## *THE SMALLER LECTURESHIPS AT THE LONDON MEDICAL SCHOOLS*

### I.—THE CONSERVATION OF FORCE

ABOUT sixty years ago the student who determined to enter the medical profession was usually bound as an apprentice to some respectable country practitioner, and spent several years in acquiring the rudiments of his profession, by bandaging bad legs, dressing simple wounds, bleeding freely everybody that presented himself and prescribing and dispensing for the poor. He then came to London, or attended one of the larger provincial towns provided with a hospital, and followed the practice of some celebrity, hearing an occasional lecture and much clinical discussion, and finally presented himself for examination before the Master and Court of Assistants of the College of Surgeons, and started in practice. Such training was solid and good; practice went before, and theory followed after; some thought, indeed, the cart went before the horse; yet the excellence of the plan was shown in the high scientific position and lucrative practice obtained by many a well-known name. As Shakespeare knew little Latin and less Greek, our student knew little anatomy and less physiology, but what he did know was substantial, and served him in good stead.

A few years after the time we are speaking of, systematic courses of lectures upon various subjects, as upon chemistry, botany, anatomy and physiology, medicine and surgery, began to be delivered at the larger schools, at the instigation of the Society of Apothecaries, who were constituted by the Act of 1815 the guardians of "general practice," two or even three subjects being given by the same lecturer; and attendance upon these soon came to be regarded as an important part of the student's education. So far all was well. The several subjects mentioned above were treated broadly by such men as Abernethy, Cooper, Babington, and others, generally speaking with direct reference to medicine or surgery; and the student underwent a training that possessed considerable value in relation to his future profession, whilst it furnished him with the rudiments of various sciences that he could pursue and extend in his leisure moments. A few years more passed away, and the advances made in every department of knowledge rendered it impossible for any man to undertake singly to lecture upon two different sciences, such as chemistry and botany, or even upon two such cognate subjects as anatomy and physiology. Each required its separate professor, who delivered from thirty to ninety lectures upon his special science, and attendance upon them was rigorously enforced both by the lecturer himself and by the examining bodies.

And now ensued a period that was undoubtedly opposed to all true intellectual training. The student, as soon as he entered the profession, saw little practice, but was everlastingly in attendance upon lectures. No mental effort was required, and, except in the case of first-rate lecturers, none, we are convinced, was ever exerted in acquiring and assimilating the information conveyed. Here and there a good lecturer, thoroughly master of his subject, chained his audience; but the substance of four out of five lectures either entered at one ear to pass out at the other, or was altogether refused admission to the brain by the locked portals of the slumbering student. The horses were indeed put before the cart, but the team was so strong that they often ran away with the cart before anything useful had been put into it. The requirements of the examining bodies in regard to these lectures rendered it imperative for every school, however small, to have as numerous a staff of lecturers as the largest. The senior officers of the medical staff consequently took the more important subjects of medicine and surgery, anatomy and physiology, whilst the younger ones divided amongst them chemistry and botany, materia medica, forensic medicine, and midwifery. In many instances these latter posts were filled by gentlemen who had received no special training, but who accepted them and often worked at them with praiseworthy energy, merely to secure the succession to the medical staff, upon obtaining which the minor lectureship was at once given up.

It is obvious that lectureships so obtained and so held must have been in many instances valueless alike to the lecturer himself and to the student who sat under him, yielding to the former a barren honour, and to the latter a signed schedule,—the advantage of the professor and not the advancement of the student being the point considered. During the last few years a reaction has been setting in against this perpetual lecturing, and the number required to be attended has been considerably reduced. The University of London deserves the credit of having been the first to break through this absurd system, by requiring attendance on only one or two courses, and this rather as evidence of the student being really engaged in the study of medicine than for any other purpose, leaving him free to acquire his information as best he can, but testing its extent and value by a searching examination.

No doubt many of the posts above alluded to are filled by men of great talent and ability, but their powers are crippled by the small means at their disposal, which prevents many illustrations or experiments from being exhibited which are almost essential for thorough teaching.

As a means of improving the system of education by supplying a better class of lectures on some subjects than those at present given, and at the same time obtaining better remuneration for the lecturers themselves, a scheme has recently been advanced by which it is proposed that certain medical schools in the metropolis should be amalgamated, a reduction in the number of lecturers being thus effected, whilst the pecuniary value of those that remain will undergo considerable augmentation. It is hoped that the value of these posts would then be sufficient to lead to their being accepted not by those who only use them as a stepping-stone for advancement, but by gentlemen who have devoted themselves exclusively to the study of the department of science on which they lecture.

At the present moment the lectureships in several of the smaller schools yield such small returns to their holders as would astonish many of their hearers. As a matter of fact we could mention an instance where the proceeds of an entire summer course of lectures has amounted on the average for the past three years to a sum not exceeding 6*l*. Can this for a moment be regarded as in any way proportionate to the intellectual labour, the time, and the money expended in their preparation, illustration, and delivery? It might be considered to be a moderate recompense for one lecture, but as payment for a course it is simply monstrous. Is it surprising that the lectures are often given without animation, and listened to without interest?

By amalgamating several schools, however, such chairs might, it is hoped, be so far increased in value as not only to lead men of high ability, and distinguished for their knowledge in particular branches of science, to accept them, but to provide ample funds to admit of their copious illustration, and for the purchase of expensive apparatus — apparatus which the smaller schools now find it difficult or impossible to procure. It would not be difficult, we imagine, to find room for those who at present hold appointments as demonstrators, with lighter but not less important duties than they have hitherto performed. At all events it seems to us that the amalgamation scheme, if fairly carried out, would prove the most splendid example of the Conservation of Force with which we are acquainted, and on that ground alone should receive the cordial support of the medical teachers throughout the metropolis. In a future article we shall suggest what appears to us a desirable and practical scheme for medical education.

---

## *THE LITERATURE OF CHEMISTRY*

THE appearance of the April number of the "Journal of the Chemical Society" marks the commencement of a new era in English Chemical Literature, containing, as it does, besides the papers which have been read before the Society, the first instalment of the promised "abstracts." The papers selected for this purpose by the accomplished editor are ninety-one in number, comprising every branch of Chemical Science, Technology included, and are classified under six various headings, as "Physical Chemistry," "Inorganic Chemistry," &c. The abstracts themselves, made by the gentlemen whose names appear on the wrapper of the journal, are naturally of different degrees of literary merit, but seem to be carefully and conscientiously done; all the points of essential importance in the original papers being retained. The reader will thus not only have a good general notion of the extent of the researches made by any particular author, but also be able to repeat any of the experiments, or prepare any of the substances from the directions given. These abstracts are therefore really what they profess to be, and not merely notices of a few lines in length, from which but little more information can be gleaned than from the title of the paper.

The Council of the Chemical Society is to be congratulated on the energetic way in which it has endeavoured to supply a great defect in our scientific literature, by affording us the means of obtaining a general view of the progress of Chemistry both here and on the Continent. Chemists have hitherto had to depend chiefly on Will's "Jahresbericht," which, although useful in its way, has the double disadvantage incident upon its method of arrangement, first, in not being published until long after the end of the year, and, secondly, of being rather a *résumé* of the chemical work done, than a condensed account of particular researches. There is no doubt that these abstracts, if furnished with a full and comprehensive index, both of the subject-matter and the names of the authors, will become a standard work of reference, not only here but on the Continent.

It is to be hoped that other Scientific Societies will be induced to follow the example of the Chemical Society, and, by publishing abstracts of all papers connected with their particular branch of science, give an impetus to its cultivation, and render a knowledge of its general progress easily attainable. The value of such abstracts is greater than might at first sight appear; for the study of Science, both for its own sake, and in its application to the Arts, is extending so rapidly that it requires a considerable expenditure of time to acquire a knowledge of the numerous researches and discoveries which are now being made in any particular science, and leaves but little for the study of the sciences allied to it. If, then, each of the learned societies were to publish abstracts similar to those of the Chemical Society, it would render it comparatively easy for the workers in any one department of science to acquire something more than a superficial knowledge of the discoveries made in the others.

## *GLAISHER'S TRAVELS IN THE AIR*

*Travels in the Air.* By James Glaisher, Camille Flammarion, W. de Fonvielle, and Gaston Tissandier. Second and revised edition. With 125 illustrations. (London: R. Bentley, 1871.)

BOTH the scientific and the lover ot adventure will find abundance to interest them in this handsome volume. The terrestrial fields of enterprise are getting exhausted. Mont Blanc has long since been used up. We are getting tired of Central Africa and the Steppes of Tartary. Even the invitation "Try Lapland" fails to stimulate the jaded nerves of the zealous explorer of "fresh fields and pastures new." In the realms of air, however, there is still plenty of new ground, if we may be allowed the Hibernicism. Mr. Glaisher and the illustrious French trio can claim this field as almost exclusively their own, though, doubtless, they will not long be left in undisturbed possession of it. After a brief history of the rise and progress of aërostatics in England, Mr. Glaisher here recounts to us the particulars of ten of his most remarkable ascents; and the Frenchmen then follow suit. The volume is got up in drawing-room style, as a veritable *livre de luxe*; we wish we could transfer to our pages some of the beautiful chromo-lithographs by which it is illustrated, in particular, the wonderful mirage and luminous aureole which serves as frontispiece, and the falling stars as observed from the balloon, at p. 262. We must, however, content ourselves with two or three of the scarcely less effective woodcuts.

FIG. 1—MIRAGE IN THE SKY, AS SEEN FROM THE BALLOON

The scientific information contained in the volume is important, though rather as showing how little we know at present of even the fundamental principles of Meteorology, than as establishing any new laws. With regard to temperature, Mr. Glaisher remarks that the decrease as we ascend is far from constant, and we must entirely abandon the theory of a decline of 1° of temperature for every increase of 300 ft. of elevation. With reference to the colour of the sky, he states that, as viewed from above the clouds, it presents a deep blue colour, which deepens in intensity with increase of elevation regularly from the earth if the sky be free from clouds, or with the increase of elevation above the clouds if they be present, and on this subject he gives the following laws :—

"The azure colour of the sky, though resembling the blue of the first order when the sky is viewed from the earth's surface, becomes an exceedingly deep Prussian blue as we ascend, and, when viewed from the height of six or seven miles, is a deep blue of the second or third order. 2. The maximum polarising angle of the atmosphere, 45°, is the same as that of air, and not of water, which is 53°. 3. At the greatest height to which I have ascended, namely, at the height of five, six, and seven miles, where the blue is the brightest, the air is almost deprived of moisture. Hence it follows that the exceedingly deep Prussian blue cannot be produced by vesicles of water, but must be caused by reflection from the air, whose polarising angle is 45°. The faint blue which the sky exhibits at the earth's surface is therefore not the blue of the first order, but merely the blue of the second or third order rendered paler by the light reflected from the aqueous vapour in the lower regions of the atmosphere.

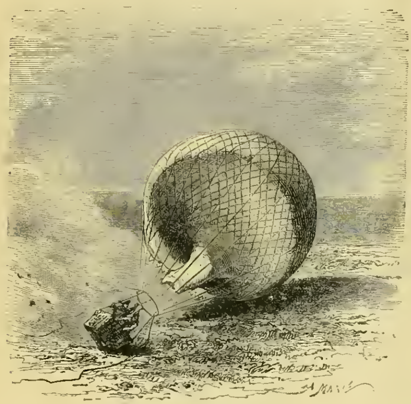

FIG. 2—DRAGGING

To appreciate all the beauty of cloud scenery when the air is loaded with moisture, an aërial voyage must be made on an autumn morning before sunrise, when the atmosphere is charged with the vapours of night."

Clouds were frequently met with to a height of 20,000ft. or nearly four miles, and heavy rain at almost as great an altitude; and on one occasion, while descending, rain fell on the balloon at a height of three miles, and then for the next 5,000ft. lower, it passed through a beautiful snowy scene; there were no flakes in the air, the snow was entirely composed of spiculæ of ice, of cross spiculæ at angles of 60°, and of an innumerable number of snow crystals, small in size, but of distinct and well-known forms easily recognisable as they fell and remained on the coat. The drawings show many a beautiful scene—sunrise from a balloon, moonlight effects, a lunar halo, the shadow of a balloon on the clouds, sometimes surrounded by an aureole, though, perhaps, none more remarkable than the mirage represented in our first illustration.

Humorous incidents occur here and there; as when the whole apparatus is taken by the French peasantry for "le diable" himself, or when the travellers approaching the earth are required by too zealous gensdarmes to show their passports! And the adventures are not without their serious attendant dangers. More than once the diminished pressure and the intense cold produced so great a numbness and tendency to sleep that it has required the greatest presence of mind for all control over the balloon not to be lost—and for ever. Life and limb were also not unfrequently endangered by the too sudden descents, sometimes to escape the imminent peril of an involuntary dip into the sea. Fig. 2 depicts the manner in which the "Swallow," having Tissandier and de Fonvielle on board as passengers, was dragged along the ground by a furious gale, and both those eminent aëronauts were considerably hurt and in danger of losing their lives.

There is not much contribution in the volume to the mechanics of aërostation, and that mostly from the French

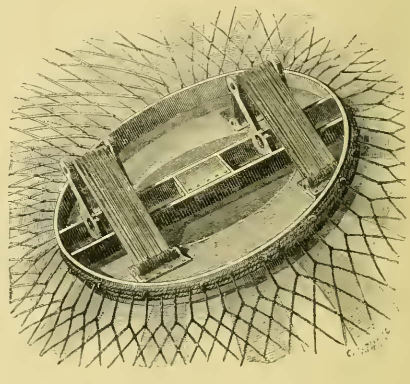

FIG. 3—THE VALVE OF THE "ENTREPRENANT" BALLOON

contributors. We have drawings of the weighing machine and pulleys of the great Captive balloon of Chelsea, and Fig. 3 represents the valve of the "Entreprenant" balloon from which M. de Fonvielle attempted to take photographs of an eclipse of the moon. The book is one which will doubtless find a large circle of readers, and will greatly increase the public interest in aërostatics.

## *OUR BOOK SHELF*

*A Text-Book of Elementary Chemistry, Theoretical and Inorganic.* By George F. Barker, M.D. (New Haven. Conn.: C. C. Chatfield and Co., 1870, pp. 336.)

THIS little book is evidently the result of much labour on the part of the author, and cannot fail to be of much value to students of chemistry. In the preface a list of books is given of which the author has made free use; consequently the peculiarities of the systems of many chemists are to be found in the book; but though it cannot be said that any school has been followed, yet all are more or less represented. The prevailing ideas are that each element has a definite combining power or equivalence, and that the arrangement of atoms in compounds is of as much importance as their kind or number. This work is remarkable for the conciseness of its definitions; one of the first is on chemical and physical changes, in which it is said that "physical changes in matter are those which take place outside the molecule; they do not affect the molecule itself, and therefore do not alter the identity of the matter operated on. Chemical changes take place within the molecule, and hence cause a change in the matter itself." Some of the definitions would not, however, find general acceptance; thus, an acid molecule is said to be "one which consists of one or more negative atoms united by oxygen to hydrogen;"—a definition which excludes hydrochloric acid and its analogues. And a saline molecule is defined to be one containing a "positive atom or group of atoms, united by oxygen to a negative atom or group of atoms," which removes sodic chloride from the list of salts. The term base is confined to the hydrates of positive elements or groups of elements, and the hydrates of the metals calcium, zinc, and iron are sometimes called calcic base, zincic base, ferrous base, and ferric base. The nomenclature of the acids is systematised, but peculiar names are the result: an ortho-acid is one containing as many atoms of oxygen and hydrogen as is equal to the equivalence of the negative atom or group; and a meta-acid is derived from an ortho-acid by the subtraction of molecules of water, thus orthophosphoric acid would be $P(OH)_5$, metaphosphoric acid $(PO)'''(OH)_3$, and dimetaphosphoric acid $(PO_2)'(OH)$. These names and those of most other acids are liable to some misunderstanding, as the compounds they represent have long been known by other designations. The theoretical part of the book contains chapters on elemental molecules and atoms, compound molecules, volume relations of molecules, and stoichiometry. The part on inorganic chemistry is divided into eleven chapters, on hydrogen, the negative monads, dyads, triads, boron, negative tetrads, the iron group, positive tetrads, triads, dyads and monads, thus treating of the elements according to their electro-chemical characters, commencing with the most negative. Each chapter is divided into sections containing the history, occurrence, preparation, and properties of the elements, and is followed by a series of questions intended as exercises for the students, a method now much adopted, and found to be of great assistance to teachers. This book is another of the evidences of the rapid progress of pure science in America.

*Czermak's Electric Double Lever. (Der Electrische Doppelhebel, von J. N. Czermak.)* (Leipzig: Engelmann. 1871. London: Williams and Norgate.)

A DESCRIPTION of a most ingenious little contrivance for marking the exact moment in which a movement begins or changes its direction. The old arrangement, by which a lever, forming part of a circuit, comes, when set in motion, in contact with a fixed point connected with the other part of the same circuit, and so closes the circuit and makes a signal, is modified by Prof. Czermak as follows. The fixed contact point is replaced by a secondary lever, whose axis of revolution is the same as that of the primary lever. This secondary lever bears at one end a contact point. The primary lever touches in its swing this contact point, and so closes the circuit; it then pushes the secondary lever before it, but having reached the limit of its oscillation, leaves the secondary lever at rest in a position marking the farthest point of the excursion. A counter contact-point, however, on the other arm of the primary lever (where the lever is a double-arm one; with single arm levers, a special arrangement is introduced), as the primary lever is returning into position gives to the secondary lever a movement in the same direction. Thus the two levers are continually following each other, making and breaking contact. The instrument is in this way made capable of being used for signalling all manner of movements. It is impossible fully to explain its construction in a few lines, and we therefore refer the reader to the pamphlet itself, which, we should say, is published in celebration of the Jubilee of the great Leipzig Professor, Ernst Heinrich Weber. By the invention of his delightful "Rabbit Holder," Czermak has endeared himself to every physiologist, and we may well share his hope that this new double lever will be found no less useful. M. FOSTER

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Pangenesis

IT appears from Mr. Darwin's letter to you in last week's NATURE,* that the views contradicted by my experiments, published in the recent number of the "Proceedings of the Royal Society," differ from those he entertained. Nevertheless, I think they are what his published account of Pangenesis (Animals, &c., under Domestication, ii. 374, 379) are most likely to convey to the mind of a reader. The ambiguity is due to an inappropriate use of three separate words in the only two sentences which imply (for there are none which tell us anything definite about) the *habitat* of the Pangenetic gemmules; the words are "circulate," "freely," and "diffused." The proper meaning of circulation is evident enough—it is a re-entering movement. Nothing can justly be said to circulate which does not return, after a while, to a former position. In a circulating library, books return and are re-issued. Coin is said to circulate, because it comes back into the same hands in the interchange of business. A story circulates, when a person hears it repeated over and over again in society. Blood has an undoubted claim to be called a circulating fluid, and when that phrase is used, blood is always meant. I understood Mr. Darwin to speak of blood when he used the phrases "circulating freely," and "the steady circulation of fluids," especially as the other words "freely" and "diffusion" encouraged the idea. But it now seems that by circulation he meant "dispersion," which is a totally different conception. Probably he used the word with some allusion to the fact of the dispersion having been carried on by eddying, not necessarily circulating, currents. Next, as to the word "freely." Mr. Darwin says in his letter that he supposes the gemmules to pass through the solid walls of the tissues and cells; this is incompatible with the phrase "circulate freely." Freely means "without retardation;" as we might say that small fish can swim freely through the larger meshes of a net; now, it is impossible to suppose gemmules to pass through solid tissue without *any* retardation. "Freely" would be strictly applicable to gemmules drifting along with the stream of the blood, and it was in that sense I interpreted it. Lastly, I find fault with the use of the word "diffused," which applies to movement in or with fluids, and is inappropriate to the action I have just described of solid boring its way through solid. If Mr. Darwin had given in his work an additional paragraph or two to a description of the whereabouts of the gemmules which, I must remark, is a cardinal point of his theory, my misapprehension of his meaning could hardly have occurred without more hesitancy than I experienced, but I certainly felt and endeavoured to express in my memoir some shade of doubt; as in the phrase, p. 404, "that the doctrine of Pangenesis, pure and simple, as I have interpreted it, is incorrect."

As I now understand Mr. Darwin's meaning, the first passage (ii. 374), which misled me, and which stands: " . . minute granules . . . which circulate freely throughout the system" should be understood as "minute granules . . . which are dispersed thoroughly and are in continual movement throughout the system;" and the second passage (ii. 379), which now stands: "The gemmules in each organism must be thoroughly diffused; nor does this seem improbable, considering . . . the steady circulation of fluids throughout the body," should be understood as follows: "The gemmules in each organism must be dispersed all over it, in thorough intermixture; nor does this seem improbable, considering . . . the steady circulation of the blood, the continuous movement, and the ready diffusion of other fluids,

* NATURE, vol. iii. p. 502.

and the fact that the contents of each pollen grain have to pass through the coats, both of the pollen tube and of the embryonic sack." (I extract these latter *addenda* from Mr. Darwin's letter.)

I do not much complain of having been sent on a false quest by ambiguous language, for I know how conscientious Mr. Darwin is in all he writes, how difficult it is to put thoughts into accurate speech, and, again, how words have conveyed false impressions on the simplest matters from the earliest times. Nay, even in that idyllic scene which Mr. Darwin has sketched of the first invention of language, awkward blunders must of necessity have often occurred. I refer to the passage in which he supposes some unusually wise, ape-like animal to have first thought of imitating the growl of a beast of prey so as to indicate to his fellow monkeys the nature of expected danger. For my part, I feel as if I had just been assisting at such a scene. As if, having heard my trusted leader utter a cry, not particularly well articulated, but to my ears more like that of a hyena than any other animal, and seeing none of my companions stir a step, I had, like a loyal member of the flock, dashed down a path of which I had happily caught sight, into the plain below, followed by the approving nods and kindly grunts of my wise and most-respected chief. And I now feel, after returning from my hard expedition, full of information that the suspected danger was a mistake, for there was no sign of a hyena anywhere in the neighbourhood. I am given to understand for the first time that my leader's cry had no reference to a hyena down in the plain, but to a leopard somewhere up in the trees; his throat had been a little out of order—that was all. Well, my labour has not been in vain; it is something to have established the fact that there are no hyenas in the plain, and I think I see my way to a good position for a look out for leopards among the branches of the trees. In the meantime, *Vive* Pangenesis. FRANCIS GALTON

### The Hylobates Ape and Mankind

THE readers of Mr. Mivart's communication in NATURE for April 20, on the affinity of the Hylobates genus of ape to the human species, may be interested to learn that the fact was well known to the author of the Ramayana, the earliest Sanscrit epic, probably contemporaneous with the Iliad. In this poem the demigod Rama subdues the demon Ravana, and regains his ravished bride Sita by the assistance of a host of apes, which may be identified with *Hylobates Hoolook*. The human characteristics of these semi-apes, their gentleness, affection, good humour, sagacity, self-importance, impressionability, and proneness to melancholy, are portrayed with the most vivid strokes, and evidently from careful observation. See Miss Frederika Richardson's charming volume, "The Iliad of the East," a selection of legends drawn from the Ramayana. (Macmillan and Co., 1870.)

April 27 R. G.

### Tables of Prime Numbers

WHEN a number is given, and it is required, without the aid of tables, to find its factors, there is not, I believe, any other method known except the simple but laborious one of dividing it by every odd number until one is found that measures it, and if the number should be prime, this can only be proved by showing that it is not divisible by any odd number less than its square root. Thus to prove that 6966007 is prime, it would be necessary to divide it by every odd number less than 2639, and even if a table of primes less than 2639 were at hand, about 380 divisions would be requisite.

On the other hand, there are few tables which are more easily constructed than tables of divisors, and it is the extreme facility of a systematic tabulation compared to the labour of isolated determinations, which has led to the construction of such elaborate tables on the subject as have been produced.

The principal tables are Chernac's, which give the factors of numbers from unity to a million; Burckhardt's, which extend as far as three millions, and Dase's, which form a continuation of Burckhardt's, and extend to ten millions.

The mode of formation of these tables was extremely simple. By successive additions, the multiples of 3, 5, 7, 11, 13, 17 . . . were formed up to the limit to which the table was intended to extend; this gave all the numbers having these numbers for factors, and the primes were recognised from the fact of their not occurring as multiples of another prime less than themselves.

Practically the work was rendered even simpler by mechanical means; thus, forms were printed containing, say, a thousand squares, and in these were written consecutive thousands of odd numbers in order; one number in each square, room being left for its divisors, if any, in the square. A pair of compasses was then taken and opened a distance corresponding to the prime whose multiples were to be obtained; for example, in marking the multiples of seven, the compasses were opened the width of seven squares, and then "stepped" along the lines starting from 7, thereby marking the numbers 7, 21, 35 . . . and the number 7 was written in each of the squares in which a leg of the compasses fell. When the factor was large it was more convenient to form a separate table of its multiples, and enter it in the square corresponding to the latter Many simplifications were introduced in the details of the construction; for instance, Burckhardt had a copper plate engraved with 77 ($=7\times 11$) squares one way and 80 the other; by this arrangement the multiples 7 and 11, which were of the most frequent occurrence (for all multiples of 2, 3, and 5 were rejected from the tables), occupied the same place on each sheet, and he was thus enabled to engrave the numbers 7 and 11 on the plate, so that these numbers were *printed* in all the squares containing the numbers they measured.

Dase, who originally applied himself to the construction of the tables at the suggestion of Gauss, left behind him in manuscript at the time of his death, in 1862, the seventh and part of the eighth million complete, besides a considerable portion of the ninth and tenth millions. The seventh, eighth, and ninth millions were completed by Dr. Rosenberg, and published by a committee at Hamburgh. In the preface to the ninth million (1865), which is the last I have seen, it is stated that the tenth million, which was nearly ready, was the last the committee intended to publish.

My object in writing this letter is not only to call attention to a most valuable series of tables, which seem to have scarcely excited so much interest as they deserve, but also to ask if any of your readers can inform me if the work is being continued, or if there is any chance of its continuation. It is not often that tables are so indispensable as in the present case, or that a want so pressing can be supplied with such comparative ease; and the cessation of the tables would be a real calamity. The tenth million has, I presume, been published.

At the British Association Meeting at Dundee in 1867, a list of 5,500 large prime numbers was communicated to Section A by Mr. Barrett Davis. A short discussion took place on the "reading" of the paper, in the course of which it was stated that Mr. Davis's table was unaccompanied by any explanation of how the numbers had been obtained, or on what grounds they were asserted to be prime; it was also asserted that Mr. Davis wished to keep his method secret.

Perhaps some reader of NATURE can say whether Mr. Davis's numbers have been printed. If they exceed Dase's limit, their publication (if they have not yet been published) is very desirable; and even supposing they are given in Dase's tables, it would be valuable to know how far the latter have been verified by them. The statement about Mr. Davis's method being secret was probably founded on some mistake, and no doubt Mr. Davis would not object to explain it. J. W. L. GLAISHER

Trinity College, Cambridge, April 29

### Units of Force and Energy

THE best root for the name of a unit of force is δύναμις. There is, therefore, no ground for Mr. Muir's complaint (NATURE, vol. iii. p. 426), and I now venture to propose that the name *dyne* be given to that force which, acting on a gramme for a second, generates a velocity of a metre per second. A thousand dynes to make one *kilodyne*, and a million dynes one *megadyne*.

Borrowing a hint from Mr. Muir, I would point out that the kilodyne may also be defined as the force which, acting on a *kilogramme* for a second, generates the velocity of a *metre* per second, or, as the force which, acting on a *gramme* for a second, generates a velocity of a *kilometre* per second.

The *kinit*, or pound-foot-second unit of force, is about 138¼ dynes. Very roughly expressed in terrestrial gravitation measure, the kinit is the gravitating force of half an ounce, the dyne of about 1½ grains, the kilodyne of about ¼ of a pound, and the megadyne of 2 cwt., the approximation being much closer in this last case than in the others, so that within one part in 400 we have 10 megadynes = the force of terrestrial gravity on a ton.

I have often felt the want of a name for an absolute unit of energy, or, what amounts to the same thing, an absolute unit of work. If the above names be adopted, they give us at once the foot-kinit as the unit of work based on the pound, foot, and second, the foot-pound (which varies with the value of $g$) being equal to $g$ foot-kinits.

In like manner we have, for the metrical system, the *metre-dyne* and its derivatives.

But it would, I think, be advantageous to have short and independent names for these units. For, in the first place, we are thus saved from such cumbrous names as *metre-kilodyne* and *metre-megadyne*, which would be necessary in expressing large quantities of work; in the second place, energy of motion depends directly upon mass and velocity, and is only indirectly connected with the unit of force; and, in the third place, the characteristics of energy are such as specially entitle it to names suggestive of simplicity rather than of compositeness.

I propose, therefore, to call the foot-kinit, whether of work or energy, the *erg*. A thousand ergs to make one *kilerg*, which will be about 31 terrestrial foot-pounds, and a million ergs to make one *pollerg*, which is a little less than the work done by one horse-power in a minute.

The kinitic energy of $m$ pounds, moving with a velocity of $v$ feet per second, is $\frac{1}{2} mv^2$ when expressed in ergs.

The energy value of a Fahrenheit unit of heat is $772 \times 32{\cdot}194 = 24{,}854$ ergs.

In the metrical system, let the metre-dyne of work or energy be called the *pone* (from πόνος). A thousand pones to make one *kilopone*, which is the work done by a *kilodyne* working through a *metre*, or by a *dyne* working through a *kilometre*, and is about $\frac{1}{9{\cdot}81}$ of the variable unit of work in common use among French engineers, called the kilogrammetre. A million pones to make one *megapone*, which is about 723 terrestrial foot-pounds.

In employing the prefix *mega* to denote a million, I have followed the excellent example set by the B. A. Committee on Electrical Standards. As *megerg* would be intolerable, and *megalerg* sounds like a confusion of genders, I have substituted *pollerg*.

In constructing a new nomenclature, the metrical system is entitled to the best names which can be found, but the pound and foot cannot be ignored. J. D. EVERETT

### The Name "Britain"

IN his remarks on the derivation of the name "Britain," "A. R. H." says that tin "is found only in one of the Britannias." This is incorrect, for tin occurs in Brittany, and also in Gallicia. The fact of the three Britains mentioned by "A. R. H." being all tin-bearing districts seems to confirm the derivation given by Mr. Edmonds in NATURE for February 16.

C. L. N. F.

Piedimulera, Val d'Ossola, Piedmont, April 25

---

### Derivation of the Word "Britannia"

IF Mr. Edmonds considers himself right in his derivation of "Britannia" and "tin," he will have to explain on the same basis the conformable names, and this he will find difficult to do.

The name B-ritannia corresponds with S-ardinia, D-ardania, and possibly with Mauritania, and these again with a number of river names of the root RDN (=RND, BRN, &c.), such as Rotanus, Rhodanus, Drinus, Eridanus, Artanus, Triton, Orethus, &c. B-radanus, P-rytanis, P-arthenias, V-artanus, are examples of B. K-artenus, I-ordanes, I-ardanes, I-ardenus. Then there are examples of Aternus, &c., Tanarus, &c., Mæander, &c., Orontes, &c. These must all be explained on one principle.

In the same way as Britannia is allied to river names, so are many of the ancient (classic) names of countries (except such as are volcanic) allied to river names of various roots, as RBD, &c., RKN, &c., SBN, &c.

These names are not explainable in Phœnician, because they were given long before the Phœnicians entered on the stage of history. They are Palæogeorgian, in a language to which Georgian, Lesghian, and other Caucasian languages are allied. These names were given by the Caucaso-Tibetans.

This is explained in my paper lately read before the Anthropological Institute and recorded in NATURE, and the name of Britannia is illustrated in papers sent in to the Society of Antiquaries and the Royal Irish Academy.

32, St. George's Square HYDE CLARKE

### Aurora by Daylight

THAT the Aurora Borealis has been seen by daylight has never been doubted by me, although till now I have not been able to collect sufficient evidence to induce others to believe in the possibility of it. Your correspondent Mr. John Langton, in your last issue, gives two instances of the aurora having been seen during day time, which, I think, ought to dispel all further doubt. However, to satisfy the most sceptical of your readers, the following few cases have occurred to me:—

"A.D. 1122. . . . . . . This same year died Ralph, Archbishop of Canterbury; that was on the 13th of the kalends of November (October 20). After this were many shipmen at sea and on the water, and they said that they saw on the north-east along the earth a great and broad fire, and it increased speedily upwards in extent towards the sky, and the sky opened itself in four parts and fought there against it as if it would extinguish it: but nevertheless the fire extended up to heaven. They saw that fire in the dawn of the day, and it continued until it was quite light. This was on the 7th of the ides of December (December 7)."—*Anglo-Saxon Chronicle*.

It may seem bold to advance this as the record of an auroral appearance, but not to those who have studied this and other chronicles with their wearying vaguenesses. This passage gains clearness by the following lines from the "Prose Edda," concerning "The Twilight of the Gods and the Conflagration of the Universe," which I have elsewhere* supposed to be a description of the aurora borealis:—

"The fire-reek rageth
Around Time's nurse,
And *flickering flames*
With heaven itself playeth."

In the "Second Continuation of the History of Croyland," there is the following curious passage, under A.D. 1467:—"For one day . . . . . . . . . . horsemen and men in armour were seen rushing through the air; so much so, that St. George himself, conspicuous with the red cross, his usual ensign, and attended by a vast body of armed men, appeared visibly in great numbers. To show that we ought not to refuse our belief to what has been just mentioned, those persons to whom revelations of this nature were made were subjected to the most strict examination before the venerable Father Thomas, the Lord Archbishop of Canterbury."

I understand this occurrence to have taken place in the day between the rising and setting of the sun, because this passage is only part of a longer account of remarkable events which were said to have been observed in "one day." I do not put this instance forward as one of very great value,† as the Chronicle of Ingulf is undoubtedly spurious, as shown by Dr. Hickes and Sir Francis Palgrave, but the continuation, I think, can be safely said to date about the end of the 15th or the beginning of the 16th century, which, if correct, will place the phenomenon above referred to amongst the earliest notices of daylight Auroras in English History, and will come next to that mentioned in the *Anglo-Saxon Chronicle*. Of course I only speak here of my own acquaintance with the Chronicles, there may be other records, but I have not had the opportunity of searching through every monastic production.

Leaving this field of speculation, I come next to a more reliable record. I give the whole of the passage, as it is not very long:—"Aurora Borealis, seen in the Day-time at Canonmills." "The morning of Sunday, September 9, was rainy, with a light gale from the N.E. Before mid-day the wind began to veer to the west, and the clouds in the north-western horizon cleared away: the blue sky in that quarter assumed the form of a segment of a very large circle, with a well-defined line, the line above continuing dense, and covering the rest of the heavens. The centre of the azure arch gradually inclined to the north, and reached an elevation of 20°. In a short time, very thin fleecy clouds began to rise from the horizon within the blue arch; and through these very faint perpendicular streaks of a sort of milky light could be perceived shooting; the eye being thus guided, could likewise detect the same pale streaks passing over the intense azure arch, but they were extremely slight and evanescent. Between nine and ten in the evening of the same day, the aurora borealis was very brilliant, so that there is no reason to doubt that the azure

* Vide NATURE, vol. iii. p. 175.

† For a similar case to this see note to my letter on the aurora borealis in NATURE, vol. iii., p. 487.

arch in the morning, and the pale light seen shooting across it, were connected with the same phenomenon."*

I have just been informed by a friend whose veracity I would be the last to question, that he saw a very faint arch in the eastern sky on the afternoon of the 10th inst. (about 4.30 P.M.). There were no clouds near it, while the background was a beautiful azure. The colour of the arch was of a much fainter blue, or, as he calls it, "a whitish blue," and was almost a perfect semicircle. I have not the least doubt that it was a "daylight" aurora; it must be remembered that on the previous night there was a most magnificent aurora borealis.

In conclusion, after carefully examining the facts contained in the various communications to your journal, as well as those which I have collected, I cannot see any reason for doubting the possibility of the aurora borealis being seen by daylight. It will be interesting to know what those daylight phenomena are, if not auroras.

### The Irish Fern in Cornwall

YOUR correspondent having, much to my regret, so exactly informed the "ruthless collectors" where they are to look for this fern, I fear that after the ensuing autumnal ravages not a single frond will be left to speak for itself. Permit me, therefore, to state that the fern unquestionably grows, or did grow, at the place indicated, and was, I believe, first recognised in 1866 by Mr. Robert Were Fox, F.R.S., who has a plant he thus obtained still growing in his fernery at Penjerrick near this town.

W. P. DYMOND

Falmouth, April 29

### The Prevalence of West Winds

IN a letter with this heading in NATURE for February 16th, Mr. Murphy has very roundly objected to certain views which I have put forward regarding the predominance of westerly winds. In the paper read before the British Association, to the abstract of which he refers, and which was itself little more than a *résumé* of the propositions maintained at greater length in my "Physical Geography," reviewed by "A. B." in NATURE for March 16th, my object was not so much to show that westerly winds predominated in volume over easterly winds, as to show that all prevailing winds, not westerly, may be properly considered as deflected or secondary currents of air, and that more especially the trade winds may be so considered. I have supported this view by a detailed examination of the geographical circumstances, habitudes, and characteristics of the principal winds; but to have included every local exception—as "A. B." seems to consider I ought to have done—would have required more time than even the most industrious can spare, an amount of special topographical knowledge which is practically unattainable, and would have had no important bearing on the main question. I may go even further. I may say that, from a general point of view, isolated local registers have no value at all, unless the method of observing and the position of the vane are distinctly made known. It would be perfectly easy to name a dozen localities in Wales, in the Lake District, or in Scotland, where a vane would show a prevailing wind widely different from the W.S.W., which, however, we have no difficulty in accepting as the prevailing wind of the country; even at Liverpool the prevailing wind has been observed to be W.N.W., and at Valentia there is a marked difference between the wind in the northern and southern entrance. In Mr. Buchan's paper in the Transactions of the Royal Society of Edinburgh, December, 1869, I find that at Irkutsk the wind is almost always due north, or due south, would "A. B." imply that the Irkutsk observations afford any information as to the prevailing wind of Siberia?

In another paragraph, "A. B." considers that the preponderance of westerly winds cannot be very great. So far as the area over which westerly winds blow is concerned, I would partly agree with him; taking into account the constant interruptions to the west winds in the temperate zones, and on the other hand their frequent intrusion into latitudes considerably below 30°, more especially in the Pacific, and their prevalence during several months of the year over a large portion of the Indian Ocean, I am inclined to reckon the ratio of the area of westerly winds to the area of easterly winds as approximately 13 : 10. But such an estimate does not in any way include the velocity of the wind; and since the velocity of the west winds of temperate latitudes is, in the mean, about double that of the easterly winds of tropical, it would follow that the respective volumes of the winds bear to each other a much larger ratio, which, allowing freely for every reasonable reduction, cannot be less than 2 : 1. And this estimate still relates only to the lower strata of the atmosphere, through a height probably not exceeding 12,000 feet. Our knowledge of the winds above that height is very limited; but since, wherever observation extends, it points out to us a strong, frequently even a violent west wind, it seems to me that we have a fairly presumptive proof that the prevailing direction of the upper current is from the west. I base this belief entirely on the evidence which we have, defective as it is and as it almost necessarily must be; to explain the fact by a reference to a difference of barometric pressures, concerning which we have positively no evidence at all, is a task which I most willingly leave to my reviewer. But if, as I have maintained, we may fairly assume that the upper current has an almost invariable direction from the west, and that too with a comparatively high velocity, the ratio of the volumes of westerly and easterly winds is enormously increased, and if the upper part of the air, being quite half of the whole, is moving from the west with a mean velocity of 40 miles an hour, then, as we have already taken 20 miles, or the velocity of the trade winds, as the standard or unit of reference, we have the ratio of westerly to easterly winds as about 6 : 1.

The question which Mr. Murphy has suggested no doubt here arises: Must not this preponderance of westerly winds affect the rotation of the earth? I have throughout maintained the existence of this preponderance solely by geographical proof, and conceiving that the evidence is conclusive, whilst no meteorological theory points to any explanation of it, I am compelled to attribute it to the action of some force external to the earth; possibly, as I have endeavoured to show, to the attraction of the sun, moon, and other heavenly bodies; possibly also to some other force, magnetic or meteoric, of whose action we have as yet no knowledge or understanding: but supposing, as I do, that the force which produces this motion is external to the earth, it is impossible to avoid the conclusion that it does tend to increase the earth's velocity of rotation. On the other hand, there are forces, admitted by all naturalists, in constant action, which tend to decrease the velocity of rotation; and a certain amount of wonder that the decrease so caused is so small as observation proves it to be is implied, rather than expressed, in our most valuable works on Natural Philosophy. If it is impossible in the present state of our knowledge to show exactly what such decrease is and ought to be, it is certainly impossible to say that it is not to some extent counterbalanced by a contrary tendency towards an increase, such as I have shown probably exists. At any rate, I know of nothing connected with the rotation of the earth which in any way controverts or affirms the proposition which I have put forward, based on geographical evidence only.

I had written this before seeing Mr. Murphy's second letter on the subject in NATURE for March 30, but as he has in it merely repeated his former arguments, it is unnecessary to notice it more particularly.

J. K. LAUGHTON

Royal Naval College, Portsmouth

* Jameson's Journal, quoted in the "Arcana of Science and Art" for 1828.

## *SUBMARINE TELEGRAPHS*

IT may possibly be within the memory of some persons that, about the year 1840, Sir C. Wheatstone first conceived the idea of transmitting messages under the sea, and practically carried out at that time the first submarine telegraph cable. Selecting Swansea Bay, South Wales, as the chosen spot for his experiment, the great inventor sat in an open boat, about three miles from the Mumbles Lighthouse, with the lighthouse keeper as his assistant. A conducting wire, insulated with hemp and a resinous compound, served as the electric communication between his open boat and the shore. It is from the successful results of this first crude experiment, and Wheatstone's investigations into the laws that regulate the transmission of electric currents through metallic conductors, published shortly afterwards in the Philosophical Transactions of the Royal Society of London, that our present system of the testing of submarine cables is based, and the vast system of inter-oceanic communication that connects the civilised world together, has been framed.

At the date of Wheatstone's first experiment, gutta-percha was undiscovered, and its insulating power unknown. By the employment of this gum, the electrical condition of the submarine cable, up to a certain standard, has been under ordinary circumstances rendered secure. Such being the case, and for the purpose of comparison hereafter, it is well to examine a little into the properties of this gum and that of india-rubber, another vegetable substance possessing insulating properties of the most remarkable kind, as applied to the construction of submarine cables. Gutta-percha, as is well known, is a vegetable gum, which becomes plastic and soft at a comparatively low temperature, about 100° F. Subjecting the gum to repeated cleansing processes to free it from impurities and extraneous vegetable matter, it is rendered tolerably dense and homogeneous, and in this state it is applied in successive layers or coats round the copper conducting wire as the insulating material, forming the "core" of the submarine cable, which is then termed "insulated," that is, capable to a certain extent of preventing the lateral escape of any electric current or charge which may be passed into the wire. A short investigation is now necessary to be made of some of the circumstances which take place when a wire thus insulated is submerged and subjected to the charge of an electric current. If the wire were absolutely insulated, that is, if gutta-percha were a perfect insulator offering an indefinite resistance to the passage of the current through its substance, any given quantity of electricity passed into the wire would remain there for a given time without loss, in the same way as when water is poured into a vessel, the level remains intact so long as there is no leakage. The amount of this leakage through the gutta-percha, or, in other words, its "conductive resistance," determines the insulating power of the cable. But this is not all that has to be considered ; other circumstances affecting the value of the insulation come into play. The following analogous example will explain. When a leech is allowed to crawl through a glass tube, the head and body pass out first, while the tail—long and attenuated—is slowly withdrawn. So with the passing of an electric current through an insulated conductor, a portion of the current lags sluggishly behind, absorbed, as it were, into the substance of the insulating medium, and taking time to discharge itself in proportion to the amount of the sucking up, or "inductive capacity" of the insulator, for, in this respect, both gutta-percha and india-rubber may be regarded as a sponge, the current penetrating into the pores of the substance.

Without entering further into detail regarding the laws regulating the transmission of the current, it is sufficient to remember that the speed or power of transmitting a given number of messages in a given time over any cable depends materially upon the proportionate values of the "conductive resistance" and "inductive capacity" of the insulation. Thus there is at once established a measure by which the value of all known insulating materials may be determined and compared together, that is to say, if two cables of equal length and similar construction are taken—the one insulated with gutta-percha, and the other with india-rubber (Hooper's india-rubber)—the relative value and working speed of each can be accurately determined and compared. The successful employment of india-rubber as an insulating medium for submarine cables is of more recent date, and the estimation in which it is now held for that purpose is entirely due to the beautiful process employed in its manipulation by Mr. W. Hooper, of Mitcham. It is well known that india-rubber possesses a much higher insulating power than gutta-percha ; as a gum it is also denser, more homogeneous, and infinitely more pliable and elastic than gutta-percha, while it is not affected in any considerable degree by variation of temperature—all qualities of the greatest importance as connected with submarine cable insulation.

Before entering upon a comparative statement of the insulation and speed of gutta-percha and Hooper's insulation, a short notice of the mode by which this insulating material is manipulated will be interesting, and will serve to give value to the practical data hereafter stated. The copper conductor, after being tinned, is coated with an insulation of pure india-rubber applied in the shape of a ribbon, lapped spirally round it. Next, two strips (one laid above and the other below) of india-rubber, chemically prepared to resist the action of sulphur, and called the "separator," are applied so as to completely surround the first rubber covering, as it were with a tube ; a pair of grooved die-wheels giving the contour, and at the same time regulating accurately the guage of the core. Exterior strips are then similarly applied of a compound of rubber and a small percentage of sulphur. The whole is then lapped round with water-proof felt tape, and exposed for some hours in an oven to a heat of about 383° F. By this process the three successive coatings are welded into one solid, dense, homogeneous mass, having its distinctive features preserved as regards the individual character of the several layers. Thus the heat, in driving off the sulphur from the outside coating, has converted that envelope into an indestructible vulcanised rubber jacket. The second layer, or "separator," has intercepted the passing of the sulphur by reason of its chemical properties, while at the same time it has allowed an infinitesimal trace of the sulphur to combine with the internal coating of pure rubber round the conducting wire, sufficient to change its character into an indestructible and non-liquifying material, without its becoming in any way vulcanised. It is by this beautiful chemical affinity between the several layers, each performing its special part towards the production of one individual whole, that the "Hooper insulation" has succeeded in establishing the durability of the preparation, the comparative value of which, as compared with that of gutta-percha, will now be given.

First as regards temperature—it has been already stated that gutta-percha became plastic at about 100° F. At this temperature it loses also almost entirely its insulating properties ; that is to say, if at a temperature of 32° F. the insulation of gutta-percha is taken as representing 100, at 75° it is reduced to 5·51, or little more than a twentieth part, while at the increased temperature of 100°, its insulating power has further decreased to 1·43, or about one seventieth part. Gutta-percha as an insulator is therefore unsuited for hot climates, or any exposed position where the temperature rises above 70°. Taking now Hooper's india-rubber insulation at 32° F. to be the same, 100, at 75° we find its insulation to be 24·50, or about one-fourth part, while at 100° it is 10·60, or about one-tenth part. Thus at the ordinary temperature of 75°, Hooper's core establishes its superior insulating properties under temperature in the proportion of four to one. The "inductive capacity" of Hooper's core, from its superior density, is only about two-thirds that of gutta-percha, while its insulation or resistance of the dielectric is fully twenty times greater than that of gutta-percha core, as exemplified in the tests given of some of the best known cables now at work.

The following is a list of some of the more important cables insulated with Hooper's core laid up to the present time :—

| | | |
|---|---|---|
| 1. Cable crossing rivers in India, laid in 1865, | length | 46 nauts. |
| 2. Ceylon Cable, India, laid in 1866 . . . | ,, | 35 ,, |
| 3. India Cable . . . . . . . | ,, | 40 ,, |
| 4. Persian Gulf Cable . . . . . | ,, | 500 ,, |
| 5. Danish-English Cable . . . . . | ,, | 363 ,, |
| 6. Scotch-Norwegian Cable . . . . | ,, | 247 ,, |
| 7. Danish-Norwegian Cable. . . . . | ,, | 73 ,, |
| 8. Orkney and Shetland Islands Cable . . | ,, | 103 ,, |

| | | |
|---|---|---|
| 9. Pentlands Cable | length | 11 nauts. |
| 10. Scilly Islands Cable | ,, | 27 ,, |
| 11. Swedish-Russian Cable | ,, | 103 ,, |
| 12. Moen Bornholm Cable | ,, | 80 ,, |
| 13. Hong-Kong-Shanghae Cable | ,, | 1200 ,, |
| 14. Shanghae-Possiette Cable | ,, | 1100 ,, |

These two latter cables have recently been completed, and the Shanghae-Possiette cable is now in course of submergence; the Hong-Kong-Shanghae cable was successfully laid last month. These lines give a total distance of over 3,978 nautical miles of submarine cable with Hooper's indiarubber insulation. The following observations as regards the electrical conditions of these cables as compared with well-known gutta-percha insulated cables is remarkable. The electrical tests of well-known cables with both the gutta-percha and the Hooper core are taken at the temperature of 75° Fahr., and in terms of British Association (B.A.) units, the standard measure now most generally adopted in England for comparison:

| | | | |
|---|---|---|---|
| | | Gutta-percha. | |
| England and Hanover Cable, laid | 1866 | 239 million B.A. units | |
| Persian Gulf Cable | ,, 1864 | 190 ,, | ,, |
| Atlantic Cable | ,, 1865 | 349 ,, | ,, |
| Atlantic Cable | ,, 1866 | 342 ,, | ,, |
| Placentia Bay Cable | ,, 1866 | 455 ,, | ,, |
| Cuba and Florida Cable | ,, 1867 | 464 ,, | ,, |
| | | Hooper Core. | |
| Ceylon Cable (Hooper's Core) | ,, 1865 | 7949 ,, | ,, |
| India Cable | ,, 1865 | 8064 ,, | ,, |
| India Cable | ,, 1866 | 8526 ,, | ,, |
| Danish-English Cable | ,, 1868 | 8123 ,, | ,, |
| Scotch-Norwegian Cable | ,, 1869 | 7923 ,, | ,, |
| Scilly Islands Cable | ,, 1870 | 7819 ,, | ,, |

With such results, it is not to be wondered at that the relative speed of two cables of similar length and construction, the one employing a gutta-percha core and the other a Hooper core, should be found greatly in favour of the latter, in the proportion of 130 to 100; that is to say, in any given time the Hooper core, from its superior insulating properties, will transmit thirty per cent. more words than a gutta-percha core, a most important circumstance when it is considered that the earnings or dividend upon each cable is dependent upon the work it can perform in a given period. As regards the apparatus employed for transmitting the currents through submarine conductors, the "Wheatstone" automatic recording system is the most successful. By this apparatus an average speed of over thirty words a minute is regularly maintained upon the Danish-English cable, a distance of 363 nautical miles, exclusive of a further land circuit of over 140 miles, making a total distance of about 500 miles. This speed must be compared with that of seventeen words per minute, the highest result recorded over the same circuit by the most improved Morse system. From the results of the "Wheatstone" apparatus working over this circuit since September 1868, it appears that to obtain maximum speed, the currents through a submarine cable require to be transmitted of equal duration, at equal intervals, in alternate directions, and the line discharged to earth between each successive reversal or current to neutralise the charge, all of which conditions are fulfilled in the "Wheatstone" Automatic Jacquard arrangement, which can only be compared to a loom weaving the currents into the line, the sequence of the currents representing the pattern on the cloth. This apparatus is now organised as the transmitting and recording register upon the vast system of submarine circuits belonging to the Great Northern Telegraph Company, and the extensions from Possiette Bay (Russian-Chinese frontier) to Nagasaki, Shanghae, and Hong-Kong. The subject of high speed transmission through insulated conductors, both by land and sea, is one which demands special attention, now that the telegraph is daily encroaching upon the postal service, a service in which both speed and accuracy are more than ever demanded by the public.

NATH. J. HOLMES

## PFLÜGER'S NERVE-ENDINGS IN GLANDS

IN his "Archiv für die Gesammte Physiologie" (Bonn, 1871), E. Pflüger gives a short and summary answer to those many observers who have thrown doubt on the accuracy of his remarkable discoveries as to the continuity of nerves with the secreting cells of the salivary glands and liver. Pflüger's opponents in this matter have been Mayer, Hering, Krause, Henle, and Schweigger-Seidel. The objections which have been made are divided by him into three heads. 1st. It was said that the nerves he had seen were capillary vessels. 2nd. That they were threads of mucus. 3rd. They were disintegrated fat. These objections are successively shown to be groundless, and Pflüger stoutly maintains his original position. What is far more important in this short paper than these answers to objections is that the professor at length publishes an account of some of his methods as to which he has so long left every one in the dark. They are certain to be interesting to some of our readers. *Salivary glands.* A fresh submaxillary gland from the ox must be taken, and very fine sections made; these must be at once teased out in perosmic acid sp. gr. 1003, and covered with a thin glass in a shallow cell. A great many preparations should be made, and the best picked out. They will be sufficiently stained in 24 hours. As the water dries up it may be replaced by glycerine. *Liver.* A great number of very fine sections must be made from the fresh liver of a dog or pig. These sections must be placed 10 or 12 together in watch-glasses filled with Beale's carmine solution, and thus kept in a moist chamber 14 days. The sections must then be taken out, washed one by one in a drop of perosmic acid, sp. gr. 1003, transported to a fresh drop of the same on a slide, and carefully teased out, covered, and examined.

