f}\left[1 + \frac{f\left(1 - \frac{D}{D_1}\right)}{2D - f - f\,\frac{D}{D_1}}\right] =$$

* Concluded from page 802.

$$\frac{D_1 f}{D_1 - f}\left[\frac{2D - f - f\,\frac{D}{D_1} + f - f\,\frac{D}{D_1}}{2D - f - f\,.\,\frac{D}{D_1}}\right] =$$

$$\frac{D_1 f}{D_1 - f}\,.\;2D\left(1 - \frac{f}{D_1}\right) : \left(2D - f - f\,\frac{D}{D_1}\right)$$

$$\Delta = \frac{f}{1 - \frac{f}{D_1}}\left[1 - \frac{f}{D_1}\right] : \frac{1}{1 - \frac{f}{2D} - \frac{f}{2D_1}} =$$

$$1 - \frac{f}{\frac{f}{2D} - \frac{f}{2D_1}} = \frac{2Df}{2D - f - \frac{2Df}{2D_1}} =$$

$$f\,.\,\frac{2D - f - \frac{Df}{D_1} + f + \frac{Df}{D_1}}{2D - f - \frac{Df}{D_1}}$$

$$\Delta = f\left[1 + \frac{f + \frac{Df}{D_1}}{2D - f = \frac{Df}{D_1}}\right] =$$

$$f\left[1 + \frac{f\left(1 + \frac{D}{D_1}\right)}{2D - f\left(1 + \frac{D}{D_1}\right)}\right] \quad \ldots \quad \ldots \quad \text{(VII.)}$$

$$\frac{1}{f} = \frac{1}{\Delta} + \frac{1}{Do}\;;\quad \frac{1}{Do} = \frac{1}{f} - \frac{1}{\Delta} =$$

$$\frac{1}{f} - \frac{1}{f}\,.\,\frac{1}{\frac{1 + f\left(1 + \frac{D}{D_1}\right)}{2D - f\left(1 + \frac{D}{D_1}\right)}}$$

$$\frac{1}{Do} = \frac{1}{f}\left[1 + \frac{f\left(1 + \frac{D}{D_1}\right)}{2D - f\left(1 + \frac{D}{D_1}\right)} - 1\right]$$

$$: \left[1 + \frac{f\left(1 + \frac{D}{D_1}\right)}{2D - f\left(1 + \frac{D}{D_1}\right)}\right]$$

$$Do = f\left[1 + \frac{2D - f\left(1 + \frac{D}{D_1}\right)}{f\left(1 + \frac{D}{D_1}\right)}\right]$$

$$Do = f\left[\frac{f\left(1 + \frac{D}{D_1}\right) + 2D - f\left(1 + \frac{D}{D_1}\right)}{f\left(1 + \frac{D}{D_1}\right)}\right]$$

$$Do = \frac{2D}{1 + \frac{D}{D_1}} \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \ldots \quad \text{(IX.)}$$

Photographers' Benevolent Association.—At a meeting on the 17th inst. (Mr. W. Benham in the chair), two applications for assistance were granted, and Messrs. Lott, H. Chapman, H. G. Parry, H. Francis, W. J. Tabrum, A. E. Dean, G. W. Pember, and F. Dudman were elected members.

Photographic Society of Great Britain.—Technical meeting on Tuesday, October 28th, at the Exhibition, 5A, Pall Mall East, at 7·30 p.m., when the whole of the apparatus will be shown and explained. At the lantern show on Monday, October 27th, the "Field Club" will exhibit its slides.

REPORT OF THE PROGRESS OF PHOTOGRAPHY DURING THE YEAR CLOSING AUGUST, 1890.*

BY W. H. H. CLARK.

Photographic Optics.—While there have been some improvements in lenses and lens mounts, which are no doubt of great importance, much yet remains of accomplishment before the maximum of our desires is reached. In lens mounts, aluminium, or aluminum, appears to be the coming metal, owing to its great strength and extreme lightness; also its freedom from tarnishing. The announcement was recently made of the invention of a lens that will be in focus for any and all distances, the same as the human eye. I am not, however, prepared to state this as an accomplished fact. As perfect as our lenses are, their full powers are not always understood, or brought into requisition by those using them. Often this is occasioned by a too short operating room. The lens in use cannot be removed a proper distance from the subject, hence an exaggerated perspective; and here I will quote Dr. Vogel in "Anthony's International Annual for 1888," which may prove of value to the progressive artist photographer. The doctor says:—"Artists place their models always higher than they stand themselves. Photographers, on the contrary, do the reverse, that is, the former is generally in a higher position than the sitting person. Photographers give for this an optical reason; with full opening of the objective, face and hands can be brought out with more sharpness in a sitting position if the apparatus inclines towards the front. But we should not be forced any more to this necessity. With the use of our present highly sensitive dry plates, and the application of smaller diaphragms, we ought to be able, particularly with the application of our improved cameras, to obtain hands and face sharp without inclining the apparatus. It is, therefore, a question whether it is not time now to adopt the arrangements of the artists."

Electricity is coming more and more to the front, and being brought more and more into intimate connection with photography. We have it now for lighting our studios, also the subject to be photographed, for printing by enlargement, for heating the burnisher, and furnishing power to operate the same; but the subtle fluid, so little known and understood by man, is destined to play a far more important part in connection with photography in the very near future. Balloon and kite photography, now successfully accomplished, would not be possible without its aid.

Photographic applications to the Sciences become more varied and numerous each year. Without doubt the most astonishing results in all of the sciences have been produced in astronomy by the aid of photography. *Ad astera per aspera.* To the stars through difficulties.

A photographic marvel is, after an exposure of thirty-three minutes, the same instrument which renders visible to the human eye stars of the fourteenth magnitude, which in the entire heavens would register about 44,000,000 of stars, shows to the photographic eye 134,000,000, and on an exposure of one hour and twenty minutes would throw before the astonished gaze of the beholder a luminous dust of 400,000,000 stars. Never before in the history of humanity has man possessed the power of penetrating so profoundly into the depths of the infinite. Photographs of the star Mizar, in the handle of the Big Dipper, show that star to be double, or that there are two suns too

* Continued from p. 812.

close to be distinctly separated by any telescope, and it was noted that on certain occasions the lines in the spectrum of Mizar were double. After continued photographing, it was found that the lines were doubled once in fifty-two days. The star Menkalina, the second in magnitude of the constellation Auriga, has also been found by photography to be double. I have received from Mr. S. W. Burnham, of the Lick Observatory in California, some beautiful examples of photographs of the Milky Way, the Corona during a total eclipse of the sun, and other celestial bodies, as photographed through the great Lick telescope. In this connection it will be interesting to show the progress of astronomical photography, by quoting from a report on "Celestial Photographs," by E. E. Barnard, M.A.:—"Two negatives were made of the great nebula of *Andromeda*, with exposures of 3h. 15m. and 4h. 18m. Throughout these exposures, as in the other cases, the eye was kept constantly fixed on a star bisected by cross wires in the eye-piece, and the clock controlled by the slow-motion rods. Both negatives clearly show the dark spaces and the nebulous rings that were first shown to exist by Mr. Roberts in his exquisite photographs of this nebula. The rings of nebulosity are seen at a glance, though the image on my negatives is on a small scale, the full extent of the nebula covering one inch. I tried to see these with both the 12-inch and the 6½-inch, but without success, though the so-called "canals" on the north side are clearly seen in both instruments. In studying the distribution of the stars in space and the structure of the Milky Way, it is clear that any legitimate means of exaggerating peculiarities, or, rather, of bringing them out more strikingly, is greatly to be desired. It would appear that the best way to do this is to photograph large areas of the sky so as to include enough material. If, now, we reduce this to a small scale, relations that would otherwise escape the eye are brought prominently forward. Acting upon this idea, I have made reduced copies of the above negatives. The result is striking. In the Milky Way pictures the cloud-like masses of stars stand out more boldly, and their forms are more definite than in the original. Reduced in this way, the picture of the region of the *Andromeda* nebula is singularly beautiful; and it shows in a most remarkable manner the peculiar structure of that part of the heavens. The intricate arrangements of the stars in rings and segments are thus shown as nothing else can show them. Previous to these experiments, at Professor Holden's suggestion, I had attempted to photograph the Milky Way with a 1-inch (9 inches focus) Voightlander lens mounted on the 12-inch and the 6½-inch telescopes at different times. These exposures—running up to an hour and a half—showed absolutely no trace of the cloud-forms that are so striking to the eye. The plates were, however, literally sprinkled with stars, most of which were beyond the reach of the eye alone, and therefore much less bright than the Milky Way itself. The sensitive plate was not deceived by a quantity of light as the eye was; but, as its action depends upon the intensity of the light, it had gone to work systematically to pick out the individual stellar points of the Milky Way. Of course, we know, if it had had time enough, it would have finally begun the impression of the luminous groundwork. Nothing could show more beautifully the difference between intensity and quantity in the action of light upon the sensitive plate than these attempts to photograph the Milky Way." The great Lick telescope is now supplemented by a remarkable piece of mechanism—an eyepiece which has just been completed—outrivalling anything of the kind before made. The largest before in use was not over two inches in diameter, while the new piece measures over three inches. The light from the heavenly bodies seen through the Lick telescope and this new eyepiece will be two thousand times as bright as that seen with the naked eye. With the increased powers of the new telescope now in process of construction for the University of Southern California, we may look for still greater advance in stellar photography. Mr. Alvin G. Clark, probably the most famous optician in the world to-day, has received the glass for the 40-inch objective, and which weighs over two tons. For the sum of $108,000 he agrees to make the telescope complete, visually and photographically. When it is remembered that with the Lick 36-inch glass the moon is brought within about 100 miles of the earth, with this new power in the hands of the astronomer we may expect to be able to produce better photographs than heretofore of our satellite.

(*To be continued.*)

THE CAMERA AND ITS VARIOUS MOTIONS.

BY PROFESSOR W. K. BURTON.

Introductory.

From the cameras of the time of Daguerre—of which we learn that the whole wooden sliding-box that constituted the arrangement had to be removed to the dark room for the insertion of the plate, the exact position of the camera on a kind of table being first marked—to the most modern forms of landscape cameras, with double swing-backs, double-action sliding fronts, revolving front, revolving base-board, and heaven knows what not all, what a stride there is!

Indeed, the complications of the modern camera have become such that there are those who say that some of them are worse than useless, and that they would prefer to have cameras lacking many of the most modern improvements.

In this matter I incline in part, at least, to agree. In the most complicated of modern cameras there are many motions, some of which come into use so very seldom that the complication arising from their presence rather detracts from the general usefulness of the camera than otherwise. Still, it must be admitted that every motion—so far as I know—that has been added even to the most complicated, has at least some occasional use, and that it must be a matter of opinion as to what extent the "game is worth the candle," or, to be plain, at what point the advantage of further motions is more than counterbalanced by the disadvantage of the additional complication.

One thing is quite certain: every motion that a camera has that is not thoroughly understood by the user, is a disadvantage rather than the reverse. As I have seen many amateurs struggling with cameras in which the various complications were evidently impediments instead of useful additions, I venture to think that a few short papers describing, as concisely as possible, the various motions in a modern landscape camera, may be useful to some readers. What I have to say will be chiefly, or perhaps I should say entirely, addressed to amateurs, and for that reason will refer almost entirely to the landscape camera. Of the various forms of landscape cameras in use in England I think I may say that, from the old-

fashioned sliding wooden box camera with which I took my first negative, to the most modern of cameras—a brilliant mass of polished mahogany and brass—I have either actually worked, or helped in the working, of nearly every one; I should, perhaps, except the genus "detective camera." Its name is truly legion, and I doubt if any human being could boast that he has used every variety that is offered in the open market.

(*To be continued.*)

A FEW HINTS AND DEVICES.

BY F. M. GILES, M.B., F.R.C.S.

The few notes that are offered below do not pretend to be in any way original, but are mostly plans suggested in photographic periodicals which have stood the test of trial.

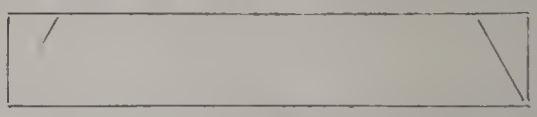
1. *Apparatus for Developing.*—No doubt the plan to be described has often been used by photographers who, like myself, are accustomed to work at volumetric analysis; but I do not remember seeing it suggested anywhere. Everyone knows the spilling, delay, and annoyance involved in measuring out solutions by means of measure glasses in the chastened light of the dark room, all of which may be avoided, together with the attendant staining of the fingers, by the plan described below.

Procure three burettes, holding about 25 c.c. each, and graduated to either the metric or English system, as preferred; three short pieces of rubber tube, 2½ inches long, to fit the burettes; three glass jets for ditto; and three pinch-cocks. Place the three burettes, duly fitted up, in the holders of a burette or retort stand. Prepare three labels of black, non-actinic paper, as large as can conveniently be affixed to the burettes, and mark with a brush dipped in scarlet vermilion water-colour a large A on one, B on the other, and S on the third, the letters being made thick and as large as possible; when dry, give each a dab of varnish to prevent their washing off. Now fill A with alkaline solution—saturated solution of carbonate of soda is what I prefer; B with ten per cent. solution of bromide of ammonia; and S with sulpho-pyrogallol—the letter S being used instead of P for pyro because the latter is too like a B to be a safe sign to use in the dark room. The quantities required for the development of each plate can now be measured off on the graduation of the burettes with the greatest quickness and ease.

There is no need to empty the burettes after use provided each be furnished with a well-fitting cork, which is only removed during actual use; the fluids would, of course, not run with the corks *in situ*. The first drop or two of the sulpho-pyrogallol may be discoloured if many hours have elapsed since use, but not more, and, in this case, should be rejected; but the waste from this source is insignificant.

The whole apparatus can be got at a very small cost from any of the large chemists' stores in the Presidency towns, but can be easily made up at home from glass tubing by the aid of a big spirit lamp. About four feet of soft English tubing, ⅜ internal bore, are required for the burettes, and about a foot of ¼-inch soft tubing for the jets. They can be graduated by gumming a very narrow strip of black paper along one side, measuring the contents of a given number of inches by means of a measure glass, then marking the divisions in bold lines in vermilion, and finally varnishing. A burette stand, too, can be easily knocked up out of a few pieces of wood, the tubes being pinched into notches in a horizontal bar by a lath held against it by rubber correspondence bands, notches and lath being alike guarded with wash-leather.

2. *Developing Trays, Cheap and Self-Cleansing.*—Most of our members are acquainted, no doubt, with that very useful water-proof material, Willesden paper. It forms by far the best material for developing trays I have met with. The trays are made by cutting out a square 2½ inches larger each way than the required size of plate, and folding up the sides in the way children make a paper box. The corners are secured by a few stitches along the edge, the finished tray presenting the appearance as below. Now paint with a brush dipped in vermilion in



very large, bold letters, in the middle of the bottom in the inside, a word indicating its future use, such as pyro, oxalate, toning, hypo, &c. Next, melt in a beaker or an old jam tin some solid paraffin, about 125° melting point; a paraffin candle will do, or, if paraffin cannot be procured, use an ozokerite candle, or even the stearine of a common or domestic composite. Heat this up so that the temperature of the fluid is well above the melting point—nearly boiling, in fact. Place your paper tray on a piece of window glass, and pour into it the whole of the contents of the beaker. Tilt the glass quickly to all four sides so as to wet the sides up to the edge, and then pour back into the beaker, doing all as smartly as you can. When in use, the trays are held on a slip of window glass an inch larger each way than the size in use. They have many advantages over any other form of tray, of which the following are the most important:—

First.—They require no cleaning, as, when emptied, the water runs off them as it does off a duck's back, so that they become quite dry instantly. As the fluids never adhere, pollution of one solution by another becomes impossible, even if the same tray be used for several purposes.

Secondly.—The weight of the contained fluid presses them down on to the piece of glass on which they are held, so as to obtain a perfectly flat surface, so that less solution is required than with any other tray. It is easy to develop a whole-plate film with six drachms of solution.

Thirdly.—Besides being very cheap, they are so portable that half-a-gross would scarce weigh as much as a single porcelain tray. For camp work nothing is so suitable as half-a-dozen of these trays, carefully made so as to "nest," and packed in a japanned tin case open along one side, so as to form a deep, narrow tank, and provided with a tin or brass spout near the bottom, on to which is slipped half a yard of rubber tubing fitted with a pinch-cock. The outer case then serves as a water-tank when developing.—*The Journal of the Photographic Society of India.*

Those who use straps in connection with the cases of photographic apparatus may be interested to know that in Geneva newly-invented buckles are on sale which look like ordinary buckles, but can be locked after fixing the strap.

Impertinence of Photographers.—Mr. Blimber (alarmed)—"My dear, what is the matter?" Mrs. Blimber (sobbing)—"That insulting old photographer sent back word with my crayon: 'The original of this portrait is carefully preserved.' The hateful thing!"—*Detroit Free Press.*

Patent Intelligence.

Specifications Published.

12,375. *August 7th*, 1890.—"A Substitute for Bone or Celluloid." William Marshall Campbell Callender, 101, Leadenhall Street, London, Engineer.

This invention relates to the manufacture of a new material designed to serve as a substitute for bone or celluloid, and which I term "Lactite."

The "Lactite" is produced by reducing casein (or the solids in milk) to a partly soluble or gelatinous condition, by means of borax, or ammonia, or by other suitable means, and then mixing it with a mineral salt dissolved in acid or water or acid and water, which liquid is subsequently evaporated.

In carrying out the invention, I advantageously place ten kilogrammes of casein in a vessel, and incorporate it under heat with three kilogrammes of borax previously dissolved in six litres of water. When the appearance of the casein becomes changed I draw off the water, and the residue will then be of a consistency somewhat resembling melted gelatine, and while in this state I add one kilogramme of a mineral salt held in solution by three litres of acid. Almost any of the salts of iron, lead, tin, zinc, copper, or other mineral salts which are soluble in acid may be used. The acid employed depends upon the salt used, as only such acid should be used as will properly dissolve the salt. The salt employed depends upon the exact colour required in the finished material. In practice I have obtained good results by the use of acetate of lead and acetic acid. The solution of the mineral salt in acid must be thoroughly incorporated with the previous mixture of casein and borax; this is a matter of some difficulty, but can be accomplished in a mechanical mixer. When the mixture is effected the solid matter will be found separated from the greater portion of the acid and water, which should now be drawn off. The solid matter should be subjected to great pressure to drive out all possible moisture, and any moisture which may remain should be evaporated under great heat, or by other suitable means, the resulting product being the new material. The new material may either be supplied in the form of sheets or rods, or moulded in any form desired, and it can be coloured, as required, either by the admixture of pigments or by aniline or other dyes.

The cost of the material may be lessened by the admixture of a certain proportion of other substances, such as precipitated lime or chalk, or other similar substances soluble either in the acids, in the casein, or in the borax and water.

Instead of rendering the casein soluble or gelatinous by means of borax, I may effect the same result by the use of ammonia, or by any other suitable means.

The combination of the materials can be effected in many ways, and I do not bind myself to the precise details above described, or to any exact process of manufacture or proportions of the different ingredients used in such manufacture, as these can be varied according to the exact use for which the "Lactite" is intended; for general purposes, however, I find satisfactory results from the above described process, proportions, and ingredients, and they will sufficiently illustrate the subject of my invention.

What I claim is:—

1. The manufacture of a new material designed to serve as a substitute for bone or celluloid by reducing casein into a partly soluble or gelatinous state by mixing it with borax, or ammonia, or by other suitable means, then combining the mixture with a mineral salt dissolved in acid, the free acid being subsequently evaporated, substantially as hereinbefore described.

2. In manufacturing the material as described in claim 1, the admixture of other subtances for the purpose hereinbefore described.

3. In the manufacture of the material described in claim 1, the use, instead of acid for dissolving the mineral salt, of water or of water in combination with acid.

4. The new material designed to serve as a substitute for bone or celluloid, substantially as hereinbefore described.

16,492. *October 18th*, 1889.—"Washing Trough for Prints." Percy Ellis, The Manor House, Wallington, Surrey, Gentleman.

This invention has for its object the construction of a trough for washing photographic prints, photographic negatives, and the like, which shall be simple in construction, and shall automatically empty itself when filled or nearly filled with water or liquid.

The trough is shaped or formed as follows:—

Three of its sides and the bottom are rectangularly disposed with respect to each other. The fourth side is joined to and inclined upwards from the bottom of the trough, and outwards or away from the side to which it is opposite, thus leaving an angular space between the inclined or fourth side and the surface on which the bottom of the trough rests. Two of the three sides of the trough which, as already mentioned, are rectangularly disposed with respect to each other, are prolonged so as to join the inclined or fourth side. Thus it will be seen that a side elevation of the trough would be a figure formed of a rectangle joined to a right-angled triangle, the hypothenuse of the latter forming the fourth side of the trough, and one of the sides of the right angle being continuous with the top of the trough.

The trough is weighted at that side or part opposite to the inclined or fourth side in such manner as to cause it to stand upright or on its bottom when empty or partly filled, and also to allow it to automatically turn over and empty itself when the trough is nearly or entirely filled or the height of the water has exceeded a certain limit. When the water has been emptied to the requisite amount the weight will cause the trough to return to its normal position with its bottom on the surface on which the trough rests.

I provide the trough with a false bottom, which may be removable if desired, upon which I place the photographic prints to be washed when the trough is to be utilised for this purpose; and I fix a wire or other reticulated partition to the trough at the middle or other part of the fourth side, to prevent the photographic prints from being washed away when the trough empties itself.

When the trough is to be utilised for washing photographic negatives, the negatives are inserted in a holder and the holder placed in the trough. The latter may be provided with supports for bearing the said holder.

By the construction of trough above described, which automatically empties itself, I am enabled to dispense with the siphon arrangements used for that purpose.

Bedford and District Camera Club.—At the meeting on Tuesday, October 25th, a paper will be given by Mr. D. Beaman on the "Making of Stereoscopic Negatives."

Developing Dishes.—Messrs. Samuel Fry & Co. have sent us a dish with wooden sides and a glass bottom in which to develop lantern plates. A projecting pin prevents the plate from resting flatly on the glass bottom, and enables it easily to be raised for removal. Developing dishes with bottoms of ordinary sheet glass, and with sides of paraffined wood, are, when well made, likely to become popular, especially with those who use glass-platformed rocking tables, and wish to examine plates in the developer by transmitted light.

A Sulphocarbide of Platinum.—At a recent meeting of the Paris Academy of Sciences, a paper was read on "A Sulphocarbide of Platinum," by M. P. Schutzenberger. By passing a current of dry nitrogen charged with the vapour of carbon bisulphide over spongy platinum contained in a glass tube heated to about 400° C., the carbon bisulphide was entirely absorbed, and the platinum converted into a finely-divided black powder. An examination of the product showed that it had the composition Pt_2S_2C. The powder is very dense, and appears entirely homogeneous when microscopically examined. Neither hydrochloric nor nitric acid have any action upon it, and even with *aqua regia* there is very little action. When heated to redness in dry oxygen the powder burns, with the formation of carbon dioxide, and sulphur monoxide and dioxide, leaving a residue of pure platinum.

Correspondence.

MR. LYDDELL SAWYER'S PICTURES AT THE CAMERA CLUB.

Sir,—Mr. Lyddell Sawyer's reply to the critique of his pictures now at the Camera Club was not conceived in an unkiudly spirit, and I should not have thought it necessary to make any reply, but that there are one or two assumptious in his letter which do injustice to the cause of naturalism.

Mr. Sawyer assumes that uaturalism does not admit of any arrauging and posing. This is certainly not the case. Naturalism forbids the use of means aud the application of principles which must of necessity introduce artificiality and waut of harmony ; but it certainly does not condemn "arranging and posing." It is where puerile subjects have been treated, and badly treated, that naturalism takes offence at Mr. Sawyer's productions.

Mr. Sawyer also makes capital out of a false assumption that his critics are not aware that the figures in "Waiting for the Boats" and "On their own Hooks" are arranged. The fact is, these photographs are liked because the figures are *naturally* arranged in their proper and fitting characters and occupations.

The astonishing refereuce to pure landscape art as "the insignificant proceeding of pilfering pictures of nature's sole production" may be allowed to work its own confutation in every sensible person's miud.

Mr. Sawyer is improving in this letter. A little severity with himself will soon render hostile criticism unnecessary.

October 20th. X.

SPHERICAL ABERRATION AND DEPTH OF FOCUS.

Sir,—Absence from town has delayed my notice of Mr. Debenham's article on the above subject in your issue of the 19th ult., aud I regret that it is necessary to further trespass upon your space, for, although a record of Mr. Debenham's views, it must not go unchallenged in its statements auent the subject under discussiou. First, to history. I have for reference the *British Journal of Photography* aud the *Photographic News* of 1867. Iu the former: "Mr. Debenham said he proposed to show that the effect of introducing spherical aberration, as advocated by Mr. Dallmeyer and others, was to eularge the circle of confusion at all points anywhere near the focus of a lens, and at no part of the path of light to diminish it." Then follows au explanation dealing with transversal measurements that I have exploded.

In the *Photographic News* Mr. Dallmeyer's reply was: "In relation to as much as he could understand of Mr. Debenham's remarks, he seemed *to have overlooked the fact entirely* that the effective power of the rays was *altogether altered* by the diffusion of focus. He might easily satisfy himself, however, by reference to practical illustrations, when he would find that by such diffusion objects in planes wide apart were better defined, not simply relatively, but absolutely."

The last five words brought about the commeuts from the late Mr. Grubb and the comparative diagrams. Mr. Grubb's diagram compared lenses of unequal foci, and was erroueous in calling the least circle of aberration that of best focus, as I showed in a properly disposed diagram, in this respect, in my recent paper. (I fouud Mr. Grubb's diagram somewhat indistinct, and purposely favoured it in the direction of a more correct disposal to avoid any hair-splitting.)

Mr. Debenham now comes in with astounding statements from a practical photographer of many years' experience, and a discovery (save the mark) of a "phase of the case against spherical aberration that has not, I think, as yet been enforced"!

The apex of the axial coue of rays leaving the lens, as I have previously shown, is the best focus, and Mr. Debenham *still tries to controvert* it. Let Mr. Debenham first have corroboration of this froun Monckhoven's optics ; second, let him take a wide-angle landscape lens—that is, without spherical aberratiou up to about F/15—aud focus carefully ; then open out the aperture for excessive positive spherical aberration, and see if the plane of best focus alters. Then take a patent portrait combination well unscrewed, and get his best focus, and see how much stopping dowu by diaphragms to remove it alters the plane of best focus.