## NOTES

ST. BARTHOLOMEW'S HOSPITAL has, we learn from the *British Medical Journal*, sustained a great loss in the resignation by Mr. Paget of his active duties as Surgeon to the Hospital. Mr. Paget will, of course, receive the appointment of Consulting Surgeon to the Institution which he has served long and faithfully, and on which he has conferred lustre.

THE following excursions have been arranged by the Geologists' Association to take place in May:—To Oxford on Friday, 12th May. On arriving at Oxford the New University Museum will be visited. Subsequently the party, accompanied by the President, Prof. Phillips, and Prof. Morris, will walk to Shotover Hill, where the Middle and Upper Oolites are well exposed. To Grays, Essex, on Saturday, 20th May. Exposures of the Mammaliferous beds of the Thames Valley, and afterwards sections of the Upper Chalk will be visited, under the guidance of Prof. Morris. A four days' excursion to Yeovil, Weymouth, and Portland is proposed for Whitsuntide. Particulars of arrangements will be duly announced.

THE Edinburgh Naturalists' Field Club, which has since its formation carried on active operation only from April to July inclusive, held its adjourned annual meeting and conversazione on Saturday, the 22nd April, when Mr. Robert Scot-Skirving, the president, delivered an introductory address, enlarging mainly on entomology as a fit summer field study. The business meeting was held in November last, when, in addition to the present president and committee, Prof. Liston was elected vice-president, and Mr. Andrew Taylor honorary secretary and treasurer.

THE following is the programme of the lectures on the Experimental and Natural Sciences in Trinity Term, in Trinity College, Dublin. Mineralogy, 11 A.M., on Mondays, Wednesdays, and Fridays. Demonstrations in Organic Chemistry, 12, Mondays, Wednesdays, and Fridays. Magnetism, 2 P.M., Mondays, Wednesdays, and Fridays. Comparative Anatomy, 11 A.M., Mondays, Wednesdays, and Fridays. Demonstrations in Botany, 11 A.M., Tuesdays, Thursdays, and Saturdays. Applied Geology, 1 P.M., Tuesdays, Thursdays, and Saturdays.

THE grace for allowing French and German as an alternative for Greek, was submitted to the Senate of the University of Cambridge on Thursday last, and rejected by a majority of three only. The subject will doubtless be reopened, and probably some slight modification of the original scheme will ultimately be accepted.

THE following gentlemen have been elected, by the Senate of the University of London, Examiners in Science and Medicine for the ensuing year :—Logic and Moral Philosophy : Prof. G. Croom Robertson and Rev. John Venn. Political Economy : Prof. W. Stanley Jevons and Prof. T. E. Cliff Leslie. Mathematics and Natural Philosophy : Prof. H. J. S. Smith, F.R.S., and Prof. Sylvester, F.R.S. Experimental Philosophy : Prof. W. G. Adams and Prof. G. Carey Foster, F.R.S. Chemistry : Henry Debus, F.R.S., and Prof. Odling, F.R.S. Botany and Vegetable Physiology : Dr. J. D. Hooker, F.R.S., and Dr. Thos. Thomson, F.R.S. Geology and Palæontology : Prof. Duncan, F.R.S., and Prof. Morris. Practice of Medicine : John S. Bristowe, M.D., and Prof. J. Russell Reynolds, M.D., F.R.S. Surgery : Prof. John Birkett and Prof. John Marshall, F.R.S. Anatomy : Prof. Geo. Viner Ellis and Prof. John Wood. Physiology, Comparative Anatomy, and Zoology : Prof. M. Foster, M.D., and H. Power. Obstetric Medicine : Rob. Barnes, M.D., and Prof. W. M. Graily Hewitt, M.D. Materia Medica and Pharmaceutical Chemistry : Thos. R. Fraser, M.D., and Prof. A. Baring Garrod, M.D., F.R.S. Forensic Medicine : E. Headlam Greenhow, M.D., F.R.S., and Thos. Stevenson, M.D.

MR. C. T. CLOUGH, of Rugby School, has been elected to an exhibition at St. John's College, Cambridge, of 50*l.* per annum, for proficiency in Natural Science. There were ten candidates.

SCIENCE appears to have penetrated even into the recesses of Christ's Hospital. Since October 1869, there has been a Chemistry class of about fifty boys, in connection with St. Bartholomew's Hospital. The work done is both practical and theoretical ; at the first, Dr. Matthiessen was the lecturer, and at his lamented death, Dr. H. E. Armstrong. Since Christmas the class has been under the care of Dr. W. T. Russell, F.C.S. For some weeks past, Prof. Tennant has been lecturing on Mineralogy, and next week commences on Geology. This class is very well attended. There has been established a permanent class for Natural Philosophy, under the care of Mr. James Noon, B.A. We believe also that those boys who are intended for the Navy are instructed in theoretical and practical Astronomy. There have been wishes expressed for a Museum, and numerous specimens are constantly brought to Prof. Tennant for information. It is much to be wished also that some sort of a Natural History Society might be established, notwithstanding the city-site of the Hospital.

WE continue to receive intelligence from the French Academy, and are in a position to give the full list of members who were present at the sitting on the 21st April, eighteen in number, viz., three astronomers, Yvon Villareau, Mathieu, and Langier ; one mathematician, Chasles ; one physicist, Jamin, three chemists, Chevreul, Payer, Peligot ; one mechanician, Ameral Paris ; and the others medical men or naturalists, Milne-Edwards, Blanchard, Robin, Trécul, Bienaymè, Duchartre, and Quatrefages. M. Egger, of the Academy of Inscriptions, sat with his colleagues, and M. Simon Newcomb, the American astronomer, sat at the place allotted to foreign learned men.

THE seventh part of the illustrated work on the butterflies of North America, by Mr. Wm. H. Edwards, has just been published, containing numerous well-engraved and coloured plates of butterflies.

THE Commune has its own balloons, twelve in number, but they are kept apart for the private use of members when the final exit shall take place. One was sent up into the air, as it was said in the political newspapers for carrying away the masonic proclamation, but it was a little one without aëronaut.

THE *Gardener's Chronicle* for last Saturday prints an interesting letter from Dr. Hooker, dated Tetuan, April 12. In the journey from Tangier to Tetuan, Dr. Hooker notices that the general features of the flora of the low grounds and moderate hills in that part of North Morocco coincide with those of South-western Spain. Whole tracts are covered with masses of broom, so that the hills precisely resemble those of Scotland or Jersey. The previous day a guard had been obtained in order to ascend Beni-Hosmar, which mountain had only been visited previously by one botanist, Mr. Webb, some forty years since. The party ascended to 3,500 feet, and obtained a superb view across the Mediterranean to the Spanish coast, and south to the snowy crest of Beni-Hassan. It is a splendid rugged mass of limestone peaks, separated by very steep narrow-floored valleys, the flanks of which are crested with rifted white precipices. The whole is clothed with stunted shrubs up to 3,000 feet. They found some rare, and some probably new plants, but at a height of 3,400 feet no signs of a sub-alpine flora. The party did not succeed in reaching the summit.

THE principal object of interest at the *soirée* of the Linnean Society on the 26th ult., was again Mr. Wilson Saunders's collection of mimetic plants, which was even more remarkable than last year. The following is a list of the pairs exhibited :

| | |
|---|---|
| Olea europœa | Oleaceæ |
| Swammerdamia antennata | Compositæ |
| Anemone coronaria | Ranunculaceæ |
| Pelargonium triste | Geraniaceæ |
| Osmanthus heterophyllus | Oleaceæ |
| Ilex aquifolium *var* | Aquifoliaceæ |
| Gnaphalium orientale | Compositæ |
| Lavendula lanata | Labiatæ |
| Iris pulchella | Iridaceæ |
| Dicrypta iridoides | Orchidaceæ |
| Pothos argyrea | Araceæ |
| Peperomia arifolia | Piperaceæ |
| Adonis autumnalis | Ranunculaceæ |
| Pyrethrum inodorum | Compositæ |
| Heterotropa asaroides | Aristolochiaceæ |
| Cyclamen persicum *var* | Primulaceæ |
| Oxalis Plumieri | Oxalidaceæ |
| Crotalaria laburnifolia | Leguminosæ |
| Gentiana lutea | Gentianaceæ |
| Veratrum viride | Melanthaceæ |
| Gymnostachyum Verschaffeltii | Acanthaceæ |
| Echites rubro-venosa | Apocynaceæ |
| Grevillea *sp.* | Proteaceæ |
| Acacia *sp.* | Leguminosæ |
| Rosa *sp.* | Rosaceæ |
| Xanthoxylon *sp* | Xanthoxylaceæ |
| Euphorbia mammillaria | Euphorbiaceæ |
| Apteranthes Gaponiana | Asclepiadaceæ |
| Dancus Carota | Umbelliferæ |
| Pelargonium rutæfolium | Geraniaceæ |

A SERIES of scientific lectures, in connection with the School of Science and Art, has been for some time in contemplation at Taunton. It has recently commenced with a course of botanical lectures, by the Rev. W. Tuckwell, headmaster of the College School, which attract a large and diligent audience, consisting both of artisans and amateurs.

AT the annual dinner of the Institution of Civil Engineers held on April 22, Prof. Huxley, in responding to the toast of the learned societies in this country, gave the company some very sound advice as to the duty of the body of civil engineers in enforcing upon the public mind the truth that there can be no technical education of any value or soundness which is not based on a thorough preliminary training in abstract or theoretical practical science.

MR. JOHN GIBBS, of the Essex and Chelmsford Museum, publishes, at the price of a shilling, "A First Catechism of Botany," which has received the sanction of the Committee of Selection for the International Exhibition. Although the catechismal form always seems to us a needlessly cumbrous and circumlocutory one, for those who think otherwise a large amount of useful elementary information will be found in this little publication.

WE learn from Trübner's *American and Oriental Literary Record* that the American Ethnological Society was permanently reorganised under the name of "The Anthropological Institute of New York," on the 9th of March, and the following officers were elected:—E. Geo. Squier, president; J. C. Nott and Geo. Gibbs, vice-presidents; J. G. Shea, J. K. Merrill, E. H. Davis, C. C. Jones, jun., and W. H. Thomson, executive committee; A. J. Cotteral, treasurer; Charles Raw, foreign corresponding secretary; H. T. Drowne, domestic corresponding secretary; H. R. Stiles, recording secretary; and Geo. H. Moore, custodian. The objects of the institute are declared to be:—1. The study of man in all his varieties, and under all his aspects and relations. 2. Its special object the study of the history, conditions, and relations of the aboriginal inhabitants of America, and the phenomena resulting from the contact of the various races and families of men on this continent, before and since the discovery. 3. The physical characteristics, religious conceptions, and systems of men; their mythology and traditions; their social, civil, and political organisations and institutions; their language, literature, arts, and monuments; their mode of life and their customs are specifically within the objects of the Institute. 4. The collection of manuscripts, books, and relics illustrating these several subjects; the stimulation and encouragement of inquiry and research, particularly in unexplored American fields; and by means of such publications as may be deemed proper, to utilise the results of its investigations and efforts for the benefit of science and of mankind. 5. It recognises the widest range of discussion, and a complete tolerance of individual opinions on all subjects within the scope of the Institute's objects. The Institute proposes to publish a series of Memoirs, and a Journal.

THE attention of astronomers throughout the world is directed toward the approaching transit of Venus, to occur on the 18th of December, 1874, and it is hoped, we learn from *Harper's Weekly*, that the United States Congress, with the same liberality that induced it to make an appropriation for the observation of the solar eclipse of December last, and for the polar exploration under Captain Hall, will also, at the proper time, advance the funds necessary for the research in this case. Professor Hall, of the Washington Observatory, in a late communication to the *Journal of Science*, expresses the hope that a concert of action will be settled upon by American astronomers, in order that they may not be behind their European *confrères* in the attempt to secure satisfactory results. A committee has been appointed by the National Academy of Sciences to take into consideration a general plan of operations, and it is expected that a report will be made on the subject at the approaching meeting in Washington city.

THE annual report of Professor Cooke, State Geologist of New Jersey, for 1870, has just been published; and although less in bulk than some of its predecessors, it contains some important information in regard to fertilisers used in the State, the marshes and tracts of land subject to protracted freshets, the soils, the iron and zinc ores, and other miscellaneous topics. The subject of drainage has attracted Professor Cooke's especial attention, on account of the vast tracts of land in the eastern portion of the State now either regularly overflowed at certain periods of the tide, or liable to freshets or inundations. In order more properly to qualify himself for this inquiry, Professor Cooke paid an extended visit to the drained lands of Holland and England, the results of which he presents in his report.

M. LONGET, the celebrated physiologist, member of the French Institute and of the French Academy of Medicine, died at the age of sixty-eight, at Bordeaux, a few days since. M. Longet is the author of works on the nervous system, which explain many of his own discoveries. His death was sudden, and was referred by his friends to the horror with which he was stricken when hearing the sad news from Paris.

IN the forthcoming number of the *American Journal of Science* will be found an article, by Professor Marsh, upon some new serpents of the Tertiary deposits of Wyoming. It will be remembered that in a previous notice of Professor Marsh's discoveries in the Rocky Mountains, we called attention to the difference observed by him between the contents of the Tertiary beds in the vicinity of Fort Bridger and those of the Mauvaises Terres of the Upper Missouri, the former being especially characterised, as compared with the latter, by the presence of reptiles in great variety. Among these are many terrestrial species, including several kinds of land lizards; and among the forms generally serpents appear to be quite predominant. Of the latter, Professor Marsh has already determined the existence of five new species, belonging to three new genera; and others will probably be yet brought to light.

AT the present day, when the columns of our newspapers teem with advertisements of various preparations for promoting the growth or changing the colour of the hair, the following account of the results of the use of a preparation of boxwood for that purpose may be of interest. Boxwood, according to the old herbalists, was used from a remote period to render the hair auburn; and we are told by Phillips that a young woman in Lower Silesia, whose hair had fallen off after a severe attack of dysentery, was advised to wash her head with a decoction of boxwood, in order to induce it to grow again. This she did; and "hair of a chestnut colour grew on her head, as she was told it would do; but, having used no precaution to secure her face and neck from the lotion, they became covered with red hair to such a degree that she seemed but little different from an ape or a monkey!"

MR. JAMES BOYD, of Panama, published some time ago in the *Panama Star and Herald*, under the head of "The Migration of Butterflies across the Isthmus," an account of the phenomenon of the migration in one direction of the *Urania Leilus*. This being republished in England has led to some correspondence with Mr. Boyd, particularly from a naturalist resident at Liverpool. This gentleman states that in January 1845, he observed the same habit of the Urania in the Island of Caripi, one of those near Para, in the Brazils. From an early hour in the morning until nearly dark these insects passed along the shore in amazing numbers, but most numerously in the evening. It was very seldom that one was seen in the opposite direction. The main course was from west to east. He also saw it at Pernambuco, at Rio Janeiro, and in the Southern States of America, but nowhere so abundant as on the Amazons. The Urania is scarcely a butterfly; but between the day and night butterflies, something between a skipper and a hawk moth. By Latreille they were called Hespero-Sphyngidæ. The larvæ and pupæ are supposed not to have been adequately examined. The Liverpool naturalist could not identify them, and as yet they have not been able to find them at Panama. In Central America the Urania is found as far north as Guatemala. Mr. Darwin observed a butterfly of similar habits, the *Papilio feronia,* which frequents orange groves.

## THE ROYAL SOCIETY'S LIST FOR 1871

THE following fifteen have been selected by the Council of the Royal Society out of the fifty candidates, and recommended to the Fellows for election:—*William Henry Besant*, M.A., Mathematical Lecturer at St. John's College; Senior Wrangler and First Smith's Prizeman in 1850, Moderator in 1856, Examiner in the University of London from 1860 to 1865; author of Treatises on "Hydromechanics and the Theory of Sound," 2nd ed. 1867; "Elementary Hydrostatics," 2nd ed. 1867; "Geometrical Conic Sections," 1869; "Roulettes and Glissettes," 1870. *William Budd*, M.D. (Edin.), physician, author of various medical papers, especially relating to contagious diseases. *George W. Callender*, F.R.C.S., lecturer on Anatomy at St. Bartholomew's Hospital School, and Assistant Surgeon to Bartholomew's Hospital; author of Anatomical papers. *William Carruthers*, F.L.S., F.G.S., keeper of the Botanical Department, British Museum; author of "Fossil Cycadean Stems from the Secondary Rocks of Britain;" "On the Structure and Affinities of Sigillaria and Allied Genera;" "The Cryptogamic Forests of the Coal Period;" "On the Structure of the Stems of the Arborescent Lycopodiaceæ of the Coal-measures;" "Revision of the British Graptolites," &c. *Robert Etheridge*, F.R.S.E., F.G.S., Palæontologist to H.M. Geological Survey of Great Britain; Demonstrator on Palæontology, Royal School of Mines; author of numerous geological papers. *Frederick Guthrie*, B.A., F.R.S.E., F.C.S., Professor of Physics in the Royal School of Mines; author of various papers on Chemistry and Physics. *Captain John Herschel*, R.E., of the Great Trigonometrical Survey of India. *Captain Alexander Moncrieff*, Militia Artillery, C.E., inventor of the Moncrieff gun-carriage, and author of the Moncrieff system of defence. *Richard Quain*, M.D. (Lond.), Fellow and late Censor of the Royal College of Physicians; author of a paper "On Fatty Degeneration of the Heart," which has exerted a marked influence on certain branches of Pathological Science; and of numerous communications published in the Transactions of the Pathological Society, of which Society he was President (1869-70). *Carl Schorlemmer*, Senior Assistant in Owens College Laboratory, Manchester; author of a series of papers on the Constitution of the Paraffins, chiefly published in the Proceedings of the Society since 1862. *Edward Thomas*, Treas. R.A.S., author of numerous papers on Indian Coins and Gems. *Edward Burnet Tylor*, author of "Researches into the Early History of Mankind;" "Primitive Culture;" and various memoirs on Savages and their Customs. *Cromwell Fleetwood Varley*, Civil and Telegraphic Engineer, M.I.C.E.; Consulting Electrician to the Electric and International Telegraph Company, the Atlantic Telegraph Company, la Société du Cable Transatlantique Français; author of many inventions in connection with the Electric Telegraph. *Viscount Walden*, President of the Zoological Society of London; author of various papers on Ornithology. *John Wood*, F.R.C.S., Examiner in Anatomy at the University of London; author of a number of anatomical papers published in the Phil. Trans.

## ON COLOUR VISION *

ALL vision is colour vision, for it is only by observing differences of colour that we distinguish the forms of objects. I include differences of brightness or shade among differences of colour.

It was in the Royal Institution, about the beginning of this century, that Thomas Young made the first distinct announcement of that doctrine of the vision of colours which I propose to illustrate. We may state it thus:—We are capable of feeling three different colour-sensations. Light of different kinds excites these sensations in different proportions, and it is by the different combinations of these three primary sensations that all the varieties of visible colour are produced. In this statement there is one word on which we must fix our attention. That word is, Sensation. It seems almost a truism to say that colour is a sensation; and yet Young, by honestly recognising this elementary truth, established the first consistent theory of colour. So far as I know, Thomas Young was the first who, starting from the well-known fact that there are three primary colours, sought for the explanation of this fact, not in the nature of light, but in the constitution of man. Even of those who have written on colour since the time of Young, some have supposed that they ought to study the properties of pigments, and others that they ought to analyse the rays of light. They have sought for a knowledge of colour by examining something in external nature—something out of ourselves.

Now, if the sensation which we call colour has any laws, it must be something in our own nature which determines the form of these laws; and I need not tell you that the only evidence we can obtain respecting ourselves is derived from consciousness.

The science of colour must therefore be regarded as essentially a mental science. It differs from the greater part of what is called mental science in the large use which it makes of the physical sciences, and in particular of optics and anatomy. But it gives evidence that it is a mental science by the numerous illustrations which it furnishes of various operations of the mind.

In this place we always feel on firmer ground when we are dealing with physical science. I shall therefore begin by showing how we apply the discoveries of Newton to the manipulation of light, so as to give you an opportunity of feeling for yourselves the different sensations of colour.

Before the time of Newton, white light was supposed to be of all known things the purest. When light appears coloured, it was supposed to have become contaminated by coming into contact with gross bodies. We may still think white light the emblem of purity, though Newton has taught us that its purity does not consist in simplicity.

We now form the prismatic spectrum on the screen. These are the simple colours of which white light is always made up. We can distinguish a great many hues in passing from the one end to the other; but it is when we employ powerful spectroscopes, or avail ourselves of the labours of those who have mapped out the spectrum, that we become aware of the immense multitude of different kinds of light, every one of which has been the object of special study. Every increase of the power of our instruments increases in the same proportion the number of lines visible in the spectrum.

All light, as Newton proved, is composed of these rays taken in different proportions. Objects which we call coloured when illuminated by white light, make a selection of these rays, and our eyes receive from them only a part of the light which falls on them. But if they receive only the pure rays of a single colour of the spectrum, they can appear only of that colour. If I place a disc containing alternate quadrants of red and green paper in the red rays, it appears all red, but the red quadrants brightest. If I place it in the green rays both papers appear green, but the red paper is now the darkest. This, then, is the optical explanation of the colours of bodies when illuminated with white light They separate the white light into its component parts, absorbing some and scattering others.

Here are two transparent solutions. One appears yellow, it contains bichromate of potash; the other appears blue, it contains sulphate of copper. If I transmit the light of the electric lamp through the two solutions at once, the spot on the screen appears green. By means of the spectrum we shall be able to explain this. The yellow solution cuts off the blue end of the spectrum, leaving only the red, orange, yellow, and green. The blue solution cuts off the red end, leaving only the green, blue, and violet. The only light which can get through both is the

* Lecture delivered before the Royal Institution, March 24th.

green light, as you see. In the same way most blue and yellow paints, when mixed, appear green. The light which falls on the mixture is so beaten about between the yellow particles and the blue, that the only light which survives is the green. But yellow and blue light when mixed do not make green, as you will see if we allow them to fall on the same part of the screen together.

It is a striking illustration of our mental processes that many persons have not only gone on believing, on the evidence of the mixture of pigments, that blue and yellow make green, but that they have even persuaded themselves that they could detect the separate sensations of blueness and of yellowness in the sensation of green.

We have availed ourselves hitherto of the analysis of light by coloured substances. We must now return, still under the guidance of Newton, to the prismatic spectrum. Newton not only

> Untwisted all the shining robe of day,

but showed how to put it together again. We have here a pure spectrum, but instead of catching it on a screen, we allow it to pass through a lens large enough to receive all the coloured rays. These rays proceed, according to well-known principles in optics, to form an image of the prism on a screen placed at the proper distance. This image is formed by rays of all colours, and you see the result is white. But if I stop any of the coloured rays, the image is no longer white, but coloured; and if I only let through rays of one colour, the image of the prism appears of that colour.

I have here an arrangement of slits by which I can select one, two, or three portions of the light of the spectrum, and allow them to form an image of the prism while all the rest are stopped. This gives me a perfect command of the colours of the spectrum, and I can produce on the screen every possible shade of colour by adjusting the breadth and the position of the slits through which the light passes. I can also, by interposing a lens in the passage of the light, show you a magnified image of the slits, by which you will see the different kinds of light which compose the mixture.

The colours are at present red, green, and blue, and the mixture of the three colours is, as you see, nearly white. Let us try the effect of mixing two of these colours. Red and blue form a fine purple or crimson, green and blue form a sea-green or sky-blue, red and green form a yellow.

Here again we have a fact not universally known. No painter, wishing to produce a fine yellow, mixes his red with his green. The result would be a very dirty drab colour. He is furnished by nature with brilliant yellow pigments, and he takes advantage of these. When he mixes red and green paint, the red light scattered by the red paint is robbed of nearly all its brightness by getting among particles of green, and the green light fares no better, for it is sure to fall in with particles of red paint. But when the pencil with which we paint is composed of the rays of light, the effect of two coats of colour is very different. The red and the green form a yellow of great splendour, which may be shown to be as intense as the purest yellow of the spectrum.

I have now arranged the slits to transmit the yellow of the spectrum. You see it is similar in colour to the yellow formed by mixing red and green. It differs from the mixture, however, in being strictly homogeneous in a physical point of view. The prism, as you see, does not divide it into two portions as it did the mixture. Let us now combine this yellow with the blue of the spectrum. The result is certainly not green; we may make it pink if our yellow is of a warm hue, but if we choose a greenish yellow we can produce a good white.

You have now seen the most remarkable of the combinations of colours—the others differ from them in degree, not in kind. I must now ask you to think no more of the physical arrangements by which you were enabled to see these colours, and to concentrate your attention upon the colours you saw, that is to say, on certain sensations of which you were conscious. We are here surrounded by difficulties of a kind which we do not meet with in purely physical inquiries. We can all feel these sensations, but none of us can describe them. They are not only private property, but they are incommunicable. We have names for the external objects which excite our sensations, but not for the sensations themselves.

When we look at a broad field of uniform colour, whether it is really simple or compound, we find that the sensation of colour appears to our consciousness as one and indivisible. We cannot directly recognise the elementary sensations of which it is composed, as we can distinguish the component notes of a musical chord. A colour, therefore, must be regarded as a single thing, the quality of which is capable of variation.

To bring a quality within the grasp of exact science, we must conceive it as depending on the values of one or more variable quantities, and the first step in our scientific progress is to determine the number of these variables which are necessary and sufficient to determine the quality of a colour. We do not require any elaborate experiments to prove that the quality of colour can vary in three and only in three independent ways.

One way of expressing this is by saying, with the painters, that colour may vary in hue, tint, and shade.

The finest example of a series of colours varying in hue, is the spectrum itself. A difference in hue may be illustrated by the difference between adjoining colours in the spectrum. The series of hues in the spectrum is not complete; for, in order to get purple hues, we must blend the red and the blue.

Tint may be defined as the degree of purity of a colour. Thus, bright yellow, buff, and cream-colour, form a series of colours of nearly the same hue, but varying in tint. The tints corresponding to any given hue form a series, beginning with the most pronounced colour, and ending with a perfectly neutral tint.

Shade may be defined as the greater or less defect of illumination. If we begin with any tint of any hue, we can form a gradation from that colour to black, and this gradation is a series of shades of that colour. Thus we may say that brown is a dark shade of orange.

The quality of a colour may vary in three different and independent ways. We cannot conceive of any others. In fact, if we adjust one colour to another, so as to agree in hue, in tint, and in shade, the two colours are absolutely indistinguishable. There are therefore three, and only three, ways in which a colour can vary.

I have purposely avoided introducing at this stage of our inquiry anything which may be called a scientific experiment, in order to show that we may determine the number of quantities upon which the variation of colour depends by means of our ordinary experience alone.

Here is a point in this room: if I wish to specify its position, I may do so by giving the measurements of three distances—namely, the height above the floor, the distance from the wall behind me, and the distance from the wall at my left hand.

This is only one of many ways of stating the position of a point, but it is one of the most convenient. Now, colour also depends on three things. If we call these the intensities of the three primary colour sensations, and if we are able in any way to measure these three intensities, we may consider the colour as specified by these three measurements. Hence the specification of a colour agrees with the specification of a point in the room in depending on three measurements.

Let us go a step farther, and suppose the colour sensations measured on some scale of intensity, and a point found for which the three distances, or co-ordinates, contain the same number of feet as the sensations contain degrees of intensity. Then we may say, by a useful geometrical convention, that the colour is represented to our mathematical imagination by the point so found in the room; and if there are several colours, represented by several points, the chromatic relations of the colours will be represented by the geometrical relations of the points. This method of expressing the relations of colours is a great help to the imagination. You will find these relations of colours stated in an exceedingly clear manner in Mr. Benson's "Manual of Colour," one of the very few books on colour in which the statements are founded on legitimate experiments.

There is a still more convenient method of representing the relations of colours, by means of Young's triangle of colours. It is impossible to represent on a plane piece of paper every conceivable colour, to do this requires space of three dimensions. If, however, we consider only colours of the same shade, that is, colours in which the sum of the intensities of the three sensations is the same, then the variations in tint and in hue of all such colours may be represented by points on a plane. For this purpose we must draw a plane cutting off equal lengths from the three lines representing the primary sensations. The part of this plane within the space in which we have been distributing our colours will be an equilateral triangle. The three primary colours will be at the three angles, white or gray will be in the middle, the tint or degree of purity of any colour will be expressed by its distance from the middle point, and its hue will depend on the angular position of the line which joins it with the middle point.

Thus the ideas of tint and hue can be expressed geometrically on Young's triangle. To understand what is meant by shade, we have only to suppose the illumination of the whole triangle increased or diminished, so that by means of this adjustment of illumination Young's triangle may be made to exhibit every variety of colour. If we now take any two colours in the triangle and mix them in any proportions, we shall find the resultant colour in the line joining the component colours at the point corresponding to their centre of gravity.

I have said nothing about the nature of the three primary sensations, or what particular colours they most resemble. In order to lay down on paper the relations between actual colours, it is not necessary to know what the primary colours are. We may take any three colours, provisionally, as the angles of a triangle, and determine the position of any other observed colour with respect to these, so as to form a kind of chart of colours.

Of all colours which we see, those excited by the different rays of the prismatic spectrum have the greatest scientific importance. All light consists either of some one kind of these rays, or of some combination of them. The colours of all natural bodies are compounded of the colours of the spectrum. If, therefore, we can form a chromatic chart of the spectrum, expressing the relations between the colours of its different portions, then the colours of all natural bodies will be found within a certain boundary on the chart defined by the positions of the colours of the spectrum.

But the chart of the spectrum will also help us to the knowledge of the nature of the three primary sensations. Since every sensation is essentially a positive thing, every compound colour-sensation must be within the triangle of which the primary colours are the angles. In particular, the chart of the spectrum must be entirely within Young's triangle of colours, so that if any colour in the spectrum is identical with one of the colour-sensations, the chart of the spectrum must be in the form of a line having a sharp angle at the point corresponding to this colour.

I have already shown you how we can make a mixture of any three of the colours of the spectrum, and vary the colour of the mixture by altering the intensity of any of the three components. If we place a compound colour side by side with any other colour, we can alter the compound colour till it appears exactly similar to the other. This can be done with the greatest exactness when the resultant colour is nearly white. I have therefore constructed an instrument which I may call a colour-box, for the purpose of making matches between two colours. It can only be used by one observer at a time, and it requires daylight, so I have not brought it with me to-night. It is nothing but the realisation of the construction of one of Newton's propositions in his "Lectiones Opticæ," where he shows how to take a beam of light, to separate it into its components, to deal with these components as we please by means of slits, and afterwards to unite them into a beam again. The observer looks into the box through a small slit. He sees a round field of light, consisting of two semicircles divided by a vertical diameter. The semicircle on the left consists of light which has been enfeebled by two reflexions at the surface of glass. That on the right is a mixture of colours of the spectrum, the positions and intensities of which are regulated by a system of slits.

The observer forms a judgment respecting the colours of the two semicircles. Suppose he finds the one on the right hand redder than the other, he says so, and the operator, by means of screws outside the box, alters the breadth of one of the slits, so as to make the mixture less red; and so on, till the right semicircle is made exactly of the same appearance as the left, and the line of separation becomes almost invisible.

When the operator and the observer have worked together for some time they get to understand each other, and the colours are adjusted much more rapidly than at first.

When the match is pronounced perfect, the positions of the slits, as indicated by a scale, are registered, and the breadth of each slit is carefully measured by means of a gauge. The registered result of an observation is called a "colour equation." It asserts that a mixture of three colours is, in the opinion of the observer (whose name is given), identical with a neutral tint, which we shall call Standard White. Each colour is specified by the position of the slit on the scale, which indicates its position in the spectrum, and by the breadth of the slit, which is a measure of its intensity.

In order to make a survey of the spectrum we select three points for purposes of comparison, and we call these the three Standard Colours. The standard colours are selected on the same principles as those which guide the engineer in selecting stations for a survey. They must be conspicuous and invariable, and not in the same straight line.

In the chart of the spectrum you may see the relations of the various colours of the spectrum to the three standard colours, and to each other. It is manifest that the standard green which I have chosen cannot be one of the true primary colours, for the other colours do not all lie within the triangle formed by joining them. But the chart of the spectrum may be described as consisting of two straight lines meeting in a point. This point corresponds to a green about a fifth of the distance from *b* towards F. This green has a wave-length of about 510 millionths of a millimetre by Ditscheiner's measure. This green is either the true primary green, or at least it is the nearest approach to it which we can ever see. Proceeding from this green towards the red end of the spectrum, we find the different colours lying almost exactly in a straight line. This indicates that any colour is chromatically equivalent to a mixture of any two colours on opposite sides of it and in the same straight line. The extreme red is considerably beyond the standard red, but it is in the same straight line, and therefore we might, if we had no other evidence, assume the extreme red as the true primary red. We shall see, however, that the true primary red is not exactly represented in colour by any part of the spectrum. It lies somewhat beyond the extreme red but in the same straight line.

On the blue side of primary green the colour equations are seldom so accurate. The colours, however, lie in a line which is nearly straight. I have not been able to detect any measurable chromatic difference between the extreme indigo and the violet. The colours of this end of the spectrum are represented by a number of points very close to each other. We may suppose that the primary blue is a sensation differing little from that excited by the parts of the spectrum near G.

Now, the first thing which occurs to most people about this result is that the division of the spectrum is by no means a fair one. Between the red and the green we have a series of colours apparently very different from either, and having such marked characteristics that two of them, orange and yellow, have received separate names. The colours between the green and the blue, on the other hand, have an obvious resemblance to one or both of the extreme colours, and no distinct names for these colours have ever become popularly recognised.

I do not profess to reconcile this discrepancy between ordinary and scientific experience. It only shows that it is impossible, by a mere act of introspection, to make a true analysis of our sensations. Consciousness is our only authority; but consciousness must be methodically examined in order to obtain any trustworthy results.

I have here, through the kindness of Professor Huxley, a picture of the structure upon which the light falls at the back of the eye. There is a minute structure of bodies like rods and cones or pegs, and it is conceivable that the mode in which we become aware of the shapes of things is by a consciousness which differs according to the particular rods on the ends of which the light falls, just as the pattern on the web formed by a Jacquard loom depends on the mode in which the perforated cards act on the system of movable rods in that machine. In the eye we have on the one hand light falling on this wonderful structure, and on the other hand we have the sensation of sight. We cannot compare these two things; they belong to opposite categories. The whole of Metaphysics lies like a great gulf between them. It is possible that discoveries in physiology may be made by tracing the course of the nervous disturbance

Up the fine fibres to the sentient brain;

but this would make us no wiser than we are about those colour-sensations which we can only know by feeling them ourselves. Still, though it is impossible to become acquainted with a sensation by the anatomical study of the organ with which it is connected, we may make use of the sensation as a means of investigating the anatomical structure.

A remarkable instance of this is the deduction of Helmholtz's theory of the structure of the retina from that of Young with respect to the sensation of colour. Young asserts that there are three elementary sensations of colour; Helmholtz asserts that there are three systems of nerves in the retina, each of which has for its function, when acted on by light or any other disturbing agent, to excite in us one of these three sensations.

No anatomist has hitherto been able to distinguish these three systems of nerves by microscopic observation. But it is admitted in physiology that the only way in which the sensation excited by a particular nerve can vary is by degrees of intensity. The intensity of the sensation may vary from the faintest impression up to an insupportable pain; but whatever be the exciting cause, the sensation will be the same when it reaches the same intensity. If this doctrine of the function of a nerve be admitted, it is legitimate to reason from the fact that colour may vary in three different ways, to the inference that these three modes of variation arise from the independent action of three different nerves or sets of nerves.

Some very remarkable observations on the sensation of colour have been made by M. Sigmund Exner in Prof. Helmholtz's physiological laboratory at Heidelberg. While looking at an intense light of a brilliant colour, he exposed his eye to rapid alternations of light and darkness by waving his fingers before his eyes. Under these circumstances a peculiar minute structure made its appearance in the field of view, which many of us may have casually observed. M. Exner states that the character of this structure is different according to the colour of the light employed. When red light is used a veined structure is seen; when the light is green, the field appears covered with minute black dots, and when the light is blue, spots are seen, of a larger size than the dots in the green, and of a lighter colour.

Whether these appearances present themselves to all eyes, and whether they have for their physical cause any difference in the arrangement of the nerves of the three systems in Helmholtz's theory I cannot say, but I am sure that if these systems of nerves have a real existence, no method is more likely to demonstrate their existence than that which M. Exner has followed.

### Colour Blindness

The most valuable evidence which we possess with respect to colour vision is furnished to us by the colour-blind. A considerable number of persons in every large community are unable to distinguish between certain pairs of colours which to ordinary people appear in glaring contrast. Dr. Dalton, the founder of the atomic theory of chemistry, has given us an acccount of his own case.

The true nature of this peculiarity of vision was first pointed out by Sir John Herschel in a letter written to Dalton in 1832, but not known to the world till the publication of "Dalton's Life" by Dr. Henry. The defect consists in the absence of one of the three primary sensations of colour. Colour-blind vision depends on the variable intensities of two sensations instead of three. The best description of colour-blind vision is that given by Prof. Pole in his account of his own case in the "Phil. Trans.," 1859.

In all cases which have been examined with sufficient care, the absent sensation appears to resemble that which we call red. The point P on the chart of the spectrum represents the relation of the absent sensation to the colours of the spectrum, deduced from observations with the colour box furnished by Prof. Pole.

If it were possible to exhibit the colour corresponding to this point on the chart, it would be invisible, absolutely black, to Prof. Pole. As it does not lie within the range of the colours of the spectrum we cannot exhibit it; and, in fact, colour-blind people can perceive the extreme end of the spectrum which we call red, though it appears to them much darker than to us, and does not excite in them the sensation which we call red. In the diagram of the intensities of the three sensations excited by different parts of the spectrum, the upper figure, marked P, is deduced from the observations of Prof. Pole; while the lower one, marked K, is founded on observations by a very accurate observer of the normal type.

The only difference between the two diagrams is that in the upper one the red curve is absent. The forms of the other two curves are nearly the same for both observers. We have great reason therefore to conclude that the colour sensations which Prof. Pole sees are what we call green and blue. This is the result of my calculations; but Prof. Pole agrees with every other colour-blind person whom I know in denying that green is one of his sensations. The colour-blind are always making mistakes about green things and confounding them with red. The colours they have no doubts about are certainly blue and yellow, and they persist in saying that yellow, and not green, is the colour which they are able to see.

To explain this discrepancy we must remember that colour-blind persons learn the names of colours by the same method as ourselves. They are told that the sky is blue, that grass is green, that gold is yellow, and that soldiers' coats are red. They observe difference in the colours of these objects, and they often suppose that they see the same colours as we do, only not so well. But if we look at the diagram we shall see that the brightest example of their second sensation in the spectrum is not in the green, but in the part which we call yellow, and which we teach them to call yellow. The figure of the spectrum below Prof. Pole's curves is intended to represent to ordinary eyes what a colour-blind person would see in the spectrum. I hardly dare to draw your attention to it, for if you were to think that any painted picture would enable you to see with other people's vision I should certainly have lectured in vain.

### On the Yellow Spot

Experiments on colour indicate very considerable differences between the vision of different persons, all of whom are of the ordinary type. A colour, for instance, which one person on comparing it with white will pronounce pinkish, another person will pronounce greenish. This difference, however, does not arise from any diversity in the nature of the colour sensations in different persons. It is exactly of the same kind as would be observed if one of the persons wore yellow spectacles. In fact, most of us have near the middle of the retina a yellow spot through which the rays must pass before they reach the sensitive organ: this spot appears yellow because it absorbs the rays near the line F, which are of a greenish-blue colour. Some of us have this spot strongly developed. My own observations of the spectrum near the line F are of very little value on this account. I am indebted to Professor Stokes for the knowledge of a method by which any one may see whether he has this yellow spot. It consists in looking at a white object through a solution of chloride of chromium, or at a screen on which light which has passed through this solution is thrown. This light is a mixture of red light with the light which is so strongly absorbed by the yellow spot. When it falls on the ordinary surface of the retina it is of a neutral tint, but when it falls on the yellow spot only the red light reaches the optic nerve, and we see a red spot floating like a rosy cloud over the illuminated field.

Very few persons are unable to detect the yellow spot in this way. The observer K, whose colour equations have been used in preparing the chart of the spectrum, is one of the very few who do not see everything as if through yellow spectacles. As for myself, the position of white light in the chart of the spectrum is on the yellow side of true white even when I use the outer parts of the retina; but as soon as I look direct at it, it becomes much yellower, as is shown by the point W C. It is a curious fact that we do not see this yellow spot on every occasion, and that we do not think white objects yellow. But if we wear spectacles of any colour for some time, or if we live in a room lighted by windows all of one colour, we soon come to recognise white paper as white. This shows that it is only when some alteration takes place in our sensations that we are conscious of their quality.

There are several interesting facts about the colour sensation which I can only mention briefly. One is that the extreme parts of the retina are nearly insensible to red. If you hold a red flower and a blue flower in your hand as far back as you can see your hand, you will lose sight of the red flower, while you still see the blue one. Another is, that when the light is diminished red objects become darkened more in proportion than blue ones. The third is, that a kind of colour blindness in which blue is the absent sensation can be produced artificially by taking doses of santonine. This kind of colour blindness is described by Dr. Edmund Rose, of Berlin. It is only temporary, and does not appear to be followed by any more serious consequences than headaches. I must ask your pardon for not having undergone a course of this medicine, even for the sake of becoming able to give you information at first hand about colour-blindness.

J. Clerk Maxwell

## *SCIENTIFIC SERIALS*

The *Quarterly Journal of Science* for April commences with a very interesting account, by Dr. Hofmann, of the early days of the Royal College of Chemistry, under the title of "A Page of Scientific History." After tracing the influence of Liebig's school at Giessen on the progress of chemical science in this country, and the choice of himself, at the recommendation of Liebig, as the professor at the laboratory which it was determined to establish in London, Dr. Hofmann proceeds to a narrative of the difficulties experienced by the new school in the deficiency of the money received from the fees of students to meet the necessary expenses as well as the debt incurred by the outlay for building. At this stage the college narrowly escaped the entire abandonment of its primary object, the advancement of science by means of practical instruction and original researches, to sink into a mere commercial undertaking for conducting analyses. To the influence of Sir James Clark, one of the earliest friends of the College, was mainly due the ultimate success of the efforts of the Council to induce the Government to adopt the College as the chemical department of the Museum of Practical Geology; since which period its career of usefulness has been unchecked.—Dr. A. E. Sansom follows with an article on "The Theory of Atmospheric Germs," in which he records the investigations on this subject which have been conducted to the present time, especially those of Hallier and Bastian; and sums up adversely to the theory of abiogenesis.—Mr. Mungo Ponton, in his short paper on Molecules, Ultimates, Atoms, and Waves, suggests the use of the term "molecule" to denote the particles of chemical compounds; "ultimate," those of chemical elements; and "atom," the assumed constituents of those ultimates, themselves incapable of further analysis.—Prof. Piazzi Smyth occupies no less than thirty-eight pages with the conclusion of his article on "The Great Pyramid of Egypt from a modern scientific Point of View."—Sir William Fairbairn has some very practical remarks on Steam Boiler Legislation, in which he details the failure of voluntary associations for the purpose of diminishing the loss of life and property occasioned by the use of defective boilers, and advocates the enforced legal testing of boilers by competent authorities, maintaining that it is clearly the duty of the Government to interfere on behalf of those whose lives are jeopardised, and to enact that no boiler shall be worked unless periodically examined and certified.—The last article is an account of the Eclipse of last December, by Mr. R. A. Proctor. Notices of books and a record of the progress of science in the departments of light, heat, electricity, meteorology, mineralogy, mining, metallurgy, engineering, geology and palæontology, and botany, fill up a very good number.

THE numbers of the *American Naturalist* for March and April contain some good articles. The Polarity of the Compass Plant (*Silphium laciniatum*) is a subject which has recently attracted attention, and Mr. W. F. Whitney's short article under this title sums up what is at present known about its causes.—Mr. J. A. Allen's paper in a previous number on "The Flora of the Prairies" is followed by one on "The Fauna of the Prairies."—Dr. G. H. Perkins describes some interesting relics of the Indians of Vermont, illustrated with woodcuts.—Mr. F. W. Vogel has an article on the Principles of Bee Breeding.—Mr. E. L. Greene gives an account of the Spring Flowers of Colorado.—Mr. W. Wood has a valuable article on the Game Falcons of New England; and Dr. A. S. Packard, jun., one on Bristle-tails and Spring-tails, the Lepismas and Poduras, illustrated by plates, and containing a very full account of this interesting family. In both numbers are also reviews of recent works on natural history, and many interesting paragraphs of intelligence under the heads of botany, zoology, geology, anthropology, and microscopy, original or compiled, from American and foreign sources.

## SOCIETIES AND ACADEMIES

### LONDON

Royal Society, April 27.—"On the Increase of Electrical Resistance in Conductors with rise of Temperature, and its application to the Measure of Ordinary and Furnace Temperatures; also on a simple Method of measuring Electrical Resistances." By C. W. Siemens, F.R.S., D.C.L.

The first part of this paper treats of the question of the ratio of increase of resistance in metallic conductors with increase of temperature.

The investigations of Arndtson, Dr. Werner Siemens, and Dr. Matthiessen are limited to the range of temperatures between the freezing and boiling-points of water, and do not comprise platinum, which is the most valuable method for constructing pyrometric instruments.

Several series of observations are given on different metals, including platinum, copper, and iron, ranging from the freezing-point to 350° Cent.; another set of experiments being also given, extending the observations to 1000° Cent. These results are planned on a diagram, showing a ratio of increase which does not agree either with the former assumption of a uniform progression, or with Dr. Matthiessen's formula, except between the narrow limits of his actual observations, but which conforms itself to a parabolic ratio, modified by two other coefficients, representing linear expansion and an ultimate minimum resistance.

In assuming a dynamical law, according to which the electrical resistance of a conductor increases according to the velocity with which the atoms are moved by heat, a parabolic ratio of increase of resistance with increase of temperature follows; and in adding to this the coefficients just mentioned, the resistance $r$ for any temperature is expressed by the general formula,

$$r = \alpha T^{\frac{1}{2}} + \beta T + \gamma,$$

which is found to agree very closely both with the experimental data at low temperatures supplied by Dr. Matthiessen, and with the author's experimental results, ranging up to 1000° Cent. He admits, however, that further researches will be necessary to prove the applicability of the law of increase expressed by this formula to conductors generally.

In the second part of this paper it is shown that, in taking advantage of the circumstance that the electrical resistance of a metallic conductor increases with an increase of temperature, an instrument may be devised for measuring with great accuracy the temperature at distant or inaccessible places, including the interior of furnaces, where metallurgical or other smelting operations are carried on.

In measuring temperatures not exceeding 100° Cent., the instrument is so arranged that two similar coils are connected by a light cable containing three insulated wires. One of these coils, "the thermometer-coil," being carefully protected against moisture, may be lowered into the sea, or buried in the ground, or fixed at any elevated or inaccessible place whose temperature has to be recorded from time to time; while the other, or "comparison-coil," is plunged into a test-bath, whose temperature is raised or lowered by the addition of hot or cold water, or of refrigerated solutions, until an electrical balance is established between the resistances of the two coils, as indicated by a galvanoscope, or by a differential voltameter, described in the second paper, which balance implies an identity of temperature at the two coils. The temperature of the test-solution is thereupon measured by means of a delicate mercury thermometer, which at the same time tells the temperature at the distant place.

By another arrangement the comparison-coil is dispensed with, and the resistance of the thermometer-coil, which is a known quantity at zero temperature, is measured by a differential voltameter, which forms the subject of the second paper; and the temperature corresponding to the indications of the instrument is found in a table, prepared for this purpose, in order to save all calculation.

In measuring furnace temperatures the platinum-wire constituting the pyrometer is wound upon a small cylinder of porcelain contained in a closed tube of iron or platinum, which is exposed to the heat to be measured. If the heat does not exceed a full red heat, or, say, 1000° Cent., the protected wire may be left permanently in the stove or furnace, whose temperature has to be recorded from time to time; but in measuring temperatures exceeding 1000° Cent., the tube is only exposed during a measured interval of, say, three minutes, to the heat, which time suffices for the thin protecting casing and the wire immediately exposed to its heated sides, to acquire within a determinable limit the temperature to be measured, but is not sufficient to soften the porcelain cylinder upon which the wire is wound. In this way temperatures exceeding the welding-point of iron, and approaching the melting-point of platinum, can be measured by the same instrument by which slight variations at ordinary temperatures are told. A thermometric scale is thus obtained embracing without a break the entire range.

The leading wires between the thermometric coil and the measuring instrument, which may be under certain circumstances several miles in length, would exercise a considerable disturbing influence if this were not eliminated by means of the third leading wire before mentioned, which is common to both branches of the measuring instrument.

Another source of error in the electrical pyrometer would arise through the porcelain cylinder upon which the wire is wound becoming conductive at very elevated temperatures; but it is shown that the error arising through this source is not of serious import.

The third part of the paper is descriptive of an instrument for measuring electrical resistance without the aid of a magnetic needle or of resistance scales. It consists of two voltameter tubes fixed upon graduated scales, which are so connected that the current of a battery is divided between them, with one branch including a known and permanent resistance, and the unknown resistance to be measured. The resistance and polarisation being equal, and the battery being common to both circuits, these unstable elements are eliminated by balancing them from the circulation, and an expression is found for the unknown resistance X in the known resistances C and $\gamma$ of the voltameter, including the connecting wires and the volumes V and V′ of gases evolved in an arbitrary space of time within the tubes, viz. :—

$$X = \frac{V}{V'}(C + \gamma) - \gamma \quad . \quad . \quad . \quad . \quad . \quad (1)$$

Changes of atmospheric pressure affect both sides equally, and do not therefore influence the results; but a reading of the atmospheric pressure is obtained at both sides by lowering the little supply reservoir with dilute acid to the level indicated in the corresponding tube. The upper ends of the voltameter tubes are closed by small weighted levers provided with cushions of india-rubber; but after each observation these levers are raised, and the supply reservoirs moved so as to cause the escape of the gases until the liquid within the tubes is again brought up to the zero line of the scale, when the instrument is ready for another observation. A series of measurements are given of resistances varying from 1 to 10,000 units, showing that the results agree within one per cent. with the independent measurements obtained of the same resistances by the Wheatstone method.

The advantages claimed for the proposed instrument are, that it is not influenced by magnetic disturbances, or the ship's motion if used at sea; that it can be used by persons not familiar with electrical testing; and that it is extremely simple and easily procured.

Royal Institution of Great Britain, Annual Meeting, Monday, May 1.—Sir Henry Holland, Bart., F.R.S., president, in the chair. The Annual Report of the Committee of Visitors for the year 1870 was read and adopted. Eighty-one new members were elected in 1870. Sixty-three lectures and nineteen evening discourses were delivered during the year 1870. The books and pamphlets presented in 1870 amounted to 118 volumes, making, with those purchased by the managers, a total of 307 volumes added to the library in the year, exclusive of periodicals. Thanks were voted to the president, treasurer, and secretary, to the committees of managers and visitors, and to the professors, for their services to the Institution during the past year. The following gentlemen were unanimously elected as officers for the ensuing year: President—Sir Henry Holland, Bart., F.R.S. Treasurer—Mr. William Spottiswoode, F.R.S. Secretary—Dr. Henry Bence Jones, F.R.S. Managers—Mr. John J. Rigsby, F.R.S., Mr. George Berkley, Mr. William Bowman, F.R.S., Mr. George Busk, F.R.S., Mr. Warren De la Rue, F.R.S., Capt. Douglas Galton, C.B., F.R.S., Mr. John Hall Gladstone, F.R.S., Mr. William Robert Grove, F.R.S., the Lord Lindsay, Mr. George Macilwain, the Duke of Northumberland, William Pole, F.R.S., Sir W. Frederick Pollock, Bart., Mr. Robert P. Roupell, Col. Philip James Yorke, F.R.S.