The view of the case taken practically is, that there is a more or less considerable available aperture for perfect coucentration, and when this is overstepped, and aberration is introduced, the iuterference is distributed along the axis towards the lens, and weakens the effective defiuition of that portiou of the lens available for an aplauatic focus.

The uselessness of Mr. Debenham's "new aspect" is due to his entire neglect of the value and dispositiou in image formation of the interferiug spherical aberration *after the limit for aplanatism is passed*. Wheu this limit of area is passed, every increment of aperture has a different focus on the axis towards the lens, any given measureable zone having no focus at all, but throws, in its projection, halos around the originally distinct iuage. Every astronomer knows that the test for spherical aberration is the observation that the image lingers partially distinct beyond the best focus, and vanishes more rapidly inside the focus.

The practical test Mr. Debenham refers to (as having been characterized by me as au unfair one) is the best I could recommend, and he could not have made himself clear on the occasion referred to. I fail to find it recorded, but recommend Mr. Debeham to carefully repeat it, as *his* experience is unique.

The final paragraph of Mr. Debenham's article is quite in keeping with the rest of his "record" iu controversy with me. It speaks too openly for itself for me to waste time in commenting on it. For reply, and the inference to be drawn, I quote my own paper* :—"The subject chosen is oue of powerful contrast, aud in the image Plate XII. appears worse defined than Plate V., although the structure in Plate XIV. is, as it should be, better than Plate VII. The visual image of Plate XII. was distinctly better than that of Plate V., but the halo due to the spherical aberration appears to have worked in to the black ground, in the chemical actiou very much more than appeared visually. *In development of these plates I had the kind assistance of Mr. Victor Corbould, and chiefly in the plates where spherical aberration was present, but in fact in all cases the primary appearances in development were far truer to the visual ones than at the conclusion of development.* The other plates that I think will be particularly interesting is the process of transition to reversal of the black and white squares of the object in Plates XVII. and XVIII. ; on the other side of the focus, however, the structure is maintained by the image forming rays through very wide limits."

The experiments were checked and verified by Mr. V. Corbould throughout, and we remarked that the original negatives would have been of far more value to illustrate such a subject than the priuts hurriedly prepared in *collotype*.

In your last issue your correspondent shows again a one-sided view of the optical aspect of naturalistic focussiug. He eutirely ignores the aspect of *binocular vision* enunciated by Dr. Emerson, and sounehow forgets, in what he does write, to give credit to Mr. Dennis Taylor for having been the first to publish the important aspect referred to, which is of itself optically correct for *monocular* vision. A wordy war is useless, and I decline to continue it. The facts of the case are before those of your readers who are interested in both the theoretical and practical uses of the introduction of spherical aberration.

25, *Newman Street*, W. Thos. R. Dallmeyer.

THE EXHIBITION OF THE PHOTOGRAPHIC SOCIETY.

Sir,—As I find myself placed in a false position at the Photographic Society's Exhibition—a medal haviug been awarded me, and now withdrawn on account of my having infringed the rules—I trust you will grant me space to make the following statement.

In the first place, I had no idea of exhibiting at Pall Mall this year, and should not have sent, but that, incidentally meeting the hanging committee at the restaurant where I lunch, they particularly requested me to do so. I promised

* The *Journal of the Camera Club* for March, 1890.

to see if I could find something, and the same day I sent an enlargement—a life-size single figure—which, in the hurry, I quite forgot had been exhibited at the Draper's Hall last season. This picture, on delivery, was recognised, refused, and brought back.

For several succeeding days I met the committee at the same place, and one day I spoke to Mr. Cocking, the secretary, and expressed to him my regret at the mistake, and told him that I had nothing else I cared to send which had not been exhibited at the Crystal Palace or in the city, upon which he told me, in a friendly aside, that he did not think there would be any objection to the Palace, it being so nearly out of the postal district, but that anything shown in the city was out of the question; and he again urged me to send something that day, as, though the hanging was practically finished, he could yet find room if my pictures were not large. Two small photographs were accordingly sent that evening.

I hope that this will show that I acted in perfect good faith. With regard to the medal system, I should like to say something, but will leave that for another letter. H. Vanderweyde.

182, *Regent Street*, W., *October 21st*.

Proceedings of Societies.

The Camera Club.

On Thursday evening, last week, at a meeting of the Camera Club, Mr. Wilson Noble, M.P., presided.

Mr. A. Maskell exhibited a Claude de Lorraine mirror, which, he said, was not a thing easy to procure in England. It was a convex black mirror, of glass, and used to judge values, an important point in photography, because on a bright, sunshiny day it lowers the tone of the view to something like the tone of Claude Lorraine paintings. He also exhibited a plate of metal of French make, with pinholes of definitely measured apertures, any one of which could be used at will, according to the size of plate to be exposed; the apertures varied in diameter from about $\frac{1}{100}$ to $\frac{1}{20}$ of an inch.

Mr. T. Charters White stated that he had exhibited a Claude de Lorraine mirror at the Photographic Convention at Birmingham; it was useful because it gave everything in neutral colours. He thought that a blue ground-glass focussing screen would be better than a white one, because it would give everything in neutral colours.

The Chairman said that a larger pinhole than used in photography was of value in the first instance, to let the operator know easily how much of the view his plate was taking in.

Mr. Lyonel Clark then spoke of some additional experiments of his own in toning with the salts of certain noble metals, and gave some demonstrations. He preferred to use Arnold's pure paper in photographic printing. He minutely described his methods of salting and sensitising rough plain papers. As a colloid vehicle he now prefers gelatine to starch and leaves out organic salts except when extra vigour is required in the prints. His gelatine solution is a strong one, and sets into a jelly when cold; he applies it at a temperature of from 120° F. to 130° F. For the intensification of silver prints he still employed the intensifier used for negatives in the collodion days—namely, water, acetic acid, and small proportions of pyrogallol and nitrate of silver. He, like Captain Pizzighelli, had failed in his attempts to tone silver prints with iridium; the salt he had tried for the purpose was the sesquichloride of iridium and potassium, procured from Messrs. Hopkin and Williams. With palladium toning there was a great loss of intensity on the immersion of the print, and a colour produced which looked greenish by daylight; the intensity was next brought back by the pyro-silver intensifier. The palladium toning could then be repeated if desired, followed by another intensification, and so on, until any desired depth was obtained. The palladium toning bath was an acid one, and it had a tendency to yellow the paper; the price of palladium was objectionable. He believed the prints to be more permanent than those on albumenised paper.

Next Thursday will be a lantern evening. The meetings of the Camera Club now begin at 8.30 p.m.

London and Provincial Photographic Association.

October 16th.—A paper was read by Mr. G. W. Atkins on "Stereoscopic Photography" (see page 820).

A discussion followed as to the cause of the decline of this branch of photography. It was generally conceded by the members present that the introduction of vulgar, or so-called comic slides had much to do with this.

Mr. W. E. Debenham was more inclined to the opinion that it was due to the "carte" mania. He illustrated by means of the black board the theory of stereoscopic vision, and also described the telestereoscope. By a little practice objects could be viewed stereoscopically without the aid of the stereoscope. One method was by looking a long way off; a slide is interposed at arm's length, and gradually brought nearer until the effect is obtained; or put two coins near together on the table, take a piece of card and hold it between the eyes, then gradually separate the coins until they superimpose.

A question was asked, of what use was the centre partition in the stereoscope?

A Member replied that without it three images would be seen.

Mr. Atkins showed how stereoscopic prints were mounted to obtain the best effect.

Mr. A. L. Henderson, who was unable to be present, sent to the meeting a number of stereo slides and two stereoscopes.

Mr. T. E. Freshwater also brought a series of slides.

The exhibits were viewed with a great deal of interest.

Mr. W. A. Casson was elected a member of the Association.

South London Photographic Society.

At a meeting held on the 17th instant at Hanover Hall, Rye Lane, Mr. Leon Warnerke was elected an honorary member, and was voted to the chair.

The president (Mr. F. W. Edwards) demonstrated the capabilities of alpha paper.

Mr. Warnerke said that some six years ago he produced a large number of prints on chloride paper; one of these, which he handed round for inspection, was in as good a state of preservation as when first produced.

Three members were elected, and eight names proposed.

West London Photographic Society.

At the adjourned annual meeting on October 17th (Mr. C. Bilton in the chair), the following officers were elected for the ensuing year:—*President*—Mr. Walter Adam Brown; *Vice-Presidents*—Messrs. C. Bilton, G. F. Blackmore, Walter L. Colls, and Dr. F. H. Low; *Council*—Messrs. England, Horton, Richardson, Scanlan, and Whiting; *Hon. Sec.*—J. A. Hodges; *Assistant Hon. Sec.*—Mr. L. C. Bennett; *Hon. Treas.*—Mr. W. H. Whitear; *Hon. Librarian*—Mr. J. Wilson; *Hon. Lanternist*—Mr. R. Horton; *Hon. Auditors*—Messrs. H. and L. Selby.

A general discussion then took place relative to the drawing up of the syllabus, in the course of which Mr. Whiting expressed the opinion that it would be advantageous to hold technical meetings more frequently than hitherto.

Mr. Miller thought that instead of negatives and prints being handed round promiscuously, it would be better if some one qualified took the exhibits and demonstrated their merits or faults.

Mr. Whiting thought that a technical meeting would effect the objects aimed at, because at such meetings members could bring forward novelties or avail themselves of the opportunity of having their difficulties solved.

Mr. Hodges considered that the success of a technical meeting depended very much upon the members themselves. If the objects in view were supported by a larger number of exhibits, a good practical result would be assured.

Mr. Lamley, in a letter, suggested that in order to avoid prints becoming damaged, and to give everyone an opportunity of inspecting them, a drawing board covered with grey cloth should be provided, to which the prints might be attached with drawing pins—which met the approval of the meeting.

Messrs. Rogers, J. C. Adams, and F. Adams were unanimously elected members. Mr. W. Schooling, F.R.A.S., was nominated for election.

The next meeting, on the 24th October, will be a lantern night.

NORTH MIDDLESEX PHOTOGRAPHIC CLUB.

October 13th.—Mr. RODGERS gave a lecture on "Pictures of Egyptain Life," and illustrated the same by the optical lantern. He first showed the apparatus by which the pictures, afterwards exhibited upon the screen, were taken; this was a Shew's camera, quarter-plate, fitted with Eastman's roll holder and celluloid film.

He then gave an accouut of the places visited by him, also of the manners, dress, customs, and method of living of the people.

On October 27th Mr. Bishop will give a lecture on "Stereoscopic Photography."

NOTTS AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE seventh annual meetiug was held iu the Society's rooms, Cavendish Chambers, Market Street, on October 20th; Mr. S. WELLS occupied the chair.

The HON. SECRETARY presented the annual report, which was passed.

The meeting endorsed the aetion of the committee in giving notice to vacate the present rooms and endeavour to meet with more suitable premises. A motion that the subscription be one guinea per annum was also agreed to.

The officers were then elected for the ensuing year:—*President*—Mr. S. Wells; *Vice-Presidents*—Messrs. G. E. Williamson and E. Smith; *Hon. Treasurer*—Mr. B. Sturges Dodd; *Hon. Secretary*—Mr. P. E. Knight; *Committee*—Messrs. R. S. Armitage, W. Burrows, T. Carnell, F. Hodgson, J. C. Lancaster, J. Furley Lewis, A. Pickard, T. S. Piggin, J. Spray, W. Towers, and M. Tuquet.

NEWCASTLE-ON-TYNE AND NORTHERN COUNTIES PHOTOGRAPHIC ASSOCIATION.

ON the 14th inst. a meeting was held in the Mosley Street Café, Newcastle, Mr. J. P. GIBSON in the chair.

The subject of "Halation and Backiug Plates" was opened by the chairman, who said that he had not seen reason to change the opiniou that black paper smeared over with glycerine and squeezed into contact with the plate, was the easiest, and at the same time a practical method of avoiding halation. In extreme cases he would pin his faith to the method of Mr. J. Hedley Robinson—viz., drop black mixed in gum-water aud alcohol.

Mr. AUTY recommended black paper ready gummed, which only required to be damped with a sponge and then put on the plate.

Messrs. J. Brown and Edgar G. Lee both expressed their preference for a solution of bitumen in benzole, on account of its immediately drying, and they usually postponed its removal until after fixation of the plate, a scratch of a finger across the back being sufficient to show how the negative is as to density.

DERBY PHOTOGRAPHIC SOCIETY.

A MEETING was held at Smith's Restaurant, Victoria Street, Derby, on the 14th inst.; Dr. GREEN presided. The election of officers for the year 1891 was proceeded with, and resulted as follows:—*President*—Captain Abney, R.E., &c.; *Vice-Presidents*—Dr. Green, Richard Keene, and T. Scotton; *Committee*—C. B. Keene, C. Bourdin, W. Hart, A. H. Bennett, R. Woods, and R. L. Warham; *Secretary*—C. J. Chadwick; *Treasurer*—A. B. Hamilton.

After the business was transacted, a fine collection of slides was exhibited by the maker, Mr. Warham, who was accorded a most cordial vote of thanks for the treat he had given.

THE PHOTOGRAPHIC CLUB.—October 29th, Lantern Slide Competition, first lanteru night of the season; November 5th, Annual General Meeting.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

B. N.—*Kallitype Process.* Supplementing the information we gave you last week, it ought to have been stated that the developed prints are not immediately washed with water, but are first treated with acid and alkaline clearing solutions. These are—

I.—The developer	¼	oz.
Nitric acid	20	drops
Water	1	pint.

followed by two successive baths made as under—

Ammonia	2	drms.
Citrate of soda	1	drm.
Water	1	quart

and finally washed in plaiu water.

EXPERIMENTER.—*Are Amylic Compounds Hurtful?* Fusel oil (amylic alcohol) has an irritating action on the lungs, provoking cough, and amylic acetate has a similar property in less degree. The latter is, however, largely employed in confectionery for making pear drops. Methylic alcohol (wood spirit) has an uupleasant smell, but is not harmful.

J. W. (Leeds).—*Reducing Bromide Prints.* 1. The chloride of lime method is so potent that it is difficult to restrain it within moderate bounds. A much better process is to immerse in a weak hypo rendered just yellow, or a fuller tint, with potassium ferricyanide (red prussiate). This answers excellently well also for reducing over-intensity in negatives. 2. Three lessons ought to be sufficient.

B. C.—*Pinhole Apertures.* Instead of trusting to a single layer of tin foil, you may employ several thicknesses, or perforate a more substantial piece of the rolled metal, inserting this in the place of your diaphragm, with the lenses, of course, removed.

A. M. M.—*Woodburytypes with Clear Margin.* Upon testing, with oil and hot water, the print which formed the frontispiece of the YEAR-BOOK for 1889, we come to the conclusion that the print in question is a veritable Woodburytype. We conceive it possible, with a highly resisting paper, and covering the central picture with a guard under pressure, to clear off the superfluous margin by sponging with hot water. We know of no method of providing for the escape of the excess of gelatinous ink in the event of the plate being thickened at the edges, and so would rather infer that it has been removed subsequently.

W. L. (Java).—*Furnell's Adjustable Shutter.* You are mistaken in supposing that the figure 4 in the time arrangement is intended to represent four seconds. As a matter of fact, aud in confirmation of your own experience, we find that 4 actually corresponds to *ten seconds*, so that you have only to construct for yourself a time-table founded upon actual observatiou with your instrument and a good watch.

A. W., G. R. B., and others are referred to the advertisement columns for information respecting the supply of primuline materials and likewise of sensitised silk.

HEREFORD is thauked for his explanatory letter relative to Watkins' exposure meter, and for the intimation that it will be shown and described next Tuesday at the technical meeting of the Parent Society.

L. P.—The gentleman named in your letter is a member of the Photographic Society—date of election, 1881. His name is printed in the last published list, that of February, 1889.

NOTICE.—The musical and lantern soirée of the Photographers' Benevolent Association will be held this evening at Anderton's Hotel, Fleet Street.

D. J. S.—Received your negative showing three poses by triple exposure. The result is fairly good, but would be improved by fixing short partitions in the camera, reaching about half way.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1678.—*October* 31, 1890.

CONTENTS.

WARM GLASS STUDIOS FOR THE WINTER.

HEAT rapidly escapes through glass windows, and more coal has to be burnt in the fire-place or stove to make up for this loss. Over a considerable portion of Europe the houscholders are wiser in their day and generation than we are in England; there are some portions of Europe in which double windows are the rule, and not the exeeption; in some parts of Switzerland even the agricultural labourers have double windows to their eottages. In the space between the inner and the outer window, flowers or plants are eommonly grown in the miniature greenhouse, and they often form an elegant substitute for a curtain. The inner window is usually from a foot to eighteen inches behind the outer window. In the summer-time we have sometimes, at Swiss hotels, utilised the spaee between the two windows by drying negatives therein in the sun, for there they are proteeted from dust from within and without the house. If, in a large hotel restaurant, the inner panes of glass of one of the windows ehance to be broken in frosty weather, nobody will sit at the table nearest that window, beeause it is palpably so much colder there than at other parts of the room. How much more, then, must the ordinary glass studio of a photographer tend to keep eold in the winter?

A remedy whieh may be worth trying is to double the glass part of a studio, so that it shall resemble one glass studio within another, and with a spaee of one or more feet between the two; the layer of still air between the inner and outer glass coatings will do mueh to prevent the loss of heat, and to sustain an interior equable temperature in the winter time. Should the studio have doors opening to the outer air, two doors would have to be provided, with a suitable spaee between them.

Melloni was the first to experimentally test the extent to whieh radiant heat from a partieular souree would pass through glass, and he found glass to be nearly opaque to heat rays from non-luminous sources. It, however, absorbs the heat, becomes warmer, and then itself radiates it in all directions. This faet reveals the philosophy of the glass fire-screen; mueh of the heat of the fire is thereby kept from the face, yet none of it is lost; the screen grows warmer, and radiates its heat to all parts of the room; the heat it receives is distributed in other directions than would have been the ease in its absence.

A model studio for the winter may be imagined, with its glass and other thin parts doubled, leaving a layer of imprisoned air between them to prevent rapid escape of heat. Into a ehamber below the whole of the studio, the outside air might pass through large openings, each covered with three or four layers of coarse eanvas soaked in glyeerine; much of the dirt in the air would stiek to these sheets; the rest of the dirt could be filtered out by passing the air through boxes lightly stuffed with eotton wool. The clean air eould then be warmed with hot water pipes, and afterwards passed through openings in the floor into the studio above. Suitable means should be provided in the roof of the studio for carrying off breathed and impure air. Sueh a studio should be approaehed through a long passage, with swing doors across it at intervals, so that any person entering the studio eould not let in mueh bad air from outside with him There are photographers who may upraise their hands and eyes at these ideas, and speak of the impraeticability of the whole scheme; but, unfortunately for them, the system has been at work for a long course of years in our Houses of Parliament at Westminster, and with additions whieh have not herein been set forth. Some English photographie dry plate makers have arrangements for filtering the air before it enters the eoating rooms.

The only question is one of money; otherwise it is perfeetly practieable for a photographer to provide himself with a glass studio free from fog and dirty air even in the worst days of November, and to keep the studio at a comfortably warm temperature with less consumption of coal and gas than he now finds to be necessary. Any system of artificial ventilation is destroyed by direet openings to the outer air. At the Houses of Parliament are devices for keeping the interior cool during hot days in the summer, and the late Dr. Percy, who had eharge of the ventilation

department, was sometimes irritated by members of Parliament opening the windows of some of the rooms to cool themselves, as they thought, such being the force of habit. As a matter of fact, by opening the windows they were letting in dirty air, hotter than the purified air they had previously been breathing.

COMPRESSED GASES.

The time of year has now approached when the tourist camera is set aside, and when many of those who have laid up a goodly store of negatives during the summer months will be thinking either of reproducing them as lantern slides, or as enlargements. To both kinds of photographic workers, the subject of compressed gases is of interest, for the limelight, in the absence of electricity, is the best illuminant for lantern slide projection, and is, perhaps, the best by which to enlarge one's negative when daylight is not available. And the limelight, nowadays, is best and most conveniently produced by using either one, or both, of its constituent gases in a compressed form.

The first workers with the lime—or Drummond light, as it was then called, after its inventor—had to be content with bladders for their gas-holders, or, perhaps, with some arrangement with inverted washing tubs, which had a faint resemblance to the receptacles for gas which tower above our gas works. Then, when demand justified supply, the familiar wedge-shaped india-rubber bags were introduced, and now these will probably be soon consigned to oblivion in favour of the less cumbrous and more convenient steel cylinders in which various kinds of gas are supplied commercially.

There is no doubt that the too frequent reports of accidents with the limelight deterred several from meddling with it, and those who have been interested in noting these disasters know full well that many occurred which never got into the newspapers. Unless, indeed, an accident had a fatal result, it was hushed up, for those chiefly concerned knew well that publicity would do them no good. Although many disasters occurred by careless admixture of oxygen and hydrogen, the great majority happened during the actual making of the oxygen—sometimes due to gross ignorance or carelessness, and often to the presence of some foreign agent in the chemicals employed. When the gas is bought ready-made, and in a compressed state, this greater part of the risk is altogether obviated, and the limelight is placed upon a safer footing than ever it was before.

Some persons, unfortunately, are so constituted that with them everything is dangerous, and gas and all things inflammable should be put beyond their reach. Their type is well known, and is often exemplified in those newspaper accounts of household explosions which tell how John Smith goes to look for an escape of gas with a lighted candle. To the surprise of nobody but the ill-fated John himself, the chief actor in the drama suddenly finds the room blown inside out, and himself almost in a similarly disrupted state. Last week was such an accident reported, the only peculiar feature of which being that the hero had his skull fractured, a feat which we should have considered to be an anatomical impossibility. The explosion was evidently of unusual violence.

But those who, like photographers, are accustomed to the use of apparatus, the weighing out of chemicals, and other operations which require both thought and delicacy of touch, are not the persons to blow themselves up in this inconsiderate manner, and with the modern conveniences for the production of the limelight they would find it extremely difficult to do so. An explosive mixture, either of hydrogen and air, or of hydrogen and oxygen in certain proportions, is necessary before an explosion can take place, and such mixture is now well guarded against at the compressed gas works by a simple expedient. The oxygen cylinders are painted black, and those for the reception of hydrogen are coloured red, in addition to which the nozzle of one has a left-hand threaded screw. This means that that cylinder, the hydrogen one, can by no possibility be attached to the pumping arrangement which is designed for the oxygen supply. It is therefore out of the power of the most careless workman to fill a hydrogen cylinder with oxygen, or, conversely, one that is painted black with hydrogen.

The supply of these compressed gases has assumed the position of a great industry of late years. This has been partly due to the introduction of cylinders of mild steel in lieu of those which were used at first, and which were made of iron. The new cylinders are tested to stand a pressure of 3,000 pounds to the square inch, but they are issued from the works with a pressure of 1,800 pounds only. But more especially is the new industry due to the success with which oxygen can now be separated from its associate, nitrogen, in the atmosphere by the method perfected by the Messrs. Brin. This bottled oxygen is used for various other purposes besides those which have to do with photography, and the Brin Company are now establishing works in several of our larger cities. At first the great initial pressure of the gas in its cylinder caused some slight difficulty in dealing with it for limelight purposes, but since improved regulators have come into use the objection has vanished. The number of those who employ gases under compression is constantly on the increase.

Steps are being taken in the United States to form a National Association of Amateur Photographers.

Transparencies.—Mr. James Colgrove has exhibited at the Chicago Camera Club some fine transparencies, developed by the following formula, which he said wrought admirably :—

No. 1.

Hydroquinone, eikonogen, potassium, meta-bisulphite, of each	90 grains
Water	16 ounces

No. 2.

Potassium carbonate, sodium carbonate, potassium ferrocyanide, of each ...	1 ounce
Water	16 ounces

To make the developing solution, take water one ounce, No. 1 one ounce, and No. 2 one drachm, more or less according to circumstances.

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

Photographs of animals are always interesting. *They*, at least, do not pose for their pictures, and one is sure to get nature of some sort. Saving sheep and cattle already mentioned in dealing with the landscapes, animals are but poorly represented. In regard to cattle, by-the-way, Mr. H. P. Robinson's "What is it?" (No. 362) deserves special mention, because the cow with the look of wonder in her eyes, and every muscle rigid with intense curiosity, really is the picture, and makes one forget the landscape. Whether the photograph was the result of accident or design, it is exceedingly happy. Mr. S. R. Brewerton has been fortunate in securing a series of photographs of foxhounds, to which he has given the title of "The Pick of the Pack" (No. 337). The series, however, does not call for extended mention. The couple of pictures (Nos. 347 and 389) by Mr. Gambier Bolton, of kittens, are undoubtedly among the most popular in the Exhibition. To those who know the difficulties, these two successful photographs must represent a score or so of spoiled plates. Mr. Henry Little's picture of Kempton Park (No. 394) illustrates the shortcomings of instantaneous photography when art is in question. It would almost seem as if a horse were one of those subjects best left unphotographed —at least, broadside on. The horse, when photographed in motion, always looks deformed, and Mr. Little's horses are no exception to the rule. Mr. Ernest Spencer has some studies of cats and dogs (No. 414) which have merits, but his "Busybody and her Promising Litter" (No. 383) might have been left unhung with advantage. It must be said that, on the whole, the photographs of animals are disappointing. There is nothing in the Exhibition to touch the work of the famous Posen photographer, whose studies are famous all over Europe.

Of Mr. Walter R. Cassel's two pictures (No. 340, entitled "A Sad Story," and No. 341, "Derwentwater") I prefer the landscape. The composition of "A Sad Story" seems to be faulty. The figure of the girl leaning back in the chair appears to be so far from the one sitting on the ground that the latter may, at first sight, be overlooked. The arrangement of the salient lines is apparently too diffused.

Some of Mr. Shipton's work has already been noticed, but he deserves praise for his bit of woodland scenery and figures (No. 346), and the artistic "The Village under the Cliff" (No. 390). Mr. J. Pattison Gibson's clever series (No. 369 to 376) are full of the right feeling; No. 372, "The Ford," is perhaps the best. Mr. Ernest Spencer's landscapes (Nos. 384 to 387) have a suggestion of muddiness which is unpleasant, while his skies are of the old-fashioned woolly order, which have been so often condemned that it seems strange to find them making their appearance over again. Mr. Dudley Arnott has an excellent interior, "Norwich Cathedral" (No. 413), evidence of very careful work. How "Tired" (No. 417), by Messrs. Adams and Scanlan, came to be admitted into the gallery, is rather puzzling. The idea is puerile, but even were it not, the inartistic treatment would condemn it. The figure of the girl huddled in a chair is what ladies sometimes call a dress "skimping," and there is an air of absurdity about the whole which provokes a smile.

Of course the Exhibition would not be complete without our old friends Burnham Beeches. Mr. C. F. Urquhart is responsible this year for a picture of the much photographed trees, and all that need be said of it is that it is as good as most of its predecessors. Mr. Urquhart also sends a little composition, "Which hand will you have?" (No. 428) which narrowly misses being very good. Mr. Urquhart has, however, like scores of other men who have tried the same line, come to grief over his models, whose expressions do not much assist the story. Mr. J. C. Douglas, in No. 437, has attempted a "Gretchen." It wants colour and feeling, however, and cannot be called a very successful piece of work. The Hon. Slingsby Bethell has given us a sort of puzzle in his view of "The New Forest" (No. 445). The foliage is cut so curiously by the sky that it is distressing to look at. Verily, it is without form and void.

"The Path to the Shore" (No. 444), by Mr. A. Horsley Hinton, is a landscape which very nearly approaches the front rank. It is well conceived and well carried out. Mr. J. Bracebridge Hilditch has, I am inclined to think, exhibited more interesting pictures than in No. 447, "Toilers from Early Morn," and No. 448, "Village of Streatley." They do not repel, but, unfortunately, they do not attract. "A Midsummer Evening" (No. 456), by the Rev. H. B. Hare, is a pleasing picture of rural placidity. Mr. Hare has well named it; the calm of a June evening has been admirably conveyed. Sir David Salomons shows two figure subjects, No. 458, a study of a girl's head, and No. 459, "A Boulogne Fisher Girl." The first might have been better vignetted. The fisher girl is pleasing, though I have my doubts whether her acquaintance with fish is very intimate. She looks like the fisher girl of the studio. Mr. R. H. Lord's "Work and Play" is not remarkable, and it would almost seem as if the word "copyright," which stares at one from the mount, were superfluous. There is a look of the "made" picture which detracts from its merits.

Mr. Lyddell Sawyer's pictures have already been alluded to. I have, however, not mentioned No. 479, "Towing up Stream," where he is seen at his best. It is a very fine picture. "Beating in" (No. 490), by Mr. Ernest Beck, is a clever little marine study.

The reproductions, if scarcely so numerous or remarkable, are, as in former times, excellent. The Autotype Company show a variety of specimens which testify—if testimony were wanting—their care and skill. Messrs. Boussod, Valadon, & Co. have long ago made good their claims to recognition, and some of their work is simply exquisite. I can imagine nothing more pleasing, judged as a mechanical piece of work, than their reproduction of Mr. Fildes' well-known picture, "An Alfresco Toilet" (No. 504). Mr. T. Julius Hurst shows three meritorious copies of oil paintings by Leader, Ansdell, and Erskine Nicol, and among other exhibitors are the Typographic Etching Co. and Mr. Walter L. Colls (reproductions in copper plate).

Photo-micrography is represented by Mr. Andrew Pringle, who shows a frame of microscopic work, chiefly bacteria. Mention is also due to Col. J. Waterhouse, B.S.C., who exhibits an example of photo-etching by his special process recently described. Wide-Angle.

Amateurs and Professionas.—Mr. J. Hubert says: "With regard to the vexed question of amateurs and professionals, there is one thing to be noted, that the partly educated of both classes will always be at war with each other, while the better educated and more intelligent will always endeavour to exercise that courtesy and forbearance in their intercourse which is one of the signs of civilisation."—*The Beacon*, Chicago.

THE CAMERA AND ITS VARIOUS MOTIONS.

BY PROFESSOR W. K. BURTON, C.E.

The Essentials of a Landscape Camera.

It should be Light-tight.—I incline to put this qualification first, although it may not be of greater importance than others. Indeed, in so far as the two or three qualifications to be here dwelt on *are actually essentials*, they must be considered to be of exactly equal importance.

When I say that the camera should be *light-tight*, I mean a great deal more than is commonly meant. Pretty well any photographer, if you ask him, "Is your camera light-light?" will reply, "Oh yes, to be sure!" but if you watch him working, you will see that he keeps his camera covered with an opaque cloth during exposure, only opens the dark slide a few seconds before he takes off the cap, and, in fact, takes every precaution lest light should leak into the camera. In fact, it is very evident that he does not trust the light-tightness of his camera, and it is ten to one that he has never tested it.

Now I do not say that it is not right to take the precautions against the leakage of light into the camera mentioned above, but it certainly ought not to be necessary to take them.

If a camera be bought from any maker, there is, I have no doubt, an "implied guarantee" that it is actually light-tight, and I know that, in the case of any *respectable* maker, if a test show that the camera is *not* light-tight, the said maker will be glad to correct the defect free of charge; that is, assuming the camera to be new. As I shall presently point out, the best of cameras need occasional overhauling.

I think that the first thing that should be done when a camera is bought, is to test it for light-tightness, by putting a plate in a dark slide, placing the camera in full sunshine, drawing the shutter of the slide, and turning the whole gear partly round from time to time. so that all sides may receive the action of the light, for ten minutes or so. The plate, on development, should show no sign of fog. It is a good thing, to facilitate the detection of the action of light, to stretch a strip of opaque paper across the film, so that, if the action of light have been but slight, it may still be made visible by the comparative clearness of the part of the film protected by the paper.

I consider, indeed, that, should the first test show no action of light, it is worth while going through with all the slides full, trying one plate after another. The satisfaction of knowing that the camera and each dark slide is thoroughly to be relied on to keep out light is cheaply bought at the price of two plates per dark slide.

One word in warning. The test recommended is for the *camera*, and it is necessary to make very sure that no light enters by the *lens*. Light certainly will enter by the lens, if it be one with Waterhouse or rotary diaphragms, unless special means be taken to cover the slit. Indeed, if the camera be a new one, it is fairest to the maker to perform the test above described before any opening is cut in the front to take the lens.

Even if a camera prove light-tight when new, it should be tested from time to time, as there is a liability to some change even in the best made cameras through time, at any rate if they receive the rough usage that cameras do at my hands. This is particularly true of *large* cameras, for the difficulty in making cameras light-tight, and in keeping them so, increases greatly with the size.

It would be a good rule to test a camera in the way described at the beginning of every season. I mean at the beginning of each photographic working year.

The Camera should be Rigid.—This is a qualification well recognised, at least by English makers of cameras. Indeed, by far the greater number of cases of want of rigidity at the present may be traced to defect in the tripod stand, or in the manner of fixing the camera to the stand, rather than to actual want of stiffness in the camera itself.

I would point out that there are two entirely different kinds of want of rigidity. One is due to the general lightness of the camera, or ill proportion of parts, resulting in "springing" of something, generally the base-board; another is due to looseness of screws, pins, &c., allowing a certain amount of "shake," or even the chance that some adjustment—say the swing-back—may actually slip after focussing.

The "springing" of cameras is most likely to give rise to a tremulous motion during exposure started by taking off the cap. In fact, there are few cameras that do not show this defect more or less when they are extended to the full extent. In the days of long exposures this want of rigidity was of comparatively little consequence; the camera had time to come to rest whilst the exposure was still only beginning, and the effect was inappreciable. With the exposures common at present, if any tremor is imparted to the camera when the cap is taken off, it generally lasts during the whole exposure, and, indeed, there must be few landscape photographers who have not had experience of images entirely blurred by tremor of the camera started by taking off the cap.

A less common, but by no means uncommon, cause of tremor in the case of cameras that "spring" much is wind.

Another effect that I have known to arise from want of rigidity in the base-board of a camera is, that the weight of a double dark slide has "sprung" the base-board sufficiently to put the image perceptibly out of focus. It is true that this defect is only likely to be found in large cameras, and even then the springing has never, in my experience, been so great that the image was likely to be put perceptibly out of focus with lenses other than those of very large aperture. With a portrait lens used full aperture, however, a movement of $\frac{1}{20}$th of an inch will put the image quite perceptibly out of focus, and I have known cameras of the size of 10 by 8 and upwards that would spring quite enough to increase the distance between the lens and the back to that amount with the additional weight of a loaded double dark slide.

The looseness of joints, pins, or screws, giving rise to what I may call "ricketiness," is often found in cameras of second-rate manufacture, and is liable to be developed in the best of cameras after a time if they be subjected to rough usage. This looseness is not nearly so liable to give rise to tremors as is "spring," but it is very liable to result in a disturbance of adjustment after focussing, particularly in placing the slide in position, an operation which, unfortunately, often needs some force, even in the case of cameras of the very best make—a thing that seems a pity.

There is no way of testing the rigidity of a camera but by fixing it up and trying it by hand; and then it is important to distinguish between want of rigidity due to the camera itself, and that due to the stand. Some knowledge of mechanics and some experience also are necessary to

know whether a camera is likely to *remain* stiff or not after much use.

Lightness and Portability.—Perhaps these qualities should barely be described as *essentials*, inasmuch as photography of the highest class would certainly be possible without them; but a certain amount of portability, as compared with the ancient box-camera, or even with the earliest forms of so-called "portable camera," is really essential to amateur photography as it is now known.

It is in the qualities just mentioned that the most modern cameras chiefly excel, and, indeed, it is wonderful to what feather-weights of lightness, and to what sandwich-like thinness (when folded) have been reduced cameras that are capable of opening to more than twice the length of the plate to be used, and even to be moderately stiff at that.

Concerning lightness and portability, the only thing I incline to say is that, although they are of the highest importance, not a jot of stiffness—or, if desirable, strength—should be sacrificed for the sake of a few ounces of weight, or for a quarter of an inch of thickness of the folded camera. I have no hesitation in saying that some of the very lightest of modern cameras are *too* light to be strong and lasting instruments.

A PHOTOGRAPHIC EXHIBITION AT TUNBRIDGE WELLS.

The Tunbridge Wells Amateur Photographic Association will hold its fourth annual Exhibition at the Sussex Assembly Rooms on Wednesday, Thursday, Friday, and Saturday, November 26th, 27th, 28th, and 29th. The officers of the Association are:—*Patron*—Sir David L. Salomons, Bart.; *President*—Mr. F. G. Smart; *Vice-Presidents*—Rev. A. T. Scott, Mr. J. G. Calway, Rev. J. E. Rogers, Mr. G. Percival Smith; *Hon. Treasurer*—Mr. B. Whitrow; *Hon. Secretary*—Mr. Joseph Chamberlain.

In the Exhibition, the following are the classes for members only:—(1) Architecture, exterior or interior; (2) interiors, other than architectural; (3) landscape; (4) instantaneous, including marine subjects; (5) genre; (6) lantern slides, best series of six, any subject; (7) transparencies; (8) best photograph of trees, without leaf. The following are the open classes:—For amateurs—(9) landscape or seascape; (10) genre; (11) lantern slides, best series of six; (12) architecture, exterior or interior. For professionals—(13) landscape or seascape; (14) genre; (15) lantern slides, best series of six; (16) portraits. The rules of competition may be obtained from Mr. Joseph Chamberlain, hon. sec., 14, Calverley Park Gardens, Tunbridge Wells. The judges are Sir David Salomons, Mr. H. P. Robinson, and Mr. C. W. Hastings. There will be a lantern demonstration each evening, and Sir David will bring his special lantern for the first night, and exhibit it at work.

Enfield Camera Club.—It has been decided, provided sufficient interest is taken in the movement, to hold an exhibition of the work of the members in the Byculiah Athenæum, Enfield, in the early part of January next, at which prizes and certificates will be given for the best photographs in the following classes: architecture, landscape, instantaneous, genre, lantern slides, and portraiture.

Camera Club Notices.—Monday, November 3rd, 8.30 p.m., Smoking Concert; Thursday, November 6th, 8.30 p.m., Mr. J. Gale, "Country Rambles with a Camera Illustrated;" Thursday, November 13th, 8.30 p.m., Demonstration of the Primuline process by Messrs. Green, Cross, and Bevan; Thursday, November 20th, 8.30 p.m., Mr. Andrew Pringle, "On Certain Old Processes for Lantern Slides;" Thursday, November 27th, 8.30. p.m., Lantern Evening; Monday, December 1st, 8.30 p.m., Smoking Concert; Thursday, December 4th, 8.30 p.m., Mr. H. Sturmey, "On Rollable Transparent Films."

THE PHOTOGRAPHIC TOUT.

BY JAMES MEW.

But the unkindest cut of all in this semi-religious and semi-commercial excitement was a cut which affected very seriously the photographic tout. Indeed, on the occasion of the suggestion of that particular cut, he had a very near squeak of it—as the fox-terrier said of the rat when he had bitten off the tip of his tail—for nothing less was proposed than to delete him. This was regarded by some as a measure of strict retaliative equity. He had cut out his rivals, and his rivals were for cutting him out in return. But, notwithstanding much urgent effort and passionate perspiration, the tout, or the doorsman, as he was then contemptuously called, still survived. Even the Association for Sunday Closing, "under distinguished patronage," could not annihilate him. When every respectable photographer inveighed bitterly against his desecration of the Sabbath at Tottenham, he coolly changed his locality, and walked with a cabinet in one hand and a carte-de-visite in the other up and down, like the polar bear in the Zoological Gardens, before his well-known case of photographic specimens at Turnham Green. "Here we are again," we hear him in our mind's ear exclaim, with a smile of satisfaction only inferior to that of the clown in a Christmas pantomime. "Here we are again! Here is our *specialité!*" Why the cognate English word would not have answered his purpose it is no easy problem to discover. Speciality sufficed for Hooker and for Hale, but it can find no favour in the eyes of the photographic tout. Nor is it altogether justified in the eyes of the author of "Slip-shod English in Polite Society," who says, "the British tradesman *will* talk about and advertise his *speciality*, whereas he means *specialty*." But our best dictionaries hold both words to have the same meaning. "Here is our *specialité!* Here is our art gallery! Here our superior finish! Here our best work! Here are our portraits by day and by night! Here are our three cartes-de-visite for half-a-crown, and one carte-de-visite for a shilling! Here are our three cabinets for four and sixpence, and one cabinet for two shillings! Here are our cabinet and carte combined for eighteenpence the pair;" and Sairey Jane and 'Arry in their best Sunday dresses—'Arry with a big flower in his buttonhole, and Sairey Jane with a flaunting red feather in her hat—having nothing better to do on the Christian day of rest, come and bask in the sunshine of his rhetoric, and listen to the words of this charmer, turning no deaf ear, like the adder, to the voice of his persuasion, and in due process of time are "took," and so depart contented with fading caricatures in their pockets, and a lingering look at that portion of the advertisement on the door-post which speaks of portraits "taken on steel and warranted never to fade."

And what has the poor tout to say in his defence? What plea of excuse or avoidance has this photographic sabbath-breaker to urge against his immediate execution? Stoning to death was, if we remember rightly, the Jewish penalty for an offence of this nature against the Sabbatical law. Well, he might say many things. He might say, for instance, in his unregenerate ignorance, that the taking of a photographic picture involves no more toil than the driving of an omnibus or a train, the playing on an instrument of wind or strings, the preparing of a dinner, or the pursuit of a thief. He might say that the majority of his

* Continued from p. 822.

customers have no time at all to have their portraits taken except on Sunday. He might say, with respect to his patter of persuasion, which has been cruelly called his discreditable method of inducing custom, that there are thousands of people who will not purchase goods except under this same pressure of rhetorical influence. It is probable that neither Mrs. Harris nor Mrs. Gamp ever visited the greengrocer's while she could buy a succulent adjunct to her tea from the blatant hawker who fills our humbler streets o' afternoons—aye, and o' Sunday afternoons—with his false but piercing cry of "Fine fresh *spring* watercresses" in the month of September. And in that section of society which is called with some vagueness of description the higher classes, are not the Dowager Lady Dash and the Honourable Mrs. Asterisks often indebted for their ultimate decision of buying two pieces of haberdashery which they do not want, to the gentle persuasion of the linendraper's "pushing" young man, who has descanted in terms of superlative praise on the merits of each of them in turn? And with regard to what has been called his unscrupulous impudence in the recommendation of wares which he knows to be comparatively worthless, may not the tout whisper a word or two about the common condition of commercial morality, and ask, supposing him to be a member of the Christian Young Men's Association, whether those were alone guilty upon whom the tower of Siloam fell? And he might conclude his apology something after the following fashion: My customers will buy their portraits cheap, or they will not buy them at all. They also require urgent solicitations to induce them to purchase. The superior person who does not like me is not obliged to listen to me. I hold him neither by his buttonhole nor, like the ancient mariner, by my glittering eye. He may pass on his way in peace. But to that humbler wight, not blessed with this world's goods, who listens to and eventually employs me, I give, I conceive, his money's worth. I give him, or more frequently her, a picture not, indeed, such as the Virgin Queen is said to have desired, painted without a single shadow—it is urged against me that my pictures are all too full of shadows—nor a portrait with all the little defects of nature smoothed away by the retoucher's pencil, but a portrait painted by the sun, of which the linear accuracy is unapproachable by any painter that ever lived, a portrait which, notwithstanding its many technical defects—which I should be the first to acknowledge, not, indeed, in the open publicity of my portrait saloon before the faces of my customers, but in the private seclusion of my dark room to myself—is without the conventional mannerisms and peculiarities of such famous painters as Lely, and Hoppner, and Gainsborough, and Reynolds, and in that sense truer and better than any work of theirs—a portrait, finally, which is cheap and will bring happiness to many a home of which the means are inadequate to purchase anything more costly. For with these humble livers it is Hobson's choice. It is my portrait, or none at all. And of the benefits conferred by these pictures—poor things as they are at best—what need is there now to speak at large? Like mercy, they are twice blessed, in the pleasure of those that give, and of those that receive them, sent as they often are from parents to children, or from children to parents, across vast continents, to recall the familiar faces of those dear ones who are so many thousands of miles away, and parted from them by so many a land and sea.

PHOTO-CHEMICAL INVESTIGATIONS.*

BY FERDINAND HURTER, PH.D., AND V. C. DRIFFIELD.

VI.—Rapidity of Sensitive Plates.

We gave two formulæ as the result of our investigations; one of them, the approximate one, is the direct result of our experimental work; the other is the mathematical expression of the idea that a certain definite amount of energy is needed to bring a particle of silver bromide into the condition in which it can afterwards be developed, and that it is only to the light absorbed by unaltered silver bromide that increase of density consequent on increased exposure is due.

Whilst the approximate formula is never strictly true, and can be used only for exposures which fall within the period of correct representation, it is extremely simple, and we are about to describe an important application of it, viz., the determination of the speed of the sensitive plate.

The more correct formula cannot be used for practical applications owing to its complication, but it serves to indicate the limits within which the approximate formula may safely be used.

In the formula—

$$D = \gamma . \log \left(0 - (0 - 1)\, \beta^{\left(\frac{It}{i}\right)}\right)$$

we may replace $(0 - 1)$ by the symbol 0 when that represents a large number, that is, when the plate is richly coated with silver bromide. If, in addition, we remember that $\log \epsilon \beta$ is $-\frac{1}{0}$, the equation can be transformed into another, viz.:—

$$D = \gamma . \log \left(\frac{It}{i}\right)$$

which equation holds good only when the numerical value of $\frac{It}{i}$ is greater than 1 and less than the opacity 0. It is between these two limits only that this equation gives tolerably correct results. Comparing this last equation with the approximation we gave before, it will be seen that the constant C of that approximate formula is the logarithm of i, the symbol measuring those properties of the film which together constitute its sensitiveness, and which we termed the inertia of the plate.

Supposing we had two richly-coated plates, with different inertias, i and i_1, and we wished to impress the same density upon them by a given intensity of light I. They would require different exposures and the exposures would have to be such that—

$$\frac{It}{i} = \frac{It_1}{i_1}$$

or the times would have to be chosen so that—

$$\frac{t_1}{i_1} = \frac{t_0}{i_0}$$

This means that if the values of i are known for different plates, the exposures required to obtain the same results are also known for those plates, if the exposure is known for any one of them.

The determination of the numerical value of the symbol i is, therefore, an important problem.

Since the density of the image is an abstract number, it follows that the ratio $\frac{It}{i}$ is an abstract number also,

* Continued from page 829.

and that i is therefore an exposure. We termed this symbol the inertia, and it really measures that exposure which will suffice to change a particle of silver bromide into the developable condition. But for its practical application it has another meaning. It measures the least exposure which will just mark the beginning of the period of correct representation.

The speed of the plate is the inverse value; the longer the exposure needed to bring the plate just to the beginning of the period of correct representation, the slower is the plate. Therefore we measure the speed of the plate by the value $\frac{1}{i}$.

The method we adopt for measuring the value of i is, briefly, as follows:—We give to the plate at least two exposures falling within the period of correct representation, and develop. We then measure the densities exclusive of fog. We thus obtain two equations connecting the two densities D_1 and D_2 with the two known exposures E_1 and E_2, viz.:—

$$D_1 = \gamma . \log \frac{E_1}{i} \text{ and } D_2 = \gamma . \log \frac{E_2}{i}$$

from which we obtain by elimination—

$$\log i = \frac{D_2 \log E_1 - D_1 \log E_2}{D_2 - D_1}$$

and—

$$\gamma = \frac{\log E_2 - \log E_1}{D_2 - D_1}$$

The value of i is expressed in candlemeter seconds, and can be found by reference to ordinary tables of logarithms.

We will now describe our practice. For the determination of the inertia, only the central portion of the plate should be used; the margin should be avoided, as it is liable to be irregular in thickness of film. In order to insure at least two exposures falling within the period of correct representation, we give to the plate eight different exposures of 2·5, 5, 10, 20, 40, 80, 160, and 320 C.M.S., leaving a portion of the plate unexposed. We develop this plate with ferrous oxalate, and, after properly washing, fix in a perfectly clean bath of thiosulphate. We then wash and dry spontaneously, or by means of alcohol. The length of time for development is judged by the density of the image. We avoid too great density, but develop sufficiently long to obtain a decided deposit for the lower exposures. When all the densities have been measured, we subtract from every one of them the density of the fog strip in order to obtain densities "exclusive of fog."

From this series of densities we may calculate the value of i. For that purpose we find the differences between the consecutive densities, and we choose from the series those points which give differences most nearly alike. As an example, we quote the series of results obtained with the Manchester slow plate of experiment No. 21:—

Exposures	2·5″	5″	10″	20″	40″	80″	160″
Densities	·085	·175	·250	·460	·755	1·010	1·270
Differences		·09	·075	·210	·295	·255	·260

We should take the results of exposures from 20 C.M.S. to 160 C.M.S. as those falling within the period of correct exposure. Choosing the exposures 20 and 160 for the calculations, we should obtain, in accordance with the formula given—

$$\log . i = \frac{1·270 \times \log . 20 - 0·460 \times \log . 160}{1·270 - 0·460}$$

or $\log . i = 0·787$, and, from an ordinary logarithm table, we should find $i = 6·12$ candlemeter seconds.

In another experiment with a plate of the same make the following results were obtained:—

Exposures ...	10″	20″	40″	80″
Densities ...	·300	·590	·910	1·260
Differences ...	·290	·320	·350	

Choosing only the 20″ and 80″ points, we have—

$$\log . i = \frac{1·260 \times \log . 20 - 0·590 \times \log . 80}{1·260 \times 0·590} = 0·771$$

or $i = 5·90$ candlemeter seconds.

It will be seen that these values for the inertia of the Manchester slow plate are almost alike. With faster plates it is not so easy to obtain quite such concordant values; but they are always sufficiently accurate for practical purposes, for, whether an exposure in practice be four or five seconds, it will not appreciably alter the resulting negative, so that in the determination of the inertia an error of ten per cent. is, fortunately, not of very great consequence, and in most cases two determinations carefully made will not differ more than 10 per cent.

We prefer, however, to obtain the result by a graphic method, by means of which we avoid all calculations and all references to tables of logarithms. We scratch on an ordinary slate a horizontal scale of inertias similar to the scale of an ordinary slide rule, but we repeat the scale four times instead of twice, as in the case of the slide rule. Diagram No. 11 shows this arrangement. We scratch at points 2·5, 5, 10, 20, 40, 80, 160, and 320 of this scale vertical lines (exposure lines), and divide them each into twenty equal parts, marking the highest as density 2·0, the lowest as 0. Having measured the densities, we mark them on the scales of the corresponding exposure lines, and draw a straight line through those points which appear to fall most accurately within such a line. It is better to stretch a white thread across these points, as the portion of the line can thus be more easily determined. Where the thread or the straight line intersects the inertia scale we can at once read off the inertia of the plate.

The solutions of the problem of ascertaining the inertia or its inverse, the speed of the plate, have hitherto been unsatisfactory, and always depended finally upon the judgment of the comparative visibility of letters or numbers printed upon a sensitive plate.

Our method, by referring the speed to a standard candle as unit, will enable different operators to obtain almost identical and definite numerical results. Should at any time a better practical unit of light be found, the method is at once applicable with it also. The fact is, we have based our method on the measured effects produced by a given unit of light, excluding the influence of alterations in development, whilst the present method, by means of Warnerke's sensitometer, depends entirely upon development. We could so alter the composition of the developer as to make a rapid plate give most misleading results.

Such a proceeding is impossible with our method.

(To be continued.)

Hackney Photographic Society.—Arrangements for members' lantern nights:—November 27th, "Kallitype Paper," Dr. Roland Smith; December 11th, exhibition of pictures and lantern slides (in competition, Messrs. H. P. Robinson and J. Traill Taylor judges) at St. Andrew's Hall, Hackney. Music. Slides will be put through the lantern during the evening.

APPARATUS AT THE PHOTOGRAPHIC EXHIBITION.

IV.

THE Watkins' exposure-meter is on view at the Photographic Exhibition, and is represented in the accompanying cut. Much intellectual skill has been displayed in the invention of this instrument, of the practical merits of which we shall speak farther on. The time of exposure of a plate in a camera depends upon a number of varying conditions, and the plan of Mr. Watkins is to measure these conditions, and to express their numerical values by means of slide-rules. These slide-rules are circularly placed, so that the whole instrument is little larger than an ordinary reel of cotton. Bacon distinguishes the philosopher from the empiricist by describing the former as a man who can divide and define. Certainly the instrument under notice gives the power of dividing and defining various conditions.