Geological Society, April 5.—Prof. Morris, vice-president, in the chair. The following communications were read :—1. "On a new Chimæroid Fish from the Lias of Lyme Regis," by Sir Philip Grey Egerton, Bart., M.P., F.RS. The fish for which the author proposed the name of *Ischyodus orthorhinus*, was represented by a specimen showing the anterior structures imbedded in a slab of Lias. It exhibited the characteristic dental apparatus of the Chimæroids, surrounded with shagreen, a very large prelabial appendage six inches long, and terminating in a hook abruptly turned downwards, and a process which the author regarded as representing the well-known rostral appendage of the male Chimæroid, but in this case attaining a length of 5½ inches, and covered more or less thickly with tubercles, bearing recurved central spines somewhat toothlike in their aspect. This appendage is attached to the head by a rounded condyle, received into a hollow in the frontal cartilage. The dorsal spine, which measured 6 inches in length, was articulated by a rounded surface to a strong cartilaginous plate projecting upwards from the notochordal axis, and was thus rendered capable of a considerable amount of motion in a vertical plane. This structure also occurred in *Callorhynchus* and *Chimæra*. Dr. Günther commented on the interest of this discovery, as in no other sharks is the same articulation of the dorsal spine as that described in the paper to be found. He inquired whether the granulated plate supposed to be dorsal might not be a part of the armature of the lateral line, as in sturgeons. He thought that the Chimæroids would eventually prove to be intermediate between the ganoid and shark types, and that all belonged to one subclass. Mr. Gwyn Jeffreys inquired what other remains were found with these fishes such as might represent the food, molluscan or otherwise, on which they lived. Sir P. Egerton replied that there was no deficiency of pabulum for any kind of fish in the sea represented by the Lias of Lyme Regis. He also made some remarks on another somewhat similar specimen in his own museum. The plate referred to by Dr. Günther, he stated, was symmetrical, and not like the lateral plates on the sturgeon, which are unsymmetrical. He therefore thought it dorsal.—2. "On the Tertiary Volcanic Rocks of the British Islands," by Archibald Geikie, F.R.S. In this communication the author gave the first of a series of papers which he proposes to lay before the society upon the volcanic rocks of Britain of later date than the chalk. In a general introduction to the whole subject, he pointed out the area occupied by the rocks, showing that they are chiefly developed along the broad tract which extends from the south of Antrim, between the chain of the Outer Hebrides and the mainland of Scotland, up into the Faroe Islands, and even to Iceland. The nomenclature of the rocks was discussed, and the following arrangement was proposed :—

| | Felspathic series | | | | | Pyroxenic, or Augitic. | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|
| | Syenite | Felstone and Quartz porphyry. | Trachyte and Trachyte-porphyry. | Pitchstone | Porphyrite. | Dolerite | Basalt | Trachylite | Diallage-rock ? altered dolerite. | Felspathic tuffs. | Pyroxenic tuffs and agglomerate. |
| I. INTERBEDDED OR CONTEMPORANEOUS. | | | | | | | | | | | |
| A. *Crystalline.* | | | | | | | | | | | |
| Sheets or beds | ... | ... | ? | * | * | * | * | ... | * | | |
| B. *Fragmental.* | | | | | | | | | | | |
| Beds or layers | ... | ... | ... | ... | .. | ... | ... | .. | ... | ? | * |
| II. INTRUSIVE OR SUBSEQUENT. | | | | | | | | | | | |
| A. *Crystalline.* | | | | | | | | | | | |
| α. Amorphous masses | * | * | ? | ... | ... | ? | | | | | |
| β. Sheets | ... | ... | ... | ... | ... | * | * | | | | |
| γ. Dykes and veins | * | * | ? | * | ... | * | * | * | | | |
| δ. Necks | ... | ? | ... | ... | ... | ... | ? | | | | |
| B. *Fragmental* | | | | | | | | | | | |
| Necks | ... | ... | ... | ... | ... | ... | ... | ... | ... | ... | * |

The age of the rocks was shown to be included in the Tertiary period by the position of the volcanic masses above the chalk, and by their including beds containing Miocene plants. As an illustrative district, the author described the volcanic geology of the island of Eigg, one of the Inner Hebrides, and brought out the following points :—1. The volcanic rocks of this island rest unconformably upon strata of Oolitic age. 2. They consist almost wholly of a succession of nearly horizontal interbedded sheets of dolerite and basalt, forming an isolated fragment of the great volcanic plateau which stretches in broken masses from Antrim through the Inner Hebrides. 3. These interbedded sheets are traversed by veins and dykes of similar materials, the dykes having the characteristic north-westerly trend, with which they pass across the southern half of Scotland and the north of England. Veins of pitchstone and felstone, and intrusive masses of quartziferous porphyry, like some of those which in Skye traverse or overlie the lias, likewise intersect the bedded dolerites and basalts of Eigg. 4. At least, two widely separated epochs of volcanic activity are represented by the volcanic rocks of Eigg. The older is marked by the bedded dolerites and by the basalt veins and dykes which, though strictly speaking younger than the bedded sheets which they intersect, yet probably belong to the same continuous period of volcanic action. The later manifestations of this action are shown by the pitchstone of the Scùr. Before that rock was erupted the older doleritic lavas had long ceased to flow in this district. Their successive beds, widely and deeply eroded by atmospheric waste, were here hollowed into a valley traversed by a river, which carried southward the drainage of the wooded northern hills. Into this valley, slowly scooped out of the older volcanic series the pitchstone and porphyry *coulées* of the Scùr flowed. Vast, therefore, as the period must be which is chronicled in the huge piles of volcanic beds forming our dolerite plateaux, we must add to it the time needed for the excavation of parts of those plateaux into river-valleys, and the concluding period of volcanic activity during which the rocks of the Scùr of Eigg were poured out. 5. Lastly, from the geology of this interesting island we learn, what can be nowhere in Britain more eloquently impressed upon us, that, geologically recent as that portion of the Tertiary periods may be during which the volcanic rocks of Eigg were produced, it is yet separated from our own day by an interval sufficient for the removal of mountains, the obliteration of valleys, and the excavation of new valleys and glens where the hills then stood. The amount of denudation which has taken place in the Western Islands since Miocene times will be hardly credible to those who have not adequately realised the potency and activity of the powers of geological waste. Subterranean movements may be called in to account for narrow gorges, or deep glens, or profound sea-lochs; but no subterranean movement will ever explain the history of the Scùr of Eigg, which will remain as striking a memorial of denudation as it is a landmark amid the scenery of our wild western shores. Prof. Haughton inquired whether Mr. Geikie's attention had been called to the Morne Mountains in Ireland, which seemed to present some analagous phenomena to those described in the paper. In the Morne district were dykes of dolerite, pitchstone, and other volcanic rocks of the same constitution as those of Antrim. He believed that a chemical examination of these rocks in different districts would prove their common origin. The evidence in Antrim was conclusive as to their Tertiary age in Ireland, and he was glad to find that the view of their belonging to a different age in Eigg was erroneous. Prof. Ramsay had hitherto believed in the Oolitic age of these trap-rocks in Eigg, but accepted the author's views. The interbedding of volcanic beds among the Lower Silurian beds in Wales was somewhat analogous. He was glad to find the history of these igneous rocks treated of in so geological a manner, instead of their being regarded from too purely a lithological and mineralogical point of view. The great antiquity of these Middle Tertiary Beds had, he thought, been most admirably brought forward in the paper, as well as the enormous amount of denudation; and he would recommend it to the notice of those who had not a due appreciation of geological time. Mr. Forbes hoped that the geologist would remember that his father was a mineralogist. It was refreshing to find a paper of this kind brought before the Society, as it was to be regretted that the details of mineralogy were so little studied in this country when compared with the Continent; and this be attributed to the backward state of petrology (admitted by Mr. Geikie) in this country. He quite agreed in the view of the Tertiary age of these rocks. With regard to the terminology employed by the author, he objected to the use of the word dolerite, as distinct from basalt; basalt properly comprised, not only dolerite, the coarse-grained variety, and anamezite, the finely-grained variety, and the true basalt, but also trachylite, which was frequently confounded with pitchstone. All four names merely referred to structure, and not to composition. Mr. Geikie, in reply, stated that he had not examined the Morne Mountains. He had not in any way wished to disparage mineralogy, but, on the contrary, had attempted to classify the different rocks according to their petrological character. He used the term dolerite in the same sense as the German mineralogists, both as the generic name for the whole series, and also for the coarser variety of basalt. 3. "On the formation of 'Cirques,' and their bearing upon theories attributing the excavation of Alpine Valleys mainly to the action of Glaciers," by the Rev. T. G. Bonney, M.A., F.G.S. The paper described a number of these remarkable recesses, which, though not restricted to the limestone districts of the Alps, are best exhibited in them. The author gave reasons why he could not suppose them to have been formed either as craters of upheaval, or by the action of the sea, or by glacial erosion. With regard to the last he showed that, even if glaciers had been the principal agents in excavating valleys, there were some cirques which could not have been excavated by them; and then went on to argue from the fact that glaciers had occupied cirques, and from the relation between them and the valleys, that they could not be attributed to different agents. He also showed that commonly the upper part of the valley, where the erosive action is perhaps least, is very much the steepest, and urged other objections to the great excavatory powers often attributed to glaciers. He then described one or two cirques in detail, and showed that they were worked out by the joint action of many small streams, and of the usual mete ric agents working upon strata whose configuration was favourable to the formation of cliffs. Mr. Whitaker suggested an analogy between the cirques and the combes in our own limestone countries. Mr. Geikie regarded the cirques as analogous with the combes of Wales and the corries of Scotland. They were not, however, confined to limestone districts, but occurred also in gneiss and granite rocks. He thought that the shape was much influenced by the bedding and jointing of the rocks, as there was an evident connection between these and the shape of the combes. He could not, however, see his way to account for the vertical cliffs surrounding the cirques. The Rev. T. G. Bonney, in reply, observed that though cirques were not confined to limestones, the finest instances occurred in such rocks. When cirques occurred in crystalline rocks, the talus was usually much larger than in limestone.—The following specimens were exhibited: Specimens of Fossil Fish-remains from the Lias of Lyme Regis; exhibited by Sir P. de Malpas Grey Egerton, in illustration of his paper.

Royal Society of Literature, April 26.—Mr. Hyde Clarke read a paper on the "Classic Names of Rivers," more particularly in Greece, Asia Minor, and Italy. After referring to the discoveries in the stone period by Mr. Finlay and others, and to the megalithic and cyclopean structures, he proceeded to consider what evidence was afforded by topographical nomenclature of the populations which preceded the Hellenic. He showed that the river-names in the classic regions conformed with each other, and that this was not attributable, as supposed, to Hellenic colonisation. These names also conform to those of India, and of the ancient world generally; but the explanation was not to be found in Aryan etymologies, but that it was to be sought in earlier forms. These are represented in the languages of the Caucasus, of which the Georgian, Suan, Latian, and Lesghian afford examples now. With these the Thracian and the languages of Asia Minor corresponded. The local facts gave colouring to the legends of the occupation and invasion of Attica by the Amazons, and of the existence in Europe of a Thracian population allied to that of Asia. The eastern connection of the Etruscan and Italian populations, too, was to be accounted for as with the Caucasus, and not with America. He referred likewise to the influence of the river-names on classic mythology, and particularly on the nomenclature of Tartarus.

Linnean Society, April 20.—Notes on Mr. Murray's paper on the Geographical Relations of the chief Coleopterous Faunæ, by Dr. Roland Trimen. The author considered that the argument of a continuity of land at a previous epoch is too often resorted to to explain the occurrence of the same species of insects in widely remote countries. He entered in considerable detail into the chief features of the distribution of the genera and species of Coleoptera, especially at the Cape; laying much stress on the difficulty which introduced species find in establishing themselves in soil already well stocked.

Society of Biblical Archæology, April 4.—Dr. S. Birch, F.S.A., president, in the chair.—Mr. Henry Theodore Bagster, Mr. Richard Bosanquet, Mr. A. W. Franks, M.A., V.P.S.A., &c., and Mr. Burnett Tabrum were duly elected members of the society. The Secretary read a paper communicated by Mr. Henry Fox Talbot, F.R.S., &c., "On an Eclipse mentioned on an Assyrian Tablet." The tablet in question is preserved in the British Museum, and is marked 154 and 122*b*. The translation runs thus: "To the King of the World—My Lord, Thy servant, Kukuru, sends this:—May Assur, the Sun, and Marduk be propitious to my Lord the King in bis journey from his kingdom to the land of Egypt! I inform his Majesty that in the month of Su there was an Eclipse. Five portions of the full orb were obscured. Let the King be of tranquil mind, since the eclipse of the month of Su portends good fortune to the King." The translator proceeded to identify this eclipse thus recorded with one which took place in the seventh warlike expedition of Assurbanissal against Tiumman, King of Elam. The next meeting was then announced to take place on Tuesday, 2nd proximo, to which date the meeting was then adjourned.

### Dublin

Royal Irish Academy, April 10.—Rev. T. H. Jellett, president, in the chair. Prof. Hennessy, F.R.S., read a paper On the Floatation of Sand by the incoming tide at the Mouth of a Tidal River. During the course of a tour along our western coast, in the summer of 1868, the following incident came under my notice; and, although I made a note of the facts at the time, I have never hitherto made them the subject of a scientific communication: On July 26, when approaching the strand at the river below the village of Newport, County Mayo, I noticed what appeared to be extensive streaks of scum floating on the surface of the water. As it was my intention to bathe, I was somewhat dissatisfied with the appearance of the water, until I stood on the edge of the strand, and I then perceived that what was apparently scum, seen from a distance, consisted of innumerable particles of sand, flat flakes of broken shells, and the other small *débris* which formed the surface of the gently-sloping shore of the river. The sand varied from the smallest size visible to the eye up to little pebbles, nearly as broad and a little thicker than a fourpenny piece. Hundreds of such little pebbles were afloat around me, and it is probable that the flakes of floating matter seen farther off contained also a considerable proportion. The air during the whole morning was perfectly calm, and the sky cloudless, so that, although it was only half-past nine, the sun had been shining brightly for some hours on the exposed beach. The upper surface of each of the little pebbles was perfectly dry, and the groups which they formed were slightly depressed in curved hollows of the liquid. The tide was rapidly rising, and, owing to the narrowness of the channel at the point where I made my observations, the sheets of floating sand were swiftly drifting farther up the river into brackish and fresh water. On closely watching the rising tide at the edge of the strand, I noticed that the particles of sand, shells, and small flat pebbles, which had become perfectly dry and sensibly warm under the rays of the sun, were gently uplifted by the calm, steadily-rising water, and then floated as readily as chips or straws. I collected a few specimens of these little objects, but I regret that they have been since mislaid. This phenomenon, it is scarcely necessary to say, is due to molecular action, such as accompanies the familiar experiment of floating needles on the surface of a basin of water. Although the specific gravity of the floating objects exceeds that of the fluid on which they rest, the principle of Archimedes still holds good, because the displacement of liquid produced by the body is considerably greater than the volume of the body itself. In the case of a floating needle, the repulsion of the liquid from the polished surface of the metal presents a groove, whose magnitude is obviously many times greater than the needle; but in the case of the floating pebbles this was not so manifest. The attraction of the molecules of water for one another produces, as is well established, a tension at the surface of the liquid, which, although extremely feeble, and generally noticed only in connection with capillary phenomena, yet interposes some resistance to the intrusion of foreign substances. I have floated small flat pebbles, similar in size and appearance to the largest of those observed floating on Newport river, for more than six days, while fragments of shells, and thin pieces of slate as broad as a sixpenny-piece, have continued to float much longer. These little bodies occasionally sank from the gradual absorption of water, but much more frequently from some accidental motion of the vessel containing the liquid. It is manifest that the floatation of sand in a tidal estuary, as in the instance I have seen, can occur only under favourable conditions. The shores must be very gently inclined, the air perfectly calm, and the weather dry and warm. Under these circumstances thin cakes or sheets of sand may not only be uplifted by the water, but if the tide flows rapidly they may continue to float sufficiently long to allow many of them to be drifted far from their original place up to the higher limit of the brackish water. In this way fragments of marine shells and exuviæ might become mingled with those belonging to fresh water. The conditions favourable for sand floatation must exist during calm weather in a very high degree of perfection on the sandy shores of tidal rivers in tropical and subtropical districts of the earth. As this phenomenon can take place only with the rising tide, and never with the falling tide, the result must generally be favourable to the transport of sand and marine *débris* in the direction of the flow of flood tide; and this may sometimes hold good along a coast as well as on the shores of a tidal estuary. Geologists, as far as I am aware, have not hitherto noticed this phenomenon in connection with the formation of stratified deposits by the agency of tides and rivers, although they have paid great attention to the influence of the molecular resistance of water to the sinking of very minute solid substances, with the view of explaining the wide surface over which matter held in suspension by water may be spread when ultimately deposited over the sea bottom.—Prof. W. King read a paper, by himself and Prof. Rowney, "On the Mineral Origin of the so-called *Eozoon Canadense*." It was resolved to purchase the Bell and Bell-Shrine of St. Patrick, from Dr. C. Todd, for the sum of 500*l*.

## *THE PROPOSED COLLEGE OF PHYSICAL SCIENCE AT NEWCASTLE-UPON-TYNE*

A FEW weeks ago * we gave some account of the initiation of a movement in the North of England, having for its object the establishment of a College of Physical Science in Newcastle-upon-Tyne. As the Executive Committee appointed at the public meeting had only then begun its work, the details entered upon were given as mere indications of the general form the institution might be expected to take. A letter from the Master of University College, Durham, which appeared in our columns more recently, added somewhat to our information, and a circular which has been issued, with commendable promptitude, by the Executive, is now before us, representing the views of the promoters as modified in committee.

We shall probably best further the intentions of the Committee, whom we are anxious to aid, and at the same time give our readers the most reliable information, if we reprint this document verbatim :—

"It is proposed to found at Newcastle-upon-Tyne, in connection with the University of Durham, a College for the teaching of Physical Science, especially as applied to Engineering, Mining, Manufactures, and Agriculture.

"The want of such an Institution has long been felt in the North of England, and it is believed that while it would be useful in all the above pursuits, it would be of especial value to all persons intended for the professions of Mining and Engineering.

"Such an Institution (which it appears desirable to limit at its commencement to purely scientific objects) would offer instruction in the following branches of scientific knowledge. 1. Pure and Applied Mathematics. 2. Chemistry. 3. Experimental Philosophy. 4. Geology, Mineralogy, and Biology. Professorships and Lectureships will be founded on these subjects. It is proposed that the course of study shall last for two years, that it shall consist partly in attending lectures and partly in the work of the laboratories, that there shall be examinations at the end of each year, conducted mainly by Examiners from the Universities, and that at the final examination the successful students shall receive the title of Bachelor or Associate of Science of the University of Durham, or, upon certain further conditions, the degree of B.A. It is hoped that classes of evening lectures for those who are unable to attend during the day may soon be formed.

"The Government of the Institution will be entrusted to a Council, of which one-third will be nominated by the University of Durham. The University has offered the sum of 1,000*l.* annually towards the establishment of Professorships and of ten Scholarships of 20*l.* each to assist students. It is believed that 2,000*l.* a-year is the lowest estimate at which it is possible to place the expenses of such a College, even at its commencement, and it is proposed to appeal to the public for a subscription to create a capital fund of at least 30,000*l.* If this amount be collected, the endowment from the University of Durham will be made a permanent one. When it is remembered that such an Institution will benefit a very large portion of the population of the Northern Counties, and be directly useful to nearly all branches of Manufacturing and Agricultural, as well as of Mining and Engineering pursuits, it is believed that no difficulty will be found in ultimately raising this sum, which, according to the experience of all similar institutions, will probably be increased by private donations both for Scholarships and Professorships. It is proposed to offer Subscribers the option either of paying their whole subscription at once or of extending it over a period of five or six years. Small as well as large subscriptions are invited towards the above-mentioned fund. Upwards of 100,000*l.* has been recently collected in a similar case, or is in the course of collection, in subscriptions ranging from 2,000*l.* to the very smallest sums."

The last paragraph pleases us most. Six years is perhaps long enough to look forward in arrangements of many sorts, but not in matters pertaining to finance. The adoption of a scheme such as that originally suggested, based on a preliminary terminable endowment, would have crippled the energies of the whole staff, by suggesting the possibility of the early demolition of the structure they were labouring to build. It can scarcely be known, until the trial is made, how much may have to be done in the way of *creating the demand* for scientific education in the locality. We do not for a moment doubt its existence to a considerable extent, but we cannot suppose that the present case will form any exception to the general rule, that educational facilities are only slowly and by degrees taken advantage of by the classes for whose benefit they have been primarily designed. If the proposed college *begins* to find an appreciative public, and to promise eventual success within the six years, we should regard it as a subject of congratulation, and a proof alike of energy and judgment in its management, rather than as a matter of course. Happily, for this reason, the guarantee principle is to be put upon its best basis—funded property. Instead of 1,000*l.* per annum for a term of six years, as at first proposed, the public is asked for 30,000*l.* in one sum. This, with the consequent permanent endowment from Durham University, which may be regarded as equal to another 30,000*l.* capitalised, will provide a substantial foundation to commence upon. Nor can we doubt that the amount required will be easily raised amongst the wealthy men of the North.

We may perhaps say one word more about the selection of subjects for professorships, as our former remarks are alluded to in the Rev. Mr. Waite's letter.

We adverted to the absence of any mention of Biology as a part of the scheme of education in the report of the speech of the Dean of Durham at the preliminary meeting. In the revised programme, above reprinted, biology is *not omitted*, but that is all that can be said. The subject is tacked on to geology and mineralogy, and the result is a complete anomaly. To teach mineralogy in any modern sense, a man must be more than an average chemist—hence no one who is not an expert in geology, mineralogy, chemistry, zoology, and botany, will have the requisite qualifications for the chair which it is now proposed to constitute. We trust that the Committee are prepared to pay pretty smartly for so handsome an instalment of omniscience. Our fear that biology of itself might be thought too large a subject for a single professorship, was at any rate groundless, but we doubt whether entire exclusion would be worse than the grant of a third of a chair.

The geological knowledge of first importance in a mining district is essentially "stratigraphical," in other words, that attained by practical field work. Just so much palæontology is necessary as will enable the student to recognise the more common characteristic fossils, and sufficient acquaintance with minerals to render him fami-

* See NATURE, vol. iii. p. 461.

liar with ordinary rock specimens. It would be better that Geology of this sort should be associated with a subject like mining, instead of being placed in the position it at present occupies.

Mineralogy, in any right sense, is only applied chemistry, and would be more in place as a recognised portion of the chemical curriculum in such an Institution than as a part of geology. Few geologists pretend to mineralogy beyond a sufficient knowledge of the general external characters of rocks for the recognition of the commoner varieties. Palæontology, on the other hand, as a subject of systematic study, is but a phase of biology, and cannot without violence be linked with subjects arising out of the laws which govern the inorganic world.

In thus enlarging upon our former remarks, we are actuated solely by a desire for the success of an undertaking which has our entire sympathy.

Just as we are going to press we learn that it has been determined to push forward the arrangements so as to enable the College to open its doors in October. This is a wise decision on many grounds. The first week in October has become the recognised time for the commencement of winter courses of lectures, and delay beyond that might easily entail the loss of a whole year. Of the 30,000*l.* required, upwards of 17,000*l.* has already been subscribed, without any systematic canvass, and we can scarcely doubt that the remainder will be forthcoming. On public grounds we would venture earnestly to second the appeal made by the Committee, and to express the hope that the liberality of the coal-owners, manufacturers, and merchants of the district will enable them to open the Institution free from pecuniary embarrassment, and clear of the manifold difficulties that beset an undertaking burdened at the outset with debt. We also hear at the same moment that the Committee has again debated the question of a biological professorship. That body seems to be undecided as to whether it would be less ridiculous to ignore biology entirely, or to include it with a number of quite distinct branches of science in a sort of miscellaneous professorship, and the prevailing view *now* seems to be that, on the whole, the former alternative is the least conspicuously absurd. Surely there is a third course open to the Committee. We trust wiser counsels will prevail, and that we may never have to record that in Newcastle—the home of Bewick and Selby, Fryer and Alder, Winch and Robertson, not to name a host of living biologists—in the focus of the Tyneside Naturalists' Field Club—a College of Natural Science has been established in which Natural History in its higher aspects is excluded as a subject of study.

## *STAVELEY'S BRITISH INSECTS*

*British Insects. A familiar Description of the Form, Structure, Habits, and Transformations of Insects.* By E. F. Staveley, Author of "British Spiders." (London: L. Reeve and Co., 1871.)

TO compose a work on so extensive and difficult a subject as "British Insects," which shall convey a large amount of useful and interesting information without being too much overloaded with bare facts,—which shall be accurate without being dry, and amusing without being flippant,—is no easy task, yet it is accomplished by the author of this work in a very creditable manner. The introductory chapters are condensed and clear, just giving enough information on the general structure and economy of insects to interest the uninitiated reader, and lead him on to the more detailed account of each order given in the succeeding chapters.

An excellent feature of the work is the clearness of the type, and the well-executed woodcuts which somewhat too sparingly illustrate the text, while sixteen coloured plates by Mr. Robinson contain admirably life-like portraits of nearly a hundred of our most conspicuous or most interesting insects. A few extracts will best illustrate the author's style. In the chapter on the larvæ of Lepidoptera it is remarked, that there is neither time nor place in which we may not find the traces of these creatures or the creatures themselves.

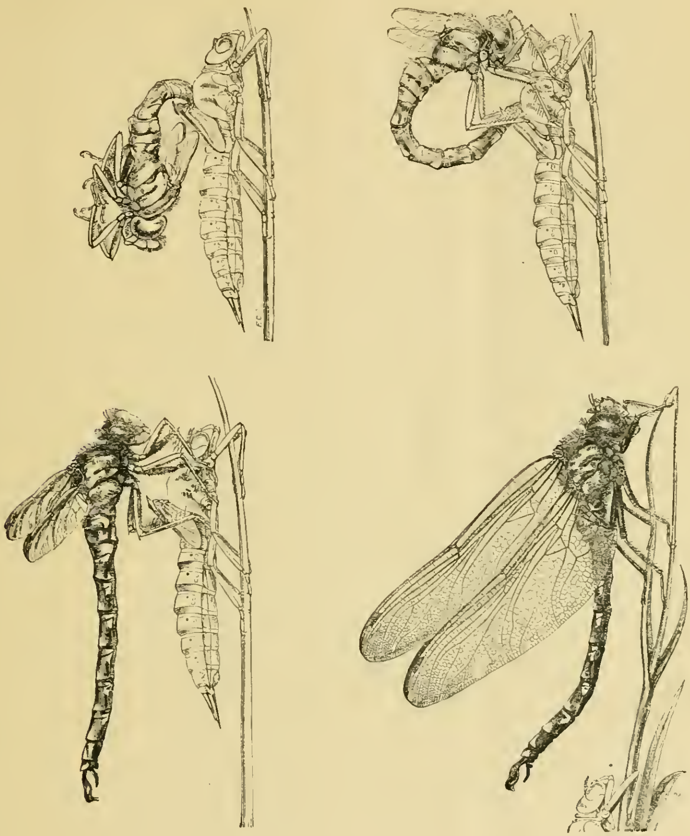
"If at one time of the year we tear a handful of moss from the trunk of a tree, out drop some little brown chrysalids; if at another we drag a tuft of grass up by the roots, there we find silken tubes, the homes of some small caterpillars. We find them in fungi, we find them in grain, we find them in teazle-heads, in fir-cones, in rose-buds, and in fruit; and the Hymenopterist, carefully watching the insect emerging from a gall, discovers that he has reared in it a moth! On the face of a lichen-covered rock we see a moving fragment, and lo! a little caterpillar, neatly encased like a caddis-worm in a tent of lichen, is moving and feeding, safe even from the bird's sharp eye. We open our drawers, and there, oh, sight of horror! What is that streak of white silk upon the best garment—the garment laid by, too good for common wear? We look farther; what is that dusty little roll? It is a great-coat on a microscopic scale. It matches our best garment ominously. It moves—a head peeps out—some little legs, and away it walks!—tell not the housekeeper!—away it walks in safety from the admiring Entomologist."

As an example of the woodcut illustrations we give the series showing the progressive stages in the transformations of the dragon-fly. The sluggish mud-coloured pupa ascends the stem of a grass or any other stalk of convenient size which rises above the surface of the water, after a time the skin cracks behind, between the wing cases, and the head and thorax of the enclosed fly are drawn out. The abdomen follows, the insect turning up and clinging to the pupa case, where it remains till the wings increase to the full size so rapidly that they can be seen to grow.

In the chapter on Diptera there are some good remarks on the many erroneous uses of the term "Fly."

"Being a 'popular name' the people have a right to mean what they choose by it, and they avail themselves of the right—some meaning by it one thing, some another, some every flying insect for which they know no other name. Thus the 'fly' of the former is usually the little hopping turnip beetle; the 'fly' of the hop-grower is an aphis; the 'fly' of the herdsman a gad; while to the citizen almost anything to be seen with wings (except pigeons and sparrows) is a fly. There are some, again, to whom flies are *flies*, one fly *the* fly, the common well-known little black house-fly. Here at last is something definite. No, not even now; for these will, at least, claim their young house-fly, and their full-grown house-fly, and expect you to believe that late in the year their house-fly takes to biting you, little dreaming that the little fly, and the big fly, and the fly which bites you, not only are different species but even belong to different genera; that the little fly never grows big, that the big fly never was little, and that their house-fly could not bite you if he would. What, then, are we to understand by the name fly? It is clear that the popular sense has no sense at all, or too many senses, and yet the word cannot be spared from our vocabulary. In any Latin dictionary we shall find *Musca* (fly), and the entomologist pounces upon it and says it shall mean the *tribe of two-winged insects.* Linnæus so used it, and his genus *Musca*, now broken up into many new genera, represented the greater number of those insects which the entomologist now claims as flies."

In some parts of the work there is rather a tendency to jump at conclusions, and to give explanations of very doubtful value. It is attempted, for instance, to explain why the bee has four wings instead of two, by the fact that it is necessary for them to fold up and pack into a small compass to avoid injury and be out of the way during work, and this it is said is "the purpose of the division of the wing." This conveys the entirely erroneous



TRANSFORMATIONS OF THE DRAGON-FLY

impression that the wings of insects are normally two, and that the four are formed by the "division" of these two, an impression which we feel sure a person so well informed as the author could not have meant to convey. It also seems carrying hypothetical life-history a little too far to say of a bee emerging from the pupa that "into his mind rushed a full sense of his responsibilities," and on finding himself, say, a worker, "he, or rather she, became aware that the duties of house-builder, housekeeper, nurse, and even soldier and sentinel, devolved upon her;" and accordingly she forthwith "addressed herself to the task of repaying to futurity that debt which the cares of a former generation had laid upon her, and daily she toiled in its fulfilment." To make this exposition of the mental state of the newly-born bee complete, we should have been told whether it regulated its conduct in doubtful cases according to the utilitarian or the intuitive theory of morality.

Such vagaries as the above are however rare, and we can conscientiously recommend this book as admirably adapted to lead its readers to observe for themselves the varied phenomena presented by insects, and thus to become true entomologists. ALFRED R. WALLACE

## *AMERICAN GEOLOGY*

*Preliminary Field Report of the United States Geological Survey of Colorado and New Mexico.* Conducted under the authority of the Hon. J. D. Cox, Secretary of the Interior. By F. V. Hayden, United States Geologist. 8vo. pp. 155. (Washington: Government Printing Office, 1869.)

THIS preliminary field report makes us acquainted with a vast tract of territory hitherto scarcely known, save to the more adventurous squatters and to the various tribes of Indians who have gradually been driven farther and farther west by the wonderful growth of the United States populations, fed as they are annually by streams of English, Irish, Scotch, and German emigrants. Unfortunately for the Red-skins, they are not only hemmed in on the one side by the United States, and on the other by the equally vigorous growth of California and its vast mining and agricultural population; but their territory, only hitherto invaded by the Mormons and the "Pony-Dispatch," is now cut in twain by the great Pacific Railroad, which, in its course, has sent forth geological reconnaissances right and left, discovering timber here, coal there, building stone in this spot, mines in that, until there is no space left for them save in the happy hunting-grounds above, to which they are fast going, aided by revolvers, alcohol, and disease.

The report refers to a line of country extending from British North America to New Mexico in a northerly and southerly direction, and from the Rocky Mountains to the Lower Missouri in an easterly and westerly one. Dr. Hayden explains the reason why he has been able in a very short time to cover so large a tract of territory—it is, that "there is great uniformity in the geology of the country, and when one has become familiar with the different geological formations over a small area, he can trace them with great rapidity over long distances" (p. 11).

First, we have the Rocky Mountain system forming the main ridges and the hills, composed of granite rocks. Resting on the flanks of these more elevated masses, the stratified deposits are exposed in succession, becoming less and less inclined as we recede from them and enter the plains.

The oldest stratified deposit met with is the Potsdam Sandstone, equivalent in geological position to our Upper Cambrian, or to the Primordial Zone of Barrande; this is followed by strata of Carboniferous age, but giving no promise of workable seams of coal. The Triassic series may be represented by certain red arenaceous deposits, sometimes containing gypsum and rocksalt; these pass upwards into undoubted Oolitic beds. Next follows a Cretaceous formation, some 4,000 feet in thickness, followed by a well-developed Tertiary series of vast geographical extent, and but very slightly inclined.

These Tertiary beds are rich in lignites, and evidence a long period of tranquil estuarine or lacustrine deposition in a region supporting dense forests of large trees, and a vegetation far exceeding in luxuriance anything now met with in these latitudes. Carnivores, Pachyderms, Proboscidea, &c., occur in great abundance. It is very interesting to know that in Tertiary times North America had its elephants, hippopotami, rhinoceroses, horses, lions, &c., and was, in the size and abundance of its Mammalia, in no way surpassed by the Continents of the Old World.

Two minor reports accompany Dr. F. V. Hayden's report, one on "Mines and Mining," by Mr. Persifor Frazer, jun., giving a most interesting account of the mining capabilities of the district; the other on the "Agriculture of Colorado," by Mr. Cyrus Thomas. There is every prospect of the Colorado territory becoming as rich an agricultural district as it has already proved to be a mining one. H. W.

## *OUR BOOK SHELF*

*Aunt Rachel's Letters about Water and Air.* (London: Longmans and Co., 1871.)

IN the form of a series of familiar letters from an aunt to a nephew and niece, we have here an account, in simple familiar language, of some of the commoner physical phenomena of nature. Recollecting the books with a similar aim that have passed through our hands, we feel grateful to find one free from conspicuous blunders. To the little book before us we need not however apply such negative praise. It is in all respects to be commended as a book to put into the hands of the young. And we fancy that even many well-educated people who are not young in years, will find a record and explanation of facts with which they are not familiar. They may learn here all about the formation of ice, latent and specific heat, the air-pump, the barometer and thermometer, the winds, combustion, and many other phenomena of daily life. A few well-executed woodcuts illustrate the text; and we would like to hear that a large circulation has rewarded the efforts of "Aunt Rachel" to popularise the elements of science.

*Handbuch der allgemeinen Himmelsbeschreibung vom Standpunkte der kosmischen Weltanschauung dargestellt.* Von Hermann J. Klein. Pp. 351. (Braunschweig, 1871. London: William and Norgate.)

*Theoretische Astronomie.* Von Dr. W. Klinkerfues. Erste Abtheilung. Pp. 256. (Ditto, ditto.)

THE first of these works is the second edition of the first part of a general description of the universe, and is devoted to the solar system: another part will be given to the fixed stars. The aim of the author is to afford a complete account of his subject, including the latest researches, which shall be at the same time thoroughly scientific, while it will not be beyond the comprehension of those who are possessed of only an elementary knowledge of astronomy, or more properly perhaps uranography. The first forty-nine pages contain a description of the sun; the next five are given to the zodiac. Then follow the planets Mercury, Venus, &c., in order, and finally we have a full and very interesting account of comets and meteorites.

Turning to the chapter on the sun, we find, after a general introduction, methods for calculating the distance between the centre of the sun and that of the earth. After this we have an account of the "spots," accompanied with tables of their numbers in different years, and their connection with the movements of the magnetic needle. The labours of Herschel, Airy, Lockyer, Huggins, and others are largely quoted, and the author begs any observer whose researches may have been omitted, to attribute the neglect to the disturbing influence of recent events. The earth and her satellite are treated at some length, and the questions of the moon's influence on the earth's atmosphere, the winds, weather, and magnets, are fully discussed. The chapter on meteorites is very interesting. We are told, on the authority of Miller and Haidinger, that the earliest mention of meteorites is probably in Iliad xv. 18—22, where the anvils spoken of by Jupiter are supposed to refer to these phenomena. Livy mentions a shower which some think may have been a star shower; and the famous black stone in the Kaaba, at Mecca, is said to be undoubtedly a meteorite of great antiquity. Numerous analyses of meteorites are given, and tables are added containing full details of all those which are recorded to have fallen from the earliest times. There are similar tables with regard to comets and star-showers; and finally we have two well-executed plates of the appearance of different sun-spots, and a chart of part of the moon's surface. We should like to see an English edition.

The Theoretical Astronomy of Dr. Klinkerfues, director of the Royal Observatory of Göttingen, is a reproduction of lectures delivered by him in that University. This is the first part of the work, and its object is to give an explanation of the means by which the courses and positions of heavenly bodies are determined. It is not adapted to the general reader, but will prove a useful companion to the mathematician who wishes to obtain an insight into astronomical methods of calculation. Several very good figures accompany the text.

G. T. A.

*Kuklos; an Experimental Investigation into the Relationship of Certain Lines.* By John Harris Part I. (Montreal, 1870)

IN a review of Prof. Bretschneider's History of Early Geometry we have mentioned some clever attempts to square a circle, made at a time when this problem engaged the attention of the first mathematicians. Then, however, as at present, there existed circle squarers of a different kind, who excel only in demonstrating their own ignorance. A fine specimen is preserved by Simplikios. Some persons had heard of square numbers which are at the same time cyclical, that is to say, the last figure in the square number is the same as that of the root, as 25 and 5. Nothing, of course, could be more evident to them than that a number which is both square and cyclos must be a measure for the circle. Mr. Harris ranks almost as high, only he does not give his conclusions in quite so short a form. His book is to consist of four parts in quarto, of which the first contains merely a preface, preliminary arguments, and on the last page an introduction. In the preface the author excuses the haste in which the publication has taken place, with the remark that if his researches are of value they cannot be brought early enough before the public,—if a failure " the communication itself would not be worth the additional labour bestowed on improving its form." This latter conclusion we willingly grant. It is only to be regretted that Mr. Harris has not had the same opinion of the time he spent in writing this communication and preparing the numerous and long figures which fill ten large plates.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Pangenesis

MR. GALTON—by acting upon the conclusion that the supposed gemmules supposed to be detached from the cells of the body at different periods of life in the case of the higher animals swarmed in the blood prior to their supposed collection and union to form the reproductive element—favoured the provisional hypothesis of Pangenesis, for he indicated a not improbable manner in which the very improbable phenomena involved in the hypothesis might actually occur.

But Mr. Darwin, in NATURE for April 27th, writes to explain that he maintains that the gemmules must be "thoroughly diffused"—I conclude, suspended in the fluids which circulate freely in every part of the very substance of all the tissues of the body. The supposed gemmules must be much more minute than the smallest particles that can be seen by the highest magnifying powers used in these days, and must be invisible to the eye when made to appear five thousand times larger than their real size. They must be capable of *diffusion*, and, as is suggested by Mr. Darwin, much as chemical substances are *diffused.** But the terms of the hypothesis would imply that the gemmules are actual particles *suspended* and not *dissolved* in the fluids.

It is not very encouraging to those who work, to discover after having performed numerous and well-devised series of difficult, laborious, and troublesome experiments honestly to test the value of a hypothesis, that they have been investigating a shadow, and to be then informed that the results they have obtained have little or no bearing on the question at issue. The "experiments are extremely curious," says Mr. Darwin, and the experimenter "deserves the highest credit for his ingenuity and perseverance."

It would, of course, be possible to remove from one animal portions of tissue which, according to the hypothesis, *must* contain the supposed gemmules, if they exist, and graft the pieces of tissue upon another. If the experiment was successful, and the offspring exhibited any of the characters of the variety from which the graft was taken, the opponents of Pangenesis would admit the doctrine at once, but if the results were again of a negative kind, would Mr. Darwin consider that his hypothesis had "received its death blow?" It would certainly be as easy to defend it as it is at this time. Nor do I believe it possible to obtain a series of experimental results which would lead the supporters of Pangenesis to abandon the hypothesis. A firm belief in hypothetical gemmules, which cannot be rendered evident to the senses, is not likely to be shaken.

Depend upon it, neither the well-devised experiments of Mr. Galton, nor any other experiments that may be devised, will overthrow this doctrine. The provisional hypothesis of pangenesis is perfectly safe, and will withstand every attack that may be made. It cannot be successfully assailed. Like many favoured hypotheses of these days, it can neither be proved to be true nor positively shown to be false, and it is open to anyone to ground his belief in the truth of this and other doctrines upon the fact that they have not been and cannot be disproved. For undoubtedly gemmules *may* be formed in the manner supposed; if formed, they *may* be detached; if detached, they *may* pass through the tissues; they *may* then collect together, and *may* form reproductive elements. Each one of the countless millions of sperm elements produced in such profusion during so many years of life *may*, indeed, be formed by the union of millions of gemmules which, after meandering through the various textures of the body, marshal themselves in order in one particular locality. From the vast company thus supposed to have collected, we *may* conceive, by the light of imagination, the formation of regiments composed of multitudes of individual gemmules of the same kind; and further, it is not difficult to imagine that each individual gemmule of every regiment *may* move away and unite with thousands and tens of thousands of others, to form at length that marvellous compound and complex speck of matter less than the $\frac{1}{50000}$ of an inch in diameter, which constitutes the active material of each small reproductive particle. This is one way in which the properties of the spermatozöon may be accounted for. Nor is it beyond the power of the imagination to picture the orderly arrangement and rearrangement of such vast hosts of potential molecules as is supposed. No confusion, no jostling of one another, no struggling would be seen, for each molecule takes its appointed place, in obedience to its own properties, knowing of course the position it is to occupy in the complex ranks at each different period of its life's progress, and, never ambitious of discharging a higher function than that which it is destined to fulfil, performs the important office of transmitting certain peculiarities, important or trivial, useful or useless, from the existing to a new being.

* In NATURE for May 1st, Mr Francis Galton very properly remarks that the term Mr. Darwin should have employed is "dispersion" not "diffusion," and there are other critical remarks which appear to me equally just.

We may be led from the consideration of the broad facts nature to conceptions of the most abstract kind, without being conscious of the slightest gap between the facts of Science and the creations of the Imagination. In these days the utmost skill is often displayed in hiding and ignoring or denying the hiatus by which the arguments deduced from the results of observation and experiment are separated from those which are based upon the fictions of the fancy. But, unhappily, the gulf cannot be filled up, or bridged over. It may be obscured by mists and clouds, but, though it be lost for a time, it is sure to be rediscovered and its limits studied by the curious and unphilosophical.

Nowadays analogical argument is employed very freely without any attempt to show, in the first place, that there is any real analogy between the facts upon which the reasoning is based. In order to convince people that a hypothetical gemmule may move long distances through all sorts of tissues, it is only necessary to show that actual matter, millions of times as large, does burrow a short distance through certain textures. Mr. Darwin remarks that it cannot be objected "that the gemmules could not pass through tissues or cell-walls, for the contents of each pollen grain have to pass through the coats both of the pollen tube and embryonic sack."

He might have advanced in his support the fact of fungi traversing tissues, of entozoa of various kinds burrowing long distances through the textures of the living body, and many well-known instances of a similar kind. But such facts do not strengthen the hypothesis of Pangenesis in the slightest degree. They were known before it was advanced, and the objection controverted has not been raised in the form indicated. We *know* that a thing infinitely larger than the hypothetical gemmule does pass through tissues, but do the gemmules really exist, and do they pass through? Certainly, if they exist, they *may* pass, but, as I have indicated, there are other matters invalidating the hypothesis besides the question of the gemmules traversing the tissues. Pangenetic gemmules might pass everywhere. They might leave the body, collect in the atmosphere and coalesce, and the compound particle formed might easily wriggle itself back again into the organism through the chinks between the cuticular cells. Such gemmules might move anywhere, up and down and in and out through any cell wall. They might pervade solids and fluids and gases. The pangenetic gemmule cannot be seen or tested, neither can its presence or absence be proved in any way. The phenomena adduced by Mr. Darwin in support of his hypothesis can be demonstrated; but the pangenetic gemmules are of the imagination alone, and the analogy between the actual facts and the supposed facts is surely but an analogy of the imagination. The facts alluded to no more support the pangenetic hypothesis than does the demonstration of living germs in the air support the hypothesis of life in the blue sky. It is possible to supply many arguments stronger than those adduced in support of the hypothesis, nay, perhaps, stronger than any Mr. Darwin himself has yet advanced in favour of Pangenesis; but yet other considerations appear to me greatly to preponderate against the acceptance of the doctrine. Mr. Darwin admits that "from presenting so many vulnerable points" the life of his hypothesis "is always in jeopardy;" but is it not this very jeopardy which lends interest and enchantment to many a hypothesis, and sustains it in the estimation of those who delight in conjectural information and scientific speculation?

LIONEL S. BEALE

---

MR. DARWIN, in his letter to NATURE of April the 27th, says: "The fundamental laws of growth, reproduction, inheritance, &c., are so closely similar throughout the whole organic kingdom that the means by which the gemmules (assuming for the moment their existence) are diffused through the body, would probably be the same in all beings, therefore the means can hardly be diffusion through the blood." Now, if in the vegetable kingdom pangenetic gemmules are able freely to be "diffused" from cell to cell by endosmosis, we should expect that in the case of grafts, where certainly such diffusion goes on between the cells of the stock and the scion, a bud borne upon the graft would certainly be affected by the gemmules arising in the root and stem of the stock. Yet we all know that the pips from a pear grafted on a quince stock will not give rise to a hybrid between a pear and a quince, neither will the stone of a peach which has been grafted on a plum stock grow into a tree whose stock bears plums, while the extremities of its branches bear peaches.

A. C. RANYARD

### Noises at Sea off Greytown

IN NATURE, vol. ii. p. 25, Mr. Dennehy gave an interesting account of a peculiar vibration, accompanied by sound, which is perceivable at night on board *all* (?) *iron* steamers which anchor off Greytown, Central America; and in subsequent pages I have read with great interest various speculations as to its origin, which is ascribed (1, the probable solution) to troops of Sciænoids (with reservation) by Mr. Kingsley (p. 46); (2) to musical fish or shells, by Messrs. Evans and Lindsay (pp. 46 and 356); and (3) to gas-escape from vegetable mud and sand, by Mr. Malet (p. 47); whilst Mr. Dennehy himself suggests the possibility of some galvanic agency.

I remarked upon this vibratory phenomenon in a communication published in the *Field* newspaper of October 26th, 1867, signed "Ubique," after having heard it myself when on board the Royal Mail steamer *Danube* (Capt. Reeks) during the nights of the 12th, 13th, 14th, and 15th of May, 1867; the new moon occurring on the 4th of the same month. As my statement serves to confirm Mr. Dennehy's report, I may be forgiven for giving it in full.

After giving an account of the sudden appearance of a huge white shark in the deep sea when a man fell overboard, I proceeded to state as follows:—"On embarking on board the *Danube* steamer, lying at anchor in the roadstead off Greytown on the 12th May, 1867, I was informed that the ship was haunted by most curious noises at night since she had arrived, and that the superstitious black sailors were much frightened at what they thought must be a ghost. The captain and officers could make nothing of it, and it afforded a great matter for discussion. On inquiry I found out that other *iron* ships had been similarly affected. Curiously enough this noise was only heard at night, and at certain hours. Some attributed it to fish, suckers, turtle, &c., others to the change of tide or current; but no satisfactory conclusion could be arrived at. When night came on there was no mistake about the noise; it was quite loud enough to awaken me, and could be heard distinctly all over the ship. It was not dissimilar to the high monotone of an Æolian harp, and the noise was evidently caused by the vibration of the plates of the iron hull, which could be sensibly perceived to vibrate. What caused this peculiar vibration? Not the change of current and tide, because, if so, it would be heard by day. Like everything else that we cannot explain, I suppose we must put it down to electricity, magnetism, &c. If this should meet the eye of any of the officers of the above-mentioned steamer, or others who have noticed this phenomenon, I should be glad to hear whether this effect still continues, or if any satisfactory conclusion has yet been arrived at. I may add that from the hold of the vessel the grunts of the toad-fish could be distinctly heard. I hope that the above notice may lead to some answers from your various correspondents."

This brief notice drew forth a rejoinder from a correspondent (November 23, 1867) who had noticed a somewhat similar sound.

"The singular sound noticed by 'Ubique,' I have also heard without knowing its origin. One moonlight night in 1854, on board a steamer anchored near the Tavoy river (Tenasserim) we were struck by an extraordinary noise which appeared to proceed from the shore about a quarter of a mile off, or from the water in that direction. It was something like the sound of a stocking loom, but shriller, and lasted perhaps five or six seconds, producing a sensible concussion on the ear like the piercing scream of the cicada; and this gave an impression as if the vessel itself were trembling, or reverberating from the sound. One or two Burmans on board said simply, the noise was produced by 'fishes,' but of what kind they did not describe. It was repeated two or three times. I never heard it before or after the occasion referred to, nor have I ever met with any allusion to this singular phenomenon until I perused 'Ubique's' communication in the *Field* of the 26th ult. The steamer in my case, I should add, was a wooden one."

Mr. Evans, in his letter, speaks of the rapid silting up of Greytown harbour this still continues, and the passage over the bar, which is continually shifting, is often a matter of great difficulty, and indeed often so dangerous that the Royal Mail Company will not undertake to allow their own boats to land, and passengers have to land in the local canoes at their own risk. The Nicaraguan Government, however, propose to carry out Mr. Shepherd's plan of diverting the waters of the San Juan river from the Colorado mouth to the Greytown channel, hoping thereby to scour the harbour clear.

Mr. F. J. Evans also refers to the vast amount of animal life, and mentions the quantities of sharks and *alligators* which abound in and about Greytown Harbour. I can fully corroborate this, although I believe that what Mr. Evans terms *alligators* are really *crocodiles* (*Molinia Americana*), I should be glad to have certain information on this point: when not actually visible, their proximity is made evident by a powerful odour of musk. The most notable, however, of the denizens of these waters, besides the turtle, is the Atlantic manatee, which Columbus mistook for a mermaid, and which Agassiz terms the modern representative of the Dinotherium. The Mosquito Indians on the Indian, Rama, and Blewfields rivers are great adepts at harpooning this paradoxical mammal, and its flesh salted is a staple article of food all along these coasts, being not unlike to ship's pork.

Southsea, April 28 S. P. OLIVER

P.S.—When at anchor off Greytown, also in the *Danube* steamer, during the night of February 15, 1867, (moon eleven days old) there was no vibration or noise perceived, but then there was a tremendous swell breaking with high surf on the bar, and the vessel rolling heavily. It would be interesting to overhaul the logs of the Royal Mail Company's vessels which have been at Greytown, in order to discover the periods of these vibrations, but I am afraid that no observations have been recorded in their books.

## Mechanical Equivalence of Heat

YOU will see from the proceedings of the Literary and Philosophical Society at Manchester, that, since the discussion there, Dr. Joule has definitely abandoned the reasonings in his famous paper on the mechanical force of electro-magnetism, steam, and horses. I have now had time to test the facts and experiments of this new theory, and find it, as I hope soon to show in detail, as untenable as his former one. Indeed, I am sure that the mechanical equivalence of heat must soon be generally abandoned as inconsistent with facts. You will see that the April number of the "Review of Popular Science," has definitely pronounced a decision in my favour; and I am sure you will soon be convinced yourself that your own first reviewer of my article in the *Quarterly Journal of Science* was more reasonable than your second. H. HIGHTON

## Aurora by Daylight

AN additional well-authenticated instance of this very rare but indisputable phenomenon, may, perhaps, be thought worthy of insertion.

In the Transactions of the Royal Irish Academy for 1788 (embodied in "Memoirs of Science and the Arts," 1798), is "An Account of an Aurora Borealis seen in full Sunshine, by the Rev. Henry Ussher, D.D.," which opens in the ensuing manner:—

"The following phenomenon being very uncommon, if not entirely new, I think it worth communicating to the Academy, principally with a view to learn whether any other person has observed a similar one at any time:—

"'On Saturday night, May 24, 1788, there was a very bright aurora borealis, the coruscating rays of which united, as usual, in the pole of the dipping needle. I have always observed that an aurora borealis renders the stars remarkably unsteady in the telescope. The next morning, about eleven, finding the stars flutter much, I examined the state of the sky, and saw whitish rays ascending from every part of the horizon, all tending to the pole of the dipping needle, where at their union they formed a small thin and white canopy, similar to the luminous one exhibited by an aurora at night. These rays coruscated or shivered from the horizon to their point of union. These effects were distinctly seen by three different people, and their point of union marked separately by each of them.'"