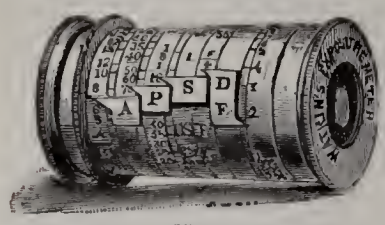


Fig. 13.

The measurement of the intensity of the light is effected by sensitive paper and a standard tint. The paper is prepared with bromide of silver, made to darken rapidly under the action of light by the presence of nitrite of potassium. Mr. Watkins once sent us one of the instruments, and we found that while the sensitive paper darkened to one tint, the standard tint alongside was of a different colour; it was also found that, after the sensitive paper had acquired a certain depth of tint, it remained thereat, and could be exposed much longer without perceptible change. All this put a stop to farther experiment, and Mr. Watkins says that the sensitive paper was not perfectly dry, hence the defective indications; he also says that of late he has been issuing a more trustworthy paper. So long as the paper contains deliquescent nitrite of potassium, it does not seem probable that its stability will be great. Mr. Watkins objects to the standard paper of Bunsen and Roscoe, on the ground that it is a chloride of silver paper; but is it certain that the darkening of bromide of silver paper is in exact relation to the formation of the invisible image on the same salt? The chloride paper had better be tried, or an analagous one of bromide.

Professor Bunsen and Sir E. Roscoe once devoted much attention to the experimental solution of the problem of preparing a photographic paper which should always possess the same degree of sensitiveness to light, and particulars relating to these researches will be found in *The Philosophical Transactions of the Royal Society* for 1863. Several other papers by the same authors, and published in *Philosophical Transactions*, should be carefully studied by Mr. Watkins, since they give a wealth of information on the subject of measuring the intensity of diffused daylight. The two investigators just named used pure paper, pure chloride of sodium, and pure silver nitrate, and, after an exhaustive series of experiments to eliminate error, adopted the following formulæ: 300 grammes of chloride of sodium were dissolved in 10 litres of water; the sheets of paper, about 0·3 metre in area, were one by one immersed in the solution; after five minutes' immersion each was taken out and suspended in a vertical position to dry. The sheets were next floated for two minutes each upon a solution containing 120 grammes of silver nitrate to 1 litre of water. After drying in the air from fifteen to twenty-four hours, this standard paper can be preserved in the dark without undergoing appreciable change in its sensitiveness. It was found by experiment that pieces cut from different parts of the sheet did not vary so much as one per cent. in sensitiveness. The standard tint was made by mixing 1 part of lamp black with 1,000 parts of oxide of zinc, and a long series of painstaking experiments was made before adopting this tint, for upon the tint much of the accuracy of the measurements of diffused daylight depends. The combined papers of the authors upon this subject would fill a volume, so to those papers must those interested in the subject refer. Suffice it to say, that later on the chemical activity of daylight at different times of the day was measured in different countries regularly by the method devised by Bunsen and Roscoe, and that the results of the observations are on record. In England the measurements were chiefly made at Kew Observatory.

A feature of Mr. Watkins' instrument is, that the adjustment of one of the rules is left to the judgment of the observer, and may be known as the "judgment ring." If the judgment of the photographer is to come in anywhere, why not use it in guessing the proper time of exposure, and not over the adjustment of a part of the actinometer?

Altogether, we think that Mr. Watkins has begun to solve a complex problem in a scientific way, and that his actinometer is now in a transition state, promising well for the future.

At the International Congress of Photographers at Paris, doubts were prevalent as to the practical value of any means of indicating proper exposures. Those who thought such instruments might be useful did so chiefly in relation to the photographing of interiors.

THE PHOTOGRAPHERS' BENEVOLENT ASSOCIATION.—The Photographers' Benevolent Association will give a lantern entertainment, by permission of the Photographic Society of Great Britain, on the 7th of November, at 5A, Pall Mall, London, from 7 till 10 p.m. Admission sixpence. Lantern at 8.45 p.m., with specially selected slides. The Association was founded in 1873.

THE "PHOTOGRAPHIC NEWS" YEAR-BOOK for 1891 will contain original articles by a long array of the chief writers and authorities connected with photography, including Capt. W. de W. Abney, C.B., F.R.S.; Dr. J. M. Eder, Director of the Imperial Institute of Photography at Vienna; Dr. H. W. Vogel, Professor in the Royal Industrial Academy of Berlin; Dr. Henri Van Heurck, Director of the Botanical Gardens of Antwerp; Mr. G. M. Whipple, B.Sc., Superintendent of Kew Observatory; M. Leon Vidal, Editor of the *Moniteur de la Photographie*, Paris; Professor W. K. Burton C.E., Tokio, Japan; Mr. Andrew Pringle; Mr. C. H. Bothamley, President of the Photographic Convention; Mr. Joseph W. Swan, M.A.; Col. J. Waterhouse, B.S.C., Assistant Surveyor-General of India; Sir David Salomons, Bart.; Sir H. Trueman Wood, M.A., Secretary to the Mansion House Committee of the last Paris Exhibition; Dr. T. L. Phipson, English Correspondent of the *Moniteur de la Photographie*; Mr. Francis Cobb, F.R.A.S.; Mr. John Spiller, F.C.S.; Mr. Arnold Spiller, F.I.C.; Mr. F. C. Beach, Editor of the *American Amateur Photographer*; Mr. Paul Lauge, President of the Liverpool Amateur Photographic Association; Mr. W. Lang, Junr., F.C.S.; Mr. James Mew; Mr. George Davison; Mr. Greenwood Pim, M.A.; Mr. W. S. Bird, President of the Photographic Section of the London Chamber of Commerce; Mr. H. P. Robinson; Mr. R. P. Drage; Mr. C. Fleetwood Pritchard; Mr. Frederick Varley, M.I.E.E.; Dr. C. S. Pattersou; Colonel W. L. Noverre, and many others well known in the photographic world.

REPORT OF THE PROGRESS OF PHOTOGRAPHY DURING THE YEAR CLOSING AUGUST, 1890.*

BY W. H. H. CLARK.

Photo-Mechanical Printing.—In this department there is nothing new to report, but the application for process blocks is rapidly on the increase. The photographic interviewer is coming to the front. Our large metropolitan dailies now photograph a man's gestures while he is being interviewed, and from the negatives process blocks are made which are printed with the report, rendering increased interest in the interview. Photographing lightning flashes, cloud effects, and meteorology, of drops of water while descending, of the effects of electrification of jets of liquid, of cannon and rifle balls in their flight, of wave sounds produced by the human voice, photographing the bottoms of oil wells, and at the depths of the deep blue sea discovering the condition of wrecked vessels, and so on, all go to show that photography is progressively advancing in all directions.

Animal Photography, under the leadership of Messrs. Muybridge and Anschutz, is making rapid strides; with results exhibited in the Zoetrope, the exact motions of the galloping, trotting, or running horse, and birds on the wing, are rendered in motion true to life.

Cameras.—This part of the photographer's apparatus is being multiplied indefinitely, but hand-cameras, erroneously called detective, take the lead, and there are some of wonderful make and extraordinary construction, and through them film photography is rendered nearly to perfection. The April number of the *St. Louis Photographer* published cuts, and a description of a machine hand-camera, which is operated by a crank, *à la* hand organ, and capable of taking a continuous series of negatives of street life in action, making a large number of exposures per second. The inventors have also invented a lantern, whereby views taken with the machine camera can be projected on to a screen, where street scenes full of life and motion can be viewed in an enlarged form. The automatic portrait machine is another wonderful contrivance, a drop-a-nickel-in-the-slot arrangement; the pictures produced are ferrotypes, commonly called tin-types. Although it is a wonderful piece of mechanism, the first cost of the machine, and constant attendance, coupled with the extremely low price of photographs, renders it doubtful if it ever pays the interest on the capital invested. It is a novelty, and as such will soon pass into oblivion.

The Educational side of photography has made little or no progress in this country. Germany is, without doubt, in the lead over all nations on the globe in respect of photographic educational facilities. Dr. H. W. Vogel is professor of an efficient school in Berlin; Zurich has its photographic laboratory; Herr W. Cronenberg is professor of a technical school at Schloss Gronebach; Austria has a splendid institution dedicated to photography, under the professorship of Dr. Eder; all of which have students from all over Europe and different parts of England and America, while here in America we have a bud or two which are trying to blossom, and have, no doubt, done much good. Quoting the President of the Photographic Society of Great Britain, Mr. C. H. Bothamley says:—"It has been proposed to found a Photographic Institute in this country, and we shall all be agreed that, founded on a right basis and conducted on right lines, it might be of incalculable benefit to photography. Founded on a right basis and conducted on right lines—that is the essence of the whole matter, so far as possible success is concerned. An Institute of Photography, I take it, should teach, and examine, and conduct original research. It might possibly also act as a court of arbitration in disputes involving technical matters, but the advancement of photography in all its branches and aspects, by teaching and research, should be its chief business. It should be thoroughly, though not ambitiously, equipped; it must be free from connection with commercial interests of any kind; above all, it must be free from the immaturism which so often clings round present-day amateurism." To which we should all say amen, and hope that a similar movement may soon be started in this country.

Developers and Development.—Under this head your committee has but little to report. Eikonogen has taken a pretty strong hold upon the craft, and is, perhaps, to-day used more extensively than any other agent for inducing the latent image to make its appearance on the exposed sensitive plates, and after the day's work is done the photographer can write his letters and figure up his profits or losses with spent eikonogen developer for ink. I am sorry not to be able to report progress in producing durable albumen prints, but the reverse appears to be the order of the day. It is patent to all that the albumen prints of to-day are not as durable as those made twenty years ago. I would also be glad to incorporate in this report an infallible remedy for that pest, blisters on albumen paper. Many remedies have been published, but in spite of them all, the trouble will now and again appear in the best regulated galleries. Is it really in the paper or the workman?

These may be minor subjects considered in the light of the more exalted questions concerning the progress of photography; still, they are important factors in connection with our progress. And it is to be hoped that the day is not far distant when these evils will be overcome.

* Concluded from page 831.

Astronomical Photography.—Professors Vogel and Eder appear to be constantly engaged in a noble competition as to which can contribute the most to the progress of photography and its application to the advancement of science and art. A short time ago we chronicled the triumph of manipulative skill accomplished by Professor Eder in photographing the image upon the retina of a beetle. We have now to record an equally conspicuous victory achieved by Professor Vogel in the realms of astronomy. It is unnecessary to remind our readers that the spectroscope many years ago enabled astronomers to demonstrate that certain fixed stars are in a state of motion, either towards or away from the earth. The evidence supporting this conclusion was furnished by the displacement of the principal lines in the spectra of the different stars. A large number of spectral observations of all the leading fixed stars have been carried out in the Potsdam Observatory by Professor Vogel, in conjunction with Dr. Scheiner, for a considerable time past. The result of these observations went to show that the displacement of the spectral lines was subject to periodic variation. Professor Vogel and Dr. Scheiner came to the conclusion that this variation was due to the motion of the earth in her orbit, as she is at one time of the year approaching certain of the fixed stars, and six months later receding from them. This annual variation in the displacement of the lines was accurately measured, and from the data thus obtained the velocity of the earth in her orbit was calculated. The result arrived at agreed, within a few fractions of a kilometre, with the velocity as calculated from other sources. It would not, we think, be too much to say that no greater triumph of the scientific application of photography has been achieved within the year.—*Invention.*

Notes.

Some of the most remarkable negatives ever produced are the five of the quagga in the Zoological Gardens, taken by Mr. Frederick York in 1872. On the authority of Mr. Bartlett, who for thirty-one years has been the Superintendent of the Zoological Gardens, we are able to state that, in all probability, the quagga is now extinct. He has no information that one has been seen either in the wild or the tame state for many years past. In South Africa the people often speak of Burchell's zebra as the quagga, but that is a mistake on their part. The quagga is a rather nice-looking animal, with ears and tail bearing some resemblance to those of the horse. In the front half of its body it resembles a zebra, and in the hinder half the common ass. Burchell's zebra is striped over its whole body, with the exception sometimes of the legs; its ears are frequently white. It roams in large herds over the plains to the north of the Orange river, but in yearly diminishing numbers. As the area of civilisation increases, animals of this class and carnivorous wild beasts are brought closer together in regions little explored by man; the quagga being heavier than the zebra, seems therefore to have been killed off the face of the earth first; the unfortunate zebra will follow. Mr. York is therefore in the position a man would have been in had he been the only person to photograph the last living dodo. A portrait of the quagga from the best of Mr. York's negatives will form the frontispiece to our forthcoming Year-Book.

Mr. A. de Blochouse, the president of the Brussels section of the Belgian Photographic Association, has been making a study of the early history of the stereoscope. He quotes a memoir published in Paris in 1860, in which Sir David Brewster sets forth that the instrument was known to Euclid, and was distinctly described by Galien 1,500 years ago. Sir David also said that Jean-Baptiste Porta described in 1393 not alone the principle, but the construction of the stereoscope, and how to make the two images combine. Such publication could scarcely have been pleasing to Wheatstone at the time, and the statements made by Mr. A. de Blochouse may be added to those, which shows how desirable it is that a school of historical criticism in photography should be established. Those who are in the habit of consulting ancient original documents are aware of the untrustworthiness of some of the items of alleged photographic history now accepted as true by the public.

Why does not one of the English photographic organisations appoint a committee to deal with all new discoveries in photography made in foreign lands? From the proceedings of most of our societies, it might be inferred that photographic workers do not exist outside the United Kingdom. In Paris the principles of action are different. Critics examine all the foreign journals for the Photographic Society of France, cull therefrom all that appears to be novel in photography, and an abstract of these extracts is read at the monthly meetings of the Society. The members are thus kept well informed as to what is going on in photography all the world over. The resolutions of the late International Photographic Congress in Paris, as to a rational system of nomenclature for photographic processes, well deserved consideration by photographers in other countries, and in our opinion were of such a sensible and useful nature as to be suitable for general adoption.

At Antwerp is the newest section of the Belgian Photographic Association, and it has taken firm root. Mr. J. Maes is the president; he is also president of the Association itself, and he is the chief photo-mechanical printer in Belgium. The section intends to hold an annual photographic exhibition in Antwerp. General experience in England is, that in any town of but moderate size, a good photographic exhibition once every three years is quite frequently enough, when quality of exhibits is held in view, and when it is not desired to tire the public by such displays.

Speaking to the verger of a certain cathedral one day, who was showing us over the building, we audibly expressed our regret that the Vandals of the past should have had so little respect for "the carved images thereof." Whereupon he told us, in a confidential manner, that those departed sinners should not be credited with all the blame, for the Goths of the present, in the guise of American tourists, were quite as bad. We resented this as a libel upon our transatlantic cousins, but the old man declared it was true. We recalled this episode last week, when we were shown an American photograph of a piece of stone which the label told us had been chipped by the artist from the summit of the great Pyramid of Egypt! Now, what can be done with a man who not only commits a crime, but hands to his friends a photograph of the evidence which convicts him of it? The Society for Protecting the Ancient Monuments of Egypt has evidently a difficult task before it if there are many of these travelling stonemasons about.

Another photograph which we lately saw was of a more innocent and interesting character. It represented a large number and great variety of insects which had committed suicide by flying into an electric arc light lantern. The brilliant light has a great attraction for all things which fly, and lighthouse keepers have often picked up large quantities of birds which have dashed themselves against their lanterns. In Bohemia just now the forests are being invaded by a greedy caterpillar which eats up every green thing, and the parent moth is being killed in great numbers by means of electric lights set up purposely to entrap them. Close by each light is a funnel, through which the air is sucked by means of an exhaust fan. The insects are drawn into the vortex by thousands, and are buried below ground.

It is often useful for a photographer to know how to cut off the bottom of a glass bottle; such an expedient, as is well known, will turn a common hock bottle into a respectable dark-room lamp. Here is a German method which is not generally known. Get some limewood charcoal, grind it up finely, and, by means of gum tragacanth and water, make it up into a paste and roll into pencils. One of these, when dry and ignited, will burn down slowly with a red-hot end. Take your bottle, put a drop of water on the spot where the division is to be, and nick it then with a file. Now touch the place, after wiping off the water, with your red-hot crayon, and the glass will crack. Follow this crack carefully round the bottle with your slow match; you can guide it in the right path, until the bottom falls in two halves.

An American paper gives a hint about sweeping a store without raising any dust, which will be useful to our readers. Do not sprinkle the floor with water, but place a line of wet sawdust right across one end of the room. Sweep this wet mass right along, bit by bit, to the other end, and on its march it will seize hold of every bit of dirt in its way without contaminating the air above. This plan should be valuable to photographers, who know well what damage can be done by flying dust, especially if it numbers among its particles traces of bronze powder, pyro, hypo, or other samples of matter in the wrong place.

The enterprising proprietors of papers of the "Bit" class are untiring in their efforts to find out fresh subjects of competition. The latest idea is a series of photographic contests, the competitors being the lady readers. The rules do not demand any knowledge of photography on the part of those who enter the lists, the only qualification being the possession of a fair amount of good looks. The thing, in point of fact, is a photographic beauty show. We do not know that any conditions are laid down as to touched or untouched photographs, but it is clear that this is essential. If the prize is to be awarded on photographic evidence alone, then all we can say is that nothing more misleading than this evidence can well be imagined unless retouching be sternly forbidden.

The painter who essays a portrait founded upon photographs enters upon a risky experiment—that is, if the original be alive, and has an opportunity of criticising the result. It seems that the disappearance of Henri Regnault's portrait of Marshal Prim from the Louvre Museum has led to much gossip, and the story of its early history has found publicity. The picture was painted entirely from photographs, and, when finished, the Marshal visited Regnault's studio in Madrid in order to pass his opinion upon it. The examination was not at all pleasing to the Marshal, and he asked the painter brusquely why he had made him look like a coal-heaver? Whether this effect was due to the painter, or to the photographer who furnished the materials upon which the painter worked, we are not told, but Regnault took the criticism to himself, and he left Madrid in anger, taking the picture away. In 1869 it was exhibited in the Paris Salon, and was ultimately bought by the State. It is stated that it will be shortly returned to its former place in the Louvre.

The old methods of extending trade are evidently played out in America. A milk jug or sugar basin "given away with a pound of tea" has no attraction for customers. Books as "premiums" were popular for a time, and one firm of publishers shipped no less than 10,000 atlases to American merchants for use in this direction; but, as a trade authority points out, there is one disadvantage attending this gift. When purchases to the amount of twenty dollars have been made, and the book has been secured, there is no particular inducement for the premium-getter to continue trading at the particular store, as one book is sufficient for one family. But this disadvantage does not extend to the use of enlarged photographic portraits as premiums, and the authority in question gives reasons for this opinion which all photographers will admit are full and convincing.

We learn, for instance, that when the picture of one member of the family has been secured and hung on the wall, there is a strong desire at once created for portraits of other members of the family to accompany it, and this desire makes the customer keep trading at your store so long as pictures are offered as premiums. When you withdraw the premium plan, you should have cemented the ties so strongly that the picture-getters will always be your friends. Another advantage possessed by portraits when used as premiums is, that a merchant is not obliged to purchase a large number in order to inaugurate his scheme, but can keep his capital untouched. When he finally has to order the pictures, he will have received enough cash trade from those desiring the premiums to give him plenty of money to pay for them. The original outlay is ten shillings, it only being necessary to have a sample portrait to show in your window. The authority shrewdly adds: "This had better be of yourself or of some handsome young lady well known in your town."

When royalty does condescend to handle the camera, "all the world wonders" at the marvellous results. During the visit of the Duke of Clarence to India, he took a number of photographs with the detective camera. These photographs have been enlarged, and, says a society journal overcome by admiration, they "certainly prove that his Royal Highness judged the exact moment for operation when grouping was at its best, chose the point of view of scenery that was most striking or picturesque, and put the camera to work when incidents were happening that were of more than ordinary interest, and worth recording." This combination of qualities is so rare that the Prince's photographs ought really to be exhibited for the benefit and edification of photographers generally.

ARTISTIC BLUE PRINTS.

THE end of the summer's wanderings, camera in hand, in field and forest, has come, and, with negatives all developed, the amateur's thoughts turn to the vexed question of printing. In these salad days of photography he has a wide field of choice. For his own collection there are the albumen, platinum, and bromide papers, but these are rather expensive methods, and hardly feasible for the large number of gift pictures which one likes to send to friends.

Here the blue print holds the field on the score of cheapness, and, when properly done, for delicacy and beauty as well. For some years I have been in the habit of making up a large number of blue prints for holiday gifts. These have all been made directly on the cards, doing away with the trouble of trimming and mounting, and, with the addition of a plate mark to give them a finish, they are all one could wish for the purpose for which they are used. Almost any good surface cardboard answers well. I am in the habit of using two or three-ply Bristol board, which seems to produce a richer blue than most other cardboards.

Any of the numerous formulæ may be employed for sensitising without much affecting the final result. My own formula is—

Red prussiate of potash	60 grains
Water	1 ounce
Ammonio citrate of iron...	100 grains
Water	1 ounce

The potash solution may be mixed in quantity, as it keeps well, but the iron solution should be mixed only as wanted for immediate use; the two solutions are mixed in equal parts immediately before using, and are applied to the cards with a Buckle's brush, which is nothing more than a piece of white cotton flannel doubled and bent over the end of a strip of glass and held in place with a rubber band. The ribbed side of the flannel is the one to use. In default of this, a soft sponge may be used. The solution is evenly applied, care being taken to avoid streakiness by not having the brush too wet, and by brushing lengthwise and across the cards. The sensitising may be done in subdued daylight. The cards soon dry, and are then ready for exposure.

As everyone knows, the best negatives for blue prints are those which we call plucky. None of the iron processes take kindly to thin negatives, and it is well to bear this in mind when selecting the negatives from which to make blue prints. The cards should be somewhat larger than the negatives, in order to leave a liberal margin of white card around the print. I use 8 by 10 cards for all sizes up to the whole-plate. The printing-frames must be as large as the cards, and provided with glass fronts. In order to protect the margins of the cards and insure their washing out white, masks of opaque paper, cut the same size as the cards and having a central opening the size of the print, are placed over the negatives, which are laid in the centre of the printing-frames.

After printing until the shadows are deeply bronzed, the cards are thoroughly washed in order to prevent subsequent yellowing of the whites. Before they are quite dry the plate mark is put in. For this purpose a sheet of hard cardboard is cut slightly larger than the printed portion of the cards, sufficient to leave a good half-inch margin around the picture, and the corners are slightly rounded off. Thin sheet brass is better if much work is to be done, but the hard cardboard answers fairly well. The proper position for the plate-card is easily ascertained by laying a piece of glass of the same size over the picture and marking or scoring the two upper corners with an ivory paper-knife. The glass form is then removed, and the plate-card put in place. The print is then placed on a piece of thick felt, the plate-card is covered with one or two thicknesses of blotting-paper, and the whole put under a letter-copying press for a minute or two. When removed from the press, the print will be found to be surrounded with a mark closely resembling the plate mark seen in copper-plate engravings. When dry, the prints are ironed or run through a burnisher to straighten them.

A very good substitute for embossing may be given to the margins outside the plate mark by cutting out an opening corresponding in size to the plate-card in a sheet of coarse sand-paper. After removing the plate-card from the print, the sand-paper is carefully adjusted in place and the pressure is again applied, thus producing indentations in the margins of the cards which at times have a very pleasing effect.

Three or four of these prints, bound in a cover of water-colour paper by punching a hole in the upper left-hand corner, and tying with a bit of ribbon, make a very pleasing and inexpensive birthday remembrance for a friend, and reflect no discredit on the taste of the maker.

There are many other charming applications of the idea, but they must wait for a subsequent paper for description. —W. H. B., in *The American Amateur Photographer*.

BIRMINGHAM PHOTOGRAPHIC SOCIETY.—An exhibition of photographs by the members will be held on December 16th, 17th, 18th, and 19th, at the Temperance Hall, Temple Street. Open each day from 10 a.m. until 10 p.m. There will be lantern displays each evening. Gold, silver, and bronze medals are to be awarded. In conjunction with this exhibition, the Warwickshire Photographic Survey Council purpose showing a collection of photographs taken during 1890 for the purpose of the Survey.

A NEW PROFESSION FOR WOMEN.—In spectroscopic work (in astronomy) the eye has been superseded of late, to a great extent, by the photographic plate, which is now able to recognise fainter impressions than the eye, and to register them permanently. Professor Pickering has been continuing at Cambridge his remarkable work, and it is also being carried on in the southern hemisphere by a party sent there in connection with the Draper memorial. The instrument employed is a photographic telescope, with a prism or a series of prisms in front of the object-glass, the whole mounted like any large telescope, and provided with an accurate driving clock. With an instrument of this kind we obtain upon the sensitive plate the spectra of all the stars which happen to be in the field of view—sometimes a hundred at a time, as when a cluster like the Pleiades is in question. This method has made it possible to complete, in a comparatively short time, a general survey of the spectra of all the brighter stars of the northern hemisphere, and the survey is now being extended to the southern hemisphere, where it is already well advanced. Whenever the spectrum of a star thus photographed on a small scale is found to present any interesting peculiarity, it is examined with a more powerful instrument, which photographs its spectrum on a much larger scale, and this second photograph is then enlarged again for special study. It is worth recording here that the examination of the Harvard photographs has been made almost entirely by women, who are assistants in the laboratory. A niece of Dr. Henry Draper, whose memorial is now being erected in the form of this monumental work—the spectroscopic survey of the heavens—had the good fortune to discover in the star spectra the delicate doubling of the lines which has proved so full of information.—*Prof. Charles A. Young.*

WILD BEAST PHOTOGRAPHY.*

In the queer little back garden of a queer little house, in a queer little road, which is composed of many other queer little houses, mostly of a shy and retiring nature, and within a thousand miles of the Zoo., Mr. Gambier Bolton has his headquarters and studio, the latter, as he remarks, being the largest in the world, for it is the world itself. Picture not artistic luxury, but conjure up a clump of gnarled and withered timber which still bears a scanty crop of foliage, and is apparently sent by nature for the purpose of holding the extremely heavy sootfall peculiar to the neighbourhood. On a rough wooden platform, supported by trestles, a monster yellow Tom sits trimming his whiskers, and gazing with melancholy indifference at a grey Tom who has taken up his position on a neighbouring wall, and is twisting his tail about in an aggravating way, as if on sport intent. The fact is that yellow Tom has no tail, being a Manxman, and the two are rivals in love, and grey Tom is laughing at him. The Manxman is Mr. Bolton's favourite puss, who earns a respectable livelihood by tantalizing dogs. I have heard of many queer professions (writes our representative who recently spent a morning with Mr. Bolton), but this is surely the queerest on record. Let me explain why the Manxman has taken up this line of business in preference to mousing, or ratting, or killing off the sparrows.