T. W. WEBB

## The Coronal Rifts

THE enclosed extract of a letter from Captain Tupman, who observed the Eclipse of December last through the finder of Prof. Harkness's telescope at Syracuse, may interest some of your readers—

"It is a singluar feature in all the photographs that the 'rifts' are so wide and distinct. They are actinic rifts. As seen in the telescope simply the corona had no such rifts. I watched it during the whole 105 seconds; such a feature would, of course, have struck me instantly. I actually pointed Prof. Harkness's spectroscope *in* the rifts as being bright parts of the corona!"

A. C. RANYARD

## The Name "Britain"

As "C. L. N. F." has in your last well answered the letter of "A. R. H.," I have now only to reply to Mr. Hyde Clarke's letter, in which he says I should find it difficult in my derivation of "Britannia" and "tin" "to explain on the same basis the conformable names" of the countries and rivers which he mentions, inasmuch as "these names are not explainable in Phœnician, because they were given long before the Phœnicians entered on the stage of history."

His paper read before the Anthropological Institute I have not seen, but as "the learned" Bochart and other authors have considered the name "Britain" to have been derived from the tin which the Phœnicians exported from Cornwall more than 3,000 years ago (Num. xxxi. 22), and as no one will venture to say that "tin" was not then the name of this metal in the most ancient Cornish as well as in the Phœnician language, from which it proceeded, I do not think I can fairly be called upon to go into the "difficult" task suggested by Mr. Clarke.

The original name of our island I have imagined to be *Bretin* ("Tin Mount"), that being at first exclusively the name of the *mount* from which the Cornish *tin* was exported by the Phœnicians, and it is highly probable that the same name was afterwards given by these ancient traders to the entire island, of which the mount was only a part, for it was Britain that gave them nearly all their *tin*, and its most beautiful natural object known to them was St. Michael's *Mount*.

There being other islands close to Britain, the Romans gave the name *Britanniæ* indiscriminately to them all. When they spoke of Britain as dissociated from its contiguous islands, they called it either *Britannia* or *Insula Britannica*, which is synonymous with *νῆσος* Βρεττανικη. This word, Βρεττανικη, used at first adjectively by the Greeks, had in the time of Diodorus Siculus become a substantive, so that he uses it as such when describing the daily insulated port or mount called sometimes *Iktin* (Tin Port), and sometimes *Bretin* (Tin Mount), adjacent to Βρεττανικη, to which *port* or *mount* at low water the tin was carried from the mainland for sale and exportation. The following is the passage:—*εἰς την νησον προκειμενην μεν της* Βρεττανικης *ὀνομαζομενην δε* Ἰκτιν.

Plymouth, May 6 RICHARD EDMONDS

*** We cannot print any more letters on this subject.—ED.

## The Sensation of Colour

PROF. CLERK MAXWELL in his valuable paper on Colour in NATURE (vol. iv. p. 13) commits himself to the opinion that there must be three distinct sets of retinal nerves, one for each of the three primary sensations of colour. It is obvious that demonstrative proof or disproof of this is unattainable: we can only reason analogically. The analogy of the ear is in favour of such an opinion, so far as it goes; for there appears to be proof, or probability almost amounting to proof, that sounds of different pitch are conveyed to the brain by different nerves. But the ear resembles the other organs of sense less than they resemble each other; and there is surely no reason for thinking that there are distinct nerves of smell for every distinct kind of smell, or distinct nerves of taste for every distinct kind of taste. Nor I believe is there the slightest proof of nerves for the sensation of heat distinct from those of touch.

JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, May 8

P.S.—I am not now at home. I intend to write in reply to Mr. Laughton's important letter on the Prevalence of West Winds, when I am at home and have the file of NATURE and other authorities to refer to.

## The Cave-Lion in the Peat of Holderness

WHILST engaged in the task of rearranging this Museum, I have been impressed with the value of two specimens in the Palæontological collection.

One is labelled "No. 7, *Felis*—metatarsal inner (Right side)," the other one is "*Felis* — 14. Femur Right side." There is no record in the catalogue by whom they were presented, nor of any of the circumstances of their *gisement*. The specimens, in fact, have no history whatever, and I can only say that I found them in close juxtaposition with a large series of red-deer bones from Holderness, with which they perfectly agree in their mineralogical condition. I have no doubt that they are *bonâ fide* from the Holderness Peat.

Their identification as bones of *F. leo* (variety *spelæa*) is also certain.

Hull Royal Institution C. CARTER BLAKE

### Eozoön Canadense

SINCE reading some of the communications on the Eozoön, which have appeared from time to time in NATURE, I have felt constrained briefly to give the results of my examination of the "Eozoic" limestone in Eastern Massachusetts. I am the more disposed to do this, hoping that a new line of investigation will be suggested to observers in other localities.

Last autumn I visited for the first time the quarries of "Eozoön" limestone in Chelmsford, under the guidance of my friend Mr. Burbank, of Lowell, Massachusetts, who has furnished many microscopists with specimens for sections. Having been long engaged in the study of the foliated series of rocks, and having years ago discovered indubitable evidence that portions of the included limestone are of vaporous origin, I was prepared to recognise the same feature in the Chelmsford "Eozoic" rock. I was accordingly not surprised on examination to find, what the advocates of the organic nature of the Eozoön seem never to have suspected, that the limestone in question is not a "sedimentary rock;" that it occupies, or rather occupied, (for it has been for the most part removed) pockets or oven-shaped cavities, which were once plainly overarched by gneiss; that it is foliated, there being a regular succession of leaf-like layers from the walls toward the centres of the cavities, witness to which is borne by a like succession of different minerals; that in some places it ramifies the surrounding rock in a vein-like way, while in others it exactly conforms with the most abrupt irregularities of surface; that in one locality, which I have repeatedly examined, it conforms with the uneven portions of a mass of syenite, with which it is so associated as to reveal its more recent origin; and that, therefore, it is not of nummulitic derivation, but was deposited in a vein-like form, the materials having been probably forced up into the cavities from below while in a vaporous state.

Such, in few words, is the result of my examination—a result which tends to show that the "Eozoön" of Eastern Massachusets is not organic, and that thus it belongs to the department of Mineralogy, and not to that of Palæontology. Waving additional particulars for the present, I may simply add that I propose in due time to give a detailed exposition of the relations of this famous "Eozoic" rock.

Cambridge, Mass., April 15 JOHN B. PERRY

## *THICKNESS OF THE EARTH'S CRUST*

I SEE that at p. 296 of your journal for February last, which has recently reached Calcutta, you print a lecture by Mr. David Forbes "On the Nature of the Earth's Interior," in which reference is made to the Mr. W. Hopkins's method of determining whether the thickness of the earth's crust is great or small when compared with the whole radius, and to M. Delaunay's objection to it.

The lecturer refers to me as having approved of Mr. Hopkins's method, which I always have done and do still, and then makes the following apparently crushing remarks to annihilate Mr. Hopkins and all who approve of his method and of the result to which it leads, viz., that the crust is very thick. He says:—"M. Delaunay, an authority equally eminent as a mathematician and an astronomer, was induced to undertake the reconsideration of the problem; a labour (!) which has resulted in altogether reversing the above decision and demonstrating the complete fallacy of the premises upon which so much elaborate reasoning had been expended."

As the lecturer had condescended to mention my name in connection with the subject, I wonder why he has taken no notice of my letter in reply to M. Delaunay, which was printed in your journal for July 1870, six months before the lecture was delivered, and which also appeared about the same time in the *Philosophical Magazine* and the *Geological Magazine*. In this I showed that M. Delaunay had evidently misconceived the problem, and that Mr. Hopkins's method is altogether unaffected by his remarks.

So much has been said about profound mathematical calculations in connection with Mr. Hopkins's investigation, that I conceive many have shrunk from attempting to understand the question at issue, from a feeling that they would not be able to comprehend it were they to attempt to do so. But this is quite a mistake. Anyone with an ordinary degree of knowledge of popular astronomy and of mechanical action is quite competent to form a good opinion on the point in dispute. What Mr. Hopkins did may be divided into two parts. He first conceived an idea, which was to be the basis of his calculation; and then he made his calculation. It is the *calculation* that calls for the "profound mathematics." But it is not this that is the matter of dispute. It is the *idea*, on which the calculation is based, which M. Delaunay calls in question.

I think I can make the matter sufficiently plain to your readers to enable them to form their own opinion.

Everyone having a knowledge of popular astronomy is aware that the earth revolves round an axis, which is fixed in the earth's solid crust, but shifts very slowly in space, producing what has been known ever since the days of Hipparchus by the name Precession. On this fact as his ground-work Mr. Hopkins reasoned as follows; and so got to his *idea*, which formed the basis of his calculation. Suppose the earth has a solid crust, the interior being filled up with fluid. If the axis remained steady in space and the crust revolved round it uniformly, no doubt, although the crust and fluid may have moved differently at one time, yet in the lapse of ages friction and viscosity in the fluid would cause the fluid at last to revolve with the crust just as if the whole were one solid mass. This being the case, suppose a slight horizontal push is given to the two poles, in opposite directions, so as slightly to shift the axis in space; what would happen? The revolving crust, by this new and additional motion, would slip over the surface of the revolving fluid, through a small space proportionate to the push given to the poles. The fluid could not possibly acquire in an instant this new motion, however small it might be, because the fluid is not rigidly connected with the crust. Suppose a second, and a third, and a succession of slight horizontal pushes to be given to the poles in a continually altering direction, the effect will be that the revolving crust will be continually slipping over the revolving fluid which has not time to acquire these new motions given instantaneously to the solid crust. These successive slight pushes given to the poles, and so to the solid crust, represent the unceasing action upon the crust of the force which causes the motion of precession in the earth's axis, and arises from the attraction of the sun and moon on the protuberant parts of the earth about the equator.

Mr. Hopkins having reasoned thus far, went a step farther, and so came to his fundamental idea. He saw that the thinner the crust the smaller would be the mass which the disturbing force producing precession would have to move, and therefore the greater would be the motion caused, that is, the precession. Here, then, he discerned a connecting link between the amount of precession of the earth's axis and the thickness of the earth's crust. This was the *idea* I have alluded to.

Starting from this idea he entered upon a profound calculation and obtained a formula, which gives the thickness in terms of the amount of precession. This amount is a matter of observation; and the thickness can therefore be deduced by the formula from the observed precession. It is, as I have already said, not this calculation which is called in question by M. Delaunay, but the fundamental idea.

M. Delaunay says the fluid will have precisely the same motion as the crust; and that, because the new motion of the crust is so slow. But it is clear that its slowness has nothing to do with the matter. The fact is that the fluid and the crust not being connected together by any solid connection, no motion, whether small (*i.e.* slow) or not, can be suddenly communicated from the crust to the fluid mass. If the crust moved uniformly, as I have already said, and around a steady axis, the fluid might, after a lapse of ages, by friction and viscosity, acquire the motion of the crust. But if the crust is continually shifting from this steady position, however slowly, the fluid cannot suddenly acquire the new motion, and the crust slips over it; and the thicker or thinner the crust, the greater or less is the solid mass to be shifted, and the less or the greater the precession produced. If the internal mass obeys at once the shifting motions of the crust, that mass cannot be fluid, but must be solid, and have a solid connection with the crust; in which case the whole question is yielded.

Mr. David Forbes speaks of the "labour" M. Delaunay has gone through in giving vent to his opinion. If the thing *done* is to be measured at all by the thing *said*, his labour must have been infinite; for what he has said is an impossibility. He has evidently altogether mistaken the problem. Mr. Hopkins's method stands unimpaired by his criticisms. Indeed Mr. Hopkins was not a man to advance a theory which could be apparently set aside by such slender means. JOHN H. PRATT

## A THEORY OF A NERVOUS ATMOSPHERE

UNDER the above title, Dr. Richardson, in a lecture published in the *Medical Times and Gazette* of last week, suggests a new theory in respect to nervous function. We propose in a few sentences to state simply the meaning of this theory.

The earlier physiological writers on the functions of the nervous system were under the impression that the brain, spinal cord, and other nervous centres acted after the manner of glands, and produced or secreted, as they said, a liquid. They called this assumed secreted liquid the nervous fluid, and they considered that it charges the nervous system, some also supposing that it makes even a circulation through tubular nervous channels or canals. It was not an uncommon notion that the nervous fluid conveys nourishment to the organs of the body; but the most common, and indeed generally accepted, hypothesis was, that it acts as a means of communication between all parts of the nervous system, and is the communicating medium of the impressions and motions derived from the outer world. Attempts were made to measure the rate of motion through this fluid, how long it took to convey an impression by it from brain to muscle.

The discovery of frictional electricity, the special discovery of the electric shock by Cuneus, of Leyden, in 1746, and the after discovery by Galvani of the inductive action of the prime conductor of the electrical machine on the muscles of frogs, threw quickly into the shade the speculations of the earlier neuro-physiologists. It was assumed at once that there exists a true animal electricity, that there is production of electrical action within the bodies of all living animals, that there is conduction, and, in short, every mechanism and method for the carrying on, if we may so say, of electrical life. The discovery of the electrical organs of the torpedo, the dissection of the animal, the descriptions of its nerves by John Hunter, and the experiments made by a very earnest investigator, Mr. Walsh, aided greatly to establish the hypothesis which Galvani and his followers advanced, and which Volta, with the whole force of his experimental argument, failed to demolish.

Of late years the old hypothesis of the nervous fluid has been lost altogether, while the electrical hypothesis infinitely varied from its original and simple character, and infinitely varying with every new step of electrical discovery, has in a certain sense retained its popular hold. It is true the hypothesis has rested on so much laboured obscurity that nobody has succeeded in making out of it a demonstration like the demonstration of the circulation of the blood, and no one has made it so simple that every scholar can read it when it is written, and every medical practitioner practise by it and act upon it as a known principle. It is true that since the time when Volta gave his undeniable proofs against the truth of the first inferences of Galvani, the best and most thoughtful philosophers have felt doubts as to the electrical character of living action, and have looked on Galvani's construction of life as a beautiful crumbling ruin rather than as a temple befitting the worship of the gods of nature; and, lastly, it is true that whoever takes up to read the tomes or volumes of the most eminent writers on the subject of animal electricity is prone to lay them down again as he would the handles of a battery that master his will without appealing to his reason. All this is quite true; but still the electrical hypothesis has, as we before said, held its place; no attempt has been made to replace it; it has maintained around it a spell of fascination.

The theory that has been suggested by Dr. Richardson is in some sense a return to the old view respecting nervous action, and in some sense also is an extension to the nervous system of the physical idea of communication of motion by molecular disturbance. In a few words, the author of the theory supposes that the blood, as it circulates in the vessels on which the structures of the body are constructed, yields a diffusible vapour or atmosphere which charges the nervous system surrounding the molecules of nervous matter and pervading the whole nervous organism. He attempts to formulate the physical qualities of this vapour; it is probably an organic vapour containing carbon, hydrogen, and nitrogen; it is insoluble in blood, it is condensible by cold, diffusible by heat; it is retained after death longer in cold-blooded animals than in warm-blooded, and longer in warm-blooded animals that have died in cold than in those that have died in heat; it possesses conducting power, and as a physical substance is susceptible of variation of pressure; it connects the nervous system in all its parts together; it is the medium of communication during life between the outer and the inner existence; by the organs of the senses the impressions and motions derived from the outer world are vibrated into or through the nervous atmosphere to the brain; in the living and healthy animal the nervous ether, if we may so designate it, is in correct tension, in the feeble it is diminished, in the dead it is absent or inactive; in the waking times of the living it is most active; it may be used up faster than it is produced during exercise; it is renewed during sleep.

On the supposition of the existence of a nervous ether or atmosphere as thus suggested, the author of the theory accounts for various phenomena connected with the partial or complete destruction of conscious, and even of organic life. The action of narcotic vapours is an illustration in point. It is assumed that these vapours—vapours of chloroform or alcohol, for example—taken into the blood and carried to the nervous system, become diffused through the nervous atmosphere, and by their presence interfere with its physical qualities and thus obscure function. "The foreign vapour that has been introduced benumbs; in other words, it interferes with the physical conduction of impressions through what should be the cloudless atmosphere between the outer and the inner existence."

Carrying out in a different way the same line of thought, the author of the theory to which we have specially called attention, accounts for the diffusion of some poisons through the body and for that rapid action of certain poisonous substances which so many experimenters have endeavoured, but not successfully, to explain; further, he suggests that in some instances poisonous products of decomposition generated within the body itself, in disease, may be diffused through the nervous ether, and that the sudden collapse of nervous function, which is often seen in acute disease, may be due to this cause. Finally, there may be conditions of disease in which there is unnatural tension of the nervous atmosphere, followed by disturbance of muscular motion, convulsion, or cerebral pressure, leading to apoplectic insensibili y.

We have sketched out thus briefly the leading points of this theory of a nervous atmosphere or ether produced, during life, within and by the living organism, as a theory calculated to give rise to much discussion and device of new experiment.

## *ASTRONOMICAL OBSERVATION*

THE statistics of modern astronomical observation would, we suspect, be very curious, if it were possible to get at them. A report showing the gradual increase in the number of telescopes manufactured during the last fifty years would be very interesting; and so would be a table comprising at once the advance in their dimensions and the diminution in their cost. The result would, we believe, be such as at first sight to cause great surprise among those unacquainted with the subject, or those whose recollection does not go back to days when five nches was as extraordinary an aperture for an object-glass, as double that size is now. But the value of these, as of other tabular statistics, would suffer material abatement, if they were applied to establish any other conclusions than those to which they directly lead. For instance they would probably be fallacious, if considered as inferring a proportionate increase in the number of important observations. In order to bring out such a result, we require, so to speak, another factor, and a very essential one—a corresponding increase in the number of competent observers. This, we fear, may not have been commensurate with the advance of optical means: at least, except upon the supposition of some such deficiency, it is difficult to understand what becomes of the multitude of really good object-glasses which are annually produced, not only in England, but in Germany and America. A large proportion of these, we are led to think, must be purchased to be looked at, and not looked through: or handled as mere toys for the amusement of people who do not know what to do with themselves in an idle evening. This was not so much the case in the early days of telescope-manufacture. The greatest master of figuring specula in his own time was also the greatest proficient in using them: it is needless to add the name of Sir William Herschel. And so the finest reflectors in Germany were placed at the same period in the hands of the leader of all accurate selenographical investigation, J. H. Schröter. These were "the right men in the right place." Even then, it may be said, many noble reflectors went, no one knows where, the greater part of them long before this time useless from tarnish, or, still more mortifying to think upon, ruined by unskilful repolishing. Still, admitting this, the disappearance of powerful instruments does not seem to have been so remarkable in those days as it is now, and the quantity of really valuable observations appears to have been greater in the end of the last and the early part of the present century, in proportion to the means of observing.

This is not a very encouraging view of the present state of this branch of astronomy. But, if well founded, as we believe it to be, we might expect that there would be some assignable reasons for it; and, in fact, several are sufficiently obvious. One certainly is, that the process of discovery is not, generally speaking, renewable. What has been once detected is usually placed on record, in bar of all future claims. So it has been in the science of music; a man might arise among us with the fervid genius of Handel, but he could not write the Hallelujah Chorus over again; and doubtless the spirit of Mendelssohn must have been cramped by the impossibility of employing many of the noblest and most impressive subjects which had been anticipated by his predecessors. And so it has been in the researches of geography. The enterprising explorer has now to go much farther in pursuit of "fresh woods and pastures new," and every Alpine season is so rapidly narrowing the number of summits untrodden by the foot of man, that the excitement of a first ascent will soon have to be sought in remoter regions. Thus in astronomy, though it cannot be said that there are no worlds left to conquer, yet all the larger and more conspicuous features of the heavenly bodies have been long ago so fully noted and recorded, that what remains for exploration is chiefly of that delicate character which, without being the less interesting from its minuteness, is less accessible, for that reason, to the possessors of ordinary instruments. And on this account many a student who might well have risen from the ranks in the earlier days of scientific campaigning, is now compelled to remain in comparative obscurity—a mere spectator, when he might well have taken his place among the discoverers of fifty years ago.

Another reason why tools have multiplied without a corresponding increase of good work, may be this, that looking upon the observer and his instrument as a complex apparatus, the improvement of the intelligent has not kept pace with that of the material part. In fact, it is impossible that it should. The eye is but what it was when David learned humility from considering God's heavens, the work of His fingers, the moon and the stars which He hath ordained; the intellect, though more developed and cultivated, is not more strong and piercing than it was in the days of Hipparchus; man does much more with his brain, but he has no more brain to do it with, than his uncivilised ancestors; and observers may, and will be, collectively multiplied without being individually improved. Every man that has eyes does not know how to use them; or, not failing in this respect, he may lack other requisites: he may not know what to look for, or where to find it; or he may be deficient in his handling of the faithful pencil or the expressive pen. And so it comes to pass that the capacities of instruments may be much in advance of the abilities of those who use them.

Besides all this, there is a physical obstacle of an entirely different character, which must not be forgotten; the unimprovable constitution of our own atmosphere. This will ever be a sore subject for the zealous observer, especially among ourselves. If even Secchi finds fault with the glorious Roman heavens, what have we not to regret in our own murky, and fuzzy, and restless skies? Who that has read the most graphic as well as instructive writings of Sir J. Herschel is likely to forget his complaints of "twitching, twirling, wrinkling, and horrible moulding?" and who that has had much actual experience of observatory work will not endorse all this with a very lively fellow-feeling? The nights may easily be numbered, during a long season, in which the defects of the atmosphere do not overlie those of the instrument, and when the observer has not rather to wish that he could see all that his telescope could show him, than to long for greater power or light, to be expended in making atmospheric disturbances yet more conspicuous and prejudicial. The only way to obviate this grievous hindrance is to get above it; and no man has yet done this except Professor Piazzi Smyth in his most successful "Experiment"; it was said, indeed, that the French observers were about to follow his example, and to plant their instruments on the Pic du Midi de Bigorre; but we have never heard whether the idea has been carried into execution. And, however striking may be the advantage of such a plan, it must ever be confined to a favoured few.

We have dwelt at some length on a view of the present state of astronomical observation, which, though rather unfavourable, we believe to be substantially true. But it is not to be inferred that this is its sole aspect. There are, as usual, two sides to the shield; and much is to be said that is of an opposite tendency. If, for instance, we have asserted that for some time past observers have not multiplied in proportion to the means of observation, this is but a relative statement; the absolute fact is that at no former period has there been so numerous, or so zealous, or on the whole so competent a band of astronomical students. And of this we have a very pleasing evidence in the recent formation of an astronomical society expressly devoted to physical observation, to which we cordially wish success. If again it is probable that not many of the great discoveries are left within the reach of ordinary instruments, it should not be forgotten that many telescopes of very superior character are now housed in private observatories; and that for them investigations are still reserved, whose delicacy is no bar to their importance, and which may be undertaken with a hope of success no longer chargeable with extravagance. Great cabinets may be unlocked by little keys. Minute researches may give the clue to discoveries of the broadest extent and deepest interest. The changes of the lunar surface, the internal motion of starry clusters; the parallax and fixity of nebulæ; the planetary attendants on the brighter stars, these are mere specimens of the magnificent arcana, whose solution may not be denied to human energy and perseverance. We may remember, too, that if the telescope and the micrometer should be found unequal to the task, we have yet a new and most powerful method of investigation, the results of which are equally important and surprising—spectrum-analysis. The revelations of this beautiful invention may be said to be only beginning, and no man can foresee their end. What has already been done would have appeared as improbable as the reveries of Kepler, had it been predicted fifty years ago; and who shall say what may be the result of fifty years more of patient and energetic application? And what might not Kepler have said and done, had such an instrument of research been placed in his hands? We may suppose how his fervid imagination would have exulted in the prospects, and with what confident joy he would have repeated the memorable words which characterise one of his lofty aspirations, "Plus ultra est."

## *NOTES*

IT is stated that the Astronomer Royal is to have the honour of a K.C.B. conferred upon him in recognition of his services in respect to the International Exhibition. We trust this rumour is not strictly correct; for unless it is to be generally understood that services are to be rewarded in the inverse ratio of their value, it is simply grotesque and unbecoming of the Government to ignore all the Astronomer Royal's services to Science, and all his unpaid services to the State in connection with subjects more important to the nation than all the exhibitions which ever have been or ever will be.

IN a Congregation to be held at Oxford on Tuesday, May 23, three forms of statute will be promulgated on the subject of the Second or Final Examination. It is proposed to have one Pass School of a mixed character and six Honour Schools. In the Pass School the examination is to be divided into three groups, as follows:—Group A.—1. One Latin and one Greek author, one at least of which shall be a philosopher or an historian. 2. The outline of Greek and Roman history, with a special period of one or the other, and English composition. Group B.—1. Either English History and a period or subject of English Literature, or a period of Modern European History with Political and Descriptive Geography, together (in each case) with English composition. 2. A Modern Language, either French or German, including composition in the language and a period of its literature. 3. The Elements of Political Economy. 4. A branch of Legal study. Group C.—1. The Elements of Geometry, including Geometrical Trigonometry. 2. The Elements of Mechanics, solid and fluid, treated mathematically. 3. The Elements of Chymistry, with an elementary practical examination. 4. The Elements of Physics, not necessarily treated mathematically. Every candidate is to select two subjects from one of these groups, and one of another of them, and must pass in all three; but may present himself for each of the three subjects in separate Terms. The six Honour Schools are to be:—1, Literæ Humaniores; 2, Mathematics; 3, Natural Science; 4, Jurisprudence; 5, Modern History; and 6, Theology. The examination in the Honour School of Literæ Humaniores is to include Philology, Ancient History, and Philosophy:—1, In Philology, the Greek and Latin languages; 2, in Ancient History, the histories of ancient Greece and Rome; 3, in Philosophy, Logic, the History of Philosophy, and the outlines of Moral and Political Philosophy, each candidate being required to offer at the least two treatises by ancient authors. Candidates shall be permitted to offer in addition, as special subjects, one or more authors or portions of authors, or departments, or periods falling within or usually studied in connection with any of the stated subjects of this school. For the purpose of this provision philology shall be taken to include textual criticism, the minute critical study of authors or portions of authors, the history of ancient literature, and comparative philology as illustrating the Greek and Latin languages, and ancient history shall be taken to include classical archæology and art, and the law of Greece and Rome.

IT is with very great pleasure that we print the following intelligence of the safety of Dr. Livingstone:—Despatches were received last week at the Foreign Office from Dr. Kirk, the Acting British Consul at Zanzibar, containing information of the safety of Dr. Livingstone in October last. The doctor was then at Manakoso, helpless, without means, and with few followers. Dr. Kirk had sent him supplies to meet his immediate necessities, which, it was hoped, would shortly reach him.

AT the annual meeting of Convocation of the University of London, held on Tuesday last, Dr. E. A. Parkes was chosen by a very large majority at the head of the list of three graduates, to be submited to Her Majesty for selection therefrom of a member of the Senate in the place of the late Dr. W. A. Miller. At the same meeting a resolution proposed by Dr. Francis T. Bond, that it is expedient to retain Greek in the Matriculation Examination only as an optional subject, was rejected by a small majority.

THE example set by Clifton College in the formation of a botanic garden in connection with the Natural History Society is, we understand, about to be followed at Marlborough, a plot of ground having been granted by the authorities for that purpose. Such a garden will be a valuable adjunct to the herbarium, if such plants are selected as are typical of the principal natural orders, especially of those which are sparingly represented in the British flora.

THE following appointments have been made in consequence of the death of Prof. Miquel:—Dr. N. W. P. Rauwenhoff to be Professor of Botany and Director of the Botanic Garden at Utrecht. Dr. W. F. R. Suringar to be Professor of Botany and Director of the Botanic Garden at Leyden.

THE *Botanische Zeitung* records the death on March 23 of Dr. Schultz-Schultzenstein, of Berlin, well known as a copious writer on vegetable morphology and physiology.

MR. F. M. BALFOUR, late of Harrow, and Mr. P. H. Carpenter, of the Royal School of Mines and University College, London, have been elected to foundation Scholarships at Trinity College, Cambridge, for proficiency in Natural Science.

WE regret to have to record the death of Mr. James Yates, at his residence at Highgate, on the 7th inst. He was a prominent member of the Royal and Geological Societies, and of late years had been best known as one of the most active advocates of the introduction of the Metric System of Weights and Measures.

THE following gentlemen have been placed in the first class of the annual examination in Natural Sciences in St. John's College, Cambridge (order alphabetical) : —Edmunds, Garrod, Read, Sollas, Yule.

THE annual *conversazione* of the members of the Society of Arts will be held on Thursday, June 1, at the South Kensington Museum.

M. ELISEE RECLUS, a very active contributor to the *Revue des Deux Mondes*, has been appointed director of the National Library in Paris, to fill the room of M. Taschereau, who has left for Versailles.

PROF. WYVILLE THOMSON delivered, on the 2nd inst., his inaugural lecture to the students of the Natural History class in the University of Edinburgh. In the course of his observations he paid a glowing tribute to the services of his predecessor, Dr. Allman, whose valuable researches in zoology will continue to be prosecuted in spite of his retirement from the chair.

WE regret to learn from *Harper's Weekly* that at the great fire which recently destroyed the printing office of Weed, Parsons, and Co. in Albany, the edition printed of the Twenty-fourth Report of the New York State Cabinet of Natural History was entirely destroyed. Fortunately a nearly complete copy of the revised proof was saved ; so that no serious difficulty will be experienced beyond considerable delay, although the loss to the State in the destruction of fifteen thousand impressions of plates, &c., will be considerable.

THE continuation of the exhaustive work of Bronn on the classes and orders of the animal kingdom contains an elaborate memoir upon the anatomy of birds, and several numbers are devoted to the peculiarities of the muscular structure alone.

AT the meeting of the Boston Society of Natural History for March 1, the principal communication was one by Mr. George Sceva, in which attention was called to the fact of the shortness of the upper jaws in the skulls of the Hindoos, and the frequent absence of the third molar. This generalisation was based upon the examination of a number of crania ; and it was found that about fifteen per cent. of the whole exhibit this peculiarity, while in an extensive series of skulls of European races only about one per cent. showed the same feature.

AT the annual meeting of the Chicago Academy of Sciences, held on April 11, various communications upon a variety of subjects of interest were presented. The most important paper read was one by Colonel Foster, upon the subject of Artesian Wells, in which an account was given of the principal borings that have been attempted in the West, with a statement of their geological relationships, and the depth to which they were carried.

THE Rugby School Natural History Society has just published its Fourth Report for 1870. Rugby having to so great an extent taken the lead among our public schools in its cultivation of Natural Science, we looked for this Report with special interest, and have not been disappointed in its value. There is an interesting paper by the President, the Rev. F. E. Kitchener, on the Times of Flowering of Plants, containing just that record of facts and minute observations which it is one of the special functions of local natural history societies to collect. It is illustrated by two plates, in which are delineated curves representing the average forwardness of flowering in the spring and early summer months of 1867, 68, 69, and 70, contrasted with other curves representing the rainfall and temperature. Other illustrated papers are by the Rev. T. N. Hutchinson on Sun-spots, and Mr. C. H. Hinton on the Mechanism of a Crane's Leg. We learn that the society now possesses a museum of its own, and has just acquired cases for its botanical and entomological collections. We are glad to see that the officers, in their report, lay great stress on the importance of completing the local collections.

IN the Proceedings of the Cotteswold Naturalists' Field Club for 1870, the President, Sir W. V. Guise, Bart., calls attention, in his Annual Address, to the unusual interest and importance of two papers which occupy nearly the whole of the volume—The Gravels of the Severn, Avon, and Evenlode, and their extension over the Cotteswold Hills, by Mr. W. C. Lucy ; and On the Correlation of the Jurassic Rocks in the department of the Côte-d'Or, France, with the Oolitic formations in the counties of Gloucester and Wilts, by Dr. Thomas Wright. The terms in which these papers are referred to by the president are thoroughly well deserved, and the Club is doing great service to science in their publication. Mr. Lucy's paper is the result of four years' labour, and is copiously illustrated by numerous sections, and a large coloured map showing the surface geology of the country between Evesham, Chipping Norton, Gloucester, and Cirencester. The work is most creditable to the club, and renders this volume of its Transactions indispensable to anyone studying the geology of the western counties.

THE Proceedings and Transactions of the Nova Scotian Institute of Natural Science for 1869-70 lies on our table, and we may take this opportunity of acknowledging the great service rendered by this society in the elucidation of the natural history o- our American colonies. Among the papers in the present number we may mention especially the continuance of Dr. Bernard Gilpin's series on the Mammalia of Nova Scotia, a monograph by Dr. Lawson of the Ranunculaceæ of Canada and adjacent parts of British America : a paper by the President, Mr. J. M. Jones, on the Laridæ of the Nova Scotian coast ; and a record of Meteorological Observations for 1869, by Mr. Henry Poole.

THE Botanical Exchange Club has just issued its Report for the current year, signed by its indefatigable curator Dr. J. Boswell-Syme. It is chiefly occupied by observations on certain critical sub-species or varieties gathered by the members, no absolutely distinct indigenous species having been added to the British flora during the year. We are glad to see a considerable increase in the number of members of this useful society.

WE have received the Report of Observations made by the members of the Observing Astronomical Society for 1869-70. A considerable proportion of these observations has already been reported in our columns. In addition, the Report includes Hints and Suggestions on the Observation of Lunar Objects by Mr. W. R. Birt, and three drawings of the Bands of Jupiter on Oct. 6, and Nov. 1 and 24, 1869. We are glad to see that the number of members has increased to fifty, and congratulate the society on the good work it is doing.

IN a recent number of the "Proceedings of the Asiatic Society of Bengal," we have a report of the Address of the President, the Hon. Mr. Justice Phear, a considerable portion of which is devoted to a statement of the importance of a systematic series of barometrical observations in India. Mr. Phear points out that in India we possess almost unrivalled opportunities for examining and analysing the atmospheric column in all its parts, and that India proper, the Bay of Bengal and Burma, constitute a region which, for the purposes of one branch at least of meteorological science, demands to be taken and treated as a whole. The actual state of the case, on the other hand, is that for administrative purposes, British India is divided into eight principal districts or provinces, viz., Bengal, Madras, Bombay, N.W. Provinces, Oude, Panjab, Central Provinces, and Burma; and in each of these, except Burma, is a separate local system of observation, with its own independent head, and very little communication with one another.

ON the 2nd May, two days before the full moon, a complete lunar halo was observed at Clifton by Mr. George F. Burder, and described fully in the *Times* of the 4th. Mr. Burder saw the two halos, the large one and the small one, the larger being very difficult to be seen. A paraselenic circle, having the zenith for its centre, was also observed, and mock moons, or *paraselenes*, four in number, were seen at the intersection of the halo with the paraselenic circle. This appearance, as usual, was followed by very bad weather. It is produced, as demonstrated by the French natural philosophers of the eighteenth century, by floating particles of ice; and the light from the moon being considerable, the phenomenon was observed in all its glory.

MR. T. LOGIN's reports on the experimental cultivation of cotton at Camp Bahalgurh in the Valley of the Jumna, are exceedingly satisfactory. Although the crops were damaged by floods and by late frosts, the yield of clean cotton has been at the rate of 307½ lbs. per acre, or from four to five times the average yield in India. Mr. Login attributes this result in great measure to his practice of irrigating the fields in the afternoon or night, rather than in the mid-day, believing that the combined action of light and heat on stagnant water makes it under almost all circumstances injurious to plants.

OF the many fresh-water fish characteristic of the continent of North America, comparatively few, with the exception of members of the salmon and trout family, are of sufficient economical value to make it expedient to introduce them into regions where, they do not naturally occur. This transfer has been made to a very disastrous extent in the case of the pike (*Esox*), which although multiplying rapidly, is at the same time the determined foe of all other kinds of fish, and soon almost exterminates them from the waters which it inhabits. For this reason, some States have passed laws prohibiting, under severe penalties, except by direct permission of the Commissioners of the Fisheries, any transfer of the species in question to new localities. There is, however, one fish that is of great value, and which can be introduced without as much doubt of the propriety of the act as exists in regard to the pike. We refer to the black bass (*Grystes salmoides*). This inhabits, in one variety or another, the basin of the great lakes of the Mississippi Valley, and the upper waters of the streams of the south Atlantic coast as far north as the James River. Within a few years it has been transferred with success to streams previously uninhabited by it—to the Potomac, for one, where it is now extremely abundant. During the past summer some public-spirited gentlemen of Philadelphia collected among themselves a fund to stock the Delaware with this noble fish, and obtained about seven hundred, principally in the vicinity of Harper's Ferry. These were carried alive in large tanks to the Delaware, and deposited in that stream at Easton, about two hundred of the number dying by the way. The same party of gentlemen propose to use a surplus fund in their hands in experimenting upon the restocking of the river with shad and salmon.

THE white sugarcane of Cuba has been tried in Columbia and found more productive than the local variety called Cinta.

## REPORT ON THE DESERT OF THE TIH*

THE following report has been sent to the Vice-Chancellor of Cambridge by Mr. C. F. Tyrwhitt Drake, who received a grant from the University for the purpose of investigating the natural history of the Tîh. He spent several months in the district, accompanied by Mr. E. H. Palmer (late of the Sinai Survey), who was travelling on behalf of the Palestine Exploration Fund:—

I have now the honour to lay before you a report of my work during last winter in the "Badiet et Tîh," or Wilderness of the Wandering. As this desert had been only partially, and even then superficially examined, I shall give, firstly, a short account of the route we took and of the general physical features of the country; and, secondly, the various traditions of beasts and birds which are current amongst the Arabs. Many of these are curious, from their similarity to Western tales; and others, though seemingly foolish in themselves, are not without interest, as illustrating the beliefs and folk-lore of the Bedawín. These stories are not so numerous as I found them to be in former journeys amongst Arabs inhabiting more fertile tracts, for the Desert of the Tîh is in truth "a great and terrible wilderness." The last winter, too, was one of unusual drought even in those parched regions, and the scattered tribes of Arabs who live there experienced great difficulty in finding pasture for the herds of camels and goats which exist in considerable numbers in some districts.

The supply of water is very scanty and variable, as springs are extremely rare, and most of the water is obtained from "Themail," or pits dug in the gravelly beds of wadies, and similar situations into which the water filtrates. The water thus obtained is very bad, being impregnated either with mineral salts or lime, to say nothing of the quantity of earthy and animal matter held in suspension by its being constantly stirred up for the daily use of the Arabs and their flocks, who naturally collect in the neighbourhood of any place where water is to be had. This want of water was the greatest drawback to the satisfactory exploration of the country: want of food may be contended with, obstructive Bedawín may be quieted, and trackless mountains crossed, but the absence of water renders a country impracticable, especially to those who travel as lightly laden as we did, dispensing with the usual suite of dragoman and servants. Picturesque and desirable as a large retinue and guard of wild Arabs may appear to some persons, had we indulged in these impedimenta, I feel convinced that we should never have got through the country by any but the ordinary route. In these districts fertility is slowly but steadily being driven northwards, for various traces of cultivation and dwellings show that the rainfall must formerly have been plentiful and regular, for surely as tillage and the consequent vegetation decreases, so will the rain-supply diminish till the land has become an irreclaimable waste.

The manner in which gardens may be made and will afterwards sustain themselves, is well shown in those which still flourish at Sinai, notwithstanding the neglect of the present degraded inmates of the convent.

Even in those parts of the Tîh near El Aujeh and Wady el Abyadh which, from internal evidence, must at one time, and that within our era, have supported a large settled population, so desolate is the general aspect, that, to a casual observer, the country would seem to be and always to have been an utter waste. That they were so always is, however, at once negatived by the existence of several ruined cities surrounded by the remains of extensive gardens and vineyards; of these, the walls alone remain to tell their tale. The vineyards are clearly to be traced on the low hills and rising grounds by the regular heaps and "swathes" of black flints, with which the chief part of the district is covered, and which still retain the name of "Teleilat el 'Aneb" or grape-mounds. These facts are of great importance as showing that the objections to fixing certain localities—mentioned in Scripture as abounding in pasturage—in what is now completely desert, may be set aside as worthless. I consider too, that the southern limit of the Promised Land, at the time of the Israelitish invasion, must be placed as far south as Wady El Abyadh. This would remove many difficulties hitherto met with in the satisfactory identification of Kadesh. Though I have not space to enter fully into the question here, I may say that there is strong evidence in favour of fixing that much-disputed locality at Ain Gadis (first dis-

* A map to illustrate this paper is printed in the "Quarterly Journal o the Palestine Exploration Fund" for January.

covered by Mr. Rowlands, though he seems to confuse it with Ain El Gudeirat). Many facts support this supposition, for instance, the suitability as a strategic position for a camp of long duration. There is abundance of water there even at the present day, and springs are found at Ain Muweilah to the north and Biyar Maayin to the south. The probability is great that a large host like the Israelites, encumbered with their families and herds, would take the easy route by the open country to the west of the Azazimeh mountains in preference to the barren and rugged passes south-west of the Dead Sea.

The desert of the Tíh consists of a succession of limestone plateaux intersected by several wadies, of which the most important are W. El Arísh, which is joined near Nakhl by W. Rowag, W. Garaiyeh, with its tributaries Mayin, Jerur, Muweileh, W. El Ain, which runs into W. El Abyadh, W. Rehaibeh and W. Seba, which drain into the Mediterranean. W. Ghamr and W. Jeráfeh—the names of which have been interchanged by former travellers—fall into the northern slope of the Arabeh, and so run into the Dead Sea, as also do Wadies Murreh, Maderah, and Figreh, which debouch into the Ghor es Sáfi.

The southernmost limit is Jebel el Ráhah and Jebel el Tih on he S.W., and Jebel el 'Ejmeh on the S. and S.E., which together form a cliff running from Suez to Akabah, and projecting into the peninsula of Sinai much in the same way as that peninsula projects into the Red Sea. The height of this cliff at its most elevated point—on Jebel el 'Ejmeh—is about 4,200 feet above the sea, and from its summit the ground descends north-westwards.

To the N.E. of the Tih rises a third steppe or promontory, its northern portion corresponding to the "Negeb" or south-country of Scripture, its southern part bearing the name of Jebel Magráh, sometimes also called "the mountains of the Azázimeh," from the tribe of Arabs which inhabits it. To the S.E. of this mountainous region we came upon the only bed of sandstone which occurs throughout the whole country. It belongs to the same formation (New Red sandstone) as that at Petra and the lower strata of the Dead Sea basin.

Having carefully considered the best means of thoroughly examining the Tíh plateau, Mr. Palmer and myself determined to proceed along the base of Jebel el Tíh, and leaving to the west the Nagbs Emreikheh and er Rákineh—the passes on the ordinary routes for travellers proceeding northwards from Mount Sinai—to cross Jebel el 'Ejmeh wherever it might prove practicable, and thus proceed through a hitherto untraversed district to Nakhl, where we had established a depôt of provisions, and where we should have to make arrangements with a different tribe of Arabs for carrying our baggage northwards.

This plan was carried out, and we entered the Tíh by the Nagb el Mirád on January 12, 1870. From the summit of the cliff—for Jebel el 'Ejmeh has no pretensions to be called a mountain—a magnificent view is obtained of the Sinaitic peninsula. The range itself is composed of mountain limestone, so worn and broken by the action of frost and weather that the hills are covered with fine detritus, which, after rain, would produce some herbage, but when we were there only a few dried-up, stunted bushes were to be seen, which here as elsewhere in the desert supply good and abundant fuel.

From Jebel el 'Ejmeh the steep, bleak, waterworn hills gradually slope down and fall away into the great plains, or rather, low plateaux, which stretch across to the Mediterranean. The sameness of outline and dreariness of this country is something terrible: the few shrubs that exist are grey or brown, and seemingly withered and dead; no animal life enlivens the scene—at times perhaps a stray vulture or raven may be seen sailing far away in the blue sky, a frightened lizard will start from beneath one's feet, or a small flight of locusts be disturbed from their scanty meal on some "retem bush." Water on the road there was absolutely none; a supply for four days had to be carried from El Biyár, a well strongly impregnated with Epsom salts, and lying a few miles to the south of Nagb el Mirád.

Under these conditions we can scarcely expect to meet with many signs of life. Judging from the numerous cairns and other primeval remains, this district must at one time have been populous. Wearily did I tramp day after day, gun in hand, but I was seldom rewarded with any thing more than a stray beetle or lizard, and now and then some small desert bird, and on very rare occasions a hare or snake.

As from former experience we had found that it was impossible to work a country thoroughly when mounted, we only employed enough camels to carry our baggage. The camel-drivers acted as guides, and, to a certain extent, as attendants, for we took no servants whatever. This added to our already heavy work, yet it enabled us to get on much more satisfactorily with the various Arab tribes than we could otherwise have done.

From the Nagb el Mirád our course lay down Wady Rouág, which takes its rise in the highest part of Jebel el 'Ejmeh, about eighteen miles east of the head of Wady el Arish, with which it holds a nearly parallel course till it joins it at a short distance to the north-east of Nakhl. The district between Wady el Arísh and Wady Rowág is drained by W. Ghabiyeh, which falls into the latter about twenty-five miles from the Nagb el Mirád; after this junction the country becomes open and comparatively level. Here the ground is almost as hard as a macadamised road, and is covered with a layer of small, black, polished flints, which glisten in the sun as though they were wet. This polish must be attributed to the dust and grit kept in motion by the almost incessant winds, which are frequently very violent. Many of the monuments in Egypt bear witness to the destructive action of the grit. In this desert sand is almost unknown. There are only two or three sandy tracts, and these may be traversed in a few hours at most. The largest sandy district we had to cross was the Rumeilet Hámed, to the north of Khalasah (the ancient Elusa) where the prevailing north-west winds have formed extensive dunes. This sand, however, seems to have been entirely brought from the coast.

On arriving at Nakhl we found a small fort with wells and cisterns. In this dreary spot, encompassed by glaring white hills, a few miserable soldiers are maintained by the Egyptian Government for the protection of the Hajj caravan, the place being halfway between Suez and Akabah. Here we were obliged to dismiss the Towarah Arabs, and taking up our provisions which we had sent on from Suez, we entered into an agreement with the Teyáhah, who, after considerable discussion and futile attempts to extort a large "ghafr" or black mail, engaged to take us anywhere we wished through their country.

Of the various tribes which inhabit the Desert of the Tíh, the most numerous and powerful are the Teyáhah, of whom there are two divisions, the Sagairát and the Benaiyat, and truly they were, as their name implies, "birds of prey." They possess large herds of camels whose numbers are frequently increased by the product of the raids which they make on their hereditary foes the 'Anazeh, whose territory lies around Palmyra and to the east of the Haurán, and is about twenty days' journey from the Tíh. These forays are sometimes carried out on a large scale; on the last occasion the Teyáhah numbered 1,000 guns. At times the plunder amounts to many hundred camels, but at others the owners come down in force and the aggressors are compelled to retire. Bloodshed in these freebooting expeditions and even actual warfare is avoided as much as possible, for it results in a blood feud which is always much dreaded by a Bedawi, since it binds the relatives of anyone who has perished either by murder or manslaughter—the Arabs do not distinguish between them—to avenge his death. The blood feud or vendetta thus exercises a most salutary influence, for without it the value of human life would be totally disregarded in these wild regions which lie beyond the pale of the law.

The Terabín, the tribe next in importance, occupy the country east of the Teyáhah, their territory extending from Jebel Bisher and Bir Abu Suweirah on the Sinai road some forty miles south-east of Suez, as far as Gaza to the north.

The Haiwátt live in the mountains to the west and north-west of Akabah, and are not numerous.

The Azázimeh occupy the mountainous region which I have before mentioned as bearing their name: this tribe is not large, and they are exceedingly poor; their only food consists of the milk and cheese obtained from their camels and goats and such roots as they can dig up. On very rare occasions they may have the luck to shoot some wild animal which, whether it be ibex or hyæna, is equally acceptable to their not over squeamish stomachs. They are obliged to live in very small and scattered communities, from the fact that—with the exception of one or two brackish and unpalateable springs, their only water supply is derived from the rains collected in hollows of rocks in the ravines and wady beds, and even these are few and far between. This water was usually putrid and full of most uninviting animalculæ: however, as no other was to be had, we were obliged to drink it.

From Nakhl we went in a north-easterly direction to Wády Garaiyeh, thence to Jebel 'Araif, which we ascended; though it is little more than 2,000 ft. high; the view is very extensive. We then proceeded to cross Wady Mayin, W. Lussán, and W. Jerúr, and afterwards reached Ain Muweileh (the supposed site of Hagar's well). Here are very numerous primeval stone remains, the most remarkable being piles of stones placed in rows at the edges of the cliffs which face the East. Cannot they be the remains of the old Baal worship followed by the Amorites, whose name is still preserved in the country to the north of W. Muweileh, at Dheigat el 'Amerin (the ravine of the Amorites), Ras 'Amir, and Sheikh el 'Amiri? At various places on our route, especially at 'Uggábeh—between Nakhl and W. Garayíeh—on S. el 'Ejmell, S. 'Araif in Wady Lussán, we found very large numbers of cairns, stone circles with graves, and open spaces, which, to judge from the burnt earth within them, seem to have been designed for sacrificial purposes; also enclosures, girt by rude stone walls; and, in W. el Biyàr, circular dwellings, some of which are still standing, quite perfect. In W. Rowág nearly every hill is topped by a cairn; there are three on the summit of Jebel Araif, and we noticed that they frequently occurred as far north as Bir Seba and El Milh (Molada).

At Muweileh and near a neighbouring spring, Ain Guseimeh, are several caves. At the former place there is one cut in the face of the cliff, and entered by a staircase, ascending from a smaller cave below; this has been at one time the dwelling of a Christian hermit, as we noticed crosses rudely painted in red and traces of frescoes. At this place, too, we found, with the exception of one place in W. Lussán, the first signs of regular cultivation in former times. Stones are laid in lines across the wady-beds to check and, at the same time, distribute the drainage, and to prevent the soil being washed down by a sudden *seil* or flood.

Our next point was *El Birein*, so called from the *two wells* in the wady; here are traces of considerable ruins, a *fiskiyeh*, or reservoir, and aqueduct, the latter ruined, and the former nearly so. In the wady are some old *butmeh* or terebinth trees, remarkable as being the first trees, with the exception of two "seyáls" or acacias, that we had seen since leaving Sinai. About six miles N.W. of El Birein lie the ruins of El 'Aujeh, confounded by Dr. Robinson with 'Abdeh, which I shall presently mention, situated on a low spur running into W. Hanein. This valley, however, on account of a superstition attaching to its real name, has always been called by the Arabs, when speaking to travellers, W. Hafír. Some five or six square miles of the wady are covered with ruined walls of gardens and fields; the sides of the watercourse are built up with large stones, and dams still exist across it, though all the valley is now barren and neglected. Ten miles to the east of El 'Aujeh we discovered the ruins of a fortress called "El Meshrifeh," perched on a projecting spur, and defended on two sides by steep cliffs, which overlook a broad plain formed by the sweep of Wady el Abyadh as it debouches from Jebel Magrah; the south face of the cliff is fortified by escarpments and towers of massive masonry, and on the summit are ruins of several houses, and of a small church; on the third side a thick wall runs across the level crest of the spur. Beneath the towers and in connection with them are numerous rock-hewn chambers; also traces of a more ancient and, indeed, primeval wall, and pieces of masonry of a date far anterior to the rest of the buildings.

On the plain above mentioned and three miles and a half to the S.E. of El Meshrifeh we found the ruins of a considerable town called S'baita. This name seems to have been heard of by former travellers, who confounded the site with Rehaibeh; but I believe we were the first Europeans to visit the ruins. Here, as in many other cases, we experienced considerable difficulty, owing to the apprehensions of our Bedawin, who did their best to dissuade us from going there. I succeeded, however, in taking sketches and photographs of the chief points of interest. The town contains three churches, which, like those at El Aujeh el Meshrifeh and S'adi, must, I think, be referred to the 5th century. There are also two reservoirs, and a tower with a rudely ornamented gateway. With the exception of a fragment or two at El Aujeh, this was the only instance of sculpture we saw, and not a single inscription was anywhere to be found.

The structure of the buildings at S'baita is worth noticing: the upper stories of the houses are supported on wide, low-spanned arches two feet wide with intervals of three feet between them, and upon these is placed the flooring of the upper rooms, which consists of narrow slabs of stone. Numerous ruined towers and walled gardens and enclosures, extending to a distance of several miles from the town, attest its former importance. The vineyards, too, marked by the "Teleilát el 'Aneb," which I mentioned before, extend over large tracts in this neighbourhood.

From S'baita we went to Rehaibeh, examining *en route* the ruins of S'adi,* which do not seem to have been visited or even heard of by former travellers. At Rehaibeh the ruins are of much greater extent than at S'adi, but so confused that it is impossible to trace the plan of any single building. There are numerous wells, cisterns, and other remains of cultivation in the neighbourhood. From Rehaibeh we went to Khalasah and Bir Seba: the ruins at the former place have nearly disappeared, as the inhabitants of Gaza find it cheaper to send camels for the already squared stones than to quarry them near their town. Owing to the drought we found Bir Seba barren and deserted, though our Arabs assured us that in good seasons the grass is knee-deep, and furnishes ample pasturage for countless flocks and herds. Our unlooked-for appearance in out-of-the-way districts was usually considered by the natives to be in some manner connected with the exceptional drought, and on several occasions we were either implored to bring rain or cursed for the want of it, since the Arabs firmly believe that every *Nasráni* holds the weather under his control.