Dog owners who want really artistic photographs of their favourites take them up to the queer little house, but you can't take a good photograph of a dog in a room or an indoor studio. He may be shy, or sulky, or savage. So Mr. Bolton just turns him into the queer little back garden, and watches him for half an hour from the window; he is then put on to the platform, and the camera is made ready. But a dog on a platform is a melancholy object. He is probably depressed by his strange surroundings, his face is long, his ears are limp, his legs are loose, and his *tail is down*. The Manxman is now introduced. Watch him stealing furtively along the path until he catches the eye of the sitter—hey, presto!—the eyes sparkle, the ears are erect, the legs stiffen, and, gentlemen, the *tail is up*, and the trick is done. Sometimes the Manxman fails, in which case the monkey appears on the scene. He had a good training at Mr. Carrington's. If both the Manxman and the monkey fail, the squeaking rat is introduced, with instantaneous effect. The queer little back garden contains other receptacles for animals—namely, a few cats and kittens, which have been used as models this past season, and there is a red dachshund—"Bruce," the picker-up. I think his profesion is even more peculiar than that of the yellow Manxman, the professional tail-raiser. Several cats and dogs having been poisoned in the neighbourhood, "Bruce" is turned loose night and day to pick up any little trifles, such as a lump of meat, liver, or bread containing prussic acid, &c., which might find its way over the wall and into the interiors of the valuable canine and feline boarders and residents in that queer little establishment. And here comes the resident model, "Pickle," a smart little fox-terrier, who has the knack of always standing or lying in a picturesque position. In taking your walks abroad, you must often have been struck by the splendid picture-photographs of lions, tigers, elephants, hippos, zebras, and ever so many other wild beasts which are exhibited in some of the shop windows. These are the results of Mr. Bolton's prolonged and assiduous studies and experiments, which I am now about to describe.

On an easel in Mr. Bolton's little drawing-room stands a magnificent picture (from a plate 44 by 36 inches), or, to be technically correct, a carbon photograph, of "Prince," the great lion at the Zoo. "I spent three days of five hours each in producing a satisfactory negative of that," said Mr. Bolton; "there's patience for you. You see, my Draconian rule in animal photography, which I have made my speciality, is: The animal shall be standing, free of the bars, free of shadow, and all four legs and the tail showing, with a natural background. No dodging and no combinations, and no double printing for me, or naturalists and scientists would bid me go hang." For three days, then, Mr. Bolton tried to take the big lion, and success rewarded his efforts at last. The photographer who deals with lions and tigers has often a good "run for his money," as the sportsmen say, for the lens of the camera is thrust between the bars of the cage.

(To be continued.)

* From the *Pall Mall Gazette*.

EIKONOGEN FORMULÆ.

The following formulæ were issued long ago by the manufacturers of eikonogen, and down to the present time the said manufacturers have seen no reason for making any alterations in them:—

A.—For portraits and landscapes.

(1) 4 parts sulphite of sodium are dissolved in 60 parts water. To this solution add 1 part of eikonogen, which has been previously finely powdered by means of a mortar, and dissolve by shaking. Should a mortar be wanting the solution can also be prepared in the following manner: To 4 parts sulphite of sodium and 1 part eikonogen, which are placed either in an earthern or enamelled vessel, 10 parts water are added, and solution is brought about by boiling and stirring. The hot solution is then poured into a flask containing 50 parts cold water.

(2) 3 parts crystallised carbonate of soda are dissolved in 20 parts cold water. Immediately before developing mix 3 parts of solution No. 1 with 1 part of No. 2.

B.—For instantaneous photographs with detective cameras.

For this purpose formula A is to be used, with the exception that the crystallised carbonate of soda is substituted by the same quantity of carbonate of potassium.

C.—For very short instantaneous exposures, and for increasing the power of the developers A and B in cases where the plate has not been sufficiently exposed.

5 parts sulphite of sodium, 2 parts carbonate of potassium, and 1 part of eikonogen, are placed in an earthen or enamelled vessel, and to these are added 30 parts water; solution is brought about by boiling and stirring. After having been allowed to cool, the developer, which is now ready for use, is preserved in a tightly closed bottle. The developer, if it has been prepared exactly according to the above method, keeps in good condition for a long time.

The following is a fixing bath for plates which have been developed with eikonogen.

Plates which have been developed by means of eikonogen should be well washed, and will greatly benefit by being fixed in a bath composed of 4 parts hyposulphite of soda, 1 part bisulphite of soda, 20 parts of water. The advantages of fixing in this bath are that:—

(1) The negatives have a perfect tone, which enables very fast printing.

(2) The new fixing bath remains, even after frequent usage, clear and water-white.

(3) The plate need not be bathed in a solution of alum before fixing, and it is therefore not possible that the plate should

be covered with a white layer in consequence of insufficient rinsing.

Should the nature of the plate require that the coating be hardened, then there is no objection to an alum bath being used, either before or after fixing, yet the quantity of alum added must not exceed 1 part to each 20 parts of water, as a stronger solution might cause the gelatine to blister. The bisulphite of soda can be replaced by ordinary neutral sulphite of soda (the same as is used when developing with eikonogen), provided that the bath be acidulated by means of a little sulphuric acid. In this case it should be made up in the following manner: Dissolve 20 parts hyposulphite of soda and 5 parts neutral sulphite of soda in 100 parts water, to which add slowly 1 part concentrated sulphuric acid. This bath, if properly prepared, answers the same purpose as the other, also remaining clear and water-white.

Formula for developing gelatine-bromide paper with eikonogen.

The paper, having been exposed to the light, is soaked in 40 parts water. The paper is hereupon taken out, and 10 parts of a solution prepared according to formula C are added to the bath. Should the picture be slow in appearing and the details not be perceptible, then add gradually a farther quantity of solution C. If the paper has been exposed too long, only a small quantity of solution C must be used from the commencement. The addition of bromide of potassium is often the cause of the details not forthcoming; it should therefore not be employed. After developing, the picture should be well washed and then placed for several minutes in an alum bath, whereupon it is again washed and fixed. It may here be stated, say the eikonogen makers, that the crystallised carbonate of soda employed in the formula need not be pure, but of the same quality which is used in every household.

Specifications Published.

16,558. *October 19th*, 1889.—"Photographic Cameras." Herbert George Heyburn, 16, Upper Montagu Street, London, Optician.

My invention has for its object to provide a combined camera and box, or receptacle for sensitised plates or surfaces, which is very simple in construction, and not liable to get out of order, the plates or sensitised surfaces being successively discharged, exposed, and then returned to the box in any desired order. According to my invention, I so combine the storage box with or attach it to the camera, that it can be moved relatively thereto, so that either of the plates therein can be brought opposite to a slot in the camera, sufficiently wide to admit only one plate at a time therethrough, and into the guides or supports for the plate in the camera. In connection with the storage box, I use a shutter which can be brought into such a position that it leaves only the desired one of the plates in the storage box at liberty to pass out therefrom. The portion of this shutter which protrudes from the apparatus may be marked so that it can readily be used as an indicator as to which of the plates is at liberty to be passed into the camera when it is brought into line with the slot in the camera.

18,167. *14th November*, 1889. — "Photographic Camera Shutters." William James Lancaster, Colmore Row, Birmingham, Manufacturing Optician.

This invention relates to camera shutters, or means for obtaining instantaneous or extended exposure, whereby light is allowed to pass momentarily or otherwise through the lens or exposure aperture, at the will of the operator; and which said invention, designated by me the "Chronolux" time shutter, is an improvement upon Application for Letters Patent made by me on the 29th day of January, 1889, and numbered 1,543.

The apparatus consists

1. Of two circular piereed shutter plates, sliding in reverse directions to and fro upon each other in manner that the piereed and unpierced parts respectively overlap each other, and thereby either form an opening or close one.

2. In means for working the shutter plates.

3. In a pneumatic operator and releaser.

4. In the combination of the time mechanism, described in my cited patent, with the operating means, and circular piereed shutter plates, as aforesaid.

20,009. *12th December*, 1889.—"Photographic Cameras." Reginald Haddon, of the firm of Herbert and Co., Patent Agents, 18, Buckingham Street, Strand, W.C., Civil Engineer; a communication from abroad by the firm of C. A. Steinheil Söhne, Opticians, Munich.

This invention relates to photographic cameras, and consists in improved mechanism for controlling the exposure, and improved mechanism for changing the plates within the camera. It can be adequately described alone by the aid of drawings.

18,224. *November 14th*, 1889.—"Photographic Shutters." Henry Grant Madan Conybeare, of "The Hut," Ingatestone, Essex, Gentleman.

This invention is an improvement in photographic shutters for making so-called instantaneous exposures. In carrying out my invention I use a box, preferably of wood or other material. This box has an aperture on each side of it, one of them of such size as to fit on the front or back of the lens with which the shutter is to be used. In the box I fit three hollow rollers, preferably of brass tube. Two of the rollers are placed at one end of the box, and one at the other end. One of the two rollers which are placed near together contains a spring, as in the spring rollers used for window blinds. But the spring may be made like a watch spring, and placed in a small case on the end of one of the rollers. To one of the two rollers at one end of the box, I attach narrow bands or strips of silk ribbon or tape, one at each end. These strips are carried to the other end of the box and passed over the ends of the one roller; they then return to the other end of the box, and are passed once or more times round the third roller containing the spring, and the ends attached to the said roller. To these two bands I fasten a piece of cloth, preferably macintosh cloth, so that it comes between and just covers the two apertures, which are in the opposite sides of the box, thus forming a blind. To actuate the shutter, I turn round one of the two rollers at one end, the one which does not contain the spring; this draws the strips or bands off the other roller, causing it to revolve and wind up the spring contained in the roller. This at the same time draws the blind from between the apertures, over the roller, at the other end of the box, and back, on the other side of the roller, between the apertures in the box. The rollers are then held and prevented from revolving by a ratchet and pawl attached to the axle of one of the rollers. The rollers may be released by hand or by a pneumatic release. The axle of the roller containing the spring may also be fitted with a ratchet or other arrangement, enabling the spring to be wound up independently of the blind.

The instantaneous exposure is made by releasing the ratchet, when the spring draws the blind from between the apertures over the roller and back again between the two apertures in the box.

19,205. *Nov. 29th*, 1889.—"Giving a Matt Surface to Albumenised Prints." John Buxton Payne, 33, Soho Square, London, Gentleman, a communication from Frederick Charles Binns, of Wellington, New Zealand, Photographer.

This inveution consists of an improved process or means for giving albumenised silver paper, photographs, or prints, a matt surface resembling matt opal plates or unpolished marble.

Accordiug to this inveution, a sheet of finely-ground glass (preferably plate glass), marble, slate, metal, or other material having on one side a finely ground or unpolished matt surface, is taken as a support for the albumenised silver paper, photographs, or prints to be treated, and it is coated (by means of a pledget of flanuel, or by other suitable means) with a solution of wax and guin, or resin, in a suitable solvent. This I will call the "waxing compound." The following has been found to answer well in practice. Dissolve by heat three drachms of best beeswax and three drachms of yellow resin in one pint of spirits of turpentine. The proportions of the beeswax and resin vary with the temperature of the air; when very warm the resin should be present in greater proportion than the beeswax. It is iupossible to give one fixed forniula for every degree of temperature, but the above is correct for general conditions in temperate climates.

The coating of the plates with this waxing compound may be effected in the following manuer:—

A quantity of the waxing compound, sufficient to coat each plate, is poured on to the pledget of flannel or like rubber, and the ground or matt surface of the plate is rubbed therewith, preferably with a rapid circular motion, uutil the whole is evenly coated. It is then polished, which can be done with a clean linen cloth, until the surface is smooth and free from waves, streaks, or marks, taking care in doing so to leave a thin even film of the compound on the plate.

When the plate has thus been treated it is set on edge in a place free from dust, and allowed to remain in that position for, say, twenty-four hours, until the solvent has evaporated. If this be not attended to carefully, the coating of gelatine and oxide of zinc, which the plate is subsequently to receive, will set in uneven patches, spoiling the resulting surface of the picture and rendering it liable to stick.

The following mixture, which I will call the "gelatine zinc compound," is then to be prepared. Gelatine, such as that of Coignet Pere et Fils et Cie., or any other suitable gelatine, is added to cold water. The proportion of gelatine to water depends upon the quality of the gelatine employed, but for that made by Coignet Pere et Fils et Cie., two ounces of the gelatine to twenty ounces of water is a proper proportion. The gelatiue and water are then subjected to heat in any suitable vessel, and when the gelatine is dissolved oxide of zinc and glyceriue are added, gently stirring with a glass rod until the ingredients are thoroughly incorporated.

The quality of ordinary commercial oxide of zinc varies. If the ordinary quality sold by chemists be used, suitable proportions will be: Oxide of zinc one half of an ounce to oue ounce of glycerine.

If Hubbock's oxide of zinc be used, fifty grains mixed with one quarter of an ounce of glycerine are suitable proportions.

Any suitable dye or pigment may be added to this formula for the purpose of tinting the resulting "matt opal-type."

The oxide of zinc, glycerine and dye or pigment (if any) should be thoroughly brayed in a mortar until they form a smooth paste, before they are added to the gelatine solution. When the oxide of zinc and glycerine (coloured or not) are thoroughly incorporated with the gelatine solution, the mixture should be strained or filtered, which can be conveniently and efficiently done through a flannel bag.

A plate coated with the waxing compound from which the solvent has evaporated, as hereinbefore described, is then covered with the gelatine-zinc compound, which should not be used at a higher temperature than 130° Fah. when the plate is dipped in the solution, and not higher than 108° Fah. when the solution is poured on to the plate, which may be effected in any of the modes used for photographic enamelling, or otherwise at the discretion of the operator.

When the gelatine-ziuc compound has set upon the plate (which will be usually in about a quarter of an hour), the plates will be fit to receive the albumenised silver print, which is prepared by first immersing it in clean cold water to render it flat and pliable. The coated plate is placed on a stand coated side uppermost, and is flooded with clean cold water, and the surface is carefully brushed (which may be done with a broad flat camel's hair brush) to remove any particles of foreign matter, and the plate is then flooded again with clean cold water. The silver print is then taken from the water, and placed carefully face downward on the plate, care being taken to avoid the formation of air-bubbles; "squeegee" in the usual manner, and then wipe with a sponge.

When glass plates are used, the uuderside should be examined for air-bubbles, or particles of dust, or other foreign matter that may have got betweeu the face of the print and the coating compound, aud if anything of the kind be present the print should be removed, washed and brushed again, and fixed anew.

When the print is satisfactorily attached to the plate all free moisture should be wiped away, which may be done with a sponge.

A backing of paper or other suitable material may then be applied to the print, and the whole may then be placed in a rack to dry, which will usually be completed in fine summer weather in from about eighteen to twenty-four hours. When thoroughly dry the print is removed from the plate, which can be done by inserting a penknife between it and the plate, and the print will leave the plate with the greatest ease, having a beautiful matt-surface pure in tint and fine in texture.

If desired, in place of the gelatine-zinc compound a solution of gelatine alone may be used, but it is preferred to use oxide of zinc or some equivalent pigment, as it gives a desirable "bloom" to the picture.

359. *8th January*, 1890.—"Photographic Cameras." A communication from Frank A. Brownell, Rochester, United States. Alfred Julius Boult, 323, High Holborn, London, M.I.M.E.

The present iuvention has for its object to provide a camera that cau be folded within small compass for carrying, and can be so extended as to take quite a large picture, and it further has for its object to provide said camera with ueans for utilising roller holders for flexible film, thereby providing a comparatively small detective camera, which is not only capable of taking large pictures, but also of containing sufficient material for a large uumber of them, these being the objects most sought after in articles of this description.

Iu the patent the details are given by the aid of drawings.

12,741. *August 14th*, 1890.—"Photographic Objectives." Ernst Gundlach, 112, South Avenue, Rochester, United States, Opticiau.

My improvement relates especially to photographic objectives, or combinations of optical lenses, used for the purpose of taking photographic portraits, views, and other subjects.

All the best photographic objectives of modern type consist of two achromatic or aplanatic meniscuses, this form of lenses being the best adapted for the purpose of obtaiuiug a wide angular field with a miuimum of distortion at or near the edges of the picture. But while, for said purpose, the meniscal form offers great advantages over any other kind of lenses, a disadvantage of the same, however, lies in the difficulty of correcting its optical aberrations, both the spherical and the chromatic, at the same time, without leaving too great amounts of the so-called "aberrations of second order."

The object of the improvement is the reduction of said secondary errors to an imperceptible miniuum.

The iuventor claims:—

In a photographic objective, a compound meniscus, consisting of a negative flint-glass meniscus, a negative crown-glass meniscus, and a positive crown-glass meniscus, so combined that the flint-glass meniscus is enclosed by the two crown-glass meniscuses, facing with its convex side toward the concave side of the negative crowu-glass meniscus, and with its concave side toward the convex side of the positive crown-glass meniscus.

Correspondence.

SPHERICAL ABERRATION AND DEPTH OF FOCUS.

Sir,—The length of Mr. Dallmeyer's letter, and the time which he has allowed to elapse before attempting to reply to my article of the 19th September, will probably serve, with those readers not especially interested iu the subject, to disguise the fact that it is essentially no reply at all to what I have put forward.

If modes of explanation dealing with the transversal measurements of spherical aberration have been "exploded" by Mr. Dallmeyer, not only have I and Mr. Grubb been arguing upon a false foundation, but so have all scientific writers upon the question, includiug Mr. N. E. Duuer, whose exposition in the last two numbers of the Photographic News would, iu that case, be mere waste of paper. As a matter of fact, transversal measuremeuts are of essential importance.

Mr. Dallmeyer's statement that the apex of the axial cone of rays is the best focus, is easily shown to be not in accordance with the fact. If in a leus possessiug spherical aberration we place a small diaphragm, we are workiug near the apex, although still somewhat short of it. If we now remove the diaphragm so as to allow the effect of spherical aberration to be visible, it will be found that the lens has to be racked inward to get the best focus. Obviously, if the apex of the axial coue were the best focus, this removal from it would not be necessary. The fact that with a lens not thoroughly aplanatic the position of the best focus is altered by the insertion of a diaphragm, is so well known that it is surprising that Mr. Dallmeyer should venture on a statement involving the fixity of that positiou.

Mr. Dallmeyer, whilst writing on my commeuts upon the photographs illustrating his Camera Club paper, has not offered any explauation of the fact to which I particularly invited attention, namely, that the photographs numbered ix. and xvi., which were stated to be taken at distances of $\frac{1}{10}$ of an iuch and half an iuch from the focus, were actually in better focus than Nos. viii. and xv., stated to be in the best focus. It is, indeed, not easy to see how any explanation could be given, and Mr. Dallmeyer's silence on the point must be accepted as sufficiently suggestive.

Experimental proofs, when fairly conducted, are of the greatest value; but an experiment in which can be found evidence of its not having been carried out under the conditious stated with regard to it, is worse thau useless. W. E. Debenham.

A PERMANENT EIKONOGEN COMPOUND.

Sir,—We have pleasure in informing you that the manufacturers of eikonogen (the Actien Gesellschaft für Aniliu Fabrikation, Berlin) have now succeeded in producing this admirable developer so that it is free from any liability to discolour. The changes necessary for obtaining this desirable quality necessitate that the eikonogen be issued in the form of a powder. The manufacturers assert that they have arrived at this result by means of a preservative, and all consumers may confidently rely that this uew uethod will keep the eikonogen perfectly free from discolouration. The old formula remains without any change. Marion and Co.

Soho Square, London.

GELATINO-CHLORIDE PAPER.

Sir,—I notice an article in your issue of 24th inst. on the subject of "Gelatino-Chloride Paper." You there practically state that there is no such paper made iu Eugland, and that we are indebted entirely to our Continental neighbours for the manufacture of the material for this most charming process of priuting-out. There are only two known makers of this paper on the Continent, and these are Obernetter and Liesegang, but you appear to have overlooked the fact that my firm placed on the market, over two months ago, an improved gelatino-chloride paper called "Celerotype" (or swift printiug) and that this paper is manufactured on their owu premises. It is very satisfactory to find that it is preferred to the foreign make. You say "it is difficult to understand why our manufacturers have allowed this branch of photographic industry to remain in the hands of foreigners." Well, the reason is not far to seek. The successful manufacture of a good gelatino-chloride printing-out paper is beset with so many difficulties and requires such close supervision, that few would care to undertake it. The paper we make has, iu addition to its own special qualities, all the advantages you mention in your article, and has this claim on all patriotic Britous, that it is prepared by British hands, with British materials, and by a British firm.

William Gourlie Blackie,
Manager to the Blackfriars Photo. and Sensitising Co.,
1, *Surrey Row, Blackfriars Road, 27th October.*

THE PHOTOGRAPHIC MANUFACTURERS' AND DEALERS' ASSOCIATION OF THE UNITED KINGDOM.

Sir,—I have the pleasure to iuform those of your readers who are interested in the photographic trade, that the above Association is now fully established, and is getting into working order. Offices have beeu taken at No. 7, Southampton Row, Holborn, W.C., and a permaneut secretary appointed, so that in the course of a very few weeks the Association will probably begin to make its influence for good felt throughout the trade. Naturally a considerable amount of time has to be spent in arranging miuor details, as an uudertaking of this description cannot be floated by the "instantaneous process."

To buyers of photographic material, both at home and abroad, the Association will prove of considerable value, as they will know, when dealing with a member of the Association, that he is a *bonâ fide* manufacturer or dealer, as the case may be.

The Council would esteem it a great favour if any cases of unfair or dishonest trading, with full particulars thereof, be imuediately reported to the Association. Such communications will, of course, be treated as strictly coufidential.

All communicatious should be addressed to the secretary, Mr. F. O. Bynoe, 7, Southampton Row, Holboru, W.C.

Birt Acres.

131, *Richmond Road, Hackney, N.E., 28th October.*

ALPHA PAPER.

Sir,—In your issue of 24th inst. you write of alpha paper in the past tense, as if such a thing was not now in existence. May we undeceive you in this by saying that the sales of this paper are larger now than ever they were.

The Britannia Works Co.

Ilford, London, E., Oct. 27th.

[Alpha paper is in widespread use now, and we print on it sometimes; a large variety of tones may be obtained with it by modifying the development.—Ed.]

The Photographic Club will hold its annual general meeting for the election of officers and other business on November 5th, and the annual dinner will take place on November 19th.

Brixton and Clapham Camera Club.—On November 6th, at 8 o'clock, a lecture, illustrated by the lautern, and entitled "A Tour in Brittany," will be given by Mr. A. R. Dresser, in Gresham Hall, Gresham Road, Brixton.

London and Provincial Photographic Association.—Subject for November 6th, "The Unnatural Character of so-called Naturalistic Focussing" (second evening), Mr. W. E. Debenham; November 13th, lantern night, judging of competition slides.

Sachse's Developer for Orthochromatic Plates.—Mr. Sachse uses for this purpose:—Sulphite of soda, 5 drachms; eikonogen, 45 grains; quinol, 15 grains; distilled water, 8 ounces. Heat the water to the boiling point and add the sulphite. When dissolved, add the eikonogen, theu the quiuol. Shake until thoroughly dissolved. Allow the solutiou to stand for ten hours, and add 90 graius of carbonate of potash. For use, take equal parts of this solution and water. The picture should come up quickly aud perfect in details, with full deusity iu the shadows.—*American Journal of Photography.*

Proceedings of Societies.

THE PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN.

At the technical meeting of this Society held on the 28th inst., Mr. T. SEBASTIAN DAVIS in the chair, the apparatus in the Exhibition was shown and explained.

Mr. A. WATKINS, in demonstrating the method of using his exposure meter, said that hitherto calculations for exposure had not sufficiently taken into account all the factors. Each factor—light, speed of plate, subject, and diaphragm or aperture—had its own influence, and should be accounted separately. In his instrument a separate column was assigned to each factor, and these columns were adjustable to one another on the principle of the slide rule. Having ascertained the value of the light by means of an actinometer containing paper coated with gelatino-bromide of silver, and sensitised for direct printing action by nitrite of potash, the column denoting light was set to the figure representing the power of light at the moment. The other columns were then set, each to the number belonging to the particular case, and at the last column an index would be found pointing to a number representing the exposure required.

Mr. T. SAMUELS showed his magazine camera, to which certain improvements had been adopted during the last year. At the front of the camera a sliding U-piece sustained the bellows and lens board. This U-piece allowed the front considerable motion, both laterally and vertically, as well as a swinging movement. Lenses of various length of focus could be used, and there was a scale marked with the distance for each lens, both when photographing objects far off and at certain nearer planes. The cases both for the camera and stand were not entirely removed, but merely opened out for use, an arrangement in virtue of which the repacking was very quickly performed. Similar cases, but made of Willesden paper, and stated to be light, efficient, and easily constructed, were also shown.

Mr. W. H. Humphries' hand-camera was shown, and the method of working it demonstrated. The plates were in metal carriers lying horizontally at the back of the camera, and were drawn out one at a time by a simple movement, held in position, and then transferred to the top of the pile from which they had been removed.

Messrs. Morley and Cooper's exhibits included a French automatic time and instantaneous shutter, and a camera and stand very light in construction.

A dark slide with a locking arrangement, preventing the shutter from being drawn out again when once it had been opened and closed, was shown by Mr. G. Renwick.

A plate rocking apparatus by Messrs. Lewis was put in action.

The Excelsior plate washer of Mr. W. Rooke was shown. The spray pipe was fitted to floats, so that it was always kept at the same height from the water.

Messrs. Pearson and Denham's reducing camera, and Swindon and Earp's hand-camera, in which certain improvements had been effected since last year's Exhibition, were put before the meeting.

Messrs. Mawson and Swan's exhibit included Loman's reflex camera, and a smaller one called the "Sport" camera, as well as Hume's cantilever enlarging apparatus, and Payne's photo-micrographic apparatus.

Mr. J. R. Gotz's camera, with aluminium fittings, was next shown, and the exhibits of Messrs. Shew and Crouch were also displayed.