From Bir Seba we went to Jerusalem, and, after a short stay there, returned to Hebron, where we engaged three of the Jehalin Arabs, with their camels, to convey our baggage to Petra. Taking a new route, we passed Tell Arad and El Milh, and struck into the unexplored mountains of the 'Azázimeh, where we discovered the ruins of the El 'Abdeh (Eboda), which are of considerable extent, and similarly placed to those of El Meshrifeh, most of the dwellings here, as there, being half excavated and half built. Of the buildings now standing, the greater part are of Christian times. The natives are perfect savages, and detained us for two hours from visiting the ruins by collecting in a gang to the number of thirteen on the top of a pass, singing their war-song, throwing down stones, and occasionally firing off one of their old match-locks in bravado, and swearing by God and the Prophet that no one should come up. As the pass was very narrow, almost precipitous, we judged it best to propitiate them, a task accomplished, after much discussion, at the cost of eight shillings. They then escorted us to the ruins, where we took such measurements and photographs as we required. From 'Abdeh we went through the 'Azázimeh mountain, a region so awfully desolate as to defy description, struck the 'Arabah at the junction of W. Jerafeh with W. Ghamz, and crossed thence to Petra. Here the Liyathineh fully maintained their character for brutality and insolence. Infidels in all but the name of Moslims, they are descended from the tribe of Khaiberi Jews, who bear such a bad character in Arabia. To add to our discomfort, we were snowed up for two days in a tent only just large enough for us both to lie down in. During a stay of six days, however, Petra was thoroughly examined by us and accurately mapped. We then bent our steps northwards, and at El Barid, about seven miles from Petra, discovered a colony of dwellings and temples cut in the rock, and some rudely chipped Nabathæan inscriptions. The walls and ceilings of the rock-chambers were decorated with frescoes, some coarse others well executed. We next travelled down the 'Arabah to the Dead Sea, and having examined the Lisan, went up into Moab. Here we stopped about three weeks and wandered over the country in search of inscriptions, as Mr. Palmer had specially come to ascertain if another Moabite stone was in existence. At last, however, we both came to the conclusion that *above ground* there are none. From Moab we crossed the Jordan, near Jericho, and returned to Jerusalem.

(*To be continued.*)

* S'adi is two-and-a-half miles E.S.E. of Rehaibeh.

## SCIENTIFIC SERIALS

THE fifth part of the nineteenth volume of the *Palæontographica* recently published, is devoted to the description by Prof. Schenk, of fossil plants from the north German Wealden formation. The plants here described and figured upon 8 plates are all cryptogamous, and with the exception of a single *Chara*, and four *Equiseta* belong to the group of ferns, of which 21 species are noticed; but it must be remarked that Prof. Schenk has considerably lessened the apparent number of species by reducing a great many of the names given by former authors to the rank of synonyms. At the same time he describes and figures seven forms as new species, one as the type of a new genus, *Marsilidium*, belonging to the Rhizocarpeæ, and he also establishes the new genus *Matonidium* for *Laccopteris Göpperti*, Schimper. The other new species belong to the genera *Sphenopteris*, *Alethopteris*, *Laccopteris*, *Olean-*

*dridium*, *Dictyophyllum* and *Protopteris*, the last being doubtfully represented by a portion of a tree-like stem.

THE second part of Tome xx. of the *Mémoires de la Société de Physique et d'Histoire Naturelle de Genève* (1870) contains an exceedingly important zoological paper, namely, a supplement to Prof. Claparède's descriptive account of the Chætopod Annelides of the Gulf of Naples. This not only includes descriptions of many new forms discovered by M. Claparède during the winter of 1868-69, but furnishes him with an opportunity of effecting a combination between his own observations and those of Prof. Ehlers, whose valuable work on the Chætophorous Annelides appeared almost simultaneously with Prof. Claparède's former publication. The memoir is illustrated with fourteen beautiful plates. This part also contains descriptions by Dr. J. E. Duby of some minor little-known exotic mosses, accompanied by four plates.

THE first and second numbers of the *Bollettino del R. Comitato Geologico d' Italia*, published together for the months of January and February of the present year, contain some interesting papers, among which, perhaps, the most important is that on the temperature of the rocks in the Mont Cenis tunnel, communicated by the engineer, M. F. Giordano. The highest temperature observed was 29·50° C. (=85·10° F.) at a distance of 6,450 metres (about 21,000 feet) from the southern opening, at the same time that the temperature of the rock at 400 metres (about 1,300 feet) from the opening was only 11° C. (= 38·2° F.). M. Giordano also publishes notes on the geological constitution of the Roman Campagna, illustrated with three long sections. These numbers also contain a translation into Italian of G. von Rath's memoir on the environs of the lake of Bolsena, an extract from a paper by Prof. T. Taramelli on the Eocene formation of Feiuli, and some short bibliographical notices.

THE editor of the *Geological Magazine*, in his April number (No. 82), has resumed his series of notices of eminent living geologists with a sketch of the scientific life of Mr. Thomas Davidson, illustrated with a good portrait. That Mr. Davidson's labours on the Brachiopoda fully entitle him to such an honour no one will be inclined to deny, but one is somewhat startled at learning what is the real result of his activity, chiefly in this field of research, and being told that his published writings occupy about 2,220 pages, and are illustrated with 244 plates, all or nearly of them drawn by his own hand! Mr. H. B. Woodward describes a curious example of the inversion of strata belonging to the carboniferous series at Vobster, in Somersetshire, to the north of the Mendip Hills, where coal is worked beneath mountain limestone. This phenomenon has been ascribed to a folding over of the main ridge of the Mendips, but the author adduces what seem to be good reasons in opposition to this view, and endeavours to account for it by local disturbance associated with faults. He illustrates his views by means of a diagram section. —Mr. G. H. Kinahan communicates a paper on Æolian drift or blowing sands in Ireland, in which he explains these peculiar deposits as being the products of the action of glaciers during the glacial period.—M. De Rance describes the pre-glacial geography of northern Cheshire. The number also contains a reprint of Mr. David Forbes' lecture on the nature of the earth's interior, and the usual reviews and short communications.

THE *Transactions of the Linnean Society*, vol. xxvii. part 3, has just been issued, containing three papers, each illustrated with 4to. plates:—Observations on the Lichens collected by Dr. Robert Brown in West Greenland in 1867, by Dr. W. Lauder Lindsay; On the Vertebrate Skeleton, by Mr. St. George Mivart; and Descriptions of some British Spiders new to science, by the Rev. O. P. Cambridge. Mr. Mivart's article is devoted to a discussion of the following questions:—1. What is the best way to seek *a priori* a general view of the axial skeleton? 2. What is the essential nature of ribs, transverse processes, and sternum? 3. What is the essential nature of branchial arches, and in what relation do they stand to the ribs? 4. What is the essential nature, as compared with branchial arches, of the hyoidean arch, mandible, and more anterior structures? 5. What relations exist between the "chevron" bones and other parts of the vertebrate skeleton? The appendicular skeleton, as distinct from the axial skeleton, consisting of the anterior and posterior limbs, is also discussed.

THE *Proceedings of the Natural History Society of Dublin* for the sessions 1867-68, 1868-69, vol. v. parts iii. and iv., was published on May 3, 1871. Among the more important papers we notice:—Prof. W. King "On some Palliobranchiate Shells from the Irish Atlantic;" Prof. Macalister "On the Myology of the Otter," "On the pyloric appendages of the common Trout," "On the Flora of Kinross-shire," and "On the arrangement of Pronator Muscles in the limbs of Vertebrate Animals.—Dr. D. Moore "On the Botanical Congress of Paris of 1867," and "On Addenda to British and Irish Muscology." Dr. A. W Foot "On some points observed in the dissection of an Aylesbury Duck." Rev. E. O'Meara "On some new Arran Diatomaceæ" (Plate 13). W. Archer "On a peculiar cyst-like structure enclosing examples of *Staurastrum cuspidatum*," &c., and "On some Freshwater Rhizopoda" (Plates 8, 9, 10). Prof. E. P. Wright "On *Tubipora musica*" (Plate 11). Notes of a tour in the spring and summer of 1868 to Sicily and Portugal (Plate 12). These Parts conclude vol. v., and have title page, index, and appendices.

## SOCIETIES AND ACADEMIES

### LONDON

**Royal Institution of Great Britain**, May 8.—Sir Henry Holland, Bart., M.D., president, in the chair.—The following Vice-presidents were nominated for the ensuing year:—Duke of Northumberland, Lord Lindsay, W. Spottiswoode, the Treasurer, Sir Frederick Pollock. William S. Burton, Arthur Samuel Hobson, Richard Liebreich, Abraham De Mattos Mocatta, and Edward Stanhope Pearson, were elected members. John Tyndall, F.R.S., was re-elected Professor of Natural Philosophy.

**Zoological Society**, April 29 (Anniversary Meeting).—Viscount Walden, president, in the chair. After some preliminary business, the report of the Council was read by Mr. P. L. Sclater, F.R.S., the secretary. It stated that the number of Fellows of the Society on the 1st of January last was 3,021, showing a net addition of fifty-five ordinary members to the roll during the year 1870. Twelve new corresponding members had likewise been elected during the year 1870. The total income of the society during the year 1870 was stated to have been 23,257*l*., being 488*l*. more than that of the preceding year. The total ordinary expenditure had been 21,364*l*., in which sum had been included every item necessary to keep the society's establishment in its present state of efficiency. Besides this the sum of 3,043*l*. had been devoted to extraordinary expenditure, in the shape of new buildings and works in the gardens. Of these works the most important was the new elephant-house, on completing which the sum of 2,324*l*. had been expended. This, when added to the sums spent upon the same building in former years, had raised the total cost of that building to 6,356*l*., in which, however, the yards, ponds, fences, terrace walk in front, and the necessary arrangement of the adjoining grounds were included. Other works carried on in the society's gardens during the past year had been the completion of the new first-class refreshment-room, and the extension of the system of heating the buildings by hot-water apparatus. The total number of visitors to the society's gardens during the year 1870 had been 573,004, showing an increase of 156 over the corresponding number in 1869. The greatest daily number of admissions in 1870 (28,457) was on Whit Monday, the 5th of June; the least number (28) on the 3rd of March; the average daily number of admissions throughout the year had been 1,570. The number of animals contained in the society's menagerie on the 31st of December, 1870, was stated to have been 2,118, showing an increase of 105 when compared with the corresponding number at the same date in the previous year. Among the additions made to the collection during the year 1870 had been a considerable number of special interest, either on account of their scientific novelty or from not having been previously brought to England in a living state. Full particulars concerning these were given, as also a list of the species that had bred in the society's gardens during the year. The report then proceeded to give a long list of donors and their several donations to the menagerie, after which, in conclusion, the council contrasted the present state of the society's affairs with that which had existed ten years ago. In 1860, they observed, the total number of Fellows was 1,716; it was now 3,021; in 1860 the number of visitors to the society's gardens had been 394,906; in 1870 it had been 573,004. The total income of the society in 1860 was 16,864*l*.; in 1870 it had amounted to 23,257*l*. In 1860 the reserve fund was 3,000*l*. Reduced Three per Cents.; it had now been augmented to 7,000*l*. of the same stock. Moreover, during the past ten years, sums amounting altogether to upwards of 46,000*l.* had been devoted to the permanent improvement of the society's garden establishment, the expenditure of which had enabled the council to renew nearly the whole of the more important buildings on an improved and enlarged scale. These facts, it was believed, could not be otherwise than gratifying to the Fellows of the society. The society then proceeded to ballot for the council and officers for the ensuing year, when Lord Calthorpe, Mr. Francis Galton, F.R.S., Captain the Count Gleichen, R.N., Mr. John Gould, F.R.S., and Dr. Hamilton were elected into the council, in the place of Professor Huxley, F.R.S., Mr. J. Travers Smith, Lord Walsingham, Mr. G. R. Waterhouse, and the Bishop of Winchester, who retired therefrom, and Viscount Walden was re-elected president; Mr. Robert Drummond, treasurer; and Mr. P. L. Sclater, F.R.S., secretary.

Zoological Society, May 2.—Viscount Walden, President, in the chair. A letter was read from W. H. Hudson, addressed to the secretary, containing observations on the habits of the various swallows met with in and around Buenos Ayres.—Mr. P. L. Sclater exhibited and made remarks on the shell of a river-tortoise of the genus *Pelomedusa*, obtained by Mr. Chapman on the Upper Zambesi.—Prof. Flower exhibited and made remarks on the mounted skeleton of the young hippoptoamus, recently born in the Society's Gardens.—The Viscount Walden read a paper on the Birds of the island of Celebes, in which the materials hitherto available for the elaboration of its avi-fauna were brought together and discussed. Out of the generic forms met with in Celebes, thirty-eight appeared to be Indian, and twenty-three Australian in character. To these were added a strong element of individuality, shown by the presence of sixty-five species, and nine genera unknown elsewhere. The avi-fauna of Celebes, so far as was certainly known, was composed of 193 species; but the author observed that a considerable portion of the centre of the island remained unexplored, which gave a prospect of future discoveries.—A communication was read from Mr. W. Harper Pease, of Honolulu, Sandwich Islands, containing a catalogue of all the known land-shells inhabiting Polynesia, together with remarks on their synonomy, distribution, and variation, and descriptions of some new genera and species.—A communication was read from Dr. John Anderson, Curator of the Indian Museum, Calcutta, containing the description of a new generic form of newt from Western Yunan, proposed to be called *Tulototriton verrucosus*.—A second communication from Dr. J. Anderson contained some drawings of and notes on the original specimens of *Testudo phayrei*, Blyth, in the Indian Museum. Having examined the skull in the British Museum upon which *Scaphia falconeri*, Gray, had been based, and re-examined the smaller example of *Testudo phayrei* at Calcutta, Dr. Anderson had come to the conclusion that Mr. Theobald's account of its history was strictly accurate.—A communication was read from Dr. J. E. Gray, F.R.S., entitled Notes on the species of *Bradypidæ* in the British Museum.

Geological Society, April 26.—Prof. Morris, vice-president, in the chair.—Mr. Robert Russell, of the Geological Survey of England and Wales, was elected a Fellow of the Society. The following communications were read:—1. "On a new species of Coral from the Red Crag of Waldringfield," by Prof. P. Martin Duncan, F.R.S. Prof. Duncan described, under the name of *Solenastræa Prestwichi*, a small compound coral obtained by Mr. A. Bell from Waldringfield, and stated that it was particularly interesting as belonging to a reef-forming type of corals which has persisted at least from the Eocene period to the present day. The single specimen consisted of several small crowded corallites, having calices from $\frac{1}{20}$ to $\frac{3}{20}$ inch in diameter, united by a cellular epithecal cœnenchyma. It was much rolled and worn before its deposition in the Red Crag, and hence the author regarded it as a derivative fossil in that formation, and he stated that it probably belonged to the rich reef-building coral-fauna which succeeded that of the Nummulitic period. Mr. Etheridge remarked that the origin of this interesting fossil seemed uncertain. It appeared, however, to be derived from some other source, and not to have originally belonged to the Red Crag. In England the genus was hitherto unknown in beds newer than those of Brockenhurst. The presence of this single specimen showed how much we had still to learn with regard to the crag formation. It was to be hoped that the coral might eventually be found attached to some organism from which its age might be determined. Prof. T. Rupert Jones remarked that he would be glad to hear of more corals being discovered in the so-called Coralline Crag. He inquired whether cœnenchymatous corals were necessarily reef-corals, observing that this coral was referred to the Miocene on account of its presumed reef-forming character. He added that some of the Foraminifera of the White Crag had the aspect of existing Western Mediterranean forms, and thus supported some of Prof. Duncan's remarks. Mr. Gwyn Jeffreys observed that the distinction between the Coralline and Red Crag seemed to be every day diminishing. The appearance of the fossil seemed to betoken its derivative character. Like other speakers, he complimented Mr. Alfred Bell on his great intelligence in the collection of crag fossils. Prof. Duncan, in reply, maintained that the differences between deep-sea and reef-building corals were well established, and around modern reefs in the deeper sea the forms were quite distinct, and the deep-sea corals never presented the cœnenchyma distinctive of the reef-building form. This, he suggested, might be connected with the difference in the amount of sea-water with which it was brought in contact, which in the surf was much greater than in the almost motionless depths of the sea.—2. "Notes on the Minerals of Strontian, Argyleshire," by Robert H. Scott, M.A., F.R.S. The paper stated that the existing lists of minerals to be found at Strontian were incorrect. The discovery of apophyllite, talc, and zircon seemed to be hardly sufficiently confirmed. On the other hand, Mr. Scott named several species which he had himself observed *in situ*, and which are not noticed in any of the books, viz., two felspars, orthoclase, and an anorthic felspar in the granite; two varieties of pyroxenic minerals in the granite and syenites, neither of which have as yet been analysed; natrolite in the trap-dykes; muscovite or margarodite in very large plates, lepidomelane and schorl. Specimens of these minerals and of the others found at the mines were exhibited; but it was stated that, owing to the fact that the old workings at the mines in Glen Strontian had been allowed to fall in, it was now no longer possible to ascertain much about the association of the species. The one is galena, containing very little silver. The gangue is remarkable for the absence of fluor and the comparative rarity of blende and heavy spar. Harmotome is found principally at a mine called Bell's Grove, both in the opaque variety and in the clear one called morvenite. Brewsterite occurs at the mine called Middle Shap, and at the mine Whitesmith strontianite is found with brewsterite, but without harmotome. Calcite is alse very common. Within the last few years a new mine has been opened called Corrantee, which is in the gneiss, whereas the other mines lie on the junction of the granite and gneiss. At this mine several fine specimens of calcite have occurred, many of them coated with twin crystals of harmotome, similar to those from Andreasberg, whereas the crystals found at the old mine are not so clearly macled. Associated with these were found a number of small hexagonal prisms, perfectly clear, and exhibiting a very obtuse dihedral termination. They gave the blowpipe reaction of harmotome; and on analysis by Dr. J. E. Reynolds, proved to be that mineral. Descloiseaux has already described a quadrifacial termination to harmotome, with an angle of 178° 20′. Mr. Scott submitted that possibly the crystals which he exhibited might bear faces which had a close relation to those described by Descloiseaux. He concluded by stating that Strontian promised as rich a harvest to the mineralogist as any locality is these islands. Mr. W. W. Smyth mentioned the wonderful collection of minerals from Strontian which had been brought to the Great Exhibition of 1861, which gave a most striking idea of the mineral riches of the locality. The occurrence of such a series of different substances in one locality in the granite was almost unparalleled, though in the Andreasberg mines, in clay state, they were to some extent rivalled. The features, however, differed in the two places, more silver and a greater number of zeolites being present in the Hartz mines. Mr. D. Forbes observed that harmotome occurred also at the Kongsberg silver-mines in Norway, at a distance from granite. He thought it remarkable that these crystals of peculiar form occurred in the same spot and in connection with crystals of the same substance, but of the ordinary form. Mr. Davis remarked that celestine was also to be placed on the list of the minerals from Strontian. Harmotome had been found in the same form of double crystals at Bodenwies in Bavaria. Mr. Scott stated, in reply to a question from the chairman, that the mineral had not been as yet optically examined, but that if he could procure more of it he should be happy to place it at the disposal of any gentleman who would examine it As regarded the idea that harmotome usually occurred near the surface, he could give no information about the old mines, as they had been allowed to fall in; but most certainly the new specimens from Corrantee came from surface-workings. He was very glad to learn from Mr. Davis that celestine had been found at the locality; and he felt sure that careful search would double or treble the number of species known to occur there. With reference to what had fallen from Prof. Smyth, he could fully corroborate his observations as to the difference between the forms of calcite associated with harmotome at Andreasberg, in the Hartz, and at Strontian. It was remarkable that the general facies of the crystals of calcite occurring at Corrantee, where the lode was entirely in the gneiss, differed from that usually observed in the old mines in Glen Strontian, which were partly in the granite and partly in the gneiss. 3. "On the probable origin of Deposits of 'Loess' in North China and Eastern Asia." By Mr. T. W. Kingsmill, of Shanghai. Communicated by Prof. Huxley, F.R.S., V.P.G.S. The author stated that the Baron von Richthofen had lately applied the term "Loess" to a light clay deposit covering immense tracts in the north of China. The author regarded this formation as in great measure corresponding to the Kunkur of India, and thought that it probably extended far into the elevated plains of Central Asia. Richthofen considered that this deposit had been produced by subaërial action upon a surface of dry land; the author argued that it is of marine origin, having been deposited when the region which it covers was depressed at least 6,000 feet, a depression the occurrence of which since the commencement of the Tertiary period he considered to be proved by the mode of deposition of the Upper Nanking sandstones and conglomerates, the bold escarpments of the hills on either side of the Yangtsze, and other peculiarities of the country. Prof. Ramsay remarked that the author had not proved that the loess he described was really stratified. He could not agree with his views of the inland escarpments he mentioned having been old coast lines. It was only accidentally that sea cliffs had any connection with the line of strike of the strata, whereas inland cliffs always followed the strike. He thought the phenomena were rather in accordance with a long exposure of the land to subaërial influences than with the loess, having been of marine origin. Even in England, in those parts which had long been free from marine action, beds of brick earth had been formed. He also instanced the plains of Picardy as exhibiting a vast extent of such subaërial beds. Prof. T. Rupert Jones said that though the area treated of by Mr. Kingsmill was too large to have its geology explained merely by reference to rain-wash and valley deposits, whatever his low-level loess might be, the higher accumulations of loamy deposits, stated to be 1,000 feet thick at an elevation of 3,000 feet, and regarded by Mr. Kingsmill as the quiet water sediments of a great gulf with the miocene conglomerates and sandstones of Nanking and elsewhere for its marginal equivalents, appeared to require different explanation. All loess need not be of sea origin; in oscillations of land marine deposits must be carried up to great heights: and, referring to Mr. H. M. Jenkins's determination of the marine origin of the loess of Belgium, Prof. Jones thought it highly probable that some at least of that in China may have been similarly formed. Mr. Hughes said that the author appeared to have grouped together all the superficial deposits of a vast area without explaining very clearly the grounds upon which he identified those deposits at distant points. He did not prove that what he called the shore deposit was marine, or that it was of the same age as the loam which he described, and which Mr. Hughes thought, from the description, was far more likely to be subaërial. Mr. Evans and Mr. Etheridge suggested the probability of much of the so-called loess might be derived from higher loamy beds, possibly derived from the decomposition of limestone rocks containing sand and clay, and redeposited by the action of rain. The following specimens were exhibited:—Minerals from Strontian; exhibited by Mr. Scott, in illustration of his paper. Corals; exhibited by Prof. Duncan, in illustration of his paper.

Royal Geographical Society, April 25.—Major-General Sir Henry C. Rawlinson, K.C.B., vice-president, in the chair. The following new Fellows were elected:—Mr. G. E. Bell; Staff-Commander Charles Burney, R.N.; Messrs. Walter J. Ellis; J. C. W. P. Graham; Simon Little; Henry Syme. A letter was read from Mr. R. B. Shaw to Sir Roderick Murchison, on that portion of his recent journey to Yarkand (with Mr. Forsyth) in which, detached from the rest of the party, he explored the rugged country between the western extremity of the Thibetan Plateau and the Valley of the Upper Shayok. He described the plateau (17,000 feet high) as ending abruptly on the west in a great limestone range, which, like the masonry *revêtement* of an embankment, has protected the level table-land from the wearing influence of the rains from clouds sweeping up the Shayok Valley. Standing on the edge of the plateau, the whole country westward appeared as an irregular mass of snowy peaks and narrow precipitous valleys. In attempting to descend one of the valleys towards the Karakoram road, the party suffered fearfully in struggling for three days through the broken ice of a torrent at the bottom of a stupendous chasm, from which, in some places, the light of day was nearly excluded.—A second communication was read "On the Journey of the Mirza across the Pamir Steppe to Yarkand and Kashgar," by Major Montgomerie. This was a detailed report of the journey of an Afghan gentleman, instructed by the officers of the Trigonometrical Survey to traverse the Mahomedan countries across the Hindoo Koosh and Pamir Steppe, eastward to the plains of Eastern Turkestan. The journey was successful in its main object; and we have now, for the first time, a scientific account of those little-known regions, with the means of fixing the geographical position of all the important places. The Mirza proceeded from Fyzabad eastward, along one of the head-waters of the Oxus, arising in Lake Pamir-Kul (13,300 feet), and thence to Tash Kurgan, Yanghissar and Kashgar. Crossing the elevated region of the Pamir, he suffered fearfully from the cold, although well clad, even to the lining of his boots, in warm woollen clothing. Sir Henry Rawlinson explained to the meeting that the Mirza's route was the same as that followed by Marco Polo and Benedict Goez, and in later times by Mahomed Amin. He also stated that the vexed problem of the longitude of Yarkand (placed by the Schlagintweits about 200 miles too far to the west) had been solved by the recent lunar observations of Mr. Shaw, the computation of which had been completed that day, at the Geographical Society, by Mr. W. Ellis of the Greenwich Observatory. These observations placed Yarkand in E. long. 77° 14′ 45″. Colonel Walker, of the Great Trigonometrical Survey of India, and Sir A. Scott Waugh also addressed the meeting, chiefly on the subject of the employment of native observers in the geographical exploration of the regions beyond the British boundaties.

Chemical Society, May 4.—Dr. Warren De La Rue, F.R.S., vice-president, in the chair. The following gentlemen were elected Fellows:—Messrs. R. S. Best, C. S. Cross, W. H. Darling, G. H. Ogston, I. Schweitzer, and. W. A. Smith. Dr. Völcker delivered a lecture "On the Productive Powers of Soils in Relation to the Loss of Plant Food by Drainage." The lecturer began by showing the futility of the belief that a soil-analysis could reveal whether a land was productive or not. To those who only imperfectly know the teachings of modern agricultural science, it appears veiy simple to remedy a deficient soil by finding out through analysis the wanting constituents, and then to supply them. But this is not so. Not only is it difficult exactly to analyse a soil, but many other conditions besides the composition of a land have to be observed. The state of combination in which the mineral constituents of a land are found, the physical condition of the soil, the presence or absence of some matter injurious to the growth of plants, all these are so many important points upon which soil-analysis throws no light whatever. The lecturer equally opposes the views of those who advocate that in a system of rational farming there should be kept up a debtor and creditor account as regards the constituents which are removed from the soil in the crops grown upon it, and the quantity of fertilising matter restored to it in the shape of manure. The fertility of the soil cannot be maintained, much less increased, if only as much fertilising constituents would be applied to the land as one removes from it in the crops. Dr. Völcker then discussed the relative values of various mineral salts as manures, quoting in support of his views the results of the classical field experiments of Lawes and Gilbert; and this then led the lecturer to speak of the examination of land-drainage waters. Lawes and Gilbert, throughout a long series of experiments on the growth of wheat, have experienced a great loss of nitrogen; the amount of nitrogen supplied in the manures was greater than that recovered in the increased produce. It appeared to Dr. Völcker that the nitrogen lost might have passed into the drains. Careful collection of such drainage waters, and their analysis, proved Dr. Völcker's supposition to be correct. It became clear that, in whatever form the nitrogen is applied to the soil, a large proportion of it is carried off chiefly in the form of nitrates. At all times of the year, but especially during the active period of growth of the crops, nitrates are found in the watery liquid which circulates in the land, whereas ammonia salts are never met with in any appreciably large quantities. It may therefore be assumed tha it is chiefly, if not solely, from the nitrates that the crops build up their nitrogenous organic constituents. Dr. Völcker's analyses of drainage waters further showed that potash and phosphoric acid, which certainly are the most important mineral constituents for the plant, are almost entirely retained in the soil, whilst the less important, as lime or magnesia, or sulphuric acid, pass with greater readiness out of the land.

Entomological Society, May 1.—Prof. Westwood, M.A., F.L.S., in the chair. Mr. Higgins exhibited fine collections of exotic Lepidoptera, Coleoptera, &c., from Natal and Borneo, and a number of photographic coloured figures of larvæ from Natal.—Mr. Meek exhibited *Nyssia lapponaria*, Duponchel, captured in Perthshire by Mr. Warrington, and new to Britain.—Mr. Champion exhibited *Scydmænus rufus*, captured by him in Richmond Park, a beetle new to Britain.—The Rev. R. P. Murray exhibited a collection of Swiss insects, including a singular variety of *Lycæna Eurydice*.—Mr. Bicknell exhibited an extraordinary specimen of *Conepteryx rhamni*, captured by Mr. Cowan at Beckenham in March 1870; this individual had the central margin of both fore wings, and of the right hind wing, broadly suffused with deep crimson; it was considered that the colour was accidental, and probably owing to the wings having come in contact with some chemical substance. Mr. Bicknell exhibited varieties of other British Lepidoptera.—Mr. Stainton exhibited drawings of Micro-Lepidoptera from New Grenada collected by Baron von Noloken.—Mr. M'Lachlan exhibited the tusk of a female Indian elephant lent to him by Dr. Sclater. The root of this tusk was much eroded and blackened, and on the diseased part were long rows of eggs, apparently those of some insect. The elephant had been shot in Malabar by Mr. G. S. Roden, of the 1st Royal, and both its tusks were in the same condition. Furthermore, it appeared from the notes of a writer in the *Field* that this circumstance was not uncommon, but always occurred in the female elephant. None of the members could give any information respecting the parasite, but it was generally considered that the parasite had not caused the decay, but rather that it had taken advantage of a previously morbid condition.—Mr. Lewis exhibited an earthern jar, like an ordinary tobacco jar, of Chinese manufacture. It had an enormously thick porous bottom, and it was stated that the inhabitants of Pekin use these jars for the purpose of confining large beetles, which they keep for fighting. The beetles are allowed no food but water, and become extremely ferocious. Prof. Westwood reminded the meeting that the Chinese were already known to keep mantides for fighting purposes.—M. Müller read notes on a gall on the common brake (*Pteris aquilina*) found by Mr. Rothway, and he remarked that Schenck had noticed the same gall in Germany, and referred it to *Diastrophus rubi*.—Prof. Westwood read descriptions of new species of *Lucanidæ*.—Mr. Bates read a description of a remarkable longicorn beetle from Matabili land, in the interior of South Africa, sent to him by Mr. T. Baines. This insect he proposed to call *Bolbotritus Bainesii*. It was especially remarkable for the enormously swollen third joint of the antennæ, the other joints being much shortened. Mr. Bates also read a description of a new species of *Mallaspis* from Chiriqui, which he named *M. præcellens*.—Mr. Kirby communicated synonymic notes on European *Lepidoptera*.—Attention was called to paragraphs going the round of the London daily papers respecting a so-called storm of insects said to have occurred on two occasions recently at Bath. These records were characrised by the usual newspaper inaccuracy and vagueness on scientific matters. Prof. Westwood thought they probably referred to *Branchypus stagnalis*, a large fresh-water entromostracon.

Linnean Society, May 4.—Mr. G. Bentham, president, in the chair. Dr. Oswald Heer, of Zurich, was elected a foreign member in the place of the late Prof. Unger. The following papers were read:—"The phenomena of Protective Mimicry, and its bearing on the theory of Natural Selection, as illustrated by the Lepidoptera of the British Islands," by Raphael Meldola, F.C.S. "On the Ascalaphidæ," by R. McLachlan.

Society of Biblical Archæology, May 2.—Dr. S. Birch, F.S.A., president, in the chair. The following new members were balloted for, and duly elected:—Louis Blacker, Rev. D. S. Heath, M.A., F.R.S.L., and Mrs. L. Blacker. The President read a paper "On a Hieroglyphic Tablet of Alexander II. (Ægus) son of Alexander the Great, recently discovered at Cairo." This tablet was dedicated to the goddess Buto, and is dated in the seventh year of Alexander (311 B.C.). It records the restoration to the priests of Buto of the district formerly given to them by Khabash, an Egyptian monarch, contemporaneous with the later years of Darius and Xerxes, which last monarch is mentioned in disparaging terms, probably to flatter Ptolemy, the Macedonian ruler of Egypt, who is styled on it, "The Satrap of Alexander." Dr. Birch also contributed a second paper, based upon communications received from Lieut. Prideaux, containing the interpretation by himself and the Baron de Moltzan, of three bronze tablets, with inscriptions in the Himyaritic character, recording adorations by Hanbaz, an Himyaritic monarch, to the deities Ath-tor and Wud on the conquest of the town of Kuderamelek.—A third paper was further read by Prof. Goldschmidt (of Copenhagen) on the derivation of the name Αἴγυπτος, from Ukh-hap-t, *i.e.*, "the land of the good stream-sending spirit." Some discussion followed the reading of these papers, Messrs. W. R. A. Boyle, S. M. Drach, Rev. T. Gorman, Rev. I. Mills, Sir Charles Nicholson, &c., took part.

CAMBRIDGE

Philosophical Society, May 1.—Mr. G. Hale, M.A., and Mr. C. Smith, B.A., Sidney College, and Mr. A. G. Greenhill, B.A., St. John's College, were elected Fellows. The following paper was read:—"On the Measurement of an arc of the Meridian in Lapland," by Mr. I. Todhunter, F.R.S. The object of this memoir was to draw attention to the numerous errors which have been made, even by distinguished astronomers, in their accounts of the two measurements of an arc of the meridian in Lapland. A comparison of the original authorities on the subject at once detects these errors, and supplies the necessary corrections.

EDINBURGH

Royal Physical Society, April 26.—Mr. C. W. Peach president, in the chair. After the appointment of committees for carrying on special investigations during the summer, Dr. M'Bain communicated a paper by Dr. John Kennedy Elis, "Remarks on a Japanese Skull."—Dr. Robert Brown read "Notes on the Breeding Places and Food of some Scottish Sea Birds," by Captain M'Donald, Fishery Cruiser *Vigilant*.—Mr. Peach exhibited a fine mass of gulf weed covered with small cirripedes, which he received on Monday last from Captain N. Leslie, of the ship *Lady Milton*, now lying at West Hartlepool, picked up on the homeward voyage; and then read the following extract from the captain's letter:—"I picked up a lot of gulf weed in 32 N. and 7 70 W., on the 9th of March. I send a sample; it looked very beautiful when fresh, so many little barnacles, and all full of life when in a bucket of water. I am now sorry that none of it was bottled, if only for curiosity; it might lead you to something of a knowledge of seasons, as I never saw so many barnacles on a voyage as I have this time, either on seaweed or wreck, and, strange to say, there are none on the ship's bottom. Last year we saw none on the seaweeds, &c., when the quarters of the ship were nearly covered with them, and this although we had not so much fine weather as this."—Mr. Peach stated that the cirripede most abundant in the parcel thus sent was covered with hars and spines, much like *Oxynaselis celata* of Darwin's monograph, but it differed in so many respects that it might prove to be a new species.—Mr. Andrew Taylor read "Notes on the Geology of Inchkeith."

NEW ZEALAND

Wellington Philosophical Society, January 28.—Hon. W. B. D. Mantell, F.G.S., president, in the chair. From the report of the Council it appears that out of fifty-nine communications made to the Society during the past year forty-four will appear in the forthcoming volume of the Transactions. The number of members has increased from 85 to 103, and the accounts show a balance in hand of 60*l*. 10*s*. 7*d*. The chief item of expenditure has been a grant of 50*l*. in aid of the Botanic Gardens, for the purpose of having the collection of native plants completed by the addition of those found in other parts of the colony, and also in providing labels for the principal trees and shrubs along the paths, giving the scientific and native names. The office bearers chosen for the ensuing year are W, T. L. Travers, F.L.S., President; J. C. Crawford, F.G.S., and W. L. Buller, F.L.S., Vice-Presidents, with J. Hector, M.D., F.R.S., and Messrs, J. Kebbell, W. Lyon, F.G.S., R. Hart, and W. Skey, as members of the Council. F. M. Ollivier, Esq., Hon. Secretary and Treasurer. Messrs. J. Prendergast, G. Allan, W. Colenso, F.Z.S., and Dr. Knox, were elected new members.—Dr. Hector called attention to a live katipo or poisonous native spider, with nest and young ones, on the table, and read a short notice by Mr. Duigan, of Wanganui, of an extraordinary flight of beetles that passed over that district in December last.—A paper was then read by Mr. Travers from Mr. Shand, of the Chatham Islands, describing the different kinds of Mokihi or flax stalk canoes that the natives used in former times, a model of one of which is in the Museum.—Dr. Hector gave an interesting account of the reports he had received from more than thirty stations respecting the magnificent meteor that passed over New Zealand on the 1st instant, at 8.30 P.M., which, he stated, had a general course from about a point west of north through the zenith of Picton, over which place it passed at less than thirty miles altitude above the surface of the earth, travelling with an apparent velocity of 12 miles per second. Its form was that of a ball intensely luminous, of a reddish hue, with a long very brilliant tapering tail, the light of which resembled burning magnesium wire, but giving off red sparks. It completely eclipsed the light of the moon which was shining brightly. The area over which it had been seen has a length of 700 miles, and width of 300, from lat. 36° S., long. 122° E., to lat. 46° S., long. 175° E. The apparent diameter of the head was 10′, and the length of the tail tapering about 1° Some of the observations appear to indicate that its course must have descended towards the earth's surface, but this depends on mere estimates of angular altitude, which cannot be depended on. The prolonged detonation which followed the passage of the meteor does not appear to have been heard at all the stations, but chiefly at those in the vicinity of Cook Strait, where the path of the meteor intersected New Zealand, all the observers in the North Island having seen it to the west, and those in the South Island to the east. When nearest to Wellington it must have been at a distance in a direct line of fifty-five miles, which agrees with the time, five minutes, which elapsed before the report was heard. This shows that the report did not proceed from the final bursting of the meteor, but proceeded from it at the time it was nearest to the observer. Indeed, from the length of the path in which the meteor was seen, its sudden disappearance, as if by bursting, must have been an optical illusion in the case of all the northerly observers. Mr. Marchant stated that he had witnessed another meteor, almost equal in brilliancy to the above, on the previous evening (27th inst.), passing from east to west. Mr. Floyd of the Telegraph Department, stated that this meteor was reported at several stations in the North Island, and appeared to have passed over Napier on the east, to Patea on the west coast. Its colour was blue.—After some further discussion two important papers on the electromotive and conductive power of mineral sulphides, were read by Mr. Skey, in which he claims to have made some discoveries.

### Paris

Academie des Sciences, April 21.—Eighteen members present. The sitting was not devoid of interest, although the communications were far from numerous. M. Egger, professor of Greek at the Sorbonne and member of the Academie des Belles Lettres, availed himself of the privilege granted to the members of different academies. He read a very long dissertation on a papyrus found in 1866, which gave a great deal of information on the state of ancient Egyptian civilisation. It related chiefly to the prices of different articles used in those times. The bursting of the shells and the thunder of French artillery was distinctly heard. It was an impressive scene to see these learned men discussing a civilisation which was swept from the earth so many centuries ago at a time when their own country was threatened by ruin not less awful and perhaps more disgraceful. The *Comptes Rendus* of the 7th April had gone through the press as usual. Its most important article was a communication from Prof. Simon Newcomb on the new method invented by him for discussing the inequalities of the moon's motion. The extract, four pages in length, is an abstract from the original communication, which was left by the American astronomer in the hands of the Committee instructed to report upon it. These *Comptes Rendus* are printed by Gauthier-Villars, printer to the Academy, at a great expense, and with the greatest difficulty. The continuation of the publication is highly creditable to that firm, of which the head, M. Gauthier-Villars, is a former pupil of the Polytechnic School. To show how difficult the business must be to manage, we must say, moreover, that the publisher of the *Connaissance des Temps* for 1872 is stopped merely because it is impossible to find working men for the printing of the last four sheets, which are ready to go through the press. If things continue for some time, French navigators sailing for distant Pacific Ocean expeditions will be obliged to resort to the Nautical Almanack.

## DIARY

*THURSDAY*, May 11.

Royal Society, at 8.30.—An Experimental Inquiry into the Constitution of Blood, and the Nutrition of Muscular Tissue: Dr. Marcet, F.R.S.—On Non-Spontaneous Generation. On the Influence of Heat on Protoplasmic Life. On the Preparation of Nitrogen: Prof. Crace-Calvert, F.R.S.
Society of Antiquaries, at 8.30.—Sepulchral Remains at Rouen: The Abbé Cochet, Hon. F.S.A.—Letter to Mr. John Stanhope, from Sir Geo. Buck: Earl Stanhope, President S.A.—Sir James Tyrrell cleared (A.D. 1483): Rev. W. H. Sewell.
Mathematical Society, at 8.—On the Singularities of the Envelope of a non-Unicursal Series of Curves: Prof. Henrici.—On the Resultant of a large number of Vibrations of Irregular Phase, as applied to the Explanation of the Coronas: Hon. J. W. Strutt.—A Question in the Mathematical Theory of Vibrating Strings: W. Spottiswoode, F.R.S.—On the Problem of Finding the Circle which cuts Three given Circles at given angles (communicated by Prof. Cayley, F.R.S.): J. Griffiths, M.A.
Royal Institution, at 3.—On Sound: Prof. Tyndall.
London Institution, at 7.30.—On Economic Botany: Prof. Bentley.

*FRIDAY*, May 12.

Astronomical Society, at 8.
Quekett Microscopical Club, at 8.
Royal Institution, at 9.—On the Defence of the United Kingdom: Col. Jervois, R.E.

*SATURDAY*, May 13.

Royal School of Mines, at 8.—Geology: Dr. Cobbold.

## *THE PEOPLE'S UNIVERSITY*

A GIGANTIC and imposing educational scheme is about to be launched, which, whether it proves feasible or not, must attract the attention and enlist the sympathy of all well-wishers to the intellectual development and material welfare of the country. This is no less an idea than the establishment of a National Working Men's University, which is to be founded with special reference to instruction in those subjects which have a direct bearing on the arts and manufactures. That our workmen are, as a rule, altogether ignorant of the scientific principles upon which the processes they ought to guide and govern are dependent, and that England in this respect stands in a much inferior position to continental nations, is now a well-recognised fact. The result of this lamentable ignorance is stated by certain authorities to be severely felt in those of our trades and manufactures in which we have to compete with other nations; and although this conclusion has been denied by many, yet concerning the necessity for scientific education amongst our artisans there has never been a difference of opinion. The question then arises, How are we to bring to our rising artisans on an extended and national scale the knowledge of scientific principles which they so much need, and for which the best of their class show so much desire and even aptitude? One solution to this problem is being attempted by the scheme of a National University for Industrial and Technical Training. The proposal is to establish a metropolitan institution in which complete and thorough instruction in all those branches of knowledge which are of importance to our manufacturing industry shall be given. It is proposed (1) to build ample lecture-rooms, laboratories, art (as well as scientific) museums on the most extended scale; (2) to create professorships both of the pure sciences and of such more technical subjects as can be systematically treated, and we will also hope chairs of at least such literary subjects as the modern languages; and (3) to found scholarships by which artisans may be enabled to live during the years of their studentship. This central university is to be connected with other similar institutions scattered over the country in the foci of the industrial pursuits, each carrying out in its locality the same function which the central one is to perform perhaps on a somewhat higher scale for the metropolis and the country in general.

The idea is a noble and grand one, but the difficulties of carrying it out are immense, whilst the dangers of the scheme proving abortive are scarcely less so. The first requisite in such a scheme for artisan education is money, the second condition of success is good management. If the wealthy city guilds come forward to the good work with subscriptions of tens and hundreds of thousands, and if men of ability and of high views and of sound practical knowledge on educational questions undertake to work the scheme, the University of the People may possibly become a reality.

That the best of the English artisans value a scientific training when it is placed within their reach, is a matter which has now been satisfactorily proved, and if any system of high science instruction can be inaugurated by which the force of thousands of powerful brains, now lying dormant, can be made productive, an increase of energy will be gained to the country of which we cannot form the slightest conception.

When, however, we come to count the cost, we may well doubt the accomplishment of the design, for we must set it down as a first principle that every artisan must not only be gratuitously taught, but also kept during the period of his studentship. This would necessitate a scholarship of at least 40*l.* per annum for each student; or 40,000*l.* for every thousand students; add to this a like sum (a moderate estimate) for the payment of professors, expenses of working the science departments, museums, &c. we see that each student will cost probably nearly 100*l.* There is, of course, plenty of money, even in the metropolis itself, which might with propriety be applied to this most laudable object, but whether such a sum can be raised as shall yield an annual income say of 80,000*l.* to 100,000*l.* large enough to support a People's University on a truly national scale (and anything less than this would be a practical failure) appears more than doubtful. For although the importance of this movement, in a national point of view, cannot in reality be overestimated, it is but too evident that this opinion is not held by the world at large, and certainly not (unless they are much belied) by rich corporations or city companies; and without aid from some such old and wealthy foundations, a scheme of this kind can scarcely be permanently supported.

The financial are, however, by no means the only or the most important difficulties which will beset the new University. These will only begin to be felt when the scheme has been started—such as dangers of giving an instruction too purely theoretic, or of running into the worse evil of teaching details without scientific *aperçu*.

In face of such difficulties it all the more behoves those who really believe the movement to be a wise and beneficial one, to exert themselves to support it. It is simply a duty to draw attention to a proposal which, if properly carried out, may improve to a very important extent the condition of Science in England.

H. E. ROSCOE

## *THE SUN*

*Le Soleil. Exposé des principales découvertes modernes sur la structure de cet astre, son influence dans l'univers et ses relations avec les autres corps celestes.* Par le P A. Secchi, S.J. Pp. 422, 8vo. (Paris: Gauthier Villars, 1870. London: Williams and Norgate.)

*The Sun: Ruler, Fire, Light, and Life of the Planetary System.* By Richard A. Proctor, B.A., F.R.A S. Pp. 480, crown 8vo. (London: Longmans, Green, and Co., 1871.)

DURING the past few years the number of workers in the domain of solar physics has been so great, their progress so rapid, and the results of their labours have been published in so many forms, that it has been difficult to keep pace with them. Under these circumstances, a summary of these labours, which shall extract what is most valuable from all, and refer the reader to the original publications for the remainder, is a great desideratum.

The work of the Père Secchi seems designed not so much to supply this particular want as to give a general popular *resumé*, of what is known of the physical constitution of the Sun. It would therefore scarcely be just to measure it by the standard in question, and all the less just because the very branch of research in which the author is most eminent is that of which he speaks the least. Only one chapter and part of another are given to spectrum analysis of the solar light and its results, and as the operation of spectrum analysis itself is described at some length, there is little space left for the discussion of the results. Roughly speaking, one half the book is devoted to a description of purely optical phenomena as observed with a telescope. The appearances and movements of the solar spots are in particular treated at great length. The other half is devoted to radiation, temperature, gravitation, spectrum analysis, and the relation of the sun to the stars. The chapter on Radiation seems designed to save the reader the trouble of referring to elementary works on natural philosophy or chemistry, and the next has nearly the same object with respect to astronomy.

The chapter on Temperature is that which has most piqued our curiosity. The author calculates that the temperature of the sun must be at least ten millions degrees centigrade. On examining the process by which he reaches this conclusion, we find that he sets aside the law of radiation of Dulong and Petit, and substitutes that of radiation proportional to the simple temperature. He gives no reason for the adoption of this new law, and we were not aware that the other had been disproved. The question is of importance, for, if the law of Dulong and Petit were true, a sun at a temperature of ten million degrees would speedily reduce our earth to vapour. It would be interesting to measure the temperature of a furnace by the effect of its radiation upon a thermometer, in the same way that Père Secchi has measured that of the sun.

The paper and typography of the work are excellent, and among the illustrations are six finely-executed charts of stellar spectra, illustrating the author's classification of such spectra.

Mr. Proctor's work, while covering nearly the same general ground with the former, is much more complete in its account of recent observations and theories, especially of the phenomena of solar eclipses. It is, on the whole, better than might have been supposed from its stilted title.

The first chapter is designed to give an historical discussion of the solar parallax. A history of this subject at the same time popular, accurate, and complete, is indeed much to be desired; but Mr. Proctor's is imperfect and inaccurate in a remarkable degree. He begins very well, but grows worse and worse as he approaches his conclusion. He suddenly stops his history with the year 1868, and ignores all that has been said or done since. Confining ourselves to two or three paragraphs and a note near the close of the chapter, we find the "ligaments," "black drops," and distortions sometimes seen in interior contacts of the limbs of Mercury or Venus with that of the Sun, described as if they were regular phenomena of a transit, without a mention of the facts and experiments which indicate that these phenomena are simple products of insufficient optical power and bad definition, which disappear in a fair atmosphere, with a good telescope well adjusted to focus; and this is followed up with a grave proposal to measure this product of bad definition during the next Transit of Venus. One might suppose, from his closing statements, that Mr. Stone was the first to "infer from the account given by the different observers, whether real or apparent contact was noticed," and to allow for the difference between the two. The subsequent examinations of the observations used by Mr. Stone are, with a single insignificant exception, entirely ignored. We cannot, therefore, but wish that the author, before printing this chapter, had submitted it for revisal to some one acquainted with the subject.

In the second chapter we find the author more at home. We rarely see the accuracy of the mathematician united with that vigour and clearness of style so desirable in the popular presentation of truth. Mr. Proctor, however, here seems to unite both qualifications in a high degree.

The third chapter gives a very clear and satisfactory account of the first principles of spectrum analysis. The historical and the logical development of this subject coincide remarkably with each other, and it is therefore that very properly adopted in its presentation. We find one statement which we must ask leave to doubt, until a more satisfactory proof is given than we have yet seen. It is that the intensity of the D light (if we may use the expression) of incandescent sodium vapour is not only apparently but actually diminished by passing sun-light through it. If this were so, it would follow that the sodium flame not only absorbed the light in question, but that, in doing so, it lost the power of emitting it. This would, indeed, be a remarkable result. We understand Kirchhoff, in the experiment alluded to, to speak only of relative light and darkness, and to assert that the D part of the combined spectrum is less bright than the surrounding and intermediate parts. But we cannot conclude from this that there was really less light there than when the sodium flame shone by itself, as Mr. Proctor does.

The succeeding chapters give a very full, classified summary of recent observations upon the sun, the protuberances, the corona, and the zodiacal light. The accounts of the phenomena observed during total eclipses are carried up to that of August 1869. From the preface it would seem that the work was passing through the press in December 1870, and it is a pity it could not have been completed by adding the observations of the eclipse during that month. The discussion of theories of the corona and protuberances is evidently honest, and perhaps intended to be complete. He tries to disprove the "atmospheric glare theory" by showing that no part of our atmosphere in the direction of the corona is illuminated by direct sunlight, a proposition which we apprehend no one ever maintained. But we know that every bright celestial object is surrounded by a certain amount of stray light, due to atmospheric reflection, which increases rapidly in intensity as we approach the object; and such a light must therefore surround the real corona and protuberances. We also know that every bright object of this kind appears larger than it really is, and of a different form, from mere optical illusion. Until these two effects are eliminated, we can gain no positive knowledge either of the exact form or the exact extent of the real objective corona. The "meteoric theory" of the corona and zodiacal light, sustained by the author, is subject to objections as grave as those he brings against other theories;

but we have no room to explain them at length in the present article. It is the less necessary to do so, as the final conclusion of the subject is very well embodied in two lines of the table of contents :—"The origin of the prominences still a mystery," "The corona's true nature also unknown."

Respecting the general spirit of the work, it may be remarked that while the author doubtless intends to do justice to all the investigators whose labours he describes, there is one feature of the work which may lead the reader to doubt whether he has really done so. We refer to the indications of personal feeling scattered here and there, and the depreciating tone adopted in treating of the labours of those he does not personally like. However this may be, there are few or no popular expositions of a scientific subject in which the observations, opinions, and labours of so many men of science have been collected and referred to their authors.

S. NEWCOMB

## *FOREIGN SCIENTIFIC ASSOCIATIONS*

*Proceedings of the Scientific Association of Trinidad*, 1866—69, Port of Spain. (London : Trübner and Co.)

*Proceedings of the Essex Institute.* Vols 4 to 6. 1864—70. Salem, U.S. (London : Trübner and Co.)

*Journal of the North China Branch of the Royal Asiatic Society.* 1864—68. New Series. (Shanghai : A. de Carvalho. London : Trübner and Co.)

THE Scientific Association of Trinidad has now been in existence for some years. Its object is "the cultivation of scientific knowledge in the West Indies ;" and if we may judge by the character of most of the memoirs contained in the parts of the Proceedings hitherto published, it must be a very useful society.

Dr. Mitchell has communicated more papers than any other member. He has contributed articles "On the Use of Sulphites in Medicine," with an "Additional Note on the Use of Sulphites and Bisulphites, whether Medicinally or otherwise," "On Earth Closets," "Hints on the Breeding and Rearing of Horses," "On the Manufacture of Sugar by the Process of Drying the Cane," and "On the Manufacture of Sugar by Evaporation." Mr. Guppy contributes three papers, "On the Mollusca of Trinidad," "On Petroleum and Naphtha," "Remarks on the Cultivation of Scientific Knowledge in Trinidad," "On the Tertiary Fossils of the West Indies," and "On the Marine Shells found on the Shores of Trinidad." Amongst other articles of permanent interest we may especially mention Dr. Goding "On the Petroleum or 'Green Tar,' and the 'Manjack' of Barbadoes," the Hon. Richard Hill, "On Poisonous Fishes," and "On Fish Poisons ;" and Mr. Prestoe's "Catalogue of Plants in the Royal Botanic Gardens." Many of the subjects treated of in these Proceedings serve to illustrate various points described by the Rev. Canon Kingsley in his charming "Letters from the Tropics."

The Essex Institute seems to have commenced its existence as the Essex County Natural History Society, and it published a "Journal" as early as 1836. This Journal subsequently merged in the "Proceedings" and "Historical Collections" of the Institute, the former commencing in 1848, and the latter in 1859. It is only with the "Proceedings" that we have to deal at present, and the volumes now before us contain "The Records of the Meetings, the Written Communications on Natural History and Horticulture, and the Naturalist's Directory." Amongst the most important memoirs we may especially notice Morse "On a Classification of Mollusca based on the Principles of Cephalization ;" Verrill's "Synopsis of the Polyps and Corals of the North Pacific Exploring Expedition from 1853 to 1856, collected by Dr. Stimpson ;" Hyatt's "Observations on Polyzoa ;" Dr. Wilder's "Revision of researches and experiments upon Silk from Spiders, and upon their Reproduction, by Raymond Mariâ de Termeyen, a Spaniard, translated from the Italian ;" Horace Mann, "On the Flora of the Hawaiian Islands ;" Cowes's "Catalogue of the Birds of North America in the Museum of the Essex Institute ;" Wood, "On the Phalangeæ of the United States ;" and Packard "On Insects inhabiting Salt Water."

These quarterly "Proceedings" came to a close at the end of the year 1868, when the "Bulletin of the Essex Institute," which appears in monthly parts, took its place. The "Bulletin," which we shall take an early opportunity of noticing, contains "All the short Communications of General Interest, both of an Historical and Scientific character, made at the Meetings of the Institute, and the Records of the Meetings and Business of the Institute."

Turning from the West to the uttermost parts of the East, we take up the "Journal of the North China Branch of the Royal Asiatic Society," of which the new series commenced in December 1864, when the Society which had been formed in 1861 was reorganised.

The papers contained in this Journal are for the most part very interesting, in consequence of their treating of subjects on which comparatively little is known in this country. The geographer will find articles "On the City of Yeddo," "On the Overland journey from St. Petersburg to Pekin, "On an Overland trip through Hunan from Canton to Hankow," "On the Sea-board of Russian Manchuria," "On a Journey from Pekin to Chefoo *viâ* the Grand Canal," "On a Journey from Pekin to Shanghai," and "On a Journey from Canton to Hankow through the Provinces of Kwangtung, Kwangsi, and Hunan." The naturalist (using the term in the widest sense) will find articles "On the Geology of the Great Plain, and of a portion of Quangtung Province," "On the Coal-fields in the South Eastern Province of China," and "On the Bituminous Coal Mines west of Pekin," "On the Birds and Beasts of Formosa," "On Chinese Notions regarding Pigeons and Doves," "On some Wild Silk Worms of China," "On the Entomology of Shanghai," "On the Sorgo or Northern Chinese Sugar Cane," and "On the mineral and other productions of North China and Shantung." Amongst other valuable papers may be mentioned those by the late Dr. Henderson "On the Medicine and Medical Practice of the Chinese," by Dr. Bastian "On the Remains of Ancient Kanbodies," Dr. Keer "On the Great Examination Hall at Canton," the Rev. A. Wylie "On the Opinions of the Chinese with regard to Eclipses, and on the Eclipses recorded in Chinese works," Mr. Hollingworth "On the Chinese Game of Chess," Mr. Forrest (acting Consul at Ningpo) "On the Christianity of Hung Tsiu Tsuen, being a Review of Taeping Books," and the Rev. S. R. Brown's translation of a curious old Japanese manuscript entitled "Annals of the Western Ocean." The last-named article is one of singular interest in many respects. It is divided into three parts, the first of which contains an account of the arrest of a Roman Catholic priest upon an island called Yaku-Shirna in the year 1708, his removal to Nagaski and examination there, and his subsequent arrival at Yeddo, imprisonment, trial, and death. The name of the person as given in Japanese syllables was Jean Baptista Shirotte, and he is supposed to have been the last Roman Catholic missionary who landed in Japan previous to the year 1859. The second part contains the report of the prisoner's examination, and the information obtained from him respecting the military and naval power, and the wars and conquests of the Western nations; while the third comprises the missionary's answers to the questions put to him about himself and his family connections, his reason for coming to Japan, and his religious creed.

From the very curious paper on the "Birds and Beasts of Formosa" which is translated by Mr. Swinhoe, H.B.M. Council at Taiwan, from the 18th chapter of the "*Tai-wan-foo-che*, or Statistics of Taiwan," we learn that "as soon as the doe that has finished suckling observes her roe getting to maturity, she deserts it and repairs to other hills, fearing that her young might entertain an improper affection for herself. Animals do not confuse the laws of consanguinity, the horse excepted. The doe deprives her offspring of any such opportunity by setting a distance between herself and her young." We have quoted this passage because it contains almost the identical views expressed by Aristotle,* but we suspect that this idea is not based on any sound foundation.

Several of the articles, and especially those of Dr. Henderson "On the Medicine and Medical Practice of the Chinese," and of Mr. Walters "On Chinese Notions about Pigeons and Doves," throw considerable light on the absurd mode of practice adopted by the native doctors. From the latter paper we learn that the eggs of pigeons are an antidote to the injurious effects of boils and smallpox. Some persons may think the remedy worse than the disease, as the following course has to be followed:—Two eggs must be hermetically sealed in a bamboo tube and placed in the middle of a cesspool for half a moon. The whites are then to be mixed with three ounces of *shen-sha*, a very fine red sand-like substance, and the compound is to be divided into pills of the size of a green pea. If thirty of these pills are taken three times a day, the patient will soon find relief, for the poisonous matter will be rapidly discharged by the bowels and kidneys. The excrement of the same bird, when roast to cinder and soaked in wine, forms a cure for cold on the chest, and there are several other affections in which it is very useful. Let us conclude with a pleasanter remedy. "Of the *shi-chin* or wood-pigeon it is written that its flesh is sweet, delicate, and without poison. It also gives one a composed mind, and enables him to do with little sleep. Its foot and leg bones have the very delightful quality of exciting affection between husband and wife. If on the fifth day of the fifth moon the husband takes one of these bones and the wife takes one, each putting the bone in a basin of water, one from the left and the other from the right side, the two bones will come together and float together, thus indicating a long and happy union to the parties trying the experiment."

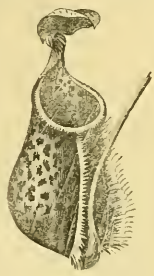
G. E. D.

* See his "History of Animals," Book ix., chap. 34 (Creswell's Translation in Bohn's *Scientific Series*), in which he tells two very remarkable stories regarding a camel and a stallion in relation to this subject.

## *OUR BOOK SHELF*

*A Manual of Structural Botany for the Use of Classes, Schools, and Private Students.* By M. C. Cooke. New Edition. (London: R. Hardwicke.)

WE have so often felt it our duty to expose the incompetence of those who attempt to write elementary text-books of science, that it is a real pleasure to come upon one like Mr. Cooke's "Manual of Botany," where a man of really accurate scientific knowledge applies himself to writing an elementary work on the rudiments of his science. The special object of the publication, as stated in the preface, is to supply a cheap manual to place in the hands of students in the Botanical Classes established for operatives in connection with the Department of Science and Art; but it may well be used as a first book to prepare for other objects, as, for instance, for the first B.Sc. examination, or that for Women, at the University of London, though it would then have to be supplemented by others on the systematic branch of the subject. The descriptions are clear and accurate, and expressed in commendably terse language. It is illustrated by over two hundred woodcuts, some of them of decided merit; and we have reserved our crowning sentence of commendation till the last—the price is one shilling! A. W. B.



Pitcher of Nepenthes

*Geographisches Jahrbuch.* III. Band, 1870. Unter Mitwirkung von A. Anvers, J. Baeyer, A. Fabricius, A. Griesbach, Fr. Müller, Fr. Neumann, L. K. Schmarda, F. R. Seligmann, J. Spörer, H. Wagner:—Herausgegeben von E. Behm, Mitredakteur von Petermann's Geogr. Mittheilungen, 1870. (Gotha: Perthes. London: Williams and Norgate.)

WE lately had occasion to speak in terms of high commendation of Vivien de St. Martin's *Année Géographique*, and we can award equal praise to Behm's corresponding work, which is the more elaborate of the two, and consequently the less agreeable to the ordinary reader. It is divided into four parts, devoted respectively to Geographical Chronology, Geographical Statistics, Essays on the Progress of Geographical Knowledge, and Tables of use in Mathematical Geography. The first part consists of a geographical calendar, stating the date of the discoveries of various countries, of the birthdays and deaths of great geographers, &c. (for example, on the day on which we are now writing, April 22nd, J. Richer arrived at Cayenne, 1672; the island of Rea or Wallis was discovered by Maurelle, 1781; Reao was discovered by Duperry, 1822; Denham arrived at India (Mandara) 1823; and the *Novara* sailed from Singapore, 1858); and it treats of the manner in which time is calculated in certain countries. The second part is extremely valuable, but is very dull; any information that may be required as to the state of the population of any country, of the number of houses and inhabitants in a square mile, &c., may be readily found here. The third part consists of extremely valuable memoirs by Baeyer, on the progress lately made in the measurement of the degree; by Griesbach, on the Geography of Plants; by Schmarda, on the progress of our Knowledge of the Distribution of Animals; by Seligmann, on the Progress of Ethnology; by Müller, on Linguistic Ethnography in Relation to Anthropology; by Fabricius, on the Progress of our Knowledge of National Statistics; by Spörer, on the History of Geography; by Neumann, on the Products, Merchandise, and Currency of Different Nations; and by Behm, on the most important Geographical Travels during the years 1868-69. Behm's memoir, which extends over more than a hundred pages, is unquestionably the most valuable portion of the book, and next in order of interest, at all events to the naturalist, we should place the essays of Schmarda and Griesbach. The last part of the volume is purely numerical, and requires no comment. Everyone desirous of keeping himself up to the existing level of geographical knowledge should purchase both the German and French annuals. For those who must content themselves with a single volume, we should say the French one was the better.

G. E. D.

*The Romance of Motion.* By Alec Lee. (Longmans: 1871.)

THIS is another of those books in which the author does not understand the first principles of the science with which he deals. The laws of motion seem to be affording more than usual trouble to certain people just now, and most unfortunately they write books about it couched in the longest scientific terms and the most formidably accurate-looking phraseology. The author alleges, as one of the extraordinary paradoxes among the opinions of the nineteenth century, "how all bodies are supposed to persevere in their state of rest or of motion, in a straight line, unless compelled to change that state of rest or motion by the impression of some force on them; and how, in opposition to this law, the planets become accelerated and retarded in their orbits without such adequate impression of force; also how bodies initially projected at the surface of the earth, fall by the force of gravitation with velocities uniformly accelerated, and how the planets similarly projected descend towards the sun with velocities comparatively equal throughout the entire duration of their revolutions." We need hardly remind the reader that these conclusions, so far from being in any way in *opposition to* the law of motion stated by the author, are in complete harmony with that law, and, as was demonstrated by Newton, follow from it on the hypothesis (to give it no higher name) of gravitation. The author at least might have observed, in comparing the case of the stone and of the planet, that the direction of the force on the former is unaltered, while that of the force on the latter is continually changing.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Thickness of the Earth's Crust

ARCHDEACON PRATT's explanation in NATURE of May 11 seems to assume that a rigid body moving in contact with a fluid body can never communicate its own rate of motion to the latter as quickly as it would do if this were also a rigid body attached to itself. Supposing the earth to consist of a rigid crust inclosing a fluid interior, and the crust to be moved by the forces producing precession, it would, he says, "slip over the surface of the revolving fluid through a small space proportionate to the push given to the poles. The fluid could not possibly acquire in an instant this new motion, however small it might be, because the fluid is not rigidly connected with the crust."

I venture to suggest that if in the last sentence Mr. Pratt would substitute the word "slow" for "small," the question would have a different aspect, notwithstanding his subsequent statement to the contrary.

Strictly speaking, when a body, however rigid, is moved, the whole of it never moves instantaneously. The particles on which the moving force immediately acts move first, and the rest move in succession afterwards. The smallness of the interval is the measure of the rigidity, but some interval must always be assumed. Bodies move as a whole through the attractive or repulsive forces of their particles; and every such force resolves itself into a power of moving something through a certain space in a certain time. The reason why a moving solid will "slip over" the surface of a fluid instead of carrying it with it, is that the rate at which it can carry it with it by reason of its attractive force is commonly less than the rate at which the solid is moving. But if the motion is slow enough to exceed that which the attractive force will cause in the fluid, it will slip over no longer; and if it be so slow that not only the power of the solid over the fluid, but of the fluid particles over each other, is able to produce an equal rate of motion, the whole mass will move together as if it were a rigid body. This rate will depend chiefly on the nature of the fluid. If a metal plate four inches in diameter is filled with lamp oil, and made to rotate at about one revolution in three minutes, the oil will move with the plate without appreciable retardation, though if the speed be doubled, the oil is seen to be "slipped over." If water is used, or the size increased, the rotation must of course be very much slower. It would appear on these grounds, I think, that the extremely slow movement of precession might practically affect the whole body of the earth as if it were rigid, notwithstanding the granting of a fluid interior.

May 14 A. J. M.

---

IT requires no little courage to attack so eminent a mathematician as Archdeacon Pratt on his own ground, and it is, therefore, with the utmost diffidence that I venture to suggest that in his defence of Hopkins against Delaunay in your last number, he has mistaken a mathematical fiction for a fact.

In calculations involving quantities which vary in magnitude, the imperfection of our methods oblige us to have recourse to an artifice, and for the benefit of the non-mathematical reader, I will try to explain what this artifice is, taking the case of nutation as an example:—

The motion of the earth's axis which is known by this name, is caused mainly by the attraction of the moon on that part of the earth which lies outside a sphere, whose centre is the earth's centre, and its radius the polar radius of the earth. Now this force of the moon's attraction is never the same in magnitude; and, however small be the interval of time we consider, it is not the same at the end as the beginning of that interval; it is incessantly changing. Everyone will realise the difficulty of estimating the effect of such a force. This difficulty is got over by the artifice I mentioned, which is as follows:—The time is divided into a number of small intervals, and the attraction is supposed to keep during anyone of these intervals the magnitude which it has at the beginning of that interval, and at the end of that interval *suddenly* to assume the magnitude which it has at the beginning of the interval next following, and so on; the force, in short, instead of varying by insensible changes, is supposed to act by a series of fits and starts. This must be what Archdeacon Pratt means when he talks of "a succession of slight horizontal pushes being given to the poles." The amount of motion produced during each interval on the above supposition is then determined, and these amounts are added together to obtain the displacement produced.

It is clear enough that such a method can only be approximately correct; but it is also clear that the smaller each interval is, the nearer will the hypothetical be to the real state of the case, and the nearer will the calculated be to the actual result. As long as the intervals are finite there must be some error, but the smaller the intervals are made the less will this error be. I need not go into the methods of mathematical analysis which enable us to get rid of this error, and which, when we have found out what will be the effects of a force acting with variable intensity by fits and starts separated by small finite intervals, enables us to deduce the effect of the same force when it comes to vary incessantly; for I hope I have made clear the nature of the mathematical artifice on which this analysis is founded.

Now it seems to me that Archdeacon Pratt all along reasons on the supposition that the moon's attraction acts after the manner the mathematical artifice I have described supposes it for the mere necessities of calculation to act. All his argument, if I understand it aright, depends upon the displacement being by fits and starts. Thus he says (NATURE, July 28, 1870), "The precessional force has its full effect in producing the precession of the solid crust, the fluid *not having time** to diminish that effect before the axis has assumed a new position;" and "The friction of the fluid within, which *has not time* to influence the nutation before the nutation is actually produced;" and (NATURE, May 11, 1871), "Suppose a succession of slight horizontal pushes to be given to the poles in a continually altering direction, the effect will be that the revolving crust will be continually slipping over the revolving fluid, which *has not time* to acquire the new motions given *instantaneously* to the solid crust."

The leading idea in all these passages seems to me to be that the attractions of the sun and moon, to which precession and nutation are owing, act by impulses, by a succession of sharp pulls quickly repeated. This is truly enough the supposition with which mathematical calculation starts; but the real action, I need not say, is a steady, continuous, though ever varying, pull, and it is the result of such an action which our calculations in the end lead us to, by a method which enables us to get rid of the error necessarily involved in the approximate result which would follow from our first supposition.

I cannot then help thinking that even Archdeacon Pratt has for once been carried away by the beauty of mathematical analysis, and has for the moment forgotten that the conditions which it is obliged to employ for its ends do not in their initial form represent the actual conditions of nature. The explanation occurred to me on first reading his paper in the *Philosophical Magazine*, but seemed to me so unlikely that I shrank from putting it forward. I can, however, in no other way imagine how he can have come to the startling conclusion, that, if a solid shall be moved by a steady, continuous pull over an interior ball of fluid, it can make no difference in the result, whether there is or is not friction between the interior of the shell and the surface of the fluid. Archdeacon Pratt, will, I know, if I am wrong, pardon my presumption and put me right.

Barnsley, May 12 A. H. GREEN

### Pangenesis: Graft-Hybrids

EACH person who assails this unfortunate "provisional hypothesis" makes the attack from his own particular point of view. Thus, in NATURE of last week Prof. L. S. Beale, as a microscopist, objects to it because the gemmules cannot be made evident to the senses. From this somewhat narrow view of the case the atomic theory of chemistry, the undulatory theory of light, or the mechanical theory of heat, must all break down, for no one has as yet seen an ultimate atom, or an ethereal undulation. Mr. A. C. Ranyard, in the same paper, publishes a letter which is quite at variance with fact, for if he will turn to pp. 390, 391, 394, 397 in vol. i. and pp. 364 and 365 vol. ii. of Mr. Darwin's work on "The Variation of Animals and Plants under Domestication," he will there find many cases given of the scion affecting the stock and producing intermediate forms known as "graft-hybrids." Pangenesis has not yet "received its death blow."

R. MELDOLA

May 13

IN your last number Mr. Ranyard brings forward an objection to Mr. Darwin's theory of Pangenesis on the ground that the grafting of a bud on a stock of a different species does not produce a hybrid offspring. I am not about to defend the doctrine of Pangenesis, which appears to me incapable alike of proof and of disproof. It is, however, a well-known fact that the stock does affect the scion, and *vice versâ*. In Prof. Henfrey's "Elementary Course of Botany" (Dr. Masters's edition) he says, "A certain amount of physiological influence of the stock over the scion is shown to exist by such facts of horticultural experience as that the fruit of the pear is smaller and more highly coloured when 'worked on' the quince and medlar than when grafted on pear-stocks, and is earlier when worked on the mountain-ash." The well-known instances of the communication of variegation from the scion to the stock in *Abutilon*, recorded by Prof. Morren and others, are considered cases of contagious disease; but what is the theory of contagion but that the blood or other

* I have taken the liberty of italicising those expressions which seem to me of vital importance to the argument in these quotations.

"fluid" of an animal or plant is affected by emanations, call them "gemmules" or what you will, from another individual? The same writer records an instance which he considers well authenticated of the production of the hybrid *Cytisus Adami* by the grafting of *C. purpureus* on *C. laburnum*.

ALFRED W. BENNETT

### The Rev. Mr. Highton and Thermodynamics

YOU are cruelly kind to Mr. Highton in giving him space to develop his absurdities.

His new remarks on Joule, like his earlier ones on a paper by Sir W. Thomson, simply show that *he does not understand* what he ventures to criticise. Of course, what Joule now says is precisely what he said a quarter of a century ago, with the simple difference that it is put in a somewhat more popular form.

No one who has taken the trouble to understand the experimental *facts* and the elementary reasoning of which the Laws of Thermodynamics are the condensed expression, has any more doubt of their truth than of the truth of Newton's Laws of Motion. They are, perhaps, a little harder to understand; but the proof is of the same nature, and already almost of the same extent, in the newer science as in the older one.

I have not seen the *Review of Popular Science* referred to by Mr. Highton, but I hope (for the credit of that journal) that he misconceives its statements as he does those of Joule.

Your "first reviewer" (or rather précis-writer) of his article, whoever he may be, certainly gives him no encouragement in the number for Jan. 19, whatever may have been the effect of my treatment of his not singular case.

YOUR REVIEWER

### On the Radial Appearance of the Corona

WOULD an indefinitely extending solar atmosphere, if its existence could be proved, be in itself sufficient to explain the appearance of the solar corona? Should we not still have to explain the apparent radiation which is so distinctly part of the phenomenon?—If the light or heat of the sun which radiates symmetrically outwards as from a point at its centre be the cause of the illumination, surely the figure of the corona would bear some relation to the figure of the atmosphere or medium on which the light or heat acts? Yet I think I may say that it is quite impossible to conceive a medium so distributed and arranged as to form rays such as those seen in the corona. If the recent photographs had not shown beyond a doubt that this irregular radiating appearance belongs to the corona and the neighbourhood of the sun,* it would have gone a long way to prove that the corona is at least partly due to the earth's atmosphere or mere optical effect. But, as it is, I think this radiation clearly proves that the corona cannot be due to the direct action of the light and heat of the sun on any surrounding matter. In fact, I cannot conceive an atmosphere the character of which varies in a radial manner, however rapidly either its nature or density may vary with the distance from the surface of the sun. If, instead of an atmosphere, we try to conceive a ring of meteors, still the radial gaps so clearly marked on the photographs present insurmountable difficulty. This, moreover, is impossible on other grounds. It is impossible that there can be an almost homogeneous mass of meteoric matter circulating round the sun in the form of an outer sphere, and if it circulated in the ecliptic or any other plane, it would present the appearance of Saturn's belt, whereas the corona appears altogether different from this, and cannot possibly be a film of light in any plane but that of the sun's limb.

Nor can these radial rifts be of the nature of shadow. For the shadow which anything like a sun spot would produce in a misty atmosphere must be conical, the vertex of the cone being outwards, so that the edges of the shadow would approach each other instead of receding as they do. Moreover, such a shadow would still be seen through a great extent of illuminated solar atmosphere, and therefore be only partial or faint, whereas the rifts are so dark and definite as to imply a total absence of coronal light; this must be the case unless the rifts or gaps in the spherical envelope extended right across the sphere from front to back, and we know that there is no obstruction on the surface of the sun that could cast such an extensive shadow.

What, then, does this radiate appearance show the corona to be? I think that it proves that the corona is an emission either of illuminated matter or of an action illuminating matter,

* Has this yet been established?—ED.

such as electricity, driven off unequally from parts of the sun's surface, and in directions radiating from points either on or beneath the surface.* If only a small portion of the sun's surface, such as that covered by sun spots, sent out such streamers, the appearance might exactly coincide with that of the corona; for these streamers, when seen projected on to the plane of the sun's limb, might in some places appear to overlap so as to form a continuous corona, whereas in others they might appear to be separated by gaps.

So far as the appearance is concerned, it would be the same whether the emission consisted of matter or was electricity; there are, however, other indications of its being of the latter kind.

The action which the sun exerts on terrestrial magnetism shows it to be in an electric state, and the observations of Stewart and others have established a connection between the variations in its electric condition and the changes in the sun-spots and red flames, and the observations on the recent eclipse have connected the red flames with the brighter parts of the corona. Here then we have a distinct and independent reason for assuming that the electric condition of the sun's surface is partial and unequal, and for connecting the corona with this electricity.

As I have already ventured to explain the solar corona, as well as comet's tails and the aurora, to be a kind of electric brush, I now offer these remarks on the radial appearance of the corona in confirmation of my views.

Owens College, May 8 OSBORNE REYNOLDS

### A few more Words on Daylight Auroras

IN NATURE for December 29, 1870, there is a letter from Dr. G. F. Burder in reply to a previous correspondent,† who had sent a description, with an illustration, of a Daylight Aurora observed by him, wherein he made the following statement:—

But auroral arcs, as far as I know, never appear in the east, and the conclusion, therefore, is unavoidable, that the object observed was nothing more than a remarkably symmetrical form of cirrus cloud."

He then states his convictions that all records of so-called daylight auroras are "errors of observation."

As assertions like these might have an undue influence on the minds of those who read my letter on "Aurora by Daylight" (NATURE, May 4, 1871), I am induced to say a few more words on this subject, especially to prove the fallacy of such reasoning.

It is well known that the aurora borealis assumes innumerable shapes; some of the most remarkable were given by me some time ago in these pages;‡ and that they appear, at times, actually in the *east*, but more often in the north, north-west, and stretching to the south. A writer of some excellence in the last century § says:—

"Sometimes the aurora appears like arches, nearly in the form of a rainbow, reaching from one point of the horizon to another. The arches always cross the meridian at right angles, *tending to the east and west point of the compass.*"

The correspondent whom Dr. Burder is so hard upon, most probably saw the arc in a position nearer to this, than directly *facing* him, with his back to the *west*, and as the illustration sent by him shows only a segment of the arc, I am inclined to think that the extremities were nearly in the east and west.‖ The "cirrus cloud" hypothesis is simply untenable, when it is known positively that on several occasions the aurora was seen against an azure background, with no form of cloud in the field of view, as for instance that mentioned by me, where a faint arc was seen before sunset in the east (possibly N.E.) against a cloudless sky.¶ His other assertion, from which I must dissent, was: "A comparison of the auroral light with the light of other objects whose visibility can be more easily measured, tends strongly to confirm the view I have advanced." He then instances the invisibility of Donati's comet by daylight. He might have instanced the invisibility of the stars, although they can be seen in broad daylight when the observer is placed at the bottom of a deep pit; but this need not be done, for daylight does not always mean bright sunshine; and with diffused light, Venus is often seen before the sun has actually gone below the horizon. This, so far, may appear mere assertion, but the following will, I hope, be sufficient to show that the view he holds requires some kind of modification.

"A.D. 678.—This year the star (called a comet) appeared in August and shone like a sunbeam every morning for three months" (Anglo-Sax. Chron.).* By every morning I take to mean daylight, because in these months the mornings would invariably be very light, especially the few moments before the comet actually disappeared.

With regard to all the record of daylight auroras being mere "errors of observation," I am sure no one will continue to entertain such an opinion after carefully examining all that has been said upon the subject in these pages. As it may be useful to those who are interested in this question, I have made a summary of all the daylight auroras recorded in this and other publications, which do not admit of doubt.

A.D. 1122. A phenomenon appeared like a great and broad fire, and lasted till it was quite light. (Anglo-Sax. Chron.)

A.D. 1467. A *most probable day aurora*, described as "horsemen and men in armour rushing through the air."† (Ingulf. Second Cont.)

A.D. 1788. May 5 at 11 A.M. an auroral display seen, consisting of "whitish rays ascending from every part of horizon." Observed by "three different people." (Trans. Royal I. Academy for 1788, quoted by Rev. T. W. Webb in NATURE, May 11, 1871.

A.D. 1827. "Aurora Borealis seen in the day-time at Canonmills" at 4.30 P.M. Described in "Jameson's Journal" and NATURE for May 4, 1871. (Arcana of Science and Art for 1828.)

A.D. 1849.—In September an aurora seen, consisting of "three slightly diverging beams of light on the eastern horizon. One might have taken them for beams from a setting sun . . . had it not been that they did not emanate exactly from the spot where the sun had set; that they had an evident motion to the southard, and that two of them extended to the zenith, and finally down to the eastern horizon." ‡ (Mr. J. Langton, in NATURE, April 27, 1871.)

A.D. 1870.—September 4, about 4.30 P.M., an aurora observed "in the form of thin reddish streaks." ("S. B." in NATURE, October 13, 1870.)

A.D. 1870.—October 25, at 4.30 P.M., a brilliant aurora seen in the *east*, and fully described with illustration of it. (NATURE, December 8, 1870.)

A.D. 1870.—December. A *probable* auroral display, which was observed a "little before sunset," and developed as the evening advanced into a brilliant aurora borealis. The day phenomenon, however, not sufficiently described to make the record trustworthy. (J. Langton, in NATURE, April 27.)

A.D. 1871.—April 10, about 4.30 P.M., a whitish arc seen, almost east, against a cloudless azure sky. On the previous night there was a magnificent aurora borealis.§ (Mentioned by me in NATURE, May 4.)

These form the whole of the most reliable records, which are certainly few, for the period embraced between the earliest and present date; but I am inclined to believe that the occurrence of daylight auroras is not so rare as is here shown, but that they have been seen and actually recorded in the works which I have here and elsewhere quoted, but for the want of the statement of the time of day or night, one cannot tell to which the appearance belongs. Often a display which can be said to have been seen in the night, might as easily be said to belong to the day, so far as the actual wording of the record goes. It will follow from this that the scanty records we have of daylight auroras referred to phenomena of extraordinary magnitude and magnificence. JOHN JEREMIAH

### The Conservation of Force

I HAVE been endeavouring to understand what is meant by the Conservation of Force; and as it is one of the most interesting subjects I have studied, I send you the result of my labours.

* We are of opinion that there is still another explanation.—ED.

† NATURE, Dec. 8, 1871. ‡ Ibid, Dec. 29, 1871.

§ "Compendious System of Astronomy," by Margaret Bryan. London: 1797, p. 132.

‖ For evidences of night auroras being seen in the east, consult the letters in NATURE for 1870.

¶ NATURE, May 4, 1871, p. 8.

* This is confirmed in Beda, Flor. of Wor. (under A.D. 677) and Chronicum Scotorum (under A.D. 673 in error for 677).

† See also Pliny, Bk. II. c. lvii.

‡ This very singularly explains the following passage in Pliny:—"Round about the sun there was seen an arch when Lu. Opimius and Q. Fabius were consuls" (about B.C. 123). This was not an ordinary halo, for he says further:—"and a *circle* when L. Porcius and M. Acilius were consuls." (Bk. ii. c. xxix.)

§ It appears curious that the majority of the displays occurred at or about 4.30 P.M., in the autumn, winter, and spring months. Cases of magnetic disturbances during this hour are not rare, accompanying the aurora. It may prove of some value to note this.

The first law of motion laid down by Sir Isaac Newton (Princip. Math. Jes. Ed. tom. i. p. 15) is not a universal law, but is only capable of a restricted application. The incapacity of matter to alter its condition, whether of rest or motion, is a doctrine which becomes untenable when we examine matters which are always *proprio motu* altering their condition. Grave as such a statement may at first sight appear, we must begin with it if we wish to arrive at the truth.

Motion is the property which matter possesses of always changing its position relatively to other matter, and each little atom of the 64 elementary substances known to chemists contains a certain amount of tendency to move; this is a part of its nature, it would not be what it is without this; as that great mathematician, M. Poisson, says, the tendency to move resides in it. The five gaseous elements, for instance, have each their respective amounts of tendency to move residing in the atoms of which they are composed. Prof. Faraday says, in his "Researches in Chemistry," p. 454, "a particle of oxygen is ever a particle of oxygen—nothing can in the least wear it. If it enter into combination and disappear as oxygen—if it pass through a thousand combinations, animal, vegetable, and mineral—if it lie hid for a thousand years, and then be evolved, it is oxygen with its first qualities—neither more nor less. It has all its original force, and only that; the amount of force, which it disengaged when hiding itself, has again to be employed in a reverse direction when it is set at liberty."

Now what is the meaning of the word *force* which Prof. Faraday uses here? is it not the certain amount of tendency to move which I mentioned before?

A particle of oxygen contains a certain amount of tendency to move, without which it would not be a particle of oxygen at all; and this tendency it can never get rid of, "it has all its original force, and only that."

What, then, does the Conservation of Force doctrine amount to in plain English?

It amounts to the simple admission that the tendency to move is a property of matter inseparable from it and coexistent with it, and it is this tendency to move which is the cause of all the changes which we observe around us.

There is, however, nothing new under the sun, for the old doctrine of Argan in *Le Malade Imaginaire* is revived again; when Argan answers his examiner for a licence to practise in medicine, he says:—

Mihi a docto Doctore
Domandatur causam et rationem quare
Opium facit dormire
A quoi respondeo
Quia est in eo
Virtus dormitiva
Cujus est natura
Sensus assoupire.

Many a clever student has laughed at this answer who little thought that research and experience would confirm it so strongly as they now do.

The virtues of opium are chiefly dependent on the morphia which it contains, and morphia is one of the vegetable alkalis containing nitrogen in combination with carbon, oxygen, and hydrogen. The *virtus dormitiva* of morphia is the certain amount of tendency to move inherent in this combination; and this tendency, if the morphia is exhibited in the human subject, comes in contact with and retards the tendencies to move which certain component parts of the body possess, and produces that state which we call sleep. The salts of morphia are largely used to allay pain and produce sleep. Dr. Bence Jones says in his Croonian Lectures on Matter and Force, p. 84, "Stimulants, tonics, and evacuants may perhaps not only take part directly in the motions of any part of the body, but they may also promote or retard the conversion of one motion into other motions. Specifics and alteratives may directly as well as indirectly change the motions in the system. And sedatives and narcotics may have the same double action in retarding or stopping the motions that take place. This view will almo t lead us to consider all medicines as alteratives, and if so we may perhaps place stimulant and sedative medicines at the two extremes of the alterative actions; the stimulants giving rise to the greatest increase of motion, and the sedatives allowing the least motion or the nearest approach to rest."

The practical student of our day, when he speaks of terrestrial matter being at rest, means that it is then moving at the same rate of motion as the earth itself. Prof. Ansted treats of motion thus:—"The first and greatest lesson that the students of Geography and Geology must learn is that motion is not limited to masses of bodies, but is actually taking place always and under all circumstances within all masses, whether solid, liquid, or gaseous, and often without approaching the surface."—"Physical Geography," p. 2.

The Universe is one mighty system of changes, and these changes arise from the inseparable connection between matter and motion; and Dr. Bence Jones says truly, "The question between materialism and spiritualism is in fact only a question between ponderable and imponderable materialism."

Trinity College, Oxford N. A. NICHOLSON

## THE BIG GUN OF WOOLWICH

WHETHER considered as a weapon of terrible power or simply as a specimen of skilful and successful forging, the 35-ton Fraser cannon is without parallel. Of extraordinary strength and proportions, and withal so carefully, and one might almost say, elegantly finished, this magnificent gun is indeed a masterpiece well worthy of the greatest factory in England, from which it emanates. Cannon of larger dimensions have, it is true, been produced, capable actually of delivering a heavier projectile than that employed with the Woolwich weapon, but none of them are to be in any way compared with this, either in respect to battering power or length of range. That the gun is, moreover, not merely a show production, as was the case with the monster Krupp cannon, but a really serviceable and efficient fire-arm, is shown by its endurance of the severe test to which it was subjected at proof. On this occasion the 700lb. projectile was thrown from the gun by the enormous charge of 130lbs. of gunpowder—the largest, in fact, that has ever been safely consumed in any fire-arm—the explosion being without the slightest injurious effect upon the steel bore or surrounding wrought-iron castings. The solid cylinder of iron which constituted the shot issued forth at the terrible velocity of 1,370 feet per second, and, after travelling some fifty yards, buried itself in the butt of loose earth to a depth of thirty-three feet.

The pressure of the gas at the time of explosion was, as may be supposed, exceedingly great, and herein obviously lies the great difficulty to be overcome in the construction of large guns; this pressure or strain, we find, increases in a much greater ratio than the amount of powder that is burnt would appear at first sight to justify, and for this reason large guns require to be proportionately much stronger than little ones. Thus, in the present instance, when a charge of but 75lb. of powder was fired, the pressure of the gas upon the copper piston at the rear of the projectile was shown to be seventeen tons per square inch, while 130lbs. of powder (not double the former charge therefore) gave a pressure amounting to sixty-four tons on the square inch. It has, by the way, been questioned whether this method of estimating the pressure, by means, namely, of a copper piston which is pushed in upon itself, affords a strictly reliable test, but in any case there can be no doubt that the strain upon the gun is increased in a greatly increasing ratio to the quantity of powder consumed. When we state, therefore, that the weapon withstood in every part this excessive strain, and that, under ordinary circumstances, the cartridge will contain but 90lbs. of powder, there is every reason to believe in the solidity and perfection of the structure.

The data obtained by the firing of the gun at proof lead us to hope for very successful results from its employment. It is calculated that at a distance of fifty yards the heavy projectile would be thundered forth with such force as to penetrate fourteen and a half inches of solid iron, an armour plate such as no vessels of our present construction are enabled to carry. At two thousand yards—at upwards of a mile, therefore—the shot would possess enough penetrating force to pass clean through the side of the strongest ironclad afloat—those of the *Hercules* class—or, in other words, is endowed with impact sufficient to pierce twelve inches of iron; and it must be remembered that this last-named distance is one at which gunners can make very good practice, so that, under ordinary circumstances, every other shot would take effect against a target such as is presented by the keel of a large frigate. As regards extreme length of range, a quality of some importance, when, as in the recent instance of the Paris siege, great projecting power is of more importance than precision of aim, this Fraser gun may vie with almost any other, with the exception, perhaps, of Whitworth's cannon. The utmost distance to which "the Woolwich infant," as it has been nicknamed, will in all probability be capable of projecting a shell is about ten thousand yards, supposing the arm to be laid at an elevation of some thirty-three degrees.

So satisfactory, indeed, has this experimental structure turned out, that a further batch of sister guns have forthwith been commenced, and will serve to arm some of our heavy iron-clads which are now building. Only a small number of such weapons will be carried by these vessels—two, or at the most four, apiece—and thus our modern men-of-war will present a perfect contrast to those of a dozen years ago, when a ship, being regarded merely as a box of guns, sometimes received on board as many as a hundred and thirty cannon. Nevertheless, a broadside delivered from four guns of these giant dimensions (for the whole armament being carried in turrets may be brought to bear at one time), representing almost a ton and a half of metal, very far exceeds that which an old first-class three-decker could throw into her antagonist, and would indeed be sufficient to sink most vessels at a first discharge.

As regards the method of building up these large guns, we need say nothing, seeing that the subject was fully discussed recently in these columns. It may be of interest to know, however, that in the present instance as much as fifty tons of metal were employed in constructing the arm, and that at one time thirty tons of this was brought to a glowing white heat for the purpose of welding. The reverberatory furnace in which this massive coil was heated is an apartment in which a dozen persons could dine comfortably, and the length of the bars before coiling amounted to upwards of 1,200 feet. The length of the arm is sixteen feet and a quarter, and its extreme diameter fifty-six inches.

## *A NEW INEXTINGUISHABLE STORM AND DANGER SIGNAL LIGHT*

THIS new Signal, possessing most remarkable properties, has now been brought before the public. It was first exhibited at the President's meeting of the Royal Society on 22nd April, when it attracted great attention. The peculiarities of the Signal Light are, that it is self-igniting when placed in water or thrown on the sea. Contact with water being the only means of igniting the lamp, it is inextinguishable when once ignited; neither wind nor storm has any effect upon the flame. The light is of intense brilliancy, and of great duration, and can be seen for a great distance in the open-air. Photographs may be taken by the light of this new signal. Experiments were tried on the evening of 25th April, at ten o'clock, in the presence of some scientific gentlemen, to determine its brilliancy as a signal. A lamp was placed in a bucket of water on the top of Primrose Hill, and the light was so intense that after the signal had been burning for twenty minutes small newspaper-print could be distinctly read at a distance of seventy feet, notwithstanding that the night was thick and foggy. This new signal light will burn for over forty minutes. In construction the lamp is exceedingly simple, and so contrived that when once burnt the whole may be thrown away. The chemical preparation contained in the lamp is a solid, hard substance, free from danger; not affected by heat, and so non-explosive; and the signal is comparatively inexpensive. Its applications for marine signals are numerous. In case of shipwreck a few lamps thrown on the sea would illuminate the entire scene, and enable assistance to be promptly and efficiently rendered. For rocket-line apparatus it is equally valuable, as, bursting into a flame on falling into the sea, it would indicate the position of the rocket-line. In connection with life buoys it would be a mark to the drowning sailor. In life-boat services it would be a signal to the vessel in distress, and the brilliant light would greatly assist in the rescue. In cases of salvage, ships' signals, tide and harbour warnings, the duration of the light renders this new invention of great value. As a railway signal, to be used by the guards and station porters in cases of accident, it is equally available, and will be of great utility. The difficulties of preparing the chemical compound have been entirely overcome by Messrs. Albright and Wilson, of Oldbury, the contractors for the manufacture of the lamp for Mr. Nathaniel Holmes the patentee.

## *FRESHWATER BATHYBIUS*

AT a late meeting of the Natural History and Medical Society of the Lower Rhine, the well-known zoologist, Dr. R. Greeff, noticed an organism inhabiting freshwater and approaching very nearly, both in its structure and mode of occurrence, the celebrated deep-sea *Bathybius Haeckelii* of Professor Huxley.

Dr. Greeff, as much as three years ago, published a notice (in Max Schultze's "Archiv für mikrosk. Anat." Bd. iii., p. 396) of a new shell-less freshwater Rhizopod, which was remarkable for its gigantic stature in comparison with all previously-known organisms of that kind. He called attention at that time to its occasional occurrence in great quantity in the mud of standing waters, and indicated that, on account of its peculiar structure, it could be referred neither to the true *Amœbæ* nor to the *Actinophryes*. Since that time, the author has never lost sight of this extremely remarkable creature, and he thinks it desirable no longer to keep back his observations, especially considering the high degree of interest that has been excited by the *Bathybius*-mud which has been discovered in the depths and abysses of the ocean (to beyond 25,000 feet).

As regards the occurrence of this freshwater organism, to which the author provisionally gives the name of *Pelobius*,* and which he considers to be truly comparable with *Bathybius*, Dr. Greeff states that it is found in many standing waters with muddy bottom, which have apparently persisted for a long time, and seldom, if ever, have dried up. Thus, near Bonn the bottom of the Poppelsdorf fish-pond is found occasionally to be *almost entirely covered with masses of Pelobius;* to such an extent, indeed, that sometimes a glass vessel brought up from the bottom contains almost more *Pelobius* than true mud-particles, &c. The *Pelobius* never disappears in these waters, but remains throughout the year in great masses, sometimes in one place, sometimes in another. The cake-like lumps of mud which rise to the surface and float about there by the agency of enclosed gas and air-bubbles, especially during the warm season, also sometimes contain *Pelobius* in masses.

In their external form, in both the living and the contracted state, these organisms present the appearance of more or less spherical lumps, varying from one or two millim. in diameter down to the most minute points, scarcely perceptible by the naked eye. Middle-sized

* From πηλός, mud. [The name *Pelobius* has been long preoccupied.—ED.]

examples of about one millim. in diameter are the most abundant. They are generally so densely filled with mud-particles, Diatomaceæ, shells of *Difflugia* and *Arcella*, &c., that by transmitted light they can scarcely be distinguished from the actual mud without experience and careful examination; they may consequently be compared to a living mud. By direct light, on the other hand, they appear as grayish-white, yellowish, or brownish bodies. Their movements consist in an amœboid and often lively creeping by means of processes which are usually broad and lobate; during this process, the transparent body-substance often protrudes at the margins in elevations and undulations. This fundamental substance of the body consists of a *hyaline protoplasm* of irregularly *frothy or vesicular* consistency, containing, besides the above-mentioned ingested particles, a great number of very peculiar elementary particles. Among these there may be distinguished *round or roundish oval nucleiform bodies*, and *fine bacilliform structures*. Of the former by far the greater number consist of *shining pale bodies without any special structural characters*, but *of great firmness*, and presenting *considerable resistance to reagents* (acetic acid and caustic potash). These bodies may possibly be correlated with the coccoliths, &c., of *Bathybius*. Besides these, however, there are less numerous roundish nuclei of softer consistency, and with more or less finely granular contents, which, from their whole nature, must undoubtedly be regarded as equivalent to the ordinary cell-nuclei.

Hence in spite of its great simplicity in other respects, *Pelobius* represents a *pluricellular organism*, and is not to be referred to the so-called Monera, like *Bathybius Haeckelii*, according to the investigations of Huxley and Haeckel. Nevertheless, in connection with its possible relationship to *Bathybius*, it must be noticed that the cell-nuclei of *Pelobius* may occur in very variable quantity, often in so small a number as almost to disappear altogether; and further, that they can be detected only in the perfectly fresh state. This latter statement applies also to the frothy vesicular arrangement of the body-substance, which disappears immediately after death or the application of reagents.

The second kind of the chief elementary parts of *Pelobius* consists of *fine, clear, shining bacilli*, which are scattered through the whole body, and likewise present great resistance to the action of acetic acid and caustic potash. These were mentioned by Dr. Greeff in a former publication, when he expressed the opinion that they originate in certain nuclei, which, however, he has since seen reason to doubt.

The author has devoted much time and trouble to the investigation of the developmental history of this interesting organism, an exact knowledge of which would be in many respects of the greatest importance. He proposes to publish what has hitherto been observed upon this point (which in some respects recalls the Myxomycetes) in a detailed memoir upon *Pelobius* in Max Schultze's "Archiv für mikrosk. Anatomie," in which some other Rhizopods found under the same conditions as *Pelobius*, and resembling it, will also be described.

## *NOTES*

THE intelligence of the death of Sir John Herschel will fall on the whole scientific world with a sense of personal bereavement. Though he had attained above the ordinary span of life, his mind was still in the maturity of its powers; and few men have been so familiarly known by their writings and their discoveries beyond the narrow pale of the world of science. Next week we hope to give a biography of the great astronomer whose loss we deplore. It is fitting that Herschel II. should be buried in Westminster Abbey, and it is creditable to the authorities that his ashes will be permitted to rest there.

THE annual visitation of the Royal Observatory by the Board of Visitors is fixed to take place on the 3rd of June.

LETTERS have been received in this country from Dr. Adolf Bernhard Meyer, who left Europe last year for a journey through a part of the Malayan Archipelago and New Guinea. He reached Manado in Celebes in November last, just as the wet season commenced. He had chosen this place as his starting point, because he had been informed by a celebrated traveller in the East that the fine season commenced at Manado in the month of October. Nevertheless, he succeeded in making large collections of birds, reptiles, and fishes, which are on their way home.

THE Anniversary Meeting of the Geographical Society takes place on Monday next at 1 P.M., and that of the Linnean on Wednesday at 3. The Victoria Institute holds its annual meeting at eight o'clock on Monday, 22nd May, at the Society of Arts Rooms, John Street, Adelphi, when the Rev. W. J. Irons, D.D., will deliver the address.

A MANUAL OF ORGANIC CHEMISTRY, by Dr. Henry E. Armstrong, F.C.S., Professor of Chemistry in the London Institution, is advertised by Messrs. Longmans and Co., as being in preparation for their admirable series of Text-books of Science.

AT a session of Council on Saturday last, the Right Hon. Lord Belper, vice-president in the chair, Mr. E. J. Poynter, A.R.A., was appointed Slade Professor of Fine Art in the College. The buildings, forming part of the north wing, which have been designed for the Fine Art School, are nearly completed, and it is intended to open the classes for drawing, painting, and sculpture at the beginning of the College session in October next. The late Mr. Felix Slade has established at the college six scholarships for proficiency in those branches of Art, each of the value of 50*l*. per annum tenable for three years, and which may be held by ladies.

AN exhibition of Palæolithic Stone Implements will be on view at the rooms of the Society of Antiquaries, Somerset House, from May 19th to 25th inclusive, from 11 A.M. to 6 P.M.

AT the General Examination of Women at the University of London, just concluded, four passed in honours and nine in the first division. It is understood there were about double that number of candidates.

WE learn from the *Academy* that the Zoological Collection of the British Museum has been lately enriched by the purchase of a magnificent series of Sponges from South Africa, the majority of which are likely to prove new to science. It is to be hoped that the group of the *Spongiadæ*, now attracting so much attention in scientific circles, will receive a more liberal allotment of space in the new museum to be erected at Kensington. The utter unfitness of the present building to meet the daily increasing requirements of the national collection is evidenced from the fact that numerous groups of the *Invertebrata* are literally "crowded out," and entirely unrepresented in the series devoted to public exhibition, for want of the necessary space. This, and the inadequacy of the present slender staff of the Natural History department to effect the thorough and systematic arrangement of the extensive and valuable collection, and to elevate it to that high scientific status enjoyed in the leading continental museums, demand the most earnest and speedy attention.

MR. BOUCARD, the well known dealer in specimens of Natural History, and traveller, formerly living in Paris, but now resident in London, proposes the publication of a work on the Coleoptera of Mexico and Central America, including the adjacent portions of the United States, especially the Pacific region. He earnestly desires contributions of specimens, whether named or not, to be used in his investigations, and will return such as he is not permitted to keep, suitably identified, and will render an equivalent in other specimens, if desired, for such as are sent to him to be retained. Any specimens intended for him may be sent to his establishment, 55, Great Russell Street, Bloomsbury.

MR. C. H. BELFRAGE, of Waco, M'Lennan Co., Texas, announces that, at the request of several gentlemen in the United States and Europe, he intends making an extensive eight or nine months' entomological collecting tour in Western Texas and Southern New Mexico, if sufficient means can be raised, and invites every entomologist who wishes to enrich his collection to assist in the undertaking. Mr. Belfrage is recommended by Dr. A. S. Packard, jun., the editor of the *American Naturalist*, as a faithful and excellent collector, and the opportunity seems to be an unusual one of obtaining specimens of rare or little-known insects. Mr. Belfrage's address is at the above township, care of Messrs. Forsgard and Co.

THE Clifton College Scientific Society has just issued the first part of its "Transactions," which affords a happy illustration of its motto, *Viresque acquirit eundo*. Not yet two years old, and commencing with eighteen members, it has steadily increased in popularity and usefulness under the able presidency, first of Dr. Debus, and then of Mr. Barrington-Ward, till at one of its most recent meetings, nearly ten times that number of visitors and members were present. In this volume a number of interesting papers by the members, on various branches of natural and physical science, are printed; but we are most interested in the sketch of the constitution of the society. The School Museum has wisely been constituted especially a British one, and in order to facilitate the study of the natural history of the neighbourhood, and promote the other objects kept in view, the Society has been divided into sections of botany, geology, entomology, chemistry, physics, and archæology, the novel principle being introduced of limiting the number of members of each section to ten, in order to ensure a thoroughly working body. The Society has entered on its work in a spirit which entitles us to hope that it will be among the leaders in the spread of a real love of science among the generation now rising up.

MR. H. ROGERS read an important paper before the Edinburgh Botanical Society on March 9, a report "On the Effects of cutting down Forests on the Climate and Health of the Mauritius." The epidemic which broke out in 1865 in the colony, previously so remarkable for its salubrity, he traced to this cause, and stated that between 1854 and 1862 vast tracts of forests had disappeared, causing a diminished amount of rainfall, an increased amount of dryness, and a proportionate elevation of temperature. The difference in seasons is now much less marked, rains are scarce, droughts frequent and excessive, vast tracts of land, formerly productive, are now barren and desolate, and districts before noted for salubrity are now notoriously unhealthy. Although the amount of rainfall is much reduced, the violence of the rain is increased when it does fall, and heavy floods are the result. It was immediately after one of these inundations that the fever broke out in February 1865, which proved so terribly fatal in the colony.

FROM Ireland we have received the First Annual Report of the Natural History and Philosophical Society of Derry. Among papers of local history we find some on the antiquities, geology, entomology, and fucology of the neighbourhood of Derry, with drawings and photo-lithographs of cinerary urns found at Grange, Malin, and Buncrana, to illustrate a paper on that subject by the president, Mr. W. Harte. The society has made a good start, and we wish it all success.

THE Manchester Scientific Students' Association has issued its Tenth Annual Report for 1870. Although none of the papers read during the past year are printed in the report, the association, judging from the list of proceedings at the ordinary meetings, the Microscopical Club, and the Mechanical and Engineering Section, appears to have been doing some good and useful work. The number of members has slightly decreased during the year, but the committee hope soon to raise it again, and thus obtain funds for some desirable additions to the library.