Mr. W. England showed holders for celluloid films of large size intended for use with the ordinary dark slide.

Dr. LINDSAY JOHNSON said that at the Berlin Medical Congress he had seen pencils made for writing upon glass, and, thinking they would be of service in photography, had brought them to the meeting. They were of various colours—red, blue, violet—and very suitable for working on either the back or front of the negative, as well as for writing upon it.

M. LEON WARNERKE said that wax was their chief constituent.

THE CAMERA CLUB.

On Thursday, October 23rd, Mr. E. J. HUMPHERY read a paper at the Camera Club, entitled "The Direct Reproduction of Negatives and Positives." Mr. A. MASKELL occupied the chair.

Mr. HUMPHERY described his method of obtaining positives and negatives direct from positives and negatives in one operation, by the reversal of the image. He stated that he had been led to his experiments by a conversation between himself and Mr. Bergheim. The method was to give an exposure many times greater than that for normal development, then to develop with an extremely dilute developer; the result was a printable negative from a negative, or fair positive from a positive. Prints taken from the secondary negatives were handed round, and the lecturer said that he hoped to so improve the results as to obtain the second negative as free from fog as the original. He added that the method was useful in photomechanical processes in which reversed negatives were necessary.* Positive prints upon platinotype paper made into excellent transparencies by treatment with paraffin, were also shown.

Dr. PATTERSON, who had seen the experiments of Mr. Humphery, said that it was almost inexplicable to him to see the rebate developing black in these plates. He believed that Dr. Jaussen was the first, and in 1880, to draw attention to the phenomenon of several successive reversals, but the matter did not seem to have been taken up practically anywhere. The plan of Mr. Humphery was to expose a plate eight or ten times longer than usual, and to develop with a solution one-eighth of the normal strength; he, however, always obtained a certain amount of fogging on the plate, due, perhaps, to not hitting exactly the right time of exposure; in negatives this slight fogging does not matter. Transferotypes could thus be obtained without going through their present reversing process.

Mr. LYONEL CLARK remarked that when reversals were thus obtained by contact and exposure to even weak diffused daylight, the plate must be subjected to vastly more than eight or ten times the normal exposure. He thought that the first man who obtained reversals was Goddard or Claudet—he was not good at remembering names—in 1842 or 1843. A remarkable paper full of information on the subject, had once been read before the Physical Society, in connection with the photographing of the dark streaks of lightning. The fact of the rebates coming out black he thought to be purely the effect of halation. Nobody that evening had touched upon the theory of the reversal of the image.

The CHAIRMAN described a case in which there appeared to have been a double reversal of the image.

Mr. GEORGE DAVISON thought the greatest objection to the method to be the amount of fog on the plates.

Major J. F. NOTT remarked that, with certain printing frames, fog was obtained when producing lantern slides by contact, and that this was due to light so reaching the edges of the plates that it could get underneath them by internal reflection.

Mr. FERRERO avoided this by printing at the bottom of an open box, so that, practically speaking, none but parallel rays could reach the negative.

Mr. W. WILLIS stated that Mr. Humphery, when exposing by means of a lantern, obtained a positive in half an hour, and in another case by an hour's exposure obtained a reversal.

Mr. ASBURY GREENE had tried to get alternating reversals by increasing the times of exposure, and had not succeeded.

Mr. GALE had once been photographing the interior of a church tower; through the open door a landscape was visible; the interior developed in the normal way, whilst the landscape gave a positive image upon the same plate.

Mr. CLARK had known the extra amount of light let in by the accidental opening of the developing room door to reverse an image. Was it possible that a certain vividness or intensity of light was necessary to get reversed images at all? It was worth trying by experiment.

Mr. HUMPHERY said that when he told a lady that he was

* Mr. Frewing has long been producing reversed negatives in this way for commercial purposes.—ED.

getting reversed photographic images, she asked whether the back of the head of the sitter came out instead of the face? When he explained the facts she thought him "no great shakes!" The whole secret of success in the method lay in reducing the developer to one-eighth the normal strength. He used no bromide, so did not know what might be its influence.

The Chairman had been trying an old process described by Hunt, in which paper was prepared with sulphate of copper and bichromate of potash, then dried and placed under a negative; but had never been able to get the reversal spoken of by Hunt, who had written that under such circumstances short action of light gave a negative, and long action a positive.

Mr. W. Willis remarked that if the solutions used by the chairman had been made acid with sulphuric acid, he would probably have obtained the white ground spoken of by Hunt; he could not, however, say anything about any reversal.

On Thursday, November 6th, Mr. J. Gale will read a paper entitled "Country Rambles with a Camera." The paper will be illustrated by lantern slides.

The London and Provincial Photographic Association.

October 23rd.—Mr. C. H. Cooke in the chair.

Mr. G. W. Atkins, referring to the discussion at the previous meeting on stereoscopic photography, said that a photograph taken with two cameras rather wide apart would show the immediate foreground greatly exaggerated; he attributed this to the use of short-focus lenses.

Mr. W. E. Debenham said the length of focus of a lens was not responsible for exaggeration of perspective; the use of a wide-angle lens might produce it, but only then when the photograph was viewed at a greater distance than the length of the focus of the lens employed. This he illustrated by means of diagrams on the blackboard.

Mr. W. E. Woodbury exhibited examples of celerotype prints, a gelatino-chloride printing process recently introduced by an English firm. Enumerating the advantages of this paper, he said it was twice as sensitive as albumenised paper, and gave brilliant images. It was necessary to print deeper than required to allow for reduction. By varying the toning bath a range of tone was available for selection according to the taste of the operator. He believed the paper to be permanent from the fact of the sensitive film being on the surface of the paper, and the soluble salts easily removed: a substratum of pink chalk was used. Mr. Woodbury stated that a new mountant would shortly be introduced into the market that would not dull the gloss of prints stripped from glass.

Mr. F. A. Bridge had tried the paper. It curled very much when immersed in the toning bath.

Mr. Woodbury said that the paper was tougher than others of its kind, and he found it very easy to work. It was especially suitable for thin negatives.

Mr. T. E. Freshwater showed some bromide prints, directing attention to one, the Paul Pinder, Bishopsgate Street, which he had taken a few days previous to its being pulled down. He also passed round the current issue of *Fun*, containing a skit on a recent photographic county court action.

Photographers' Benevolent Association.

A very pleasing combined lantern and musical entertainment was given, under the direction of Mr. F. A. Bridge, in the large hall of Auderton's Hotel, Fleet Street, on Friday evening, 24th inst., in aid of the funds of this Association. Lantern slides were contributed by Messrs. T. Charters White, J. B. B. Wellingtou, F. P. Cembrano, Atkinson, Ackland, Scrivenor, Bridge, Freshwater, Dando, Birt Acres, T. Guardia, J. Carpenter, S. T. Chang, and H. M. Hastings. The visitors completely filled the room, and included the Chinese Ambassador and suite, besides the officers of the Society. Mr. J. Traill Taylor explained the objects of the charity, its need of help, and, with music interspersed at intervals, a good entertainment was provided, which appeared to give general satisfaction. Mr. R. Beard undertook the management of the optical lantern.

West London Photographic Society.

An ordinary meeting took place on October 24th at the Broadway. Mr. C. Bilton (the retiring president) introduced Mr. Walter Adam Brown, who had been elected to fill the office for the year 1890-91. A vote of thanks was passed to Mr. Bilton for his services during the past year.

Mr. Wm. Schooling, F.R.A.S., was elected a member.

In answer to a question as to the best means of reducing a negative which had been over-intensified with mercury, Mr. Whiting said that Howard Farmer's reducing solution, composed of ferri-cyanide of potassium and hypo, would generally be found to answer well, but in the case of a yellow negative he preferred to use ozone bleach.

Mr. W. A. Brown, in the course of his inaugural address, said that it seemed to him that photography was purely in its infancy, notwithstanding the vast improvements which had been made since its discovery, both in the direction of *technique* and of art, and no one could prophesy the changes which might occur even during the short period of their own lives. Much remains to be discovered. In regard to landscape work, the photographer was brought face to face with the serious drawback that, however successful in other respects the photograph might be, it always lacked colour. Skies also were difficult to obtain in the same negative, and the relative values of distances were often misrepresented. It was one thing to see a pretty composition on the screen, and quite another to produce the same result in the photograph. Although he spoke with an indifferent knowledge of the subject, he did not think natural colours would ever be produced in the negative; but in regard to the true rendering of skies, the present difficulties would be overcome. Speaking of the manipulation of the plate, he thought very considerable art might be exhibited in its development. A very great amount of art was necessary in selecting the picture and arranging it on the plate, for they must not forget that they could not manipulate a foreground like a painter; they must take nature as they found it, or leave it alone. Many a good picture was spoilt by bad development, and in the same way many a badly exposed plate could be saved by skilful treatment. When it came to the after operations of washing, &c., the work was mere drudgery. In the first handbook he had read, it was stated that washing by hand was the most effectual method, and recommended that twenty changes of water should be given, with an interval of ten minutes between each change. Those who were fond of figures would find that that was a very protracted operation, and, to a busy man, a great waste of time. Although print and negative washers existed in every conceivable variety, it seemed to him that the washing itself might be obviated, and that the same chemical aid which introduced the hypo might be invoked to eject it in the same summary manner. Speaking of the photographer rather than of the materials, he could not help noticing the large number of people who took out six plates, and were not happy unless they shot them all off before returning. That should be altered. Comparing the photographer with the painter, the latter did not try to paint everything he came across; he selected his subject. The same principle should guide the photographer. Another fault with amateurs was the incessant craving after novelties. Before a particular make of plate was mastered it was discarded and a fresh brand chosen—it was the same with shutters, lenses, and other things. He would impress upon them the many advantages to be derived from joining a society, and he congratulated them upon the good position to which their own had attained. In conclusion, he thought it would be a great boon to their own and other societies, if they could combine together in the same way as angling societies had done, and obtain the privilege of getting railway tickets issued to them at reduced rates.

The optical lantern, under the superintendence of Mr. Horton, was then put in operation, and a large number of slides exhibited. A fine series in wet collodion, by Mr. C. Whiting, of Shakespeare's birthplace and the neighbourhood of Stratford-on-Avon, was much admired. Messrs. Wilson, Dixon, Lamley, Livingstone, Kellow, Hodges, and Winter also showed slides,

an interesting evening was brought to a close by the exhibition of some fine slides lent by Messrs. Fry and Co.

At the next meeting, November 14th, Mr. Jones will give a demonstration on printing in platinum.

Hackney Photographic Society.

The ordinary meeting was held on Thursday last at Morley Hall; Dr. Roland Smith presided.

Several pleasiug results of the Fry Manufacturing Company's samples were handed round, and, from the fact that one or two shown were the work of tyros, good results would appear to be easy to arrive at.

Mr. John Howson then gave a lecture and demonstration on "Alpha Paper Printing and Developing." Many people had said that half-tones were lost with this paper, but the productions shown (the work of a prominent professional) proved that this was not so. The emulsion on paper and plates was precisely the saue, and any colour could be obtained in the toning bath. Exposure should be made by scale, and not by guesswork. The burner to be used was an Argaud two-light at a distance of ten inches, the exposures taken as experiments to be one minute, one and a-quarter minute, and one and a-half minute. The demonstration then took place. After developing, the prints were placed in an acid bath and passed afterwards through three washing waters, and then toned and fixed in a combined bath such as used for aristotype papers. The resulting tone can be modified by stopping at the one desired, taking out the print or plate and merely washing. The results demonstrated were from a red to a platinotype colour, the blue or final colour taking about twenty-five minutes. Various lantern plates were shown illustrative of the tones obtained by the process.

Mr. Beckett showed a print on Alpha paper which had had over twenty minutes' exposure, being an enlargement from a quarter-plate.

Mr. Howson said, in answer to the Secretary, that they had some paper three years old which was still being used.

The Lantern Society.

The first meeting of the season was held at 20, Hanover Square, on October 13th, when Mr. Andrew Pringle gave an address on "The Modern Applications and Appliances of the Lantern."

After briefly alluding to the early history of the lantern, the lecturer proceeded to consider the various parts of a lantern, taking in order the body, where he dwelt on the advantage of portability, showing a small iron lantern which, whilst capable of doing all that a lantern of ordinary construction would do, packed, with all its parts complete, into a box a quarter the size of an ordinary one; the condenser, describing the various forms which have been designed and used at different times; the lens, comparing the ordinary "lantern objective" with portrait and other types of lenses: and the luminant, describing the early form of limelight as designed by Drummond and Beechey, and going into the essentials of a good lime jet; also showing a Brockie inclined arc lamp for use with the lantern. He then went on to discuss the uses and advantages of the lantern from an educational and scientific point, and showed several experiments on the screen with a projection mieroscope. The screen used by the lecturer was a portable one designed by himself, with the view of its being made as handy as possible for travelling.

Amongst other things, Mr. Pringle showed a scientific bi-unial, designed for showing diagrams on the screen before a class, and a projection microscope of a most simple construction designed by himself. Several pieces of lantern apparatus were exhibited, amongst them being a lantern constructed by Mr. J. H. Steward, for using an incandescent lamp of 100 candle power.

Birmingham Photographic Society.

An ordinary meeting was held on the 23rd inst. at the Club Rooms, Colonnade Hotel, the president, Mr. J. B. Stone, J.P., F.G.S., in the chair.

A vote of thanks was passed to Mr. Harold Baker for a set of slides he had presented to the Society.

Mr. Taylor exhibited a metal binder for slides, made by a London firm.

Mr. Jaques saw two or three objections to their use. In the first place, they would let the dust in; in the second place, the metal would have a tendency to scratch the glass; and in the third place, it added weight to the slides. Paper binding could easily be made with gelatine and sugar mixed with water.

Mr. Tucker said that if they were made of iron or steel they would be subject to rapid corrosion.

Mr. J. B. Stone said that it gave him pleasure to call on Mr. Place to put the different slides through the new lantern, which had been subscribed and paid for by the members without touching the Club's funds.

Mr. W. J. Harrison, F.G.S., said that Mr. Place had so admirably made it that it was the best in England, and therefore the best in the world.

Mr. J. B. Stone's slides were first passed through from pictures he had taken while on tour with the Vesey Club in Norway. Slides were also shown by Messsrs. Owen, Thomason, Titley, Underwood, Harrison, Palethorpe, Jaques (illustrating a nursery story from a toy book), Baxter, Pickard, and Leeson, and also about forty sent by Messrs. Mawson and Swan.

Mr. Stone offered twenty-five of his 15 by 12 negatives of Warwickshire to the Survey Council, and prints from each in platinotype.

The Photographic Society of Ireland.

A special general meeting was held on the 23rd inst. at the Rooms, 15, Dawson Street, Dublin, Professor J. Alfred Scott, M.B., in the chair.

After authorising the addition of the rule that any person elected a member during the last three months of the year should not be liable to a further subscription in the following January, and also to authorise the treasurer to remit the entrance fee to all elected members from that date until the 31st January, the meeting was resolved into an ordinary one.

Mr. M. Hedley exhibited and explained Hunter's fuming box; he also passed round specimens of Fry's bromide paper enlargements made from hand-camera negatives.

Mr. J. H. Woodworth exhibited and explained some stereoscopic transpareneies made on celluloid films.

Dr. E. McDowell Cosgrave having taken the chair, Professor Scott proceeded to give his demonstration on making photo-micrographs. He said that in 1883 he devised a small camera intended to fit on the top of his mieroscope, where it could be placed if anything notable were observed in the field. The plates were small, being $2\frac{1}{2}$ by $1\frac{3}{8}$—much too small for useful lantern slides. The camera used for all his subsequent work was practically the same camera, but elongated about fifteen inches. This gave a picture about three inches square, yet was sufficiently short to allow working all the microscope adjustments while focussing the object. For convenience and steadiness, the camera was arranged parallel with the table instead of being placed on the microscope and regardless of the position of the latter. At the outset, he desired to disclaim any idea in connection with the slides that he would presently put upon the screen other than that of lecture diagrams. In many cases detail was deliberately suppressed, and in some appearances exaggerated, to make the remainder more diagrammatic, but there was nothing more done than would be allowed in the staining and mounting of the specimens had they been specially prepared with the intention of taking photographs from them. Some which were wanted with that intent were so stained as only to exhibit the particular point wished to be shown. The actual photographic work was in most cases easy, the ordinary methods being employed; in other cases, however, the special isochromatic plates were necessary, on account of the stain employed in mounting the sections. With the modern lenses which were used, everything depended on the angle of light—the greater the angle of light, the more was to be seen. There were some objects which were not to be seen at all; the microscope would not show them unless the light passed into it at an angle; in this case a special condenser was used to give the

light at the necessary angle. Professor Scott described his method of focussing, which was done on a piece of glass coated with a solution of gelatine with which a little milk had been mixed, and said that for a second and finer focussing he could implicitly recommend a piece of clear glass on which some lines had been scratched with a diamond about a quarter of an inch apart, such lines not interfering in the slightest with the object focussed. With regard to the illumination of the object, he found an ordinary paraffin lamp amply sufficient for low powers, but in order to concentrate the light for high powers he recommended the use of an ordinary bulls'-eye. Professor Scott then illustrated his remarks by taking a photograph of the section of the eye of a house-fly, and, having given it six minutes' exposure, retired to the dark room with a number of the members and proceeded to develop the negative, which was then passed round and greatly admired.

A number of microscopic transparencies was then put through the lantern by Professor Scott, and a discussion followed.

GLASGOW AND WEST OF SCOTLAND AMATEUR PHOTOGRAPHIC ASSOCIATION.

THE first monthly meeting for the season was held in the Rooms, 180, West Regent Street, on the 20th October. Twenty-four new members were elected.

A paper on "Hand-Camera Work," by Mr. JOHN MORISON, Junr., was of special interest, and after an exhibition of novelties, the lantern was brought into requisition for slides from hand-camera work, and pictures were shown on the screen, as also some amusing studies.

THE CLUB OF AMATEUR PHOTOGRAPHERS OF VIENNA.

IN Vienna photography may be said to have begun its winter session, for both the Photographic Society and the Club of Amateur Photographers have held their first meetings. That of the latter, presided over by Mr. Charles Srna, president, on the 11th inst., offered various points of interest. Among others, we may mention the vote of thanks given to Mr. Ulrich for the trouble he took in calling the attention of English photographic circles and journals to the exhibition to be held here in the spring. The Baron Nathaniel Rothschild's pictures were deservedly admired on account of their artistic merit. As at the meeting of the Society, so here Mr. Einsle spoke of his process for the intensification and partial reduction of negatives while under development. Mr. Lewitzki exhibited some interesting magnesium flash-light pictures representing scenes from "The Czar Boris," a drama of Tolstoy's. A French developer, called "Crystalos," was spoken of by Dr. Hoffmann.

NELSON (NEW ZEALAND) CAMERA CLUB.

THE second annual meeting of the Club was held on 26th June, Mr. FELL, president, in the chair.

The SECRETARY gave a resumé of the year's work. Reference was made to the satisfactory attendance at the monthly meetings, the success attending the exhibition held in February, and the number of photographs contributed to the Club portfolio. The accounts showed that the Club was in a satisfactory financial condition. The introduction of special subject competitions on each evening had increased the interest of the members in the work of the Club.

For the ensuing year the following officers were elected :—*Patron*—H. E. the Governor ; *President*—Charles G. Fell ; *Secretary*—F. W. MacLean.

The subjects arranged for each meeting have been:—July—Old Building in Nelson ; August—General View of Nelson ; September—Interior (flash or otherwise) ; October—Snow Scene ; November—Animal Study ; December—Cut Flowers ; January—Object in Motion ; February—Marine View ; March—Life Subject (figures, portrait or nude) ; April—Forest Scene ; May—Clouds ; June—Enlargement.

THE Photographic Section of the Imperial Technical Society in Russia has decided to organise an exhibition of apparatus and photographs of a strictly academical type, to be opened during Lent, 1891.

Answers to Correspondents.

All Communications, except advertisements, intended for publication, should be addressed to the Editor of the PHOTOGRAPHIC NEWS, 5, Furnival Street, London, E.C.

All questions requiring a reply in this column should be addressed to Mr. John Spiller, F.C.S., 2, St. Mary's Road, Canonbury, London, N.

All Advertisements and communications relating to money matters, and for the sale of the paper, should be addressed to the Publishers of the PHOTOGRAPHIC NEWS, Messrs. Piper & Carter, 5, Furnival Street, London.

D. J. S.—*Portraits with White Background.* We were under the impression that the days of white sheet for background had passed and gone, but your letter is confirmed in every particular ; and, having seen the said photographs, we adhere to the opinion that they would have looked better if the contrast had been less violent. There is, however, no difficulty in producing such results, if desired. Those we saw were full-length portraits of actors taken in London, and not foreign specimens.

W. G.—*Platinum Toning.* Although the price of platinum has gone up nearly to that of gold, its use cannot be dispensed with if you wish to obtain the sepia tones, such as those now represented by numerous examples in the Photographic Exhibition.

L. E. M.—*The Cylindrograph.* The exposure is not managed in the way you suggest, but the lever arm carrying the lens is moved through an arc of nearly half a circle backwards and forwards several times, so that inequalities are practically neutralised, and are not apparent in any of the specimens shown. There is some truth in your criticism about the bent lines in perspective.

T. F.—"*An Invitation to Supper.*" With a general verdict in its favour, it seems unfortunate that a medal could not be awarded, but the regulations must be adhered to, and the Crystal Palace show is made responsible for withholding it on the present occasion. The picture is certainly very good, and the fact that the judges agreed in recommending it is proof of their coinciding in your opinion. The same four figures, differently posed, are made to do duty several times in the procession. See the letter in last week's NEWS, which answers your other enquiry.

A. B.—*Hand-Cameras.* The season being so far advanced, it would perhaps be wise to delay making a purchase until next spring ; but if a choice is now to be made, a good selection can be seen at Pall Mall, and the chief features of these were described at the technical meeting on Tuesday last.

B. N.—*Kallitype.* The patentees have written to say that we have given you the *old* formula, and that the process works better with sundry alterations which they have recently introduced ; the chief of these being the use of 1 ounce of citrate of soda, instead of 800 grains, in the developer, and the first washing solution is to contain this salt of same strength (2 oz. per pint) *without* any addition of nitric acid.

COL. WATERHOUSE.—Received your letter, and we shall have much pleasure in attending to your request.

G. S. B.—*Swan Watermark in Paper.* Our correspondent wishes to identify a photographic paper having a swan as watermark. Can any of our readers help us by giving the name of the maker ?

S. and W.—*Triplicate Portraits.* If you search the NEWS of April and May last (this column), you will find several references to methods of accomplishing this task, three poses on one plate. They are, of course, somewhat difficult of execution. You are working in imitation of Vandyke's portrait of Charles I., which, if we mistake not, is to be seen at Warwick Castle.

LINDO.—*Celluloid Films.* To keep them under pressure in the dark slide, Mr. England suggested, at a technical meeting of the Parent Society, that a slightly curved rabbet should be inserted into the carrier, but not bent enough to throw the sensitive surface appreciably out of focus.

F. M.—*Copying Apparatus for Lantern Slides.* Messrs. Marion and Co. recently showed a convenient form of apparatus at the Drapers' Hall Exhibitions, and now Mr. A. R. Dresser has a copying table for lantern slide making in the Pall Mall Exhibition.

THE PHOTOGRAPHIC NEWS.

VOL. XXXIV. No. 1679.—*November* 7, 1890.

CONTENTS.

PRINTING NEWSPAPERS BY PHOTOGRAPHY.

THE printing of newspapers by photography now seems to be coming within measurable distance. Before the Bath Photographic Society, as will be seen in another column, a machine—the joint invention of Mr. Frederick Varley and Mr. Friese Greene—has just been exhibited, by means of which machine positives from one negative have been turned out at the rate, it is stated, of three a second. This means 10,800 per hour, exclusive of the developing, washing, fixing, and drying operations, which, by means of suitable baths and mechanical appliances, need not take long. One picture turned out by the machine was of half-plate size, and slightly overdone in the high lights, which is a defect easily remedied; in other respects, nearly all the prints on the long band were good. A long roll of highly sensitive bromide paper had been used. As the matter now stands, while only a few hundred pictures have been turned out by the machine in early rough-and-ready experiments, it seems likely that it will have an important bearing on book-illustration. It would be something quite novel for a publisher to take a negative to a commercial firm, and in an hour or two to receive 10,000 dried and cut prints from it ready for binding.

As regards producing entire newspapers in this way, the suggestion has been made that the articles can be given in the handwriting of the authors. A more painful infliction upon the public can scarcely be conceived, as newspaper editors know. Some specimens of handwriting are as easy to read as Egyptian hieroglyphics. In any case, the invention does not seem likely to interfere with compositors' work; but a printed proof can quickly be photographed, and the negative used in connection with the printing operations.

For newspaper printing, silver salts would be too expensive. Mr. Friese Greene told us last Monday night that he has long been searching for a quick process with other salts, and had only succeeded that morning. He exposed, for about half a second, a sensitised card, in our presence, under a negative at a distance of about four inches from an ordinary fish-tail gas flame, then put it in a developer in which the print came up as rapidly, and in the same manner, as in the gelatino-bromide dry plate process; then he washed and fixed it. He did not inform us what chemicals he used, but assured us that there was no silver in them, and that an inexpensive salt was the agent sensitive to light.

Possibly before long a great demand for the services of photographers may arise in printing offices.

THE DIAZOTYPE PROCESS.

LAST Monday night Messrs. Green, Cross, and Bevan brought their new diazotype process under the notice of the Society of Chemical Industry at Burlington House, and gave some information on the subject in advance of that previously published.

Mr. Green read the paper, in the course of which he said that primuline and all other amido compounds are turned into diazo compounds by the action of nitrous acid, and are then, all of them, more or less sensitive to light. He demonstrated the process to the Society, and developed prints of several different colours; one of them, not previously publicly exhibited, was of a vivid dark blue; the developing agent in this case was amidobetanapthol sulphonic acid. A green remains to be obtained by the diazotype process, and then by its means all the colours of the spectrum can be typically represented at will.