IT is stated in *Land and Water* that the laudable effort of the Acclimatisation Society of Otago to introduce birds and animals into New Zealand has lately met with great success. The ships *City of Dunedin* and *Warrior Queen* have arrived in New Zealand with a living cargo of birds and animals which have thriven wonderfully well on board ship during their long voyage. Thus there are now in New Zealand five red-deer—we regret the stag died on the voyage—goldfinches, skylarks, blackbirds, sparrows, chaffinches, &c. The robins, numbering over a hundred, unfortunately died on the voyage. It is certain that the climate of New Zealand is admirably suited for the well-being and establishment of a British fauna. The colonists wisely recognised the importance of the study of "Practical Natural History," particularly as regards keeping insect life in check by means of small birds, the little feathered servants whose services are not sufficiently appreciated by agriculturists at home. Within the next fortnight thousands of young rooks will fall victims to the pea-rifle in England. How much better would it be if these unfortunate birds could have been sent across the ocean to our friends and relations in New Zealand! We understand that the cockchafer has been imported with English grasses, but the enemy to the cockchafer, the rook, has been left at home. We hope that next year the Otago Society will repeat their experiments with insect-eating birds, the unpaid "police of nature," which would keep in check the insect "pests of the farm," which have now pretty nearly their own way, to the injury of the farmer and horticulturists at the antipodes. The greatest credit is due to Mr. John A. Ewen for the pains he has taken in shipping the birds, and to Mr. Bills for the care and skill he has shown by his judicious management of the birds during the long voyage.

ON the 4th and 6th of March two shocks of earthquake were felt at Bogota, in Columbia, and these shocks were felt at the same dates at Cartago.

ON the 19th February the great earthquake in the Hawaian Islands took place. This was succeeded on the 2nd March by an earthquake at Eureka, in Humboldt County, California.

THE whole west coast of America, throughout its great mountain range, has now been seriously disturbed for some months. As far north as Washington Territory, Mount Rainer is reported as in commotion.

ON the 22nd February an earthquake was reported at Pano, in Peru, and a stronger one at two A.M. on the 23rd. These were slightly felt at Lima.

FROM recent advices we have to report the continuation of serious disturbances on land and by sea of the meteorological and physical conditions of the west coast of the Pacific. The phenomena appear to have been preceded long since, and are now accompanied, by volcanic disturbance, and some of them have passed from north to south. One remarkable feature is that of the inundations, particularly in the districts actually rainless. On the Isthmus of Central America rain is common, but this year the amount has been great, and the inundation greater. During the season immense quantities of vapour have been converted into rain along the western slopes of the Cordillera and the Andes. In northern Peru the effects have been particularly felt, and the more severely as the cities were unprovided to encounter rains or floods. Lambayegue, an interior town of 7,000 people, is destroyed, and the population have abandoned that of Supé. In some places bogs have been produced in which the cattle perish. Mud is washed far out to sea, and among the animals carried off was an alligator driven into Payta Bay. The circumstances are worthy of notice, as they illustrate some of the incidents of geological disturbance. At sea rain is met with a hundred miles out, to the surprise of captains, who report the winds and currents as changed.

It is stated in some of the papers that the system of storm-signal observations, now in progress under the direction of the Signal Corps of the army, was devised by Great Britain before it was made use of by the United States Government. This is perhaps correct, so far as it goes; but it is to Prof. Henry, Secretary of the Smithsonian Institution, that we owe the original idea of procuring despatches regularly in relation to the weather, and tabulating them, as also of placing them on a map so as to show, day by day, the general character of the weather throughout the United States. For several years prior to the beginning of the war this system was carried on regularly, and was of great interest to visitors to the Institution. The occupation of the telegraph lines for military purposes, and the fire in the Smithsonian building, broke up the arrangement; and it was about to be resumed when the Government undertook the work, thereby relieving the Institution from the necessity of its further prosecution.

The California vulture (*Cathartes Californianus*) is the largest species possessed by the fauna of Western America, where it ranges over an immense space of country in search of food. When any large game is brought down by the hunter these birds may be seen slowly sweeping towards it, intent upon their share of the prey. Nor in the absence of the hunter will his game be exempt from their ravenous appetite, though it be carefully hidden and covered with shrubs and heavy branches, as they will drag it forth from its concealment and speedily devour it. Any article of clothing, however, thrown over a carcase will shield it from the vulture. In some localities the nests are known to the Indians, who year by year take the young, and, having duly prepared them by long feeding, kill them at one of their great festivals. The California vulture joins to his rapacity an immense muscular power, as an instance of which it is stated that four of them jointly have been known to drag for over two hundred yards the body of a young grizzly bear weighing more than a hundred pounds.

Dr. Newberry, in his interesting report of the botany of the explorations for a railroad route from the Sacramento Valley to the Columbia River, speaks thus of the district lying east of the Sierra Nevada and the Cascade Mountains:—"The general aspect of the botany of this region is made up of three distinct elements. Of these the first is presented by the grassy plains which border the streams flowing down from the mountains. On these surfaces grows a considerable variety of animal vegetation, not unlike that of the Sacramento Valley in its general character. The second of these botanical phases is that of the 'sage' plains, surfaces upon which little or nothing else than clumps of artemisia will grow. The third is formed by forests of yellow pine (*Pinus ponderosa*), which apparently finds on these arid surfaces its most congenial habitat. It sometimes happened to us that, during a whole day's ride, we were passing through a continuous forest of these yellow pine trees in which scarcely a dozen distinct species of plants could be found."

The night heron of the United States (*Nyctiardea Gardeni*) is much dreaded by the Indians, who have many traditions and superstitions connected with it, and believe that it has the power of transforming human beings into inferior animals. Of the blue heron (*Ardea Herodias*), they say that he was formerly an Indian, and that perpetual quarrels raged between his wife and himself. On this account they were both transformed by a superior power, the man becoming a heron, the woman a dabchick (*Podiceps cornutus*), at the same time the brother of the woman was changed into the western grebe (*Podiceps occidentalis*), a native of the Pacific coast.

## REPORT ON THE DESERT OF TIH

(*Continued from page* 35)

The following are the various observations I have made and tales I have collected about some of the birds and mammals found in the desert of Tíh and adjoining regions. For convenience of reference I have arranged them alphabetically. In the cases of well-known animals, or of such as have been before scientifically described, I confine myself chiefly to the Arab stories or legends attaching to them:—

Bears (*Ursus syriacus*), Arabic *Dabb*, are still found on Mount Hermon and the Anti-Lebanon, and must formerly have existed in Palestine, but the destruction of the woods has now driven them northwards. They do much damage to the vineyards in the neighbourhood of Hermon, but seldom interfere with the herds of goats. The Arabs share in the widely-spread belief that bears sustain themselves during their hybernation by sucking their paws. They also say that when the female drops her cub it is quite shapeless, and that she carries it about in her mouth for fear lest it should be devoured by the ants, and then licks it into proper shape. Bear's grease is said to be useful in cases of leprosy.

Boar, wild, Ar. *Halhouf*, or usually in Palestine, *Khanzir*, which simply means pig. These animals are very abundant wherever there is cover near water, as on the banks of the Jordan and in the Ghor es Sáfi at the S. of the Dead Sea. I was much surprised to find traces of recent rooting by them in the W. Rákhamah, which lies between El Milh and 'Abdeh. This place is far from any water except what may have collected in hollow rocks, and can boast of no cover. The 'Azázimeh eat the wild boar, but the Ghawárineh, who will eat a hyæna, though it is known to frequent the grave-yards, will not touch them.

In this, as in the case of the other animals, I can insert but a few amongst the many medicinal uses to which they are put by the Arabs, as these are in general unsuited to the taste of European readers.

Bustard (*Otis hubara*) Ar. *Hubara*. I noticed a few of these birds in the Tíh; the Arabs say that the lesser bustard (*Otis tetrax*) which is also occasionally found there, is the young of the larger, but does not attain its full growth for two years. They also say that these birds, when attacked by a falcon, will cover it with their fæces, and so drive it off.

Camel, Ar. masc. *jemel*, fem. *nágah*. A stallion camel is called *fahl*. Collectively, *ibil* vulgo *bil* or *báir*, pl. *aarán*. *Hejjin* is usually applied to a dromedary, but is properly used of a man, horse, or camel having an Arab sire and foreign dam, which, in the case of the animals, is considered the best possible cross. Hence, a dromedary (or well-bred camel used for riding) is so called.

Camels are most peevish animals, docile only from stupidity; ill-tempered, they never forget an injury. I have but once seen a camel show the slightest sign of affection for its owner, although they are always well treated. All their feelings of like and dislike, pleasure and annoyance, are expressed by a hideous sound between a bellow and a roar, to which they give utterance whether they are being loaded or unloaded, whether they are being fed or urged over a difficult pass; in fact, they disapprove of whatever is done. Without them, however, it would be impossible to cross the deserts, for no other animal could endure the fatigue and want of water; I have myself seen a camel refuse water after having been without any for three days. For their food they always choose the most uninviting thorny shrubs; the seyal (acacia) which has thorns two or three inches long, is an especial favourite with them. Many of the Arabs subsist almost entirely upon the milk and cheese afforded by their herds of camels.

The Pelican is called *jemel el ma*, or water camel; and the Chameleon, *jemel el yehúd*, the Jew's camel.

Cat, or *Kutt*, also *Sinnaur* and *Hirr*. According to some lexicographers, the first name is not a pure Arabic word. Cats are held in great estimation in the east, and large prices are sometimes paid by native ladies for fine Persian specimens. In Cairo a sum of money was left in trust to feed poor cats, who daily receive their rations at the Mahkemah (law courts).

Though the Arabs in Sinai and the Tíh spoke of a wild cat, *gatt berri*, I found that this was always the lynx (*Felis caracal*), which is called in some parts of Arabia *'inak el ardh*, or earth-kid; in Sinai, it is also spoken of as *ânazeh* (from *ânz*, a she-goat). In Morocco, it is only known as *owdál*.

I may here remark that the word *Fahd*, translated by Lane and others as "lynx"—an animal that is never used for hunting—really means the *cheeta*, or hunting leopard of Persia and India.

The Arabs in the Tíh and in Morocco, as well as the Fellahin in Egypt, eat the lynx, and esteem it a delicacy, but, as some of them eat hyænas, jackals, foxes, vultures, and ravens, they can hardly be quoted as epicurean authorities.

Many animals have in Arabic a large number of names, more than 560, for instance, being applied to the lion. The following story current among them will illustrate this fact with reference to the cat. A Bedawi was out hunting one day, and caught a cat, but did not know what animal it could be. As he was carrying it along with him, he met a man, who said, "What are you going to do with that *Sinnaur?*" then another asked him, "What is that *Kutt* for?" A third called it *hirr*, and others styled it succesively *dhayûn*, *khaidà*, and *khaital*. So the Bedawi thought to himself, this must be a very valuable animal, and took it to the market, where he offered it for sale at 100 dirhems. At this the people laughed and said, "Knowest thou not, O Bedawi, that it would be dear at half a dirhem?" He was enraged at having his dream of wealth thus rudely dispelled, and flung it away, exclaiming, "May thy house be ruined, thou beast of many names, but little worth."

The Arabs say that the occasion of the cat's first appearance was as follows. The inhabitants of the ark were much troubled with mice: Noah, in his perplexity, stroked the lion's nose, and made him sneeze, whereupon a cat appeared and cleared off the mice.

In the East, as in Europe, a black cat is regarded as "uncanny," and various parts of it are used for magical and medicinal purposes; its claws, for instance, are said to be a charm against the nightmare.

Coney (*Hyrax Syriacus*) Ar. *'Waber* (lit. fur, from the thickness of their coats) *ghanem beni Israél*—sheep of the sons of Israel. Some Arabs say that this animal may be eaten, but others, as in Sinai, declare that it is unlawful, and call it Abu Salmàn, or else the brother of man, and say that it was originally a man who was metamorphosed for his sins, and they believe that any one who eats him will never see his house again. It is a common joke among the Hajjis and people of Mecca to say "A good digestion to you who have eaten Abu Salmàn."

Dog, Ar. *Kelb* (in Morocco *jero*, which properly signifies *puppy*, *whelp*), is the ordinary dog. A large kind of rough greyhound is called *Seluki*, from the town Seluk, in Yemen.* This dog much resembles the Scotch deerhound (cf. Gaelic name, *slogie*). In Syria and east of the Jordan there is a variety which is smooth, but has its ears, tail, and legs feathered like a setter; the females are said to be keener for hunting than the males, and black dogs are said to be the most patient. The dogs in Eastern towns live in communities, and have distinct bounds, usually ending at a street corner, and woe betide any dog who wanders beyond his own proper limits. I have often, when living at Cairo, amused myself by watching these animals. No sooner does a strange dog appear than all the rightful owners of the soil rush at him; the intruder takes to his heels, but the moment he has reached his own frontier, he turns round and snarls defiantly at his pursuers, and if they do not quickly retire his friends come to his assistance and drive them back in turn.

Dogs are said to have an intense hatred of hyænas, so much so that if a dog is smeared with the fat of a hyæna, he will go mad; and—which seems inconsequent—if a person carries a hyæna's tongue the dogs will not bark at him. This certainly would be most useful on entering an Arab encampment, for there a stranger is immediately surrounded by a pack of snarling brutes, who seem to sleep all day with one eye open, and at night to be continually awake and barking, either to frighten away some prowling jackal or lynx, or to repress some errant sheep or goat, who may wish to wander outside the circle of tents.

The Arabs believe that a dog can tell a dead person from one feigning death, and say that the Greeks (*Room*) never bury a person till they have exposed him to the dogs. It is, however, of only one breed that this is asserted, namely, the kind called *el Kalti*, and which is of small size, with very short legs. It is also called the Chinese dog. Of the origin of this story I am quite ignorant. The following is almost identical with a well-known Northern legend:—

A king had a favourite dog, whom he left at home one day while he went out hunting. Having ordered his cook to prepare a dish of *leben* (sour milk) for him on his return, the cook obeyed the order, but carelessly left the milk uncovered, and a snake came and drank of it and rendered it poisonous. On the king's return the dog tried to prevent him from touching it; at this moment the cook came in with some bread, which the king took and became to dip into the *leben*, when the dog immediately bit his hand. Upon this the king was very angry, and stretched out his hand again to the bowl; the dog, however, was before him, and began to lap the sop, whereupon it straightway fell down dead. The king then became aware of the sagacity and faithfulness of the beast, whose loss he mourned ever after, and erected a splendid tomb to his memory.

* The usual derivation, however, is "Seleucia."

Donkey, Ar. *Himár*. The donkey, much used by the Arabs, (for it will thrive in the desert where a horse could not exist) chiefly for carrying waterskins, as the Bedawin often encamp several miles from water, and the women bring up a supply every two or three days.* At Damascus there are three breeds of donkeys—(1) The white, which is most valuable, being sometimes worth 30*l.* or 40*l.*, and in Egypt I have heard of 60*l.* being given for a fine animal of this kind; (2) the ordinary donkey, which is used for riding, &c.; (3) A large donkey, standing from 13 to 14 hands, which is used for carrying burdens in the town; in the country, however, it is useless, as unlike the other breeds, it is far from sure-footed.

The Wild Donkey, Ar. *Air*, *fera*, or *himár wahshi*, is found to the east of Damascus; it is said to be very long-lived.

Dugong (*Halicore Hemprichii*), Ar. *otum* (called by Dr. Robinson *tûn*). This curious mammal is found in the Red Sea, and harpooned by the fishermen as it basks on the surface on the water. The skin is used by the Sinai Bedawin to make sandals of, for which purpose it is admirably adapted. In some parts of Arabia, it is said, that *khifaf*, or boots to protect the camels' feet from the rocks, are made of it. Some commentators take the Heb. *tachash*, which is translated "badger-skins," to mean the *otum*, and there is an Arabic word, *Tukkas*, applied to the dolphin species generally.

Fox, Ar. *Taáleb*, *Abou'l Husein*. In the East, as in Europe, this animal is looked upon as the type of cunning, and numberless stories are current concerning it. The following are examples:—

When a fox is over much troubled with fleas, he plucks out a mouthful of his hair, and then he takes to the water, holding the tuft in his mouth; all the fleas creep up on to this to escape drowning, and the fox then drops it into the stream and retires, freed from his enemies.

The celebrated Arabic author and theologian, Esh Shafiey, relates that when in Yemen, he and his fellow travellers prepared two fowls for dinner one day, but the hour of prayer coming on, they left them on the table and went to perform their devotions; meanwhile a fox came and stole one. After their prayers were finished, they saw the fox prowling about with their chicken in his mouth, so they pursued him and he dropped it; on coming up nearer to it, however, they found it only to be a piece of palm fibre, which the fox had dropped to attract our attention, and had, in the meantime, crept round and carried off the second chicken and left them dinnerless.

The fox is said to feign death, and to inflate his body, and when any animal, prompted by curiosity, comes to look at him, he springs up and seizes it.

The fable of the fox and stork is changed to the fox and raven; the former invites the latter to dinner, and gives him soup in a shallow wooden bowl; the raven returns the compliment, and pours out some wheat over a *silleh* bush. The *silleh* is one of the most thorny of the desert plants.

Another story told of the fox is, that one day he met five slaves, who were travelling with a large supply of food and other goods; he joined them, and after a time they reached a well, but had no rope wherewith to draw up the water. The fox suggested that they should throw down the meal and that one of their number should go down and knead it, which was accordingly done. After a while the fox said to the four who remained above, "Your comrade must have found a treasure, why don't you go down and share it?" This hint was enough, and they all hurried down, while the fox decamped with their goods and chattels.

A fox's gall is said to be a specific for epilepsy, and his fat for the gout.

Gazelle (*Gazella dorcas*), Ar. male *'ard.*, fem. *ghazaleh*, also (chiefly in poetry) *Dhabyeh* (cf. Tabitha, Acts ix. 36). This gazelle is found in the more open parts of the country between Sinai and the Lebanon; their haunts vary much with the different seasons. Though we never found any in the centre of the

* A tribe in the Desert, towards the Euphrates, is said to use donkeys only, and to possess neither horses nor camels.

Tíh, the Arabs said that, after a good rainy season, large numbers come there.

The Arabs speak of three kinds, viz. :—1. *El Rim* (*antelope addax*). 2. *El Edam* (*A. leucoryx*). 3. *El 'Afar*, which I cannot satisfactorily identify.

The tongue of an antelope must be an invaluable charm, for if it be dried and powdered, and then given to a woman who henpecks her husband, it will ensure her future good behaviour!

Goat, Ar. *ma'az* f. *ma'azeh* or *anz*. A he-goat (either wild or tame) is also called *tais*. In mountainous districts, large herds of goats are kept by the Arabs, chiefly for their milk and hair, which is used for making tents and sacking. The Arabs more usually eat a kid than a lamb on the occasion of a feast, and always a male. Full-grown animals are seldom killed. There are several varieties of goats from the upright eared kind to the Syrian goat with pendant ears, 12–14 inches long. That usually seen in the desert has ears slightly drooping and rather curling up at the top.

Horse: the generic term in Arabic, *Kheil*; a horse, *hisán* (in Morocco *'aud*); a mare, *fars*; a colt, *mohrah*.

*'Atík* is a thorough-bred Arab. Tradition says that the Devil will never enter a tent in which an *atík* is kept.

*Hejjin*: a crossed horse. (The term is explained under the head "Camel.")

*Berdhún* is a pack-horse with foreign sire and dam.

*Kadish* is a badly-bred *berdhún*.

The Bedawin reckon seven principal breeds of horses, which are as follows:—

1. *Musalsal*, which ought to be thin-crested, with short white stockings, red-eyed, short-coated, full in the barrel, and long-winded.
2. *Haikali*.
3. *Sharthar*.
4. *Hareifish*, a breed well known in Syria.
5. *Tubal*.
6. *Jij*.
7. *Kumeit*. These horses are usually bay, with black points, and ought, say the Arabs, to have a very fine muzzle; head thin, and well set on; upright, small ears; conspicuous white star on the forehead; round quarters, and to be well ribbed up; with a short or rat tail. They add, a well-bred horse is known by having the tail thick at the root, and carried well out.

The favourite colours are chestnut, gray, dun, black, and dark bay. The Prophet is related to have pronounced the following dicta:—"The best horses are black with white foreheads, and a white upper lip; next to these a black horse with a star, and three white stockings; next a bay with these marks." "Prosperity is with sorrel horses." The same authority judged *shikál*, *i.e.*, having the right-fore and left-hind feet white, to be the sign of a bad horse.

The first man who tamed and rode a horse is said to have been Ishmael. The first horse appeared when Adam sneezed on first awaking into life (cf. the story of the cat.)

Hyæna (*H. striata*) Ar. *Dhaba'*, also (in Sinai) *Arkudha*. This animal is found throughout the desert and Palestine. It is a cowardly beast, feeding chiefly on carrion, and is consequently little feared by the natives; as I have before mentioned, the Ghawárineh eat it. It is said to change its sex yearly; the same fable is told of hares.

Jackal, Ar. *Ibn 'Awi*, or in Syria *Wadwi*, in Morocco *Deeb* and *Taaleb Yusuf*. These animals are not found in the desert, but are common in the cultivated parts of Egypt and Palestine, where their weird cry is very frequently heard, beginning just after sunset. They are timid beasts, and do little damage, except in the vineyards, where they commit great ravages, being exceedingly fond of grapes.

Ibex (*Capra beden*), Ar. *Bedan* (from *bedn*, a body: probably so called as being the largest game in Sinai), the correct Arabic is *waal;* this is the name given to them north of Damascus. Some travellers have called them *Taytal*, but the word is not Arabic, and is only used by the Sinaitic Bedawin when speaking to Europeans, "poor simpletons," as they politely put it, "who don't understand Arabic." The derivation of this word I am quite unable to determine. Among themselves the Bedawin speak of the buck as *Bedan*, and the doe as *Anz* (she-goat), and the kids as *Dhalít*. A male in his first year is called *Fenaigill;* after this he is distinguished by the length of his horns; thus in his second year he is called *Abu Shibrain*, the father of two spans; in his third, *Thelathi;* in his fourth, *Rubai;* in his fifth, *Khammasi*; and they add that the horns never exceed five spans in length, which I believe to be true, for on measuring the largest pair that I have ever seen, I found them to be just 5 spans (about 41 inches) long. The term *garími* (red) is applied in a general way, much as we speak of red deer. These animals are found in Sinai and on both sides of the Dead Sea. I have reason to believe that those near Palmyra are a different variety.

Jerboa, Ar. *Yerbuah*, also *Dirs* or *Dars*, and sometimes *Zarumaih* (the lord of the little lance). There are several kinds of jerboas and desert rats; some of them are only found amongst the rock, others only burrow in the sand and gravel. Opinion is divided amongst the Arabs as to whether the jerboa is lawful for food or not; some eat it, but others reject it as being "a creeping thing." The Arabs say that they never drink, and believe that they live in communities, and appoint a sheikh, whom, however, they unhesitatingly kill should his rule not suit them. There is an Arabic proverb about a deceitful man: "He acts like a jerboa." This is said with reference to the ground outside a jerboa's hole, which, though seemingly solid, is really undermined, and gives way when trodden upon.

Leopard (*Felis leopardus*), Ar. *Nimr*, occasionally called in Sinai *Giblán** (corruption of the Turkish *Koplán*), the cubs are called *Weshek*. In the more secluded and inaccessible mountains of Sinai these animals are far from rare, and in a former visit to that country I was told that eleven camels had been killed by them during the preceding year in the district lying between Senned and W. Nasb. Like the hyrax the leopard is said to have been formerly a man changed into his present shape for performing his ablutions before prayer in milk, thus despising and diverting from their proper uses the good gifts of God.

Leopards are tolerably abundant on the shores of the Dead Sea; their tracks were here mistaken by M. de Saulcy for those of the lion, which animal is, however, quite extinct in Palestine and the Tih.

The Bedawin assert that young leopards are born with a snake round their necks, and that when a leopard is ill he cures himself by eating mice. Their fat is used medicinally, and their hair is burnt as a charm to drive away scorpions and centipedes.

Lizard. The larger lizards, especially the *Uromastix spinipes*, are called in Arabic *Dhabb*, and the smaller *Hardhun*. The Bedawin say that the former lays seventy eggs and even more, resembling pigeons' eggs, and that the young are at first quite blind. They are believed to be very long lived, indeed I have heard 700 years assigned as the term of their existence. By some tribes they are eaten, but are generally thought unclean. The Syrians curse them freely, for they say that they mock the devotions of the true believers. Certainly the way in which they jerk their bodies up and down is not unlike a caricature of the Muslim prostrations.

The dried bodies of some of the Skinks or Sand-lizards (Ar. Sakankúr) are much sought after as an aphrodisiac throughout the East. The particular kind in vogue is found in Nejed, and large quantities are brought by the Hajj caravans.

Owl, Ar. *Boomeh*. This bird is in some places regarded with veneration on account of a tradition which says that the souls of men appear on their tombs in the form of owls. I am told that they are sometimes used by fowlers as decoys.

Pigeon, Ar. *Hamám;* wild-pigeon, *Yemám*. In Egypt there are enormous numbers of pigeons who live in towers specially built for them. They are chiefly kept for their dung, which is very valuable as manure, and largely exported.

Most mosques are tenanted by pigeons, and not unfrequently a sum of money is left by some pious Moslem to buy corn for them. At Jerusalem they are especially numerous, whence the Arabic proverb, "Safer than the pigeons of the Harem." The mourning of doves is as frequently alluded to in Eastern as it is in Western poetry.

Quail, usually called in Arabia *Summana*, or *Selwa*. I only met with one specimen in the Tíh, and that was called by the natives *Firreh*. There is a tradition that the first instance of meat becoming corrupt and stinking was when the children of Israel stored up the flesh of the miraculous quails contrary to the commands of the Almighty.

Raven. There are three species of this bird scattered over the Desert, viz., *Corvus corax*, *C. umbrinus*, and *C. affinis;* all of these are called by the Arabs *Ghoráb*. They are generally found near a herd of camels, and may often be seen perched on the backs of these animals searching for ticks. Their chief food consists of reptiles and insects, but any dead or dying animal

* Giblán is the name of the chief of the Nimr (leopard) family of the Adwán Arabs in Moab.

will attract them. On one occasion I saw two ravens attack a horse which had fallen from exhaustion.

An Arabian proverb says, "Take a raven for your guide and he will lead you to a dead dog."

An Arab tradition evidently taken—as many others are—from the Old Testament, ascribes the first idea of burial to the raven. "While Adam was absent on a pilgrimage to Mecca, Cain and Abel each erected an altar for sacrifices. Cain, a husbandman, offered the refuse of his garden, but Abel chose the finest young ram of his flock and laid it upon the altar. His sacrifice was accepted, and the ram taken up to heaven, there to remain till it was required as a substitute for Ishmael when his father Abraham should offer him up on Mount Moriah. Cain seeing his offering refused, conceived so sudden a jealousy against his brother that he slew him, but being perplexed after the deed, and knowing not how to dispose of the body, he carried it about with him for many years. At last he saw two ravens engaged in deadly conflict, and one having killed the other scraped a hole in the ground and buried it, a hint which Cain took, and thus instituted the first burial rites as he had caused the first death. Adam returning mourned for his son and cursed the ground which had drunk up his blood, wherefore say the Muslims, the earth will never more absorb the blood of one who is slain, but it remains above ground, a lasting testimony to the murderer's guilt."

Sandgrouse (*Pterocles setarius*).—This species is most common in the Desert, but three other kinds are also found, viz. *P. exustus* and *P. senegalensis* (found by Tristram near the Dead Sea) and *P. arenarius*. All these are called *Kata*, or, in Bedawi dialect, *Gata* (in Morocco *Koudri*). The first and last mentioned species are called by some Bedawin *Koudriyeh* and *Sunifeh* respectively.

These birds require to drink morning and evening, and thus often prove of great service to the traveller by indicating the proximity of water. While staying at Damascus I was assured that these birds exist in such numbers in the territory of the 'Anazeh Bedawín that during the nesting season two men will go out with a camel's-hair bag between them and fill it with eggs in a very short space of time. The women then squeeze out the eggs and cook them, leaving the shells inside the bag. The Kata is said always to lay three eggs, neither more nor less. Its bones when properly prepared are said to be a cure for baldness, and the head may be used as a charm to extort secrets from a sleeping person. From its being so sure an indicator of the presence of water, the Arabs have the proverb "More truthful than the Gata."

Sheep. The proper Arabic name is *Dhán*; *Ghanem* is the general term for flocks of sheep and goats.

In the Tíh there are few sheep, but in Moab and Palestine they are numerous; these are generally the fat-tailed variety (*Ovis laticaudata*). A fine-woolled breed is found in some districts. I have always noticed that in the East sheep's milk is much better than that of either cows or goats.

Snake, Ar. *Haiyeh*, *Taabán 'Offi* (cf. ὄφις) *Dúdeh* (*lit. worm*) *Rakshah* (speckled one). Owing to its being winter when I passed through the Tíh. there were very few snakes to be found. The attitude taken by a horned snake (*Cerastes hasselquistii*) which I captured was remarkable. Immediately it saw me it began to hiss, and, tying itself as it were into a knot, created a curious grating sound by the friction of its scales. This snake is considered the most deadly of all by the Arabs, who hold it in great dread. They also affirm that if a snake has swallowed a bone which it cannot digest it will coil itself tightly round a tree or stone till the bone inside it is completely broken up.

Tortoise (*Testudo græca*), Ar. *Salahfát* (in Morocco *afkah*). The water-tortoise (*Emys caspica*) is called *Lejah*. The former is occasionally found in the Tíh. though common in Palestine. The latter abounds in the pools and streams of that country. Another species of land tortoise (*Testudo marginata*) is mentioned by Tristram, as being found on Mount Carmel. The water-tortoise is known to be carnivorous, and the Arabs declare that the land species also eat snakes, but this I believe to be quite false. Tortoises have a very strong odour, and I have frequently seen pointers in Morocco stand to them as they would to game.

Vulture, Egyptian (*Neophron percnopterus*), Ar. *Rakhamah* (Heb. *racham*) or *Onak* (in Morocco *Sew*). This is the only vulture at all frequently seen in the Desert. The Griffon (*Gyps fulvus*) and Lammer-geier (*Gypaetus barbatus*) seldom wander beyond the limits of cultivation. The Egyptian Vulture is commonly found near Arab encampments, where it shares the office of scavenger with the dogs. Many tribes, however, both in North Africa and the East, consider its flesh a delicacy.

Wolf (*Canis lupus*), Ar. *Deeb*. These animals are found in the mountains of Sinai and Palestine, but rarely in the Tíh. They do not pack like European wolves, but hunt by twos and threes.

The Bedawin say that "they sleep with one eye open," and have a similar proverb to our own, "A wolf in the stomach." Hunger is sometimes called *Da' ed deeb*, wolf's malady. Various parts of the animal are used for charms, *e.g.* a wolf's head in a pigeon cote, or a tail in a cattle stall, will keep off other wild beasts.

In addition to stories about real animals, the Bedawin have many fables of imaginary creatures, such as the Ginn, the Efreet, and the Ghoul. These hardly come within my province, and are well described by Lane ("Arabian Nights," vol. i.). I may however mention the *Nis-nás*, which is said to resemble a man bisected longitudinally, and to possess but one arm, one leg, and half a head. The story goes that it is found in Yemen, and that the people there hunt and eat it, notwithstanding that it can speak Arabic! The *Hud-hud* (so called from its cry) is a mysterious creature, not uncommon in Sinai. The Bedawin declare that it is never seen Though I often heard its plaintive cry close to my tent, and rushed out gun in hand, yet I never could obtain so much as a glimpse of it. At one moment the sound came from just over my head; the next instant it was far away up the hill side, and would either pass into the distance, or as suddenly return to me. From this I am convinced that the cry is made by some bird, probably of the owl tribe. The Arabs, of course, will accept no such materialistic solution of the mystery.

The Botany of the Tíh, especially in a season of drought such as we experienced, is very limited. The climate is so dry that mosses and even lichens are not found, except near Nakhl, where I gathered some much resembling the true Reindeer moss. This only grows on the northern side of the hillocks.

The passage in Job xxx. 4, "Who cut up mallows by the bushes," seems wrongly referred to the Sea Purslane (*Atriplex Halimus*.) In North Africa and the country east of Bir-Erba there is a small mallow which is eaten. This *invariably* grows either where an Arab encampment has stood or on the site of an ancient town. It has a small pinkish flower, and seldom exceeds seven or eight inches in height.

In the caves near Ain Muweileh a considerable quantity of salt crystallises on the surface of the limestone. Though disagreeable to the taste, it is eaten by the Arab.

At Petra the natives chip the interior of the caves. The fragments of sandstone are crushed and boiled, and a saltpetre sufficiently pure for the purpose of making gunpowder is thus obtained. The sulphur is found on the Lisan and coasts of the Dead Sea.

The above report necessarily contains but a sketch of our work. It will, however, I trust, give some idea of the country we had to examine, and of the difficulties which we encountered. In conclusion, I must here tender my best thanks to the University of Cambridge for having aided me in the investigation of this hitherto so little known but important district. It is the intention of Mr. Palmer and myself to publish together as soon as possible a full and systematic account of our explorations.

CHAS. F. TYRWHITT-DRAKE

(Note by Mr. C. R. Crotch on the Coleoptera brought from the Tíh.)

"In the small collection now before me are contained ninety species of Coleoptera, representing more or less all the larger families of the order, except the Water-beetles, an omission easily to be accounted for. The group most largely represented is, as throughout Syria, the Heteromera. These curious apterous, sluggish forms seem to thrive under the most arid conditions. The whole cast of the fauna is essentially Mediterranean; that one is on its southern side is shown by genera like Adesmia, Graphipterus, Pachyscelis, &c. The relations of this collection with an Egyptian one are very marked, many specimens being identical. None of them, however, extend to the Algerian deserts, though congeneric species occur there in their place. Nearly all are confined to the S. corner of Palestine and E. of Egypt, except the Dung-beetles (Histerida, Aphodiadæ, and Coprida), and these are more or less identical with those of S. Europe. The paucity of vegetation is very strongly indicated by the fact that the two great groups of Rhynchophera and Phytophaga number only seven species between them."

## *AMERICAN NOTES*

THE annual meeting of the National Academy of Sciences was held on the 18th of April last in the rooms of the Smithsonian Institution, in Washington, and continued in session four days. A number of interesting communications were presented. A report was presented by the treasurer of the Academy in regard to the Bache bequest, in which it was stated that its present value was about 41,000 dols., invested at 6 per cent., and bringing an income of about 2,400 dols. a year. It may be remembered by some of our readers that Prof. A. D. Bache, the late head of the Coast Survey, left his property in trust to the National Academy of Sciences, after the death of Mrs. Bache, for purposes connected with the advance of science, appointing as special trustees Prof. Agassiz, Prof. Peirce, and Prof Henry. The precise disposition of this fund has not yet been determined upon, the bequest having fallen too recently into the hands of the society to make it necessary to come at once to a conclusion.—The ship *Onward* arrived at New Bedford a few days ago, and her captain—Pulver—reports passing Sunday Island on the passage from Honolulu, and states that the volcano near by, referred to in a previous number of Scientific Intelligence, was at that time three miles long, and from 300ft. to 400ft. high. The sulphurous vapours extended around to a distance of three to four miles. He thinks that when the volcano becomes quiet there will be a good harbour between it and the main land, where before there has been only an open roadstead. The island is in latitude 29° south, and in longitude 178° west. The statement of Captain Pulver, according to the New Bedford *Standard*, is corroborated by other witnesses.—An examination has recently been made by an officer of the United States army of an old pueblo situated about twenty-five miles from the town of Socorro, on the Rio Grande. The walls of the buildings of this pueblo are composed of thin sandstone, heaped one layer upon another without mortar, and without any traces of beams or timber of any kind. The edifices seem to have been but one story high, and to have consisted of four separate buildings, arranged so as to form a hollow square with a fifth a little outside of these. The longest range was over 200ft. in length. and the whole five contained about two hundred rooms. Near the pueblo extensive silver mines have recently been discovered, and a town is to be laid out during the present year, the material for the houses to be derived from the ruins. There are evidences of ancient workings of these mines in the form of shafts now entirely filled up with earth, although it is probable that these do not antedate the period of the occupation of the country by the Spaniards.—According to late advices from South America, an unusually brilliant electric phenomenon was visible from Tacna, on the coast of Peru, early in March of the present year, around the snowy peak of Tacora, lasting for over two hours. The lightnings were of extraordinary shapes, and the thunders were of such intensity, and were heard over so wide an extent of country, as to completely terrify the population, unused to such exhibitions. This unwonted display was preceded by a slight shock of earthquake on the previous night.—According to the *Comercio*, of Lima, on the 12th of February, at Pitchican, an extraordinary meteor, of an oblong shape, and of a red colour, was seen to descend suddenly from the sky toward the earth; and, as soon as it touched, an explosion occurred, leaving a dense cloud over the place, and knocking down a fence for about five hundred yards. Among the stones heaped around by this meteoric body were found recently dead fishes of different species, which were supposed to have been lifted out of the river and dashed against the stones.—The cattle disease continues to spread throughout South America, all efforts to resist its progress having been unavailing. At the present time it is very prevalent in the Southern provinces of Chili and in the adjacent country.—The details of later advices from the Isthmus of Panama indicate the discovery of a rather low water-shed between the Atlantic and Pacific, on the Isthmus of Darien, although the feasibility of constructing a canal is, after all, by no means well-established. As far as the engineering possibilities are concerned, the chance seems to be much more favourable by way of Nicaragua, the result of a late investigation by Mr. Sonnenstern, on behalf of the Nicaraguan Government, serving to show that a route of 220 miles can be found connecting the two oceans, 196 of which is a ready constituted by the rivers and lakes of the country, leaving only twenty-four miles of land to be excavated, with a maximum elevation of not more than twenty-six feet. A slight drawback, however, to the value of this line is to be found in the fact, stated in the same paper, that the harbour of San Juan del Norte has been nearly filled up by a sand-bar, entirely preventing the entrance of vessels!

## *SCIENTIFIC SERIALS*

THE *Zeitschrift für Ethnologie* for the present quarter begins with a critical paper on "Ethnological Classifications," especially those which rest on language. The writer comments on the arbitrary character of the division of languages into "isolating," "agglutinating," and "inflecting," and contrasts the comparatively exhaustive knowledge of animal types on which zoological classifications depend, with the very scanty acquaintance which ethnologists possess of the great mass of languages beyond the Indo-European group. Exact knowledge of these latter highly complex and differentiated languages is, he argues, of very little use in tracing the origin and affinities of more primitive speech. It is suggested that peculiarities of language often depend on local characters of climate rather than on race. Thus, short words may be the result of a warm and lazy climate, like Siam, while, on the contrary, the chilly Indians of Athapascow take an athletic delight in calling their feet "choachastlsokai." Many interesting examples are given of Dog-Latin, Pigeon-English, Chinook-French, and other bastard varieties of civilised languages, which appear to be modified in a certain definite way according to climate and to race. Here is an example of Monks' Latin of the date 1127. "*Donent illis in Dominicis diebus carnem Mottotinum* (Mouton) *in quartis feriis cicerones, cum lardo.*" The second article in the same journal, by Franz Engel, is on the national types and races of Tropical America. It contains an interesting account of the habits and characters of the Spanish Americans, the Creoles, Negroes, and Indians, with the various cross-breeds among them. But there is little addition to our knowledge of their anatomical and physiological peculiarities, and the whole description is written in a diffuse and affected style, including in one passage a very prosaic travestie of verses from "Das Lied von der Glocke." A much shorter but valuable paper, by Adolf Hübner, gives an account, with figures, of a great series of drawings he discovered on a flat slate rock in the Trans-Vaal Republic of South Africa. Indigenous wild animals of all kinds were, to judge from the specimens given, very fairly represented, with a few human figures, one holding a bow; but no domestic animals were to be seen, nor was there any appearance of alphabetical or even picture-writing. The same writer gives also an account (with plans) of ancient Caffre fortifications in Mosalikatzi's kingdom.

IN the Berlin *Academy of Anthropology*, &c., a sketch by Dr. H. H. Hildebrand was exhibited (and is reproduced in the *Zeitschrift für Ethnologie*) of one of the urns with sculptured faces which have attracted so much attention in this Academy before. It was found in Cyprus. Other communications were on pile-dwellings in the Kuder See (Holstein), by L. Meyer; on an instrument of bone, about eight inches long, shaped like a knife-blade, and jagged along the edge, found in Mecklenburg. about fifteen feet deep, and covered by ten feet of chalk; on a burying-place in East Prussia, which proved by the utensils discovered in the graves to have been used by Romans; on stone implements in East Greenland; and on the ethnological characters of the Turcos of the French Army, for the study of which recent events have offered unusual facilities. At a subsequent meeting of the Academy, Prof. Virchow read a paper on the use of *tibiæ* and and other bones as skates in early times; and Herr Jagor one on the discovery of kitchen middens in the Andaman Isles.

IN a reprint from the *Archæologia* (vol. xlii.) Prof. Rolleston gives an interesting account of his researches in a Roman-British cemetery at Frilford, near Abingdon. Superficial to the more ancient interments, which were mostly in coffins and belonged to Christian times, were found later remains of the Saxon Pagan period. The latter were placed promiscuously, the former with more or less orientation, and the fact that the direction of the grave usually deviates towards the south is ingeniously explained as due to the majority of deaths having taken place then, as now, in the winter quarter of the year, when the sun would rise south of the due east. From the character of the skulls, and the urns, weapons, nails, &c., found in the graves, various important conclusions are drawn as to the social condition of this country during the obscure period between the departure of the Romans and the conversion of the Saxons; and the whole paper is illustrated by a curious and felicitous erudition which reminds the reader of the account of a Roman cemetery at Old Walsingham, given in the "Hydriotaphia" of Sir Thomas Browne."

## SOCIETIES AND ACADEMIES

### London

Royal Society, May 4.—"On the Molybdates and Vanadates of Lead, and on a new Mineral from Leadhills," by Prof. Dr. Albert Schrauf, of Vienna.

"On the Structures and Affinities of *Gwynia annulata*, Dunc., with Remarks upon the Persistence of Palæozoic Types of Madreporaria," by Prof. P. Martin Duncan.

The dredging expedition which searched the sea-floor in the track of the Gulf Stream of 1868, yielded, amongst other interesting Madreporaria, a form which has been described by Count Pourtales under the name of *Haplophyllia paradoxa*, and which was decided by him to belong to the section *Rugosa*.

The last expedition of the *Porcupine*, under the supervision of Dr. Carpenter and Mr. J. Gwyn Jeffreys, obtained, off the Adventure Bank in the Mediterranean, many specimens of a coral which has very remarkable structures and affinities. The species is described under the name of *Gwynia annulata*, Dunc. The necessity of including it amongst the Rugosa and in the same family, the *Cyathoxonidæ*, as *Haplophyllia paradoxa*, is shown. Having this proof of the persistence of the rugose type from the palæozoic seas to the present, the affinities of some so-called anomalous genera of midtertiary and secondary deposits are critically examined. The Australian tertiary genus *Conosmilia*, three of whose species have strong structural resemblance with the Rugosa, is determined to be allied to the *Stauridæ*, and especially to the Permian genus *Polycœlia*. The secondary and tertiary genera with hexameral, octomeral, or tetrameral and decameral septal arrangements are noticed, and the rugose characteristics of many lower Liassic and Rhetic species are examined. The impossibility of maintaining the distinctness of the palæozoic and neozoic coral faunas is asserted; and it is attempted to be proved that whilst some rugose types have persisted, hexameral types have originated from others, and have occasionally recurred to the original tetrameral or octomeral types; and that the species of corals with the confused and irregular septal members, so characteristic of the lowest neozoic strata, descended from those *Rugosa* which have an indefinite arrangement of the septa. The relation between the Australian tertiary and recent faunas, and those of the later palæozoic and early neozoic in Europe, is noticed, and also the long-continued biological alliances between the coral faunas of the two sides of the Atlantic Ocean.

"Remarks on the Determination of a Ship's Place at Sea." In a Letter to Prof. Stokes, by G. B. Airy, LL.D., Astronomer Royal.

May 11.—"An Experimental Inquiry into the Constitution of Blood, and the Nutrition of Muscular Tissue," by William Marcet, M.D., F.R.S. The results obtained from the inquiry which forms the subject of the paper are as follows:—

First. That blood is strictly a colloid fluid.

Second. That although blood be strictly a colloid, it contains invariably a small proportion of diffusible constituents amounting to nearly 7·3 grms. in 1,000 of blood, and 9·25 grms. in an equal volume of serum, these proportions diffusing out of blood in twenty-four hours.

Third. That the proportion of chlorine contained in blood has a remarkable degree of fixity, and may be considered as amounting to three parts (the correct mean being 3·06) in 1,000.

Fourth. That blood contains phosphoric anhydride and iron in a perfect colloid state, or quite undiffusible when submitted to dialysis, the relative proportions appearing to vary from 78·61 per cent. of peroxide of iron and 29·39 of phosphoric anhydride, to 76·2 and 23·8 respectively, the proportion of phosphoric anhydride having a tendency to be rather higher.

Fifth. That blood contains more phosphoric anhydride and potash, bulk for bulk, than serum.

Sixth. That a mixture of colloid phosphoric anhydride and potash can be prepared artificially by dialysis, and that the colloid mass thus obtained appears to retain the characters of the neutral tribasic phosphate from which it originates; it exhibits an alkaline reaction, yields a yellow precipitate with nitrate of silver, and after complete precipitation the reaction is acid.

Seventh. That by dialysing certain proportions of phosphate of sodium and chloride of potassium during a certain time, proportions of phosphoric anhydride, potash, chlorine, and soda are obtained in the colloid fluid very similar to the proportions these same substances bear to each other in serum after twenty-four hours dialysis.

Eighth. That muscular tissue is formed of three different classes of substances; the first including those substances which constitute the tissue proper, or the portion of flesh insoluble in the preparation of the aqueous extract, and consisting of albumen and phosphoric anhydride with varying proportions of potash and magnesia; the second class including the same substances as are found in the tissue proper, and in the same proportions relatively to the albumen present in that class, but existing in solution and in the colloid state; the third class including the same substances as are found in the two others, and moreover a small quantity of chlorine and soda, which, although relatively minute, is never absent. The constituents of this class are crystalloid, and consequently diffusible, the phosphoric anhydride and potash being present precisely in the proportion required to form a neutral tribasic phosphate, or a pyrophosphate, as the formula $2KO\ PO_5$ can equally be $2KO\ HO\ PO_5$.

Ninth. That flesh contains in store a supply of nourishment equal to about one-third more than its requirement for immediate use, this being apparently a provision of nature to allow of muscular exercise during prolonged fasting.

Tenth. That the numbers representing the excess of phosphoric anhydride and potash in blood over the proportion of these substances in an equal volume of serum in the regular normal nutrition of herbivorous animals, appear to bear to each other nearly the same relation as that which exists between the phosphoric anhydride and potash on their way out of muscular tissue.

Eleventh. That vegetables used as food for man and animals, such as flour, potato, and rice, transform phosphoric anhydride and potash from the crystalloid or diffusible into the colloid, or undiffusible state; and it is only after having been thus prepared that these substances appear to be fit to become normal constituents of blood, and contribute to the nutrition of flesh.

A final remark, and one which is worth consideration, is the fact established by the whole of the present investigation, that there is a constant change, as rotation in nature from crystalloids to colloids, and from colloids to crystalloids.

"On Protoplasmic Life." By F. Crace-Calvert, F.R.S.

A year since the publication of Dr. Tyndall's interesting paper on the abundance of germ life in the atmosphere, and the difficulty of destroying this life, as well as others paper published by eminent men of science, suggested the inquiry if the germs existing or produced in a liquid in a state of fermentation or of putrefaction could be conveyed to a liquid susceptible of entering into these states; and although at the present time the results of this inquiry are not sufficiently complete for publication, still I have observed some facts arising out of the subject of protoplasmic life which I wish now to lay before the Royal Society.

As a pure fluid free from life, and having no chemical reaction, was essential to carrying out the investigation, I directed my attention to the preparation of pure distilled water. Having always found life in distilled water prepared by the ordinary methods by keeping it a few days, after many trials I employed an apparatus which gave satisfactory results, and enabled me to obtain water which remained free from life for several months.

The water had to be redistilled three or four times before it was obtained free from germs, and it was then kept in the apparatus in which it was distilled until wanted, to prevent any contact with air.

Some water which had been distilled on the 20th of November, 1870, being still free from life on the 7th of December, was introduced by a siphon into twelve small tubes and then left exposed to the atmosphere for fifteen hours, when they were closed. Every eight days some of the tubes were opened, and their contents examined. On the fifteenth, therefore, the first examination was made; when no life was observed; on the 23rd two or three other tubes were examined, and again no life was detected; whilst in the series opened on the 2nd of January, 1871, that is to say, twenty-four days from the time the tubes were closed, two or three *black vibrios* were found in each field. Being impressed with the idea that this slow and limited development of protoplasmic life might be attributed to the small amount of li e existing in the atmosphere at this period of the year,* a second series of expements was commenced on the 4th of January. The distilled water in the flask being still free from life, a certain quantity of it was put into twelve small tubes, which were placed near putrid meat at a temperature of 21° to 26° C. for two hours, and then sealed. On the 10th of the same month the contents of some of the tubes were examined, when two or three small *black vibrios*

* During the intense cold of December and January last, I found it t ok an exposure to the atmosphere of two days at a temperature of 12° C. before life appeared in solution of white of egg in the pure distilled water, whilst as the weather got warmer the time required became less.

were observed under each field. This result shows that the fluid having been placed near a source of protoplasmic life, germs had become impregnated in two hours in sufficient quantity for life to become visible in six days instead of twenty-four. Other tubes of this series were opened on the 17th of January, when a slight increase of life was noticed; but no further development appeared to take place after this date, as some examined on the 10th of March did not contain more life than those of the 17th of January.

This very limited amount of life naturally suggested the idea that it might be due to the employment of perfectly pure water, so that Mr. Calvert commenced a third series of experiments.

On the 9th of February 100 fluid grains of albumen from a new-laid egg were introduced as quickly as possible and with the greatest care, into ten ounces of pure distilled water contained in the flask in which it had been condensed, and an atmosphere of hydrogen kept over it. On the 16th some of the fluid was taken out by means of a siphon and examined, and no life being present, twelve tubes were filled with the fluid exposed to the air for eight hours and closed. On the 21st the contents of some of the tubes were examined, when a few vibrios and microzyma were distinctly seen in each field. On the 27th other tubes were examined, and showed a marked increase in the amount of life. In this series, in which a *fermentable substance* was employed, life appeared in five days, and an increase in ten, instead of requiring twenty-four days, as was the case when pure water only was employed.

As the weather had become much warmer, and a marked increase of life in the atmosphere had taken place, some of the same albumen solution as had been employed in the above experiments was left exposed in similar tubes to its influence, when a large quantity of life was rapidly developed, and continued to increase. This result appears to show that the increase of life is not due to reproduction merely, but to the introduction of fresh germs; for, excepting this fresh supply, there appears to be no reason why life should increase more rapidly in the open than in the closed tubes.

"Action of Heat on Protoplasmic Life," by F. Crace Calvert, F.R.S.

Those investigators of germ-life who favour the theory of spontaneous generation, have assumed that a temperature of 212° Fahr., or the boiling-point of the fluid which they experimented upon, was sufficient to destroy all protoplasmic life, and that the life they subsequently observed in these fluids was developed from non-living matter.

I therefore made several series of experiments, in the hope that they might throw some light on the subject.

To carry out the experiments I prepared a series of small tubes made of very thick and well-annealed glass, each tube about four centimetres in length, and having a bore of five millimetres. The fluid to be operated upon was introduced into them, and left exposed to the atmosphere for sufficient length of time for germ-life to be largely developed. Each tube was then hermetically sealed and wrapped in wire gauze, to prevent any accident to the operator in case of the bursting of any of the tubes. They were then placed in an oil-bath, and gradually heated to the required temperature, at which they were maintained for half an hour.

*Sugar Solution.*—A solution of sugar was prepared by dissolving one part of sugar in ten parts of water. This solution was made with common water, and exposed all night to the atmosphere, so that life might impregnate it. The fluid was prepared on the 1st of November, 1870, introduced into tubes on the 2nd, and allowed to remain five days. On the 7th of November twelve tubes were kept without being heated, twelve were heated to 200° Fahr., twelve to 300°, and twelve to 400° Fahr.

The contents of the tubes were microscopically examined on the 1st of December, twenty-four days after heating.

In the sugar solution which was not heated there were about thirty animalcules under each field of the microscope, principally *small black vibrios*; two or three microzymes swimming slowly about; three or four *ordinary swimming vibrios*, and a few bacteria. In that which was heated for half an hour at 212 F., a great portion of the life had disappeared, and no animalcules were swimming. Four or five *small black vibrios* were observed moving energetically to and fro; two or three *ordinary vibrios* were also observed moving energetically *in the same position of the field, that is, without swimming about.* Heated for half an hour at 300° F. the sugar was slightly charred, but one or two *ordinary vibrios*, and one or two *small black vibrios* were observed in motion under the field of the microscope. In the solutions heated to the higher temperatures there was no trace of organisms.

*Remarks.*—The black vibrios here referred to are far more opaque than the other varieties of vibrios, and are the most important of all, as I have found them to resist not only very high temperatures, but all chemical solutions. I shall, in my paper on putrefaction and the action of antiseptics, describe the various vibrios, and give various drawings of them.