Supposing a picture—say a landscape—to be printed by the diazotype process, and supposing a developer to produce green to be discovered, it will be possible, by locally painting upon the faint image by means of a brush, to bring out the whole picture in somewhat the colours of nature; the colours will usually be more gorgeous, and there is no means of modifying them, except in instances in which two of the developers can be mixed. The brush work must be neatly done, because, should it extend beyond the edges of the leaves or other parts of the picture being treated, the part of the background touched will come out of the same colour as that which the developer produces, but more or less strongly, according to the relative intensity of the previous action of the light. Mr. Green expressed the belief that the colours produced were faster upon gelatine than upon cotton, and that they were

more unstable when produced by a weak developer instead of a strong one. He also stated that several persons are trying the value of the diazotised compounds in orthochromatic work with gelatino-bromide photographs, Mr. David Howard having put the question whether anyone were working in this direction.

In the course of the discussion, Dr. Boureart stated that, on the Continent, he had seen the action of the diazosulphonic bases on the phenols utilised to produce colours upon fabrics when exposed to light; the light itself brought out the colours. Those who were using the process did not tell him exactly what chemicals were employed. He had found that the rays of the sun would destroy the pink colour of eosine in one hundred and ten minutes, and that quinoline blue was more fugitive still under the action of light.

PASTELS AND PHOTOGRAPHY.

THERE are many reasons why photographers should take an interest in the revived art of pastel painting, and why they should not lose the opportunity of visiting the Exhibition of the Society of British Pastellists, which remains open at the Grosvenor Gallery for the whole of this month. For a long time photographers have depended more or less upon the use of chalk and stump for finishing enlarged portraits, and we see no reason why, in the near future, a new branch of art should not arise in which coloured chalks or pastels should be employed for working upon a photographic base. The universal use of bromide paper as a medium for obtaining quickly and with certainty large pictures from small negatives, itself constitutes a new industry of no small dimensions; and, certainly, no better foundation for a pastel picture could be imagined than such a surface, which, by treatment with pumice or other roughening agent, has been made receptive of the soft chalk.

At the Exhibition referred to, the photographer of artistic tastes—and he can hardly be called a photographer unless he can claim a right to be so described—will see much to admire. He can study the simple means by which certain effects can be rapidly executed, and enjoy the great range of colour at an artist's disposal when he employs pastels to express his ideas.

For effects of aërial perspective, the dry medium runs water colours very close indeed, while for flesh tints it is indeed hard to beat. He will, on the other hand, see much which he will do well to avoid. At all modern picture galleries in these days, when it is the fashion among certain new schools of art to set aside old traditions, and to pooh-pooh! the works of those who have hitherto been regarded as masters of their craft, mannerisms of the most absurd type obtrude themselves, and one is continually tempted to enquire whether this or that work has been executed by an inmate of Bedlam, or whether its presence is to be regarded as a huge joke. The present pastel exhibitors evidently have among their body many "cranks," as our American cousins would call them, and it would seem as if these members had tried their hardest to produce the most outlandish results. Mr. Furniss's "Artistic Joke"—as he called his skit on the Royal Academy's Exhibition which was open in Bond Street a couple of years back—contained nothing of such a burlesque character as some of these Grosvenor Gallery pastels, which are grotesque and ludicrous, the more so, perhaps, because they are intended to represent something very different. If likeness to nature be really an attribute of art, the humble worker in coloured chalks upon our pavements, with his crude attempts at sunset and moonlight effects, is nearer the goal than some of these pastellists. But it is not our purpose to review in detail the works hung at the Grosvenor Gallery. As we have already indicated, there are many most excellent pictures there, which, perhaps, gain rather than lose by the presence of those which are only remarkable by reason of their eccentricity and utter unlikeness to anything in the realm of nature. Those who visit the Gallery will quickly see from which pictures they can gain a knowledge which shall be of future use to them in their photographic work.

Bromide paper is not the only medium which may be made suitable for working upon with coloured crayons. There is just now a craze among photographers for printing paper which is not only provided with a dull matt surface, but has, in addition, a coarse grain, as may be seen by a glance round the walls of the present exhibition in Pall Mall. It is easy enough to salt and sensitise any description of rough drawing-paper—and nothing could be better as a basis for pastel work—for the necessary grain is not destroyed in the sensitising process, which merely consists of the application of silver solution with a soft brush or sponge. So that the worker is in the same position as a pastellist who is commencing a picture on blank paper, with the farther advantage that the image has been already sketched out for him by the action of light. In working, too, on such a basis, the artist will be able to cover over any portions of the photograph which it may be needful to eliminate, to subdue portions which are too obtrusive, and to bring into greater prominence outlines which, by halation or other accident, are indistinct, for the colours with which he works are, of necessity, of an opaque character; and it is well that they should be so, for the photograph, as such, must disappear, and the pastel work must take its place. The picture underneath must be regarded as a mere sketch—a guide for the crayon—and it is only as such that we recommend this wedding between two distinct branches of art.

That some of the pastellists would do well to use photography as a basis for their work will be evident from what has already been pointed out, although they will doubtless regard the suggestion as being somewhat uncomplimentary and uncalled-for. But a man challenges criticism when he publicly exhibits his work, and if he apparently strives to impress the public with the notion that he holds all the common rules of drawing in contempt, he cannot complain if we point out a remedy for his shortcomings. Both photographers and

pastellists who are inclined to adopt our suggestion that one art should help the other, would do well to bear in mind that they are working in a medium which is capable of certain effects. They must not strive to do with the chalks that which is beyond their province. At the Pastel Exhibition, there are far too many attempts to make the pictures look like works in oil or water-colour, and the result is invariably a failure.

THE BY-WAYS OF PHOTOGRAPHY.

Much has been written, and with truth, about the rapid and extensive "strides" made by photography in what may be called the highways of the world. By the aid of photography, this art or science, or both—the matter is not yet determined—almost all arts and sciences have been more or less benefited. It is connected more or less with archæology, geology, histology, meteorology, and zoology. It plays a prominent part in geography, botany, astronomy, and architecture. The use of the camera is not unknown to the professors of medicine and of jurisprudence. It investigates the heights of the starry heavens, and the bottom of the deep, blue sea; it traces the paths of the lightning flash, the falling water-drop, and the flying bird; it delineates the waves of the human voice, and prints on paper the motions of the galloping horse and the hurtling cannon ball. Dr. Eder has given us the image on the retina of a beetle, and Dr. H. W. Vogel has shown how the velocity of the earth in its orbit can be calculated by the variation in the displacement of the lines in the spectra of different stars.

All this and more has been done by the aid of photography, and all this and more is fairly well known by every amateur and professional who has laboured in its ample field; but it is not, perhaps, every one of them who has marked the humbler, the more secluded, paths of interest and utility—the by-ways of progress as yet virgin and untrodden by the foot of the photographic artist. It has not yet, perhaps, been sufficiently explained how far this artist has his moral and religious use, and how his practical services for the world may still be widened more and more.

"I am not only witty myself," says Falstaff in the second part of Henry IV., "I am not only witty myself, but the cause that wit is in other men." So the photographer may say, "I am not only clean myself, always excepting the chemical stains incidental to my craft, but the cause that cleanliness is in others;" and thus, seeing that cleanliness is next to godliness, the photographer may, in some sort, be regarded as a religious reformer of mankind. Some little time back it was remarked that if sitters were to wash their faces immediately previous to having a large photograph taken, there would be less labour for retouchers, and a better picture would be the result. This, at the first glance, seems to be an injurious reflection upon the sitters, who seldom fail, as any photographer will be ready to testify, to make themselves as spruce and clean as circumstances will allow. But the purity required by the photographer is of a superlative kind. The face must be washed—so rapid, alas! is the accumulation of dirt—the instant before it is placed opposite the camera. The lens is a keen detective of dust; it can discover foreign matter in crevices almost imperceptible as clearly as the microscope reveals coarseness in the finest cambric. But it has been urged that it would be a hazardous undertaking for a photographer to ask a sitter—let us say a lady who has spent several hours previous to her visit in the manipulation of her hair, her eyebrows, her cheeks, her lips, and other features, a retouching, as it were, of her natural countenance before the subsequent retouching of her artistic picture—to undo a work of skill, and time, and labour; in a word, to wash her face. No; a better plan would be to expose two plates in the studio, one with the hard lines of a face not washed immediately before being taken, the other the soft picture of a smiling beauty, who, in addition to being smiling, is also superlatively clean.

The photographer may lay claim to the character of a religious reformer; he is also a moral guide. Consider, for example, the indecency of drunkenness. The photographer takes several pictures of ladies and gentlemen in their inebriated habit as they stood—or, to speak more exactly, tried to stand. He exhibits them with all their imperfections on their heads and elsewhere; he presents a stern *fac simile* of the limp and listless hand, the uncertain leg, the fishy, tearful eye, the rumpled hair, the disarranged attire of the incapable and the drunk. By the side of these portraits he places others of the same ladies and gentlemen when sober, with all the graces of the human face divine, and possibly the additional embellishments of art. Other weaknesses of our frail and common human nature he treats after the same fashion: the fiery fury of rage is contrasted with the placid demeanour of repose, the ugly scowl of envy with the humility of content. Then will that photographer admit the public into his ethical gallery and give his object lesson to the world. "Look here," we hear him saying with Hamlet, "upon this picture and on this—two counterfeit presentments of the same person under different conditions, under the opposed dominations of good and evil. See what a grace is seated on this brow (and so on), and then look at the companion picture, like a mildewed ear blasting his wholesome brother," and so on. Or if that photographer be of a mercurial disposition, he will content himself, and possibly his audience, with imitating the pose of Serpolette in *Les Cloches*, and echo the familiar refrain, "Just look at this, and look at that." Such contrasted pictures would do yeoman's service in some of our reformatories, in which one photograph might represent the child as it appeared on its admission from the gutters and the streets, the other the adolescent youth ready to figure in the world as a reformed character and an honourable member of the common weal. Things let down into the ears, says the Latin satiric poet, affect the mind more sluggishly than those which are submitted to the faithful eyes. And pictures of this character would probably produce

on the lately admitted neophyte a greater impression than the inaugural lecture, of which, commonly, only one-half is understood, and that half very quickly forgotten.

In addition to the religious and moral uses of photography, there are several practical uses thereof in life's daily round which have been from time to time suggested, and need only a bold heart and a liberal hand for their development. In the way of advertisement, the use of photographic pictures might be very much extended. It is only lately that the ingenious idea of ornamenting the blank spaces above the cushioned seats in some of our first-class railway carriages with excellent and permanent pictures of places of interest in Great Britain has been imperfectly carried into act. Such photographs combine amusement with instruction. They are also supplementary advantages in giving the nervous passenger someting interesting to gaze upon, withdrawing his attention from the people opposite, who are not always grateful for the prolonged inspection of their personal appearance, and occupying his mind with thoughts of a less unpleasant nature than the sudden smashing of the carriage, and all contained in it. Many articles of domestic utility, such as soap and candles, handerkerchiefs and umbrellas, might be adorned by photographs with pleasure and with profit. Then a missing umbrella might return to its right owner, as conscience money to the Chancellor of the Exchequer. The heart of that temporary proprietor would be stony indeed which could withstand the suppliant or minatory look of its original lord imprinted upon its handle. An additional security, much wanted, would be afforded to railway companies by the photograph upon a season ticket of its lawful possessor. Some Continental companies have long adopted this notion to prevent season tickets being passed round the family circle as occasion requires. Additional interest would be conferred upon a visiting card after the same fashion. "What's in a name?" asks an ancient literary riddle. Not a quarter so much, is the correct reply, as in a photograph. The very term, *carte-de-visite*, was—as, of course, everybody is aware—originally adopted from the pleasing idea which it is proposed to revive. Photographs of houses are already commonly appended to descriptions of estates for lease or sale. It is high time to hope that the next newspaper information about the sea-serpent will contain a portrait of that interesting beast taken by a snap-shot from a Kodak.

Another incidental and subsidiary use of photography has been lately suggested. The reader is, probably, well aware of a mercantile device commonly adopted by the enterprising grocer who begins a new trade in some of the humblest of our suburban thoroughfares. "Here," he advertises on his inaugural Saturday night, "here every customer who purchases one pound of our finest Kowchee at one shilling per pound will be presented, in addition, with a really good sugar basin, or a milk jug of superior cut glass for nothing!" This generous offer, which alone is sufficient to cover with shame and confusion the face of such carping folk as impudently accuse our British tradesmen of grasping greed, might, it has been said, be changed into the offer of a cabinet photograph of the customer who bought the Kowchee, and the change has much to recommend it. Glass milk jugs and china sugar-basins are, alas! fragile, and likely soon to suffer fracture from the exigencies of domestic use, but the permanent cabinet will endure in its original glory to remind the purchaser and his family of the grocer's generosity, and then, if gratitude be anything more than a name, he and his children's children will continue to purchase from that good grocer, his heirs, and assigns, that finest Kowchee till their lives' end.

Hardly legitimate, perhaps, are some of these excursions into the by-ways of photographic art, but the world at large will possibly be found perfectly willing to walk in them. Already an ingenious example of photographic enterprise and endeavour has been shown in the writing, presumably for a reward, the word "prize" 10,858 times on the back of a common post card, and then getting the result photographed. A painstaking person, some time back, actually sent such a sample of laborious industry to the PHOTOGRAPHIC NEWS. Why the word prize should have been considered by this scribe worthy of so much manual energy was not, indeed, made clear. Possibly he lived in the hope continually set before him by his writing of some ideal gain. "We have not," said the editor on this occasion, with an equal amount of humour and conscientiousness, "we have not yet read this composition through, but it appears to be extremely interesting." And if all other by-ways be already blocked up, there is, at all events, one little lane into which the weary photographer at last may turn. When customers' visits become, like the visits of angels, as Blair says in his *Grave*, "short and far between," when the tricks of the trade are exhausted, when advertisement awakes no echo, and all else fails, some advantage may yet be found, if not in photography itself, at least in the little crystal-covered attic in which its votary was wont, in happier days, to practise it. There he may—a second Cincinnatus or Mr. Bashford—grow lettuces, and turnips, and radishes, and all sorts of green herbs, nay, grapes also, and tomatoes to his heart's content and to his purse's profit. Before Mr. Bashford became a millionaire from his market garden, he was nothing more than a humble and unsuccessful photographer.

A MUSKET bullet on one end of twenty feet of stout twine is handy to throw over and draw aside a branch that hangs in front of the lens.

PIZZIGHELLI'S DEVELOPER FOR LANTERN SLIDES.—A.—Dissolve 5 drachms of citric acid in 5 drachms of water, and neutralise with ammonia. Should too much ammonia be added, the excess may be driven off by gentle heat. Then add 3½ drachms of citric acid and make the solution up to 4¾ ounces. B.—A 1 to 3 ferrous sulphate solution slightly acidulated with sulphuric acid. C.—A 1 to 30 chloride of soda solution. This is a powerful restrainer, and should be used with care. Developer :—A, 10 parts ; B, 5 parts ; C, 1 part. A larger proportion of ferrous sulphate retards the development. Softer and less intense effects are produced by diluting the developer. Gallic acid acts as an accelerator, and produces sepia tones. Two and one-half parts of a one per cent. gallic acid solution is recommended.—*Revue Photographique.*

THE PHOTOGRAPHIC SOCIETY'S EXHIBITION.

With an examination of the pictures on the screens, these notices come to an end. Here are hung some of the best reproductions of the Autotype Company, and of Bonssod, Valadon, and Co. We have also Mr. Fred Hollyer's admirable copies of oil paintings, which, for faithful rendering of the artist's style, so far as monochrome is capable, leave little to be desired. Particularly is this noticeable in regard to Mr. G. F. Watts. Mr. Friese Greene shows a number of enlargements of cloud pictures which, years ago, would have been wondered at. Cloud negatives are, however, now common enough. Mr. Friese Greene's bromide enlargement (No. 556) is an example of the difficulty a photographer has in finding a model who shall fulfil all artistic requirements. The face of the lady is fair enough, but her long, lank, angular arms remind one of the biting criticism applied to a photograph of Madame Sarah Bernhardt and her dog: "Picture of a dog and a *bone*," observed the mercilessly sarcastic critic. An artist, if he had been painting a portrait of the lady in question, would probably have put a little more flesh on her arms: it might not have been true to nature, but it would have been more pleasing. A critic of the naturalistic school would, now-a-day, find fault with the artist for joining the face of one person to the shoulders of another, finishing off with the hands and feet of a third, but there is plenty of justification for the practice. The poor photographer, unfortunately, cannot do this. He must take nature as it comes, and nature occasionally is very provoking.

The fact that No. 573 is a specimen of home portraiture does not add to its attractiveness. The girl who, in a somewhat unmeaning way, is holding a flower-pot containing a plant, is obviously leaning her head to steady it against the back of the chair. The photography is good, and I should think that the author (Mr. H. Schulters Young, M.A.) could do better work than he is here credited with. Mr. F. Whaley's "A Tale of the World" is excellent as regards the pose of the figures and expression; indeed, he has been very fortunate in the good-looking young fellow who is explaining the "use of the globes" for the edification of the youngster, but there is something bare about the surroundings. The background, in truth, is too suggestive of the studio. Mr. Ernest Beck has some pleasant work in "Whitby Harbour" (579) and "Turning the Corner" (580). The latter is quite in the school of Mr. F. Gale. Mr. W. Barry's portraits by artificial light (No. 587) are not remarkable. Mr. R. W. Robinson's small pictures on the screen are inferior to his larger work on the walls, and are not up to his level. Mr. S. T. Chang has some agreeable mementos of enjoyable summer trips in a series (601 to 606), and this quality lends them interest. They are unpretentious, and when the grouping has been attempted Mr. Chang has been fairly successful. Mr. Henry Sturmey's Norwegian pictures bear out the popular notion of that supposed chilly region; the photographs have a cold sparkle about them, which is suggestive, and possibly characteristic of the country. Mr. A. R. Dresser has been at work at the Zoo with a hand-camera, and the result is seen in No. 617. The photography is good, but the prints seem somewhat flat and pale. Would not the negatives yield better results than Mr. Dresser has given the Exhibition?

Mr. Lyddell Sawyer's "Making Friends" (No. 623) is a capital idea, and well worked out, but it is questionable whether vignetting is quite suited to the composition. We may suppose that the scene is in an English farm, but the young lady who wants to make the acquaintance of the cow seems to be standing in a sort of jungle. The ghostly cattle in the background have also an odd effect. The picture is good enough for further experiment to be tried with it in respect to printing. Mr. J. W. Holcombe shows a series of bits of Italian life in his "Italian Ideals" (No. 625), which are welcome for their freshness and unconventionality. They are just what a tourist photographer should aim at. Mr. A. Horsley Hinton, in his two pictures, "By Reedy Ways" (No. 626), and "Where swaying reeds eternal murmur made" (No. 577), has infused a poetic tinge which makes them very agreeable; and the same may be said of Mr. J. Milnan Brown's "Out with the Morning Tide" (No. 627). Mr. John Collier has a careful photograph of the interior of the Birmingham Fine Art Gallery (No. 633), which deserves mention. It is difficult to say much in praise of Mr. A. L. Hoper-Dixon's "Fortune Teller." The old gipsy is abominably ugly, and Mr. Hoper-Dixon, not contented with one picture of her, has given us three. One is not inclined to find fault with the woman's ugliness so much as with Mr. Hoper-Dixon's obtrusive method of treatment. Under other circumstances it is possible to conceive the old creature, hideous as she is, having a certain picturesqueness about her, but in these three pictures all the picturesqueness has disappeared. The effect is square and hard, without an atom of romance. Mr. H. Van der Weyde is always clever, and his picture, "A Jap. Scandal" (No. 641), representing the children of Mr. Mortimer Menpes, if less remarkable than the majority of his work, is interesting. Mr. Paul Lange is to be commended for his excellent views of Norway; they are capital in every respect. Mr. Bedford Lemere has identified himself with interior work, and his "Drawing, Dining, and Ball Rooms, Grosvenor Square and Grosvenor Place" (No. 652), are good representative pictures.

Mr. W. Woodhouse Fry cannot be warmly congratulated on his "Young Naturalists" (No. 653). The figures are far too scattered, and the idea Mr. Fry desires to convey is not very intelligible. One is at a loss to know whether the boy looking at the pool of water has caught a trout, a tiddlebat, or a tadpole. The "Young Naturalists" is of the class of "made" pictures in which the art is too apparent.

In taking leave of the Exhibition of 1890, one cannot help comparing first and last impressions. Repeated visits and examination of individual pictures do not remove the idea that the photography of this year is disappointing. Increased facilities have not had that influence which we had a right to expect. In figure subjects, indeed, there is a distinct falling off from the pictures of years ago. In landscape, the craze for cold tones has led to the exhibition in several cases of prints which, in the old times, would probably have been rejected. Not a few examples lead one to think that the notion in the minds of the exhibitors is that they have only got to label the print "Bromide," or "Platinotype," and it becomes worth looking at. Another fancy is that cold, inky tones are suitable for every subject, and the result is that pictures which would be pleasant enough in the warm tones of silver, grow uninteresting and almost repellent. In a word, the rage for pallid hues has been carried too far, and as, probably, in many cases the results are but experi-

ments, there is, if one may so term it, a flabbiness and uncertainty about the present exhibits which are characteristic of the experimental stage. We are, it would seem, in a transition period. The outcome, however, is not easy to discover, because the style of art affected by Mr. G. Davison and Mr. Lyonel Clark can only be regarded as individual faddism. If, indeed, these efforts be the forerunners of a "school," then the out-of-focus lenses hidden away in the pawnbroker's shop will be at a premium, and Messrs. Dallmeyer and Ross may as well commence their optical education again. A curious fact in connection with the present Exhibition, which may have its significance, is the lack of interest on the part of the public. It is an open secret that the visitors have fallen off, and, considering that the number of people who now practise photography has, during the last five years, increased at least ten-fold, the apathy is difficult to explain. One would think that the greater the number of persons interested in photography, the greater number would visit the Gallery for the purpose of getting a hint or two. But this does not seem to be the case. No doubt the exhibitors will be quite as much puzzled to find an explanation as are, doubtless, the council and officers of the Society. Still, the uncomfortable fact remains.

WIDE-ANGLE.

THE UNNATURALNESS OF "NATURALISTIC" FOCUSSING.*

BY W. E. DEBENHAM.

THE question of whether fine definition, generally called "sharpness," should exist throughout a photograph; or whether in the whole, or in great part, this definition should be replaced by blurring to a greater or less extent, is one that may be conveniently considered as divided into two parts.

The first division, suggested by the appropriation of the word "naturalistic" by the modern advocates of out-of-focus effects, consists of the enquiry as to whether this blurring represents more truly what the spectator sees than does a clearly defined photograph; and the second division includes the question as to whether it is, either generally or occasionally, desirable to introduce blurring, whether such introduction yields a truer representation of nature than a defined photograph or not. It is the first question that will be considered in the present paper.

I have used the expression "fine definition" in place of "sharpness" because, although photographers accept these as synonymous terms, the word "sharpness" has often been used in another sense by painters and draughtsmen; and therefore, in their sayings, may sometimes be found complaint of too great sharpness, which may naturally cause the photographer to yield to what he supposes to be condemnation from an authority which he recognises as artistically superior. The word "sharp" is often used, out of photography, to mean having strongly defined edges, and a photograph that is not sharp, in the photographic sense—of having fine definition—may be condemned artistically as excessively sharp if, from underexposure, too great intensity, deficiency of the connecting half-tones, or any other cause, the edges of prominent objects have a raw, crude, or harsh appearance.

The so-called "naturalistic" defence of blurred definition in all but one plane of the picture, I understand to proceed as follows:—The eye can only focus for one distance at a time, and if we look at any principal object, the more distant and nearer ones not being rendered distinctly on the retina, should be rendered with equal indistinctness in the picture, in order to convey to the mind the effect produced by the scene at the moment when we fix our gaze upon that which is considered to be the principal object, that alone remaining distinctly visible, whilst if more or less distant objects be now focussed, the principal one is out of focus.

To this argument it has been naturally replied that in looking at a scene that gratifies us, the eyes linger upon it, focussing, when required, objects in the different planes, and that if we would have a picture over which we may delight to linger too, we should be able at leisure to note the details as we would in the original scene. Beyond remarking that in this respect the work of painters generally will be found to support rather the advocates of fine definition than those of the blurring school, we will, for the moment, waive this argument, and come to the consideration of the question as to what is the sort of definition, as given by a lens, that will represent out-of-focus planes with the same amount of indistinctness that they have to the eye, when some particular object is focussed by it.

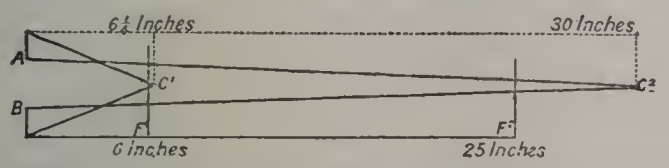
To fully understand this question, it is necessary that a fact should be grasped which is well known in scientific optics, but which I have found photographers slow to admit. That fact is, that the definition of out-of-focus planes is not dependent upon the proportion of the diaphragm or aperture to the focus of the lens, but upon the absolute size of the diaphragm itself, independent of the focal length. The argument against the naturalistic contention to be deduced from this fact has been applied to the case by Mr. W. K. Burton and Mr. J. Dennis Taylor. The latter writer has, in an article in the *Photographic Quarterly*, which has come to my notice since undertaking the present paper, given a mathematical demonstration of the optical fact referred to. It is to be regretted that Mr. Dennis Taylor's paper is not accessible in a more popular form than that of the comparatively new magazine in which it appears. As the demonstration which I have prepared is different from that of Mr. Dennis Taylor, I offer it to the meeting, that hearers may be convinced of the reality of the proposition. By equality of indistinctness it is meant that the blurring of any given point in the original shall extend to the same adjacent point in the cases to be compared.

Let A B represent an aperture of one inch used with lenses of 6-inch and 25-inch focus respectively, which focal distances are marked by lines at F^1 and F^2, and suppose an object to be focussed that is far distant—a church spire or mast of a ship two or three miles off, for instance—so that its focus shall lie as closely as can be discovered at F^1 for the 6 inch lens and F^2 for the 25 inch lens. Now suppose an object at a distance of 150 inches from the lens. This will be at a distance of $5 + 1$ foci from the 25-inch lens, and the conjugate focus of the object will therefore be $1 + \frac{1}{5}$ of $25 = 30$ inches. As the plate is fixed at 25 inches, the image of the near object will be out of focus by a distance 5 inches, or one-sixth of its focus. Each point, therefore, which would come to focus at C^2 will be represented on the plane F^2 by a circle of one-sixth of an inch in diameter. The distance from the plate to the lens being one-sixth of that from the lens to the object, the image will be on a scale of one to six, and points on lines—say interlacing twigs—one inch

* A communication to the London and Provincial Photographic Association.

apart in the object will be represented by circles just touching each other on the screen or plate.

With the lens of six-inch focus, the conjugate focus of the object at 150 inches distance will be $6\frac{1}{4}$ inches. The plate placed, as in the other case, at the focus of a distant object will be at F^1, one-quarter of an inch nearer to the lens than the focus for the near object, and the points of the image in the near object being one-twenty-



AB, aperture of lenses; F^1, focal plane for distant objects, of lens of six-inch focus; C^1, focus with same lens for object at distance of 150 inches; F^2, focal plane for distant objects, of lens of 25-inch focus; C^2, focus with same lens for object at distance of 150 inches.

fifth of their conjugate focus nearer to the lens, will be represented by circles of one-twenty-fifth of an inch. The distance—six inches from the plate to the lens—being one-twenty-fifth of that from the lens to the object, the image will be on a scale of one to twenty-five, and points in the object one inch apart will be represented by circles of one-twenty-fifth of an inch, that is to say, they will just touch one another, as in the case of the longer focussed lens.

The law, an example of which has just been demonstrated, may be proved to be true in relation to any other distances, and with lenses of any other focal lengths. Lenses of six and twenty-five inches focus have been selected as examples, because it happens that, with these proportions and the distance specified, the proof may be given without encumbering it with elaborate fractions. For the same reason, in order that the fact may be readily grasped, the proof has been submitted in a concrete form rather than in the abstract, where the mathematical arguments would have required more sustained attention on the part of the hearers.

The recognition of the optical law that the definition of the out-of-focus planes depends upon the absolute size of the diaphragm, independent of the length of focus of the lens, should be useful to photographers in other ways than that of exposing the fallacy of the "naturalistic" contention. It is generally understood that greater depth of focus can be obtained with a shorter focus lens, the aperture being of given proportion or speed, than is to be had with a longer focussed lens stopped only to the same rapidity. I have scarcely found any, however, who are prepared to admit that the difference is so great as it really is, and that the absolute size of the diaphragm, and not its proportion to the focal length, is the one factor to take into account. I have heard the question put thus: "If I take a full-length figure on a quarter-plate with, say, a seven-inch focus lens, I can get the accessories and background defined to an extent that is sufficient. Why, then, if I use a lens of double the length of focus, and a stop of the same proportion or rapidity, can I not get the same amount of general focus as in the former case?" To get this equal amount of definition, the law referred to shows us that a diaphragm of equal diameter—not proportionate to the focal lengths—is required, involving an exposure four times as long as in the other case.

The way in which the law of absolute size of aperture affects the "naturalists'" claim is this. If we admit their contention that we ought to make no allowance for the adjustability of the focus of the eye, but must represent the scene as it appears whilst the eye focusses some particular object, and that the lens ought to have the same, and no greater power of defining out-of-focus objects than the eye possesses when deprived of the privilege of adjustment, we shall find ourselves bound to the use of diaphragms of the same diameter as the aperture of the iris. This aperture, in a good light, is considered to average the one-eighth of an inch, and this, therefore, is the size of diaphragm which the naturalistic contention would indicate. Now, is that the kind of aperture used or directed to be used by the supporters of differential focussing?

It is very difficult, in a general way, to get them to fix upon any definite size or proportion so as to have a solid basis for argument, but there is no doubt that their dicta and productions point to the use of apertures much larger than those adopted by those not belonging to their sect, and, indeed, for views including no nearer objects than thirty feet or thereabouts, a diaphragm of one-eighth of an inch will give a picture in which all planes may be considered as thoroughly well-defined.

If the eye is directed to an object distant only a few feet or inches, and a more distant object is in such close proximity to the axis of the eye that it can be seen distinctly without other movement than that of altering the focus, there will be a distinct change of focus required for examining the one and the other object. This fact, no doubt, it is that has led to the supposition that, to represent objects as seen by the eye, the lens must have such a large aperture as to show planes in the picture in different focus. The argument would hold good—always supposing the power of adjustment be denied—if we are photographing objects at the same distances as those in the experimental test with the eye; this is not, however, at all commonly the case. About thirty feet is considered to be near enough for a foreground object in any general view, and if we look at any object at this distance, we shall see those beyond it to be all so well defined as not to require re-focussing of the eye to see them distinctly. To make the test, it is necessary that the nearer and distant objects should lie very near together, close to the axis of the eye. If they are at all wide apart, the removal of the axial line of the eye will be apt to lead to a confusion in the mind of the observer as to the change, if any, due to re-focussing.

Mr. T. R. Dallmeyer, in using the language of optical science to defend the "naturalistic" contention, adduces the case of a one-eyed gentleman who is stated to have the power of discriminating focussing up to a distance of sixty yards. If this is not a mistake, power to be able to discriminate between degrees of definition so minute indicates such a high separating or of defining power in the eye, that we should have to use the utmost defining power of our lenses to be able to represent it on our plates. Whatever the amount of out-of-focus want of definition discernible by the eye, however, it cannot exceed that of a lens having an aperture of the same size as the opening of the iris. Starting from the asserted power of focal discrimination possessed by the gentleman referred to, Mr. Dallmeyer has calculated sizes for openings, which he calls sight stops, for lenses of various focal lengths to give the out-of-focus effect desired, and adds* that he hopes to

* *Camera Club Journal*, May, 1890, p. 135.

arrive at an equation that shall give to other than the chief plane, at a given distance, a proportional out-of-focus effect. When the law of absolute size of diaphragm that has been demonstrated is recognised, it is seen that the equation required is exceedingly simple; it is merely necessary to take the size of the aperture of the human eye for lenses of all foci, and any elaborate calculation of different sizes for different lengths of focus is not only superfluous, but, if leading to any result inconsistent with the optical law mentioned, must be incorrect.

A great deal that is quite beside the question has been introduced into arguments in favour of blurring. Dr. Emerson introduces the question of the dispersion, spherical aberration, astigmatism, turbidity, fluorescence, and the blind spot, to which Mr. Dallmeyer adds diffused light, which he alleges to exist in much greater abundance in the human eye than in the photographic camera. I cannot do better than quote Mr. Dennis Taylor's reply to these charges brought against the most perfect and admirable of the organs of our senses. "As a matter of fact," he says, "the brain gains its impression of a photograph through the same imperfect, astigmatic, turbid, and blundering instrument of vision which it must perforce rely upon for an impression of the actual scene which the photograph represents. If the eye is astigmatic, then it will view the photograph in its own astigmatic fashion; if it is turbid, it will view it in its own turbid fashion, and so on. Allowing, too, that the photographic lens can define more minutely, and, as it were, see more than the eye can, does it therefore follow that the presence of microscopic details in the photograph implies that the eye must be conscious of them at the proper viewing distance? Certainly not, any more than that the eye will perceive all the veins in the leaves of a tree one hundred yards away because they all happen to be there."

The last resource of those who support the naturalness of naturalistic focussing is to say that we view things with two eyes, and that to represent the separate placings of the image on the retina, we ought to introduce the blurred outline of an out-of-focus lens into our pictures. How the effect of two images, taken from different points, each defined by being seen with a small aperture, should be truly represented by an image taken with a large aperture —large not only horizontally in the direction of the separation of the eyes, but vertically also—is not made clear; and, indeed, the attempt to represent binocular vision on the flat surface of a picture can only result in failure. There seem to be very strange misconceptions as to the facts of binocular vision. One writer, who now makes the fact that we see with two eyes his chief ground of defence for blurred definition, says that if images taken stereoscopically are put into a pair of lanterns and projected upon a screen, the images will coincide. The answer to this statement is very simple: they will not coincide upon the screen.

If the effect of binocular vision is really represented by the blurred image claimed to be necessary, whilst the argument in favour of a small aperture deduced from the law of equal aperture is allowed to hold good with regard to a representation of single-eyed vision, we ought to see something like the jump from the "naturalists'" blurring to the fine definition of a lens with small aperture when, after looking at a scene with both eyes, we close one of them. As a matter of fact, do we feel such an improvement, or are we sensible of seeing a scene more distinctly at all when looking at it with a single eye than when using both eyes?

A further objection to throwing part of the picture decidedly out of focus is, that the representation is in some points thereby made altogether different from the reality. It has doubtless happened to most of us to photograph a group out of doors in front of a background of trees and shrubs in which there are bright points of light from small interstices in the foliage. We have not intentionally placed this background out of focus, but have simply been unable, for fear of movement—especially in the collodion days—to employ a sufficiently small diaphragm to secure definition in the background. What has been the result? That the small angular points of light have come out as large and hideous circles of light. This sort of definition cannot truly be called natural.

Whatever may be argued on æsthetic principles in favour of blurring, or even on scientific principles if such principles are put forward as means to an end, whether natural or not, that may be desired, there is nothing to be said in favour of clothing unsound propositions in the language of optical science. Such a proceeding can only induce confusion in the minds of the many who are only too much disinclined to undertake the labour of thoroughly examining a scientific problem.

PROFESSOR LUCKHART ON ENGLISH PHOTOGRAPHY.

PROFESSOR LUCKHART, of Vienna, took the subject of the forthcoming International Exhibition at Vienna as a starting point for the following remarks at a recent meeting of the Vienna Photographic Society:—"A photographic exhibition like that planned by the Club of Amateurs at Vienna cannot but help to instruct and incite our companions of the craft. The Exhibition Committee of that Club has expressed its intention of calling together a jury consisting of eminent artists, who will select all exhibits as to their artistic merit, and reject the worthless. Pictures may be sent in anonymously, so that at the worst the exhibitor will be spared the painful feeling of public rejection. In England men such as Robinson and others have consented to take part, and I, for my part, can state that I have not only had enjoyment from those gentlemen's pictures, but have studied them, and learnt from them. I am convinced that many of my brother photographers will agree with me in this respect. It can therefore, gentlemen, only be of advantage to you to exhibit at such an exhibition, and be represented there. In the exhibitions of this Society we have often seen what you are able to accomplish, and I know that you possess the capability, if not of surpassing England's beautiful productions, yet of successfully competing with them."

THE PHOTOGRAPHIC CLUB.—At the Annual Meeting of this Club, held at Anderton's Hotel on Wednesday last, the following officers were elected for the ensuing year:—*Trustees*—W. Bedford, Frank Haes; *Committee*—H. D. Atkinson, H. E. Davis, J. Guardia, H. M. Hastings, F. Hollyer, R. H. Lloyd, J. Nesbit, E. A. Newell; *Curator*—F. P. Cembrano, Junr.; *Recorder*—E. Clifton; *Librarian*—C. D. Hesse; *Secretary* and *Treasurer*—F. A. Bridge, East Lodge, Dalston Lane, London. The subject for discussion on November 12th will be "The Advantages and Disadvantages of Toning and Fixing in One Operation." The Annual Dinner will take place on November 19th.

WILD BEAST PHOTOGRAPHY.*

Mr. Bolton has had more than one narrow escape. Once, for instance, he was taking the big tiger at the Zoo.; the lens was in position through the bars, and Mr. Bolton's head was under the cloth intent upon his work, when he heard a scream, and, before he could say Jack Robinson, the lens was rolling on the floor of the cage, and the cloth was torn off his head by the terrible claws of the man-eater. Since then Mr. Bolton has been more careful. One of his precautions, by-the-way, is to smoke, for the beasts cannot endure the smell of the weed. If one reflects for a minute, it is easy to understand the difficulties of taking one of these wild beasts, for they are no flash photographs taken by hand in a sixtieth or in the three-thousandth part of a second, like Mr. Muybridge's amusing series. Mr. Bolton gives the plate an exposure of a second, or a second and a-half, and a lion or a tiger seldom remains stationary for that period. The keepers sometimes help him by exciting the animal, or he plays a tune on a set of bagpipes, which may be bought from the man on the kerbstone for a penny. "But the most difficult of all animals, I think," continued Mr. Bolton, "is the Persian leopardess at the Zoological Gardens. The Polar bear is not easy, but you see I got him in three positions. Here he is standing up, there he is taking a dry swim, and there again you see him toes up, showing his hairy feet. It is all a matter of plates and patience. Again, it is not easy to take an oiled elephant on a warm day—oiled? he is oiled to keep his skin in condition—the flies swoop down upon him, and both tail and trunk whizz round like a teetotum. To photograph animals at all well you must have the patience of Job, and the luck of the Duke of Portland. And, by the way, talking of the big Indian elephant at the Zoo, I may tell you that he is growing, and even now he is only a few inches shorter than Jumbo. The measuring-mark is the tunnel at the gardens. Now here"—pointing to a fine photo of a European bison—"I call that Patience on a Monument, for it took me four days, shut up in his shed, to fix him. This bison has a fondness for rolling in the straw; and, as straw disturbs the harmony of a picture, I was compelled to follow him round each day, and pick off the straws! And patience was rewarded, as it always is."

Turning over the photographs which were strewn about the table, I found Guy Fawkes, the hippo at the Zoo. The difficulty in his case was to get the appearance of crackled roast pork of his skin. Here, again, is Big Jim, the Indian rhinoceros, and the Brazilian tapir—"the Conservative among animals," as that distinguished zoologist, Professor Flower, calls him, as he is the oldest type of mammal. Then there is the giraffe—who was taken walking in the fifth part of a second—the Queen's lion, and Prince Albert Victor's tiger cubs. Mr. Bolton is particularly proud of his photographs of zebras, and points out how necessary good representations of animals which are likely to become extinct will be to the naturalist in days to come. Here, again, is a photograph of three smiling crocodiles, taken in Paris the other day. Well may they smile, for have they not just breakfasted on kittens and puppies? And here, again, is a wonderful representation of the roaring sea-lion, also taken in Paris. Note the sheen on his fur, produced by the sun shining on his wet coat.

Mr. Bolton has many amusing stories to tell of his adventures in Tring Park when he was taking photographs of Mr. Walter Rothschild's famous collection of kangaroos, wallabies, emus, and rheas. It is no joke stalking a giant kangaroo on a hot day over the glades of a park which covers nearly four hundred acres, and staggering under the weight of a full-plate camera. In three days the photographer used 150 plates, of which only sixteen were perfect. "About my usual average," said Mr. Bolton. Mr. Rothschild (a son of Lord Nathaniel) is an ardent naturalist, and one of his most treasured acquisitions is a kiwi. The kiwi has no tail and no wings, and is nearly as scarce as the dodo. You may have roughed it in New Zealand wilds, and lived for years among the timber-clothed spurs of the wildest mountain ranges, without encountering this strangest of birds. But there is a live and blinking specimen of him at Tring, and here among Mr. Bolton's wonderful collection he is to be found, closely resembling a tripod; for he sleeps standing, and to support himself he digs his long beak into the ground. Another curiosity is the contumacious Australian cassowary, which is another of Mr. Rothschild's treasures. Mr. Bolton was defended from his attacks by two gamekeepers holding hurdles in front of the camera.

On the walls of the little sitting-room hangs a fine carbon print of a bloodhound, which is one of Mr. Bolton's triumphs, for he took him eighty-four times before this result was attained. It is Mr. Krehl's champion Cromwell, who is now known as the plate-smasher. This difficulty is easily understood when you look at the long ears of Cromwell. When his nose is still these ears are still going like a pendulum. How much the public appreciates a good thing when they see it will be understood when I mention the fact that four thousand copies of Mr. Bolton's well-known row of five bloodhound puppies alone have been sold. This fine specimen of a bob-tailed sheep-dog is known as "Wall-eyed Bob," and the wall-eyed feature of Bob's face is also the feature of the photo. Bob, by-the-way, was induced to stand by means of a certain monkey, who is a favourite model of Mr. Bolton, and you may see him depicted by the sun in the act of catching an active member of the flea community on his foot, which he calls "A Critical Moment." This is the result of over thirty shots.

Mr. Bolton divides his work into four series—animals, birds, dogs, and bones. These last he photographs for comparative anatomists, and a collection of them hang in the Geological galleries of the British Museum, South Kensington; and, shade of Poe! he uses a seven-year old pall, which was bought cheap from a sexton, for a background, and who can say it is not appropriate? Of the animals I have already given a brief description; the birds include a Stacy Marks series, namely, the pelican and the marabout stork, which are most comic. Amongst the dogs is a splendid specimen of a very famous corded poodle, who bears a strong resemblance to a walking door-mat. This kind of dog is much used as the duck decoy abroad. He floats down stream, and the stupid ducks mistake his cords for a bunch of seaweed, until he appears in their midst and sends them flying towards his master, who is a-gunning on the bank.

The subject of animal photography is full of interest, but we must leave it for the present.

* Continued from p. 849.

Prof. W. K. Burton has been elected an honorary member of the Photographic Society of India, in recognition of "distinguished services to photography."

Notes.

In relation to the keeping of glass studios warm in the winter, Sir David Salomons writes :—"A very simple way to warm a studio is the plan I adopt. At each end of the room is placed a Lux Calor gas stove, and the blinds are kept down at all times, excepting when work is being done. By this means the studio is kept as warm as if the roof were slated, with a ceiling below it." This plan is evidently good for adoption by amateurs and professional photographers in a small way of business, but of little advantage to a photographer who has sitters all day long. It would be well if the blinds could at the edges be made to so closely fit the wood-work as to practically imprison a layer of air between the fabric and the glass when they are not in use over portrait work.

Mr. E. de Saint-Florent has long been noted for his experimental researches in the production of photographs in natural colours upon paper, and he has recently sent to the Photographic Society of France some prints better fixed than heretofore. Four prints were forwarded. Number one was an "old one" which had been exposed "a long time" to diffused light; it had been fixed by fifteen hours' immersion in a three per cent. bath of solution of perchloride of iron. Number two was eight days old, and had not been affected by diffused light. Number three was one day old, and had been fixed in a "very dilute" bath of perchloride of iron. Number four was upon cardboard, and Mr. Saint-Florent says that the process he employed was a modification of the collodio-chloride method which he communicated to the Society in 1880. He takes a piece of Bristol board, and pours over it a thick layer of collodion containing nitrate of silver; when this is dry, he applies a second coating. After again drying in the dark, he plunges it into a fifteen per cent. bath of hydrochloric acid, and leaves it therein about ten minutes; he then takes it out and exposes it while wet to diffused light until the card turns violet-blue. He next "sensitises" it in a bath of nitrate of mercury, containing four drops of nitrate (strength not stated) to one hundred of common water. He exposes for fifty seconds under coloured glasses to the direct rays of the sun, and fixes by means of perchloride of iron. We may inform readers who have never seen photographs in natural colours, that those upon paper are inferior to those upon silver plates in appearance. The ground colour is too pronounced.

A friend who has lately had occasion to make a voyage to the Cape and back tells us that, on the particular line of steamers which he patronised, means are adopted to amuse the passengers which are indirectly dependent upon the photographer's art. When the outward bound vessel had been a fortnight at sea, and the passengers had had time not only to make each other's acquaintance, but to tire of one another's conversation, the steward brought out an optical lantern, and, upon a sheet hung in the saloon, gave a capital show of photographic lantern slides. After this, the hat was sent round, and, from the fulness thereof, our informant opined that the enterprising steward had no cause to regret his investment. The entertainment was repeated a week later, and a like exhibition was given on the return voyage.

The limelight and its paraphernalia do not seem to be easy things to rig up in a hurry, especially on ship-board, and, of course, bags and weights are out of the question in a choppy sea. On the occasion in question, the oxygen was drawn from a 40 ft. cylinder—which contained enough gas for four exhibitions—while the hydrogen was represented by an ether saturator. The arrangement, we are told, worked well, even when, on one occasion, the vessel was lurching in an uncomfortable manner. This new use for the optical lantern will, doubtless, extend to other passenger vessels which plough the seas, and certainly no better way of amusing home-sick—and, perhaps, sea-sick—voyagers could be devised.

Another somewhat novel use of the lantern was advertised a few weeks back in London. This was a "service of song" in a chapel, accompanied by dissolving views. Were such an innovation suggested in certain other places of worship, the dissolving views would be represented by vanishing congregations; but, as in all things, opinions on such points differ considerably. Many chapels are constantly used for secular lectures, and in these the lantern is in constant requisition, but, as far as we know, the case above referred to is the first in which the instrument has been used in the conduct of divine service.

While on the subject of the limelight, it may be useful to point out the urgent want of a better lime cylinder than those at present in the market. Many of these, although called "hard limes," are too soft when used with both gases under pressure, and rapidly disintegrate or split when in use. They are suitable, however, for the blow-through jet, and as this jet is more largely used than the other, the majority of buyers are content with them. The really hard kind are those known as Nottingham limes, but a box holding one dozen will hardly contain two of the same diameter, so carelessly are they turned. A lime cylinder of the requisite hardness, accurately guaged to a standard diameter, would soon find plenty of purchasers. As far as we are aware, such a thing is, at present, not to be had for love or money.

By degrees the optical lantern and photography are coming to the front in various ways—artistic, educational, commercial, and explanatory. Of the first, the ordinary lantern show may be taken as an example; of the second, the lantern is now being introduced into schools as a means of acquainting the scholars with foreign countries, and it must be admitted that it has an enormous value in connection with the study of geography. As to the commercial use of the lantern

and photography, travellers by the Underground Railway are now pretty well aware of the latest application. A small lantern containing an automatic arrangement by which a succession of advertisements is brought into position, is placed opposite a white disc, and forms an object of fascination for the people who are waiting for trains. Of course, such an arrangement is only applicable in a dark place, and the Underground Railway seems to be made on purpose for the exhibition.

As to the explanatory use of the lantern, a music hall entertainer has found it a good friend. The *metier* of this performer is the personation of prominent individuals, political and otherwise. The impersonations are produced by changing the countenance, but, as in the case of the ventriloquist, who generally informs the audience of the nature of the sound he is going to imitate, and where it is to come from, the impersonator has found it necessary to give a sort of key to the spectators, who have an unpleasant knack of being perverse, and not recognising the imitation. This key is furnished by an optical lantern containing photographs of the originals, and is so arranged that the impersonator can present a picture on the screen at the same time that he is giving the impersonation. The advantage of this plan is, that if the audience fail to recognise the human counterfeit presentment, they have the image on the screen to fall back upon.

It will not be long before the historical painter's vocation will be gone, so far as his own unaided efforts are concerned. The camera is an absolute necessity at all important functions, and though the painter may be called in afterwards, he relies upon the photographer for matters of detail. Thus, we are told that, at the recent Moltke celebration, was a presentation to him by the Emperor of a marshal's *bâton* of silver, magnificently inlaid with stars of crowns, rubies, and diamonds. Count Moltke was so overcome by emotion he could only murmur one or two words, but he took the Emperor's hand and "imprinted on it a long and fervent kiss." This was the moment seized upon by the attendant photographer. He obtained a picture of the episode, Professor Von Werner will do the rest with his brush, and a grand historic painting will be the result.

There is little doubt that this photographic innovation was initiated by the German emperor, who is an enthusiastic amateur photographer. Herr Zeisler, his personal photographic assistant, has been compelled to learn riding, to enable him, armed with his camera, to follow His Majesty on his hunts and other expeditions; in fact, he seems to "shadow" the Emperor William, and nothing is sacred from his "kodak," not even a recent well-known marriage ceremony, where Herr Zeisler played his "kodak" on the bridal couple. "Ah!" said the emperor, laughingly, seeing the astonishment of the guests, "I forgot to tell you that my photographer follows me everywhere. I gave him a personal *passe partout*, and you must not mind his goings on."

An interesting legal point has cropped up in connection with photography. Up to the present moment artists have been allowed in the courts of law, and have sketched at their sweet will plaintiff, defendant, witnesses, and judges. But it seems that if you take a snap-shot with a detective camera, it is contempt of court. Mr. P. O'Brien, M.P., who has already distinguished himself as a photographer in the Tipperary riots, has been committed for seven days for using his "detective" in the magistrate's court. The term "contempt of court" seems to be capable of a very wide application, and probably varies according to the particular taste and feelings of the judge. But would it not be best if the matter were settled once and for all, as, logically, there can be no difference between the pencil of the artist and the camera of the photographer?

Some artistic gentlemen are almost as concerned about the quality of the light by which they work as photographers. It is curious, however, to read that want of light has been the cause of the collapse of the Graphic Society. This society was an association of painters, sculptors, architects, and engravers; but somehow it has not succeeded, and the dull, lightless weather of London is given as the reason. Why does not the Graphic Society remove to Torquay, which, according to the Royal Meteorological Society, is the sunniest place in England? In 1889 there were 1,608 hours of sunshine at Torquay, and 54 sunless days. At Greenwich there were 1,158 hours of sunshine, and 105 dull days. Eastbourne comes next to Torquay, but here there is a great difference, as the dark days were 77 against the 54 of the Devonshire watering-place.

An extraordinary rumour finds publicity in a society journal. It is nothing less than a union of photographers, after the fashion of the Salt Union, which some time ago excited so much comment in financial circles. It is to take shape in the beginning of the year, and will be a combination into one great company of all the leading photographers in London. The matter at the present moment is in too nebulous a shape for comment, and it would be interesting to have some further particulars as to the authenticity of the statement. In the meantime, if the opinion of the public be that a photographic business yields enormous profits, one may venture to say that this opinion is based upon the business which used to be done, and not on the business which is done at the present time. In addition to the fact that the profits are not so large as in former years, the expenses are certainly greater, as a well-appointed studio and reception-room in a first-class position are costly affairs.

A NEW RAPID PRINTING MACHINE.*

BY FRIESE GREENE.

WHEN I was readiug in the PHOTOGRAPHIC NEWS of February 28th, 1890, a description of the camera for taking photographs consecutively from one point of view, at the rate of 600 a minute, invented by myself and Mr. Evans, I tnrned over a few pages and read a suggestion by the editor of that paper, entitled "A Printing Machine of the Future," in which he says that, "The chief value of the machine, or of a modification thereof, may hereafter be fonnd to be in a direction not contemplated by the inventors; at least, they have said nothing on this point—namely, in the printing of positives for book illustration—for in positive printing through a negative the amount of light can be made to vastly exeeed that present in the photographie street views, so that the limit of speed, especially with improved machines as yet unborn, is at present beyond calculation. One ean imagine the possibility of a practically endless band of paper being covered with some sensitive preparation as it nnrolls, then passiug on to the exposure platform, and afterwards into developing and fixing baths; at the present time, exposing a negative on a travelling band three thousand times in five minutes would not be bad work."