*Hay Infusion.*—An infusion of hay was made by macerating it in common water for one hour, then filtering the liquor, and leaving it exposed to the atmosphere all night, when it was sealed in the small tubes, twelve of which were used for each experiment. The infusion was made on the 4th of November, sealed in tubes on the 5th, and heated on the 7th.

The results were examined on the 1st of December, 1871, twenty-four days after being heated.

The hay infusion not heated contained "fungus matter" and other low organisms. The tubes, which were heated to 212° F. and 300° F., contained a few small "black vibrios," [but whether they were living or dead is not stated]. The tubes exposed to higher temperatures showed no trace of organisms.

*Gelatine Solution.*—A solution of gelatine, prepared of such strength that it remained liquid on cooling, was exposed for twenty-four hours to the atmosphere. It was then introduced into the small tubes, and the tubes sealed. The solution was made on the 4th of November, the tubes sealed on the 5th, and subjected to the different temperatures on the 7th.

The fluids were examined on the 1st of December, 1871, twenty-four days after being heated.

In the gelatine solution which was not heated, there were seven or eight animalcules under each field, five or six of which were quite different from anything observed in the other fluids. They had long thin bodies, swimming with a peristaltic motion. One or two ordinary swimming vibrios were also present; but the small black vibrios were absent. In the gelatine solution heated for half an hour at 100° F., the organisms ceased to exhibit any active movements; and in that which was heated for half an hour at 212° F., a very decided diminution in the quantity of life present was noticed. In the solutions heated to the higher temperatures no life was found.

*Putrid Meat Fluid.*—Water was placed in an open vessel, and a piece of meat suspended in it until it became putrid and contaminated with myriads of animalcules. This fluid was placed in the usual tubes, which were sealed on the 7th November, and heated on the same day.

The contents of the tubes were subjected to examination on the 1st of December, or twenty-four days after having been heated.

In the solution which was not heated, a large quantity of life was present, namely, microzyma and several distinct species of vibrios, among which were a number of the small black ones frequently mentioned. In that which was heated for half an hour at 100° F., this temperature had but slightly affected the life present, the animalcules being as numerous as in the liquid not heated, and not moving as usual. In that which was heated for half an hour at 212° F., although heat had *deprived the animalcules of the power of locomotion*, still they retained a sufficient amount of vital force to "place it beyond a doubt that life was not destroyed." In that which was heated for half an hour at 300° F. a large quantity of the life in the fluid was destroyed, but some vibrios still remained, the small black ones being the most numerous. In the solutions exposed to the higher temperatures there was no trace of organisms.

Although perfectly aware of the interesting researches of Prof. Melsens, proving that the most intense cold does not destroy the active power of vaccine lymph, still I thought it desirable to ascertain the effect of a temperature of 15° F. on well-developed germ-life, similar to that which had been subjected to the action of heat.

Some putrid-meat liquor, therefore, containing a large quantity of microzyma and vibrios, was subjected for twenty hours to the influence of a temperature ranging between the freezing-point of water and 17° below that point, when the ice was melted, and the liquor examined. The animalcules retained their vitality, but appeared very languid, and their power of locomotion was greatly decreased. Two hours after melting the ice the liquor was again examined, when the animalcules appeared to be as energetic as before.

In the discussion which followed the reading of Dr. Calvert's papers Dr. Charlton Bastian remarked upon the number of assumptions which were introduced, and gave reasons for his opinion that the experiments were wholly inconclusive in their nature. He was not aware that Prof. Tyndall had ever revealed an "abundance of germ life" in the air, whilst M. Pasteur had distinctly stated that he had been unable to recognise Bacteria or their germs in the dust filtered from the atmosphere. Even if Bacteria were widely diffused in the air, it would still have to be shown that they were alive. From the fact that some eminently inoculable fluids might be pretty freely exposed to the air for two or three weeks without showing the least signs of turbidity—though they could always be rendered turbid in two or three days after bringing them into contact with actual living Bacteria—he thought there was reason to believe that *living* Bacteria were by no means abundant in the air. And as he had found that all other naked lower forms of life with which he had experimented were unable to survive the effects of even short periods of desiccation, he thought there was much reason for the belief that the same rule would hold good for Bacteria. Dr. Bastian failed to find in Dr. Calvert's papers sufficient evidence that the organisms found in some of the solutions were really alive, and with regard to those experiments in which fermentable substances had been employed, it was assuming the very point at issue to suppose that the more numerous organisms which were present in them could only have come from the atmosphere. With regard to the influence of heat upon the life of Bacteria and many other organisms, Dr. Bastian gave some particulars concerning experiments, which tended to show, as he thought, conclusively, that they were all killed by an exposure in fluids, for ten minutes, to a heat of 60° C. (140° F.) There was no difficulty in ascertaining when Amœbæ or Ciliated Infusoria were killed, though with respect to Bacteria there was much more difficulty. Where the movements were not of an active character, after the Bacteria had been subjected to different degrees of heat, no reliable opinion as to their life or death could be arrived at. Bacteria which were really living might in many cases exhibit movements differing in no respect from those which dead Bacteria would display. From the exhibition of such movements, therefore, it could not be positively affirmed that the organisms were living, or that they were dead. The case was different, however, with regard to reproduction—dead organisms could not multiply. Having found a fluid, therefore, which was most suitable for the nourishment of Bacteria, but which seemed to be wholly incapable of giving origin to them *de novo*, he inoculated portions of it with living Bacteria, and then found that those fluids which had been heated to 50° C. or 55° C. for ten minutes became quite turbid in two or three days, whilst others, heated for the same time to 60°, 65°, 70°, 75° C. and upwards, invariably remained clear and showed no signs of turbidity. As living Bacteria will always multiply under suitable conditions in suitable fluids, their failure to multiply was the best evidence that they had been killed. The conclusion that Bacteria were killed by exposure in fluids to a heat of 60° C. was one which had been previously arrived at by Prof. Wyman and M. Pouchet, though such a conclusion was now much strengthened by Dr. Bastian's recent experiments. These results were harmonious also with the fact that Amœbæ, Ciliated Infusoria, and almost all the other lower organisms with which experiments had been made, were also killed by even a shorter exposure to a temperature of 60° C. (140° F.)

Geologists' Association, May 5.—Rev. T. Wiltshire, president, in the chair.—"On the Fauna of the Carboniferous Epoch," by Henry Woodward. In this paper the author protested against that mode of thought which seemed to imply that the globe was, during the various geologic periods, a vast aquarium, and urged the similarity of the conditions which now prevail with those that were obtained during the deposition of the various systems of the stratified rocks. Mr. Woodward combated the opinion of many, that during the Carboniferous period the atmosphere was heavily charged with carbonic acid gas, which, while it supplied the profuse vegetation of that epoch with carbon, prevented the radiation of heat from the earth, and thus produced an abnormal warmth which, with abundant moisture, was the cause of the vast growths that formed the beds of coal we now use for fuel. It was contended that the atmosphere under normal conditions was quite sufficient to supply all the carbonic acid that was required for the vegetation which composed all the beds in the world, and that, as we find the Gulf Stream exerting a great influence on the climate of England at the present time, so unusual warmth and humidity and great alterations of the isothermal lines of the globe, might have been produced by ocean currents consequent upon changes of coast-lines and other causes of which we can know little. The animal life of the epoch was then described, and some valuable lists of species were appended to the paper. The Rev. Mr. Henslow, referring to Mr. Woodward's remarks respecting the discovery by Prof. Morris of the "Mother coal" of Bradford being made up of spores and spore cases, stated that Prof. Huxley had concluded that coal generally was formed in this manner. Prof. Morris heartily approved of Mr. Woodward's opinion in favour of the contemporaneity of formations usually considered to be of successive epochs, and pointed out the great differences in the thickness in the underlying beds, and in other stratigraphical conditions of the Carboniferous limestone, millstone grit, and coal measures, in various districts. In Shropshire, for instance, the Carboniferous beds repose upon Silurian rocks, and in Scotland the coal seams are intercalated with the main limestone. Mr. Woodward, after passing a high eulogium on Prof. Morris, whose knowledge of the subject was most varied and extensive, briefly described several species of crustacea of which diagrams were exhibited, and directed the attention of the Association to a cast of the head of an undescribed species of *Anthracosaurus* allied to *A. Russelli*, recently obtained by Mr. George Maw, from the coal measures of Coalbrook Dale.

PARIS

Academy of Sciences, April 10.—M. Chasles read a very interesting paper on the properties belonging to a system of cones. Every one of these properties discovered by the law of analogy relates to a series of certain geometrical objects, compared with a series of other objects of the same nature. The demonstrations are not given except by the arrangement of the different propositions, which are sixty in number, and fill twelve closely printed pages of the *Comptes Rendus*.—Dr. Declat, who does not belong to the Academy, read a memoir on the effects of phenic acid. He attributes to this specific the power of curing the German cattle plague, or at least of preventing it. The experiments do not appear, however, very conclusive.—M. Aubert presented a memoir on the moral causes of the inferiority exhibited by French armies during the last campaigning. These causes are very numerous, and the principal of them is the making of the army an instrument for the protection of an internal despotism. The discussion of these subjects was considered as being out of the limits and province of the Academy. The memoir in former years would have been rejected under the old rules, but the president, M. Delannay, referred it to a special committee, composed of General Morin, director of the Conservatoire des Arts, and M. Amiral Paris. The *Comptes Rendus* for this sitting publishes a list of periodicals which were offered to the French Academy in the month of March. As many as fifteen publications were special periodicals, which resumed their publication during the few weeks of the cessation of fighting round Paris. The celebrated Abbé Moigno has lost no time in starting his *Les Mondes*, as the whole set for March was presented to the Academy. The foreign list was very short and incomplete, as NATURE, which had been presented, was omitted. The only English paper mentioned was the *Monthly Notices of the Royal Astronomical Society*.—M. Barral, the editor of two agricultural papers which are mentioned in the aforesaid list—*Bulletin hebdomadaire du Journal d'Agriculture* and *Journal de l'Agriculture*—having taken steps opposed to Communist rule, was obliged to leave Paris. His papers are now published at Versailles. M. Wolf, an Austrian subject, was present at the sitting. He is conducting observations at the National Observatory, where the instruments were not packed as on the occasion of the former shelling and investment. They run the risk of being smashed to pieces.

April 17.—M. Payen read an important paper on Cellulose. It is known that stony fruits or stony parts of fleshy fruits, like cherries and peaches, are composed of cellulose, impregnated with incrusting materials. The digestion of this cellulose is rendered more easy and complete by giving to the animals some fatty matters. The same may be said of stems of vegetables and straw. The application of this theory to the breeding of cattle is obvious. M. Payen exhibited some reactions, which show theoretically that the results obtained in Germany by the analysis of evacuations are truthful and genuine. The paper elicited some observations from M. Chevreul, who read afterwards on his own account a short report on a small pamphlet written by him during the investment of Paris. The title of this *brochure* is somewhat long, and explains clearly the meaning of the work: "On a fault of reasoning which is committed very often by people engaged in natural philosophy when reasoning on the concrete. The explanations are drawn from the last writings of M. Chevreul." These writings are mostly communications presented by M. Chevreul to the Academy for the last three years, when he was strenuously advocating a new classification of sciences as well as of the different objects of nature.—M. Trécul read some interesting observations on the Vegetation of Ferns. —M. Sant Venant, a member of the Section of Mechanics, presented a paper written by M. Boussinerg, a promising young French mathematician, who does not belong to the Academy. The paper related to the observations of an immense number of transcendental equations which present themselves to the mathematical inquirer when studying physical phenomena.

April 24.—The account of this sitting was published in the last number of NATURE. We have nothing of importance to add to it. All the *Comptes Rendus* of the period are signed by M. Elie de Beaumont, acting as perpetual secretary. M. Elie de Beaumont was formerly a senator, although it can hardly be said he has ever meddled with politics. M. Delaunay, the present director of the National Observatory, has inaugurated the regular publishing of a monthly abstract of meteorological observation. It is a practice which is revived from Arago's, but was stopped by M. Leverrier when he stepped into office in 1854.

### BERLIN

**Royal Prussian Academy of Sciences**, March 6.—M. Roth read the continuation of his historical remarks upon the theory of metamorphism, and the production of crystalline slates. —Prof. A. W. Hofmann read papers on phosphuretted hydrogen, and on the direct substitution of the alcoholic radicals for the hydrogen in that compound.

March 9.—M. Riess read a paper on the action of the subsidiary currents of the electrical battery upon the main current and upon each other.

March 30.—Prof. Hofmann described an eudiometer with movable wires. The apparatus consists of a glass tube, with two short narrow tubes attached to it at right-angles, and opening into it opposite to each other; these are closed by steel caps, through which steel screws pass, bearing the platinum wires. The screws are furnished with loops for the attachment of wires. —Prof. Hofmann also read a memoir on isodicyanic æthers, compounds which occupy a middle place between the cyanic and cyanuric æthers; and another on biuret and allied compounds. —Prof. Dove read a paper on the behaviour of agate in the magnetic field.

### VIENNA

**I. R. Geological Institution**, April 18.—Prof. Peters, of Gratz, sent a communication about a newly discovered mineral spring at Hengsberg, near Gratz. Besides a large quantity of free carbonic acid and carbonate of lime, the water contains chlorine, bromine, traces of iodine, boracic acid, and among the alcalies a considerable quantity of lithium.—M. J. Pauer related a remarkable phenomenon which has occurred during recent years in the large lake of Neusiedel, near Oldenburg, in Hungary. This lake, which measured nearly six German (about 150 English) square miles, was entirely dried up in the year 1865, and the ground was gradually converted into arable land. During the last winter, however, the water regained its territory, and to the great damage of the cultivators the basin is again filled up nearly to the same extent which it occupied formerly. Documents were found which prove that similar events took place in former centuries, and on one spot were discovered trunks of trees rooting in the ground as much as three feet in diameter. They prove that at a former period the lake was dry through a long series of years.—M. E. v. Mojrisovics presented a memoir on the so-called alveolaric Orthoceratites from the Triassic and Liassic deposits of the Alps. He proved that they all are the phragmocones of a particular genus of the family of the Belemnitidæ, and that their isolated rostra are the forms which Gümbel called Attractites. The genus was described many years ago by Fr. v. Hauer and named Aulacoceras, but he had united it with the family of the Orthoceratidæ. To Aulacoceras belong all formerly so-called Orthoceratites with a marginal sipho, from the mesozoic formations of the Alps, and only the species with a central sipho are real Orthoceratites.

## BOOKS RECEIVED

ENGLISH.—Discourses on Practical Physic: Dr. B. W. Richardson (Churchill).—The Coming Race (Blackwood and Sons).

FOREIGN.—(Through Williams and Norgate)—Vorwort zu der Physik der Erde: Dr. R. Reuschle.—Grundzüge der technischen Natur-lehre: Dr. Ph. Huber.—Leh-buch der Physik und Mechanik: Dr. L. Blum.—Lehrbuch der Physik: Dr W. Eisenlohr.—Anatomie und systematische Beschreibung der Alcyonarien: Dr A. Kölliker.

## *THE SMALLER LECTURESHIPS AT THE LONDON MEDICAL SCHOOLS*

### II.—THE TRUE FUNCTIONS OF THE SMALLER SCHOOLS

IN a recent article* we pointed out the prodigious waste of time and energy that results from the existence of no less than eleven medical schools in the metropolis, with from thirteen to twenty-one lectureships attached to each, and called attention to a scheme by which it is proposed that an amalgamation should take place between several of them.

It is maintained by those who have proposed this scheme that by its means a reduced number of central institutions would be created in which the preliminary subjects of medical education, such as natural philosophy, mechanics, rudimentary chemistry, and botany, could be taught in a much more satisfactory manner than at present, since the increased value of the lectureships would enable the lecturer to devote more time to their preparation, and to supply much greater wealth of illustration, whilst the larger number of students in attendance would correspondingly stimulate his zeal. At the same time the smaller hospitals and schools might still fulfil a very important *rôle* as supplying the means for the practical or clinical study of disease—certain lectureships still remaining attached to them.

The importance of good preliminary education in natural philosophy, taking it in its widest sense, for the medical practitioner, seems to us to be by no means sufficiently recognised. Up to a very recent time it has been almost entirely ignored. It is only within the last few years that any steps in the right direction have been taken by the great examining boards. Fifteen years ago the College of Surgeons required little more than a good knowledge of anatomy and the principles of surgery in those they admitted as members, and even now the acquaintance with preliminary subjects they demand is of a very rudimentary nature, as may be gathered from the fact that it includes only writing from dictation, arithmetic, algebra, geography, English history, the first two books of Euclid, and a little Latin translation, with one optional subject, which may be either Greek, French, German, mechanics, chemistry, botany, or zoology. We cannot but think that this programme might be advantageously extended.

Does it not stand to reason that the lad who is about to enter upon the study of Anatomy and Physiology ought to possess a competent knowledge of the principal facts of Natural Philosophy? How is he to comprehend the contraction of muscles, the action of the valves of the heart, the phenomena of respiration, the construction of the eye and ear, unless he is well grounded in Mechanics, already understands the lever and the pulley, and knows the principles of Hydraulics and Pneumatics, the laws of refraction of light, and the conduction of sound? Nor can it be said that such knowledge is of temporary value only. The surgeon and physician must daily and hourly see cases which can only be treated properly by reference to such knowledge.

If we might venture to suggest a scheme for the education of the student intended for the medical profession, we should recommend it to be commenced while he is still at school, at the age of sixteen, by passing the matriculation examination of the University of London. The following year should be devoted to the study of Natural Philosophy, rudimentary Chemistry, and Botany; and there could be no doubt that these subjects could be admirably taught at all the larger and better appointed schools through the country. But these are precisely the subjects that might be taught to large classes in a most superior manner in the four or five institutions with which it is proposed that the smaller schools should be amalgamated. The preliminary examination, in which considerable knowledge should be demanded, might take place at the age of seventeen. In the following winter session the student, now thoroughly grounded, should begin the study of Anatomy and Physiology, and the following summer might be employed in pursuing Chemistry in its application to Medicine; Botany in the same relations; and the recently introduced subject of Practical Physiology; the first embracing such subjects as the chemistry of the excretions and secretions, &c.; the second, the orders containing medicinal plants, and the composition and formation of the vegetable alkaloids, &c.; and the last, such points as the action of the valves of the heart, the processes of respiration and digestion, &c. The second winter session should be taken up in completing the knowledge of Anatomy and Physiology; and at the expiration of this session the first examination should take place, comprehending the subjects of Anatomy, Physiology, Chemistry, and Botany, the two latter points being at present almost wholly neglected. The second summer session might be occupied with the so-called Materia Medica, formerly merely consisting of the driest of all possible discourses on the composition and form of the various drugs, but with which our student is already perfectly familiar, and which might now be advantageously replaced by an account that could, in the hands of an efficient lecturer, be made deeply interesting, on the physiological action of drugs, and the effects of remedies on man and animals.

Up to the present time the whole work of the student could be conducted at one of the central institutions. From henceforward he might with great advantage be allowed to elect whether he would remain at this central institution, or go to one of the amalgamated schools. These might be made most serviceable as means of instruction in chemical medicine, surgery, and midwifery; and lectureships on these subjects, to avoid the loss of time to the students that would otherwise be involved in going to and fro, might be retained at the smaller schools. The instruction on these subjects would extend over the third and fourth winter sessions, at the end of which the final examination should take place. Thus it appears to us a vast improvement in the education of the medical student might be effected. He would enter the portals of his profession with a good general knowledge of the subjects he is about to study. The first years would be spent under circumstances in which he would obtain the best education on preliminary subjects the kingdom can afford, whilst the last two years would be spent under conditions in which the great field for clinical instruction possessed by the smaller hospitals could be

* See NATURE, vol. iv. p. 1.

utilised to the utmost. This is, indeed, the special field which we look to the smaller hospitals to occupy in the future. Clinical instruction is pursued to a far greater advantage with a smaller than with a larger number of pupils.

## M. TAINE ON INTELLIGENCE

*On Intelligence.* By H. Taine. Translated from the French by T. D. Haye, and revised by the Author. Part I. (London: Reeve and Co., 1871).

IN a notice, some months ago* in these columns, of M. Ribot's clever exposition of English psychology, mention was made of M. Taine's work, *De l'Intelligence*, then newly come forth, as a striking evidence of the revival of French interest in the scientific investigation of mind. The first part of the work is now put before English readers in a translation satisfactory on the whole, and the second part is announced as soon to follow.

The first part, as readers of the original must be aware, easily admits of being published separately. This happens because M. Taine's exposition, while presenting in the detail all the best qualities of his admirable style, is in its main lines laid out with a strict regard to principles of logical method. It falls into two sharply marked divisions, an analytic and a synthetic. No explanation of the different heads of knowledge making up our intelligence is attempted, until, by an analysis expressly performed, the ultimate elements of human cognition are come at. Often our English works on psychology, while they pass for, or claim to be, analytic, and do contain many cases of special analysis, are, in strictness, synthetic; the foregone general analysis being kept out of sight, and its sufficiency being left to appear from the character of the explanation which its results, as brought forward, may be made to yield. Of this description are the works of Prof. Bain, and even James Mill's professed "Analysis." M. Taine, on the other hand, prefers to do his analysis not in the secret laboratory of his own mind but under the eye of the reader; and the operation takes up the whole of his first part here translated.

Obviously, when the phenomena are so complex and manifold as in the case of mind or intelligence, the analysis, if it is thus to be exhibited, and if it is to be brought to anything like a definite issue, must be of facts carefully selected for their illustrative or representative character; and this M. Taine well apprehends. Nor does he less clearly see that normal facts or events of consciousness no more suffice for psychological science than can everyday observation take the place of artificial experiment in physical science. At different stages, therefore, he looks about him for cases either of what may be called artificial mental action, as in the ingenious processes resorted to by mathematicians, or of abnormal mental action, such as the phenomena of madness, hallucination, &c., which are a sort of nature's experiments on a field where, for moral reasons, the freedom of experimenting is greatly limited. So, at the stage of the senses where experiment becomes perfectly feasible, he effectively turns to account the most advanced results got out in late years by psychologists or physiologists; and, again, at the last stage of the analytic sounding, when he strikes upon a bottom of bare physiology, he makes apt selection from the most recent experimental work.

He begins by resolving thoughts, or (in the strict philosophical sense of the term) ideas, into images, on principles of thorough-going nominalism. Ideas the least general are shown to be impossible as mental experiences, and to need representation by particular signs, and ideas the most general and abstruse are shown to come within the mental grasp still by signs or symbols. There is the difference that in the case of natural objects, like tree or dog, the substituted sign, generally a name, is the direct expression of a mental "tendency" arising under actual impressions, varied at the same time that they are similar; while to conceptions like those of mathematical science there may correspond no distinct impressions, and the sign is struck out according to an elaborate system of indirect substitution—substitutions upon substitutions. But always some definite image is present to the mind. The question, then, is to investigate the nature of particular images; and, by a very instructive muster of normal and abnormal instances, the laws of their retention out of consciousness and revival in consciousness are brought out, with the result that the image is itself seen to be a substitute of sensation below it. Must the analysis then end in a mere description of the kinds of sensation, with account taken of physical conditions? M. Taine thinks it need not, and wisely selects for special inquiry the sensations of sound—wisely, not merely because Helmholtz's classical investigations lie ready to the psychologist's hand, but also because no other set of sensations is at once so varied in character and so free from admixture with extraneous elements. The result thence obtained, confirmed more or less from the senses of sight, smell, and taste, and not contradicted by the sense of touch, is that all qualitative differences of consciousness within each sense are explicable as different compounds of an elementary sensation not conscious; such elementary sensations, different in the different senses, being further conceivable as themselves developed by composition out of a single infinitesimal "event," of course imperceptible to consciousness, the truly ultimate element of all that appears as mind. But in relation with this there will stand a molecular displacement in nerve; for, as the physiological analysis, taken up when the psychological reaches its term, finds in the sensory ganglia the seat of crude sensation, and in the cerebral lobes with their cortical layer a "repeating and multiplying organ" through which sensations are associated and revived as images, and thus become knowledge, so it may see in the reflex action of lower nerve-centres the physical correlate of the simple unconscious "events" or elements of sensation. And thus the complete analysis of intelligence discloses two worlds, the moral and the physical, in mutual correspondence down to the lowest depths of human nature, and, by analogy, to the very foot of the zoological scale.

Save that M. Taine's method of procedure is his own, and his expression is always striking, there is little thus far in which he has not been anticipated by one psychologist or another among ourselves, notably by Mr. Spencer in the resolution of sensation. Nor in breaking up, in the last chapter of this part of his work, the metaphysical entities self and matter, regarded either as substances or as systems of faculties and forces, does he do more than

* See NATURE, vol. ii. p. 331.

follow the English authorities, as they follow their great master, Hume. But in giving final expression to the relation between the two series of "events," psychical and physical, shown by the analysis to be involved in the varied phenomena of intelligence, he is more strictly original; or, at least, his view is stated with peculiar neatness and force. How shall sensation, whether in the crude form or in the intellectual condition of the image or in the elemental state, be conceived as joined to something so disparate as a molecular movement in nerve: that is the difficulty. To say that what we have united is rather an idea of sensation had by (or, in the case of the ultimate psychical element, conforming to the type had by) direct personal consciousness, and an idea of nerve got indirectly by way of external sense, though this is philosophically true, touches the difficulty without removing it; for the two ideas are still irreducible to each other. But it may then more readily be suspected that the "events" are not two, but one, with two permanently distinct faces to cognition; and this, in M. Taine's view, is the final outcome of the analytic, though as regards the duality he hints at a possible reduction in his second part. Meanwhile, taking the physical aspect as secondary and the sign of a properly mental event, he seeks to illustrate the view and to enforce his theory of universal correspondence by a remarkable analogy. He supposes an original text with an interlinear translation; the translation plain and legible at the outset, but becoming confused farther on, and before the end no longer to be made out; on the other hand, the text very clear at the last but fainter higher up, and about the beginning not to be traced at all. The writing may represent nature; clear text and undecipherable translation mark the states of full intellectual consciousness so vaguely referred, at least in detail, to the complex of the brain; faint text and translation not too plain mark the cruder mental events referred to less but still highly complicated centres; finally, visible translation and blank instead of text mark the well-ascertained physiological phenomenon of reflex action, for which it is as legitimate, if not necessary, to suppose a psychical obverse, albeit unconscious, as it is to assume for highest consciousness a physical correspondence in brain-processes eluding our finest observation.

The analogy is instructively worked out further by M. Taine; but enough for the present. Another time we may better estimate the value of parts of his analysis, when considering how, from the materials it affords, he is able to build up the edifice of human knowledge.

G. Croom Robertson

## A STORM-ATLAS FOR NORWAY

*Storm Atlas of the Meteorological Institute of Norway.* (H. Mohn.)

A KNOWLEDGE of the laws which regulate the progress of storms would be of comparatively little practical interest without the telegraph, but, since the speed of electricity outstrips that of wind, the information by telegraph that a storm has appeared at an outpost may be of great importance to a maritime country like our own, provided we know the path which the storm is likely to pursue.

Of late years practical meteorologists have devoted a great deal of attention to this branch of their subject, and the memoir before us is not the least interesting of the various contributions which have been made. It is unnecessary to enter into the details of M. Mohn's observational system; let us rather invite attention to the general conclusions at which he arrives.

"Barometric maxima," he tells us, "often remain during a considerable period over the places where they have been formed, while, on the other hand, barometric minima are almost always in motion over the surface of the earth, transporting themselves (in Europe) almost always towards the east." He further finds that the barometric minima represented in his charts have their greatest velocity of motion before they arrive at the west coast of Europe, and a smaller velocity when they pass by Scandinavia; in Russia the velocity is again greater.

As regards the component of the movement which leads the centres towards the east, he finds a greater regularity exhibited, inasmuch as this component diminishes continuously as the minima move from the sea towards the interior of the continent. The curved paths of these minima are at north Europe sometimes very regular and sometimes very sinuous; in general they are concave towards the south. The mean movement in the direction of the meridian is towards the north in the Atlantic; towards the south, but feebly, in Scandinavia; and more strongly towards the south in Russia; in this latter country they appear to lose themselves.

Let us now invite attention to the following remarks of the author with regard to vapour:—"Vapour tension is an element of which the importance for the theory of tempests was not so evident to me until I had commenced the construction of these charts. . . . . . Charts giving the relative humidity are without any value, nor do they present any trace of that continuity which shows itself so strikingly in the charts of vapour tension." Further on he says:—"I have frequently remarked in this memoir that watery vapour is one of the most important elements in studying the movement of air; it is therefore much to be desired that the publication of meteorological observations should embrace vapour tensions (which is not always the case), and if only one element can be given, let it be rather that than the relative humidity. . . . . Charts representing the distribution of the vapour of water over the surface of the earth analogous to the temperature charts of M. Dove or the isobaric charts of Mr. Buchan would be of the greatest possible utility."

It may not be out of place to make a few remarks upon these observations of M. Mohn. Meteorologists have been in the habit of discussing in two ways the state of the air with regard to vapour. They have in the first place studied the vapour tension present in the atmosphere, and secondly, they have studied the relative humidity, or what M. Mohn calls "*l'état hygrométrique*." This latter element, representing the proportion between the vapour actually contained in the air and the full amount due to the present temperature, is an element that varies very greatly with the temperature, and is, therefore, of comparatively little use in meteorological researches.

Besides these two elements, the author of this review has suggested the *hygrometric quality* of the air as a subject of importance in meteorological discussions. This is a very different thing from what is termed by Mohn "*l'état hygrometrique*," and denotes the chemical composition of the air, as regards moisture, or the weight of vapour contained in a hundred parts by weight of air. Now, as long as the pressure remains the same, this hygrometric quality will be represented by the tension of vapour, and, since on the surface of the earth the variations of pressure are comparatively small, the vapour tension will approximately represent the hygrometric quality. If this be borne in mind, the physical significance of Mohn's conclusions will become apparent; his remark, that the charts of vapour tension present a continuity and simplicity of distribution of that element, will now mean that the distribution of *types* or *kinds* of air is of a very simple nature.

We should, in fact, endeavour to find the distribution of air of various qualities over the surface of the earth just as we should endeavour to trace on the surface of the ocean sections of different saltness. But, while on the earth's surface vapour tension will approximately represent hygrometric quality, the case will be altered if we study strata of different elevations, and therefore of different pressures. If for instance, we ascend a mountain or take a trip in a balloon, the tension of vapour will no longer approximately represent the hygrometric quality of the air; but it will be the ratio between the pressure of aqueous vapour and that of air, which will truly represent the hygrometric quality in those regions. These considerations may, perhaps, throw some light upon the formation of clouds. If, for instance, air of the same quality extends a great way up, we shall have no cloud formed in the stratum as long as the rate of decrement of temperature does not exceed a certain limit; but when this limit is exceeded, there will be a deposition of cloud through the lowering of temperature alone, even while there is no admixture with air of another quality.

B. STEWART

## *OUR BOOK SHELF*

*Ueber Entwickelung und Bau des Gehörlabyrinths, nach Untersuchungen an Saügethieren.* Von Dr. Arthur Boettcher, o. ö. Professor der allgemeinen Pathologie und pathologischen Anatomie, a. d. Universität Dorpat. Erster Theil mit zwölf Kupfer Tafeln. (Leipzig: Wilhelm Engelmann, 1871. London: Williams and Norgate.)

THE successful investigation of the structure of the internal ear must always be regarded as the crown and glory of histological research, for whilst the structures that compose the auditory organ are of extreme delicacy, they are enclosed in a bony capsule of such density as to appear to bid defiance to all attempts to exhibit them in their natural state. Yet by careful decalcification with dilute acids and by immersion in various fluids, as those of Müller Schultze's solution of chloride of palladium, Cohnheim and Gerlach's solution of chloride of gold, &c., the most delicate details have been followed out, and the structure of the ear is now almost as well known as that of the eye.

M. Boettcher's observations on the labyrinth of adult animals have been largely supplemented by his numerous examinations of the same part at various periods of fœtal life, which have led to some interesting results.

The very earliest rudiment of the labyrinth in the mammalian fœtus is not yet accurately ascertained, but in the embryo of a sheep, of which a sagittal section of the head is only a millimetre in length, it appears as a sac with a small external opening formed by an inflection of the horny layer in close contact with this and opposite the second visceral arch. The wall of the sac is formed by cylindrical cells. In a somewhat more advanced stage the vesicle becomes elongated into a tube, the upper extremity of which is divided by a fold into an internal and smaller cavity—the recessus labyrinthi, and a larger, broader cavity, the aquæductus vestibuli. The inferior extremity is pointed, and is in immediate relation with the rudiment of the cochlea.

The semi-circular canals are formed by an inflection of the wall of the labyrinth vesicle opposite to the recessus labyrinthi, the horizontal canal being the last formed. In embryoes of 2·2 cm. long, the several parts above mentioned are more fully formed, and a projection appears, the fundus of which is directed towards the brain, which is the rudiment of the sacculus rotundus, from which the utriculus or sacculus ellipticus soon becomes differentiated. The separation of a scala vestibuli from a scala tympani in the cochlea is only apparent in embryoes that have attained a length of 8·5 cm. M. Boettcher clearly shows that the recessus labyrinthi found at a very early period subsequently becomes the aquæductus vestibuli, which remains permanently in connection with the sacculus rotundus and utriculus, and contains the same fluid (endolymph) as they do. The aquæductus cochleæ, on the other hand, is a totally different formation, and is in no way connected with the interior of the labyrinth. It conducts a vein, and might more correctly be styled, as Wildberg has suggested, the canalis venosus cochleæ.

In regard to the cochlea, he shows how the canalis cochlea, or scala media, is first developed, and how the two principal scalæ (scala tympani and vestibuli) are formed by the gradual breaking down of spongy cellular tissue on either side of the scala media, and he traces out in the most interesting manner the development, chiefly from epithelium, of the complicated organ of Corti, including under this head the so-called habenula perforata, the rods, and arched fibres, &c.

He describes a remarkable ganglionic mass, the ganglion spirale, the section of which is seen in this section of the cochlea close to the attached border of the lamina spiralis. In this the cochlear nerve appears to terminate, whilst from it fresh fibres take origin, and then, having passed through the openings of the habenula perforata, join certain cells, some of which are placed outside and some inside the arcuate fibres or rows of Corti. The former kind of auditory cells are, some of them, seated with a broad base on the membrana basilaris, whilst the attenuated extremity of the cell runs upwards. Others, however, are intercalated with these, which have a broad base attached to the membrana reticularis above, and then narrow apices interposed between the broad bases of the former. The cells that point downwards are Corti's cells, and are arranged in three rows. They possess a centrically directed process. The cells that point upwards are the so-called hair-cells, which receive this name on account of their terminating at both ends in a hair. The membrana basilaris he describes as consisting of a hyaline lamella on which is a fibrous layer, both layers having a peculiar form of epithelial investment. Beneath its proximal attachment is a spiral vessel. The development of all these parts is carefully traced. A very full account is given of Corti's membrane. He denies the existence of muscular elements in Todd and Bowman's ligamentum spirale. The essay concludes with a description of the ultimate distribution of the auditory nerve. The drawings, which are upwards of sixty in number, and in some instances of large size, are very beautifully executed. On the whole, the work of Boettcher appears to be well worthy the attention of microscopists and physiologists, and to contain many facts possessing both novelty and interest.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Thickness of the Earth's Crust

UPON my return to London yesterday, I received the two last numbers of NATURE (May 11 and 18), in both of which I find communications on this subject. In the first of these, by Archdeacon Pratt, that gentleman inserts a quotation from a lecture delivered by me, on January 29, this year, "On the Nature of the Earth's Interior" (*vide* NATURE, February 9, 1871), to the effect that the recent experimental researches of the eminent astronomer and mathematician, M. Delaunay, had destroyed the basis upon which the late Mr. Hopkins's reasonings, as to the solidity of the earth's interior, were founded, and asks the lecturer, *i.e.*, me, "I wonder why he has taken no notice of my letter in reply to M. Delaunay, which was printed in your journal for July 1870, six months before the lecture was delivered, and which also appeared about the same time in the *Philosophical Magazine* and the *Geological Magazine*. In this I showed that M. Delaunay had evidently misconceived the problem, and that Mr. Hopkins's method is altogether unaffected by his remarks."

As Archdeacon Pratt has the candour to admit that "any one with an ordinary degree of knowledge of popular astronomy and of mechanical action is quite competent to form a good opinion on the point in dispute," I would, in answer to the question he puts to me, simply state that, after a careful study of the letter he refers to, upon its first appearance in the *Philosophical Magazine*, I *purposely* avoided referring to it in my lecture, since I failed to discover that the author had in it "showed that M. Delaunay had evidently misconceived the problem," or any reasons whatsoever which could shake my faith in the conclusions of M. Delaunay, subsequently confirmed experimentally by M. Champagneur. I would also mention that, previous to this lecture, I attended the meeting of the Royal Society on the 22nd December, 1870, expressly to hear a subsequent paper by Archdeacon Pratt "On the Constitution of the Solid Crust of the Earth," on which occasion the opinions of Professor Stokes and the experimental demonstration of Mr. Siemens, as to the untenable nature of the author's conclusions, still further confirmed me in the views I put forth subsequently in my lecture.

It is now superfluous to specify in detail the precise reasons for my rejecting the arguments of Archdeacon Pratt, as I have, in a great measure at least, been anticipated in so doing by the substance of two letters, signed respectively "A. J. M." and "A. H. Green," which appeared in my absence in the last number of NATURE; to these I may refer in support of my view, in which I may also add one of our first English mathematicians has concurred; that M. Delaunay has not changed his will be seen from the Proceedings of the Academy of Sciences at Paris, March 6, 1871.

Having always entertained the highest opinion of the scientific labours of the late Mr. Hopkins, I have taken pains to make myself acquainted with his writings as far as possible for me; but when Archdeacon Pratt states "what Mr. Hopkins did may be divided into two parts—he first *conceived an idea*, which was to be the basis of his calculation; and then he made the calculation," I regard the whole pith of the question as embodied in these words, which admit that Mr. Hopkins based his elaborate calculations upon *an idea*, now shown by M. Delaunay to be incorrect, whilst the latter gentleman, on the contrary, founds his deductions upon premises which he first proves to have stood the test of experiment. Where eminent scientific men are arrayed on each side of a question of this nature, the remarks made in the last paragraph of the archdeacon's communication seem rather out of place, and might be applied with equal force in an entirely opposite sense to that intended by their author.

### The Geographical Distribution of Insects

IN NATURE (No. 74, p. 435) was a very interesting article on geographical distribution by Mr. Wallace, combating some recently-urged views of Mr. Murray's. Mr. Wallace took, as an example, the Madeira Islands, and sustained his position upon the numerical statistics furnished by Mr. Wollaston in his books. That these conclusions are very different from those arrived at by Mr. Wollaston is evident and as a six months' residence in the more remote group of the Canary Islands confirmed to my mind Mr. Wollaston's position, while bringing into relief facts utterly incompatible with Mr. Wallace's, I have ventured to publish a few remarks on the question.

Mr. Murray's views of the distribution of beetles seem to me resolvable into saying that there are two faunas, a tropical (Brazilian and Africo-Indian) and an extra-tropical one. My own slight researches in exotic coleoptera (confined hitherto to the Coccinellidæ) strongly confirm this; and a curious instance of the connection between the northern and southern extra-tropical faunas occurred to me the other day. *Eriopis connexa*, a rather pretty little ladybird, occurs from Hudson's Bay and Vancouver's Island all the way to the Straits of Magellan; following, of course, the line of the Andes. But my object was principally to question some of Mr. Wallace's conclusions with regard to the Madeiran fauna. First of all, I was struck by the absence of any hypothesis for the origin of the very curious endemic forms which form the most important part of the fauna, and which most closely unite it to that of the Canaries and Azores. These Mr. Wollaston, myself, and apparently Mr. Murray regard as affording proof that these islands, or rather groups of islands, were once parts of a considerable continent, and I certainly am at a loss to see how else they are to be explained; for though Mr. Wallace regards the Madeira islets as possibly formerly connected, he would, I suppose, be unwilling to extend this to the other groups. Mr. Wallace appears to regard Mr. Murray's hypothesis to be that the Atlantic continent, of which Madeira is a remnant, derived its fauna from Europe; but it seems rather to be that in the Miocene period (or earlier) there was a similar continent, connected indeed with Europe, not deriving its fauna from Europe any more than Europe from it. Perhaps the best way of answering Mr. Wallace's view will be to take the case of the Canary Islands, whose fauna, resembling the Madeira as it does so closely, must have had a similar origin. Here the argument from apterous genera fails to a very great extent. Thus *Carabus* is represented by three species, while in S. Spain there is one, and in N. Africa only six or seven. *Thorictus* has three representatives, and here it may be noticed that ants'-nest beetles are decidedly not numerous in the islands, so that the "unusual means of distribution" fail on the whole to get them across the water. *Rhizotrogus* is represented by the closely allied also N. African genus *Pachydema*. Of the very numerous European *Rhizotrogi* only two Sicilian ones are apterous, so that its absence in Madeira tells either way. *Otiorhynchus* is no doubt absent, but its place is more than supplied by *Atlantis* (20 sp.) and *Laparocerus* (30 sp.). *Pimelia* again is represented in the Canaries by twelve species, and the apterous genera of Heteromera by more than fifty species, which almost demonstrates the necessity of looking for Tenebrionidæ in localities where they are likely to occur.

*Tarphius* it certainly is difficult to conceive carried across by winds or waves, seeing that its habits are so retired that it has escaped notice till very recently in Europe. Now, however, it is beginning to turn up in suitable mountain localities of Andalusia, Portugal, the Apennines, Sicily, and Algeria; four species are described, and I have seen two others, all agreeing *inter se* and differing in structure from any Atlantic species. Moreover, it must have been carried apparently to the Azores as well. Then of the peculiar apterous genera quoted, *Thalassophilus*, *Torneuma*, *Scoliocerus*, *Xenomma*, and *Mecognathus* occur now also in Europe, requiring only a collecting-power equal to that of Mr. Wollaston for their discovery. There remain as puzzles upon the hurricane theory twenty-two blind species in the Madeira and the Canaries, and the whole series of Euphorbia-infesting species, fifty in number, all winged, and forming for the most part special genera. Finally, with regard to the fauna of the Azores, the condition of the islands must be taken into account; if the species found round Santa Cruz, Oratava, and Funchal were enumerated, about this proportion of European species would be found. The best island, Pico, has not been worked, and in the others almost all the original vegetation has disappeared. The fact that in the scraps (as they literally were) of Euphorbias, *Tarphius* and *Acalles* occurred, shows that if any of the pristine-flora could be found a fair number of species might be expected. *Elastrus dolosus* may certainly have come from Madagascar by the very ingenious route sketched out by Mr. Wallace; but the occurrence of *Urania* in Madagascar, Brazil, and the West Indies suggests a possibly shorter route, even though no *Elastrus* be known as yet to occur in America.

In conclusion I may state that I am going to spend a year or perhaps two in the West Indian Islands, and hope there still further to investigate the theories of geographical distribution, especially endeavouring to see if they can in any way be regarded as having been connected with this submerged continent of Atlantis. G. R. Crotch

### The Coronal Rifts

Will Captain Tupman kindly explain what he means by "*actinic rifts*"? I should have supposed that the rifts are evidence of the absense of actinism at the places where they occur.

I am not at all surprised that anyone observing through a telescope should fail to notice the rifts. The eye would naturally be attracted by the bright light of the corona and the red prominences. It may be observed, also, that there is in the photographs a considerable amount of bright corona at the places where the rifts occur, so that Captain Tupman might have had the telescope pointed at the very places where the rifts were, and yet they would escape his notice. The rifts are *there*, unquestionably, in the two photographs taken (after the lapse of nearly an hour) at Cadiz and Syracuse, and the sketches taken in Spain also show the gaps. The evidence appears to me to be conclusive against Captain Tupman.

A. Brothers

### Spectrum of the Aurora

There is one point in Mr. H. R. Procter's letter in Nature, vol. iii. p. 468, which I do not agree with He says the bands of the auroral spectrum are seldom visible, with the exception of that whose wave-length is 557; whereas I have found two bands, doubtless Winlock's 464 and 431, to be invariably visible when the aurora is bright enough to show them. Also, I suspect the red line is always present when there is any red colour in an aurora, although our instruments do not show it unless the luminosity is considerable. Of the thirty-four auroras in whose spectra I have seen the line 557, fourteen showed the bands 46 and 431, and three others at least one of these, while eight showed the red line. In five auroras, all more or less red, I have seen a faint band, whose wave-length, I believe, is 500 or 510. I have never seen the line 532 (the coronal line), unless it be once; probably from want of instrumental power.

As regards the zodiacal light, I have looked at its spectrum several times when it has been at its brightest, but have never seen anything but a continuous spectrum. I am satisfied therefore that if the line 557 exists in it, it must be much fainter in proportion to the rest of its light than is the case with the aurora. T. W. Backhouse

Sunderland, May 16

### Science for Farmers

As the independent and powerful advocate of scientific education, will you allow me to draw your attention to the object of the enclosed letter?

Within a short period I have seen such remarkable results attended with such an enormous saving of money arising from a limited knowledge of science amongst a committee of farmers, that I am desirous the future generation should have at least a common sense idea of some of the laws of nature which more immediately concern their business and pecuniary interests.

I have the more faith in the success of what I am advocating, because the kind and amount of scientific instruction I propose is really a business necessity. I have not forgotten the results of the Great Exhibition of 1851, how the members of each particular profession or trade were interested, especially in such stalls or departments that concerned this main object of their lives, how to make their own calling more successful or profitable.

I believe therefore in the teaching of science a much greater prospect of success exists when it can be combined with a practical business pursuit. I have read with much interest your article "The Hope of France" on the paper read by M. Deville before the Academy of Science.

The advantages arising from scientific culture, in other words, the study of nature and her laws, are beyond appreciation, and for this reason a student of science must reason and think for himself; he must do his own thinking, and not allow any other person to do this duty for him; and it is my conviction that the real power of any State is exactly in proportion to the number of independent reasoners and thinkers that go to constitute it; and I know of no means so powerful to promote this as the extension of technical teaching applied to business pursuits.

May 18 W. Little

"TECHNICAL EDUCATION FOR THE SONS OF FARMERS

"*To the Members of the Lincolnshire Farmers' Association, and other Agricultural Associations in Great Britain*

"Gentlemen,—Will you allow me to ask your earnest consideration and reflection on a subject which I believe is of vital importance to the future generation of farmers? The question I would put to you is this: Do you wish your sons whom you destine to the pursuit of agriculture to be entirely ignorant of such of the simple elements of chemistry as would give them a complete knowledge of the application and properties of the various materials used in the manufacture of artificial manures, when such knowledge may be acquired with little trouble, in a short time, and at small expense?

"I cannot for a moment believe that any intelligent farmer, with the costly and bitter experience of the past few years in relation to the tricks and impostures of the artifical manure makers, can be so indifferent to the future success of his child as not to give him, by a brief course of practical scientific education, not only the power of protecting himself against fraud, but also the knowledge that will enable him to apply the gifts of science to the greatest possible advantage, and at the same time liberate himself from the large and plausible army of manure compounders.

"Why should the business and pursuit of agriculture be an exception in the rules of guidance for the successful pursuit of any other business or profession? For the practice of medicine, law, engineering, architecture, &c., a special course of study is required, and is really necessary. Agriculture as a business pursuit offers abundant occupation for the highest order of intelligence, and stands second to none in its claim to scientific skill and sound practical sense, and has therefore an equal claim with other professions, that those engaged in it should be properly qualified by a special form of education.

"What can be more embarrassing to the present generation of farmers than the reading of the reports of chemical analysts on the composition of soils and manures? What can they understand by 'water of combination' other than that it may have too near a relation to a pump; or the term 'organic matter,' which may mean flesh or bread, woody fibre, peat, sawdust, or coal dust, most likely a large proportion of the latter elements; or that very intelligible term 'soluble phosphate equal to bone earth or tribasic phosphate of lime made soluble;' or alumina, silica, alkaline, salts, &c., which generally mean clay, sand, and common salt, concluding with earthy matter as the dirty foundation upon which all the other perplexities stand.

"Is it not worth while, by a brief course of practical study, to rid one's self of the influence of all this chemical necromancy? The days of alchemy, witchcraft, and astrology have passed away, and so must the charlatanism and quackery of the inferior order of manure compounders.

"What would be the history of many of these occult persons if it could be traced? Should we find that they have at any time been diligent students under such guides as Liebig, Ville, Voelcker, and other honourable and distinguished chemists? No! I do not hesitate to say that many of them have been mere wandering vagabonds having no disposition or ability to get an honest living by ordinary industry, and as a last resource trade on the credulity of farmers as artificial manure makers. A case in point was recently reported to me. Two discharged lackeys, a butler and footman, embarked, for want of honest employment, in this trade. They are now millionaires; one is an M.P. and the other has received the honour of knighthood. Recently I was over the works of a large and respectable manufacturer of phosphatic manures, who was also a maker of sulphate of ammonia. He informed me that he mixed these two ingredients in such proportion that he could well afford to sell it for 6*l.* per ton. The mixture went in immense quantity to Liverpool, where it was christened under the name of phospho-guano, and was actually returned, more than a hundred miles, near to the original works, and sold for 12*l.* per ton. Are not such cases, and a thousand others, sufficient' to make every farmer ask himself f one object of his being born into this world was to feed and fatten knaves?

"A first-class tailor, hatter, shoemaker, butcher, or baker, desires before all things that his customer should thoroughly understand the composition and quality of the goods he has for sale. Can the same be said of the manure compounders? The remedy we have in our own hands: either mix for ourselves, or buy subject to analysis; but to properly understand the several terms of an analysis, a course of practical instruction in a laboratory is necessary.

"It is indeed surprising that in a country where the practice of agriculture is carried to such a high degree of perfection, and where it is one of the chief sources of wealth, and is besides the means of employing such an immense amount of labour and capital, so little should be done towards the scientific education of those engaged in its pursuit. As a rule, agriculture is practised almost exclusively under the guidance of a slowly-earned experience, and mere traditional principles and habitual routine, without those engaged in it having any appreciation of the phenomena and natural laws which govern the growth and production of animal and vegetable food, the first necessaries of man.

"The success we have already arrived to in agriculture is, I believe, more mechanical than scientific. Drainage, steam culture, and a liberal use of capital and labour, are amongst the chief causes; but now that chemistry in its relation to artificial manures is taking such a prominent position, it is of the first importance that the future generation of farmers should have such a general knowledge of science as will enable them to correctly appreciate the value and properties of the various compounds offered by the too numerous chemical manure makers.

"I cannot imagine a more dangerous, unfortunate, and lamentable position for any person to be in, whilst in the practice of his business, by which he hopes to gain his bread for himself and family, than being entirely dependent on the scientific skill and integrity of another man; or that his capital, time, labour, care, and hopes should be in many cases completely out of his own control. Such a state of things cannot—must not—last.

"What I propose to do to correct this state of things is this—at a very moderate cost to give to an agricultural pupil a six or twelve months' course of scientific education and practical laboratory teaching after he has left his regular school; and I will engage that any boy of average ability, at the expiration of this time, shall have such a knowledge of all the materials employed in the compounding of chemical manures as will enable him to dictate what should be used without the interested interference of the manure maker. He shall besides have such an insight into the science and laws of chemistry as to make the reading and future study of scientific agriculture not only perfectly easy, but a delightful and intellectual employment.

"To carry out this important object three conditions are necessary—a good qualified teacher, a laboratory, and pupils. The first could be had for a very moderate salary; the laboratory, with the necessary instruments and materials, would involve no serious outlay; the third condition, the pupils, gives rise to this question—Would farmers send their sons to supplement their previous education by a six or twelve months' practical scientific instruction? The want of such knowledge amongst the present generation must be so strongly felt that I believe they would be too glad to have the opportunity, especially if they knew that probably a moderate fee would more than pay the costs.

"The site of the laboratory might be anywhere—a small country village would in many respects offer advantages superior to a market town. The cost of erecting or hiring a building suitable for a laboratory, together with the instruments and materials, should be raised by subscription. The pupils' fees would, I have no doubt, pay all other charges, so that when once established it would ever after be self-supporting.

"I am aware that certain schools exist where agricultural science is professedly taught, but I consider such a combination as almost waste time, the two kinds of teaching cannot be well carried on together, and what is most important, the mind must arrive to a certain maturity before it can grasp with sufficient reasoning power the beautiful and wonderful phenomena arising out of laboratory practice.

"If the foregoing observations should be thought worthy of the serious consideration of persons interested in agriculture, I shall indeed be glad to receive any communications or suggestions in promotion of the object of this letter; and if our members will support this object by the subscription of a sum equal to only a tenth of one year's savings effected through the agency of our association, I will devote myself most earnestly to establish a school laboratory in this village that I trust may serve as a model and example to be followed by many other localities in Great Britain.

"I shall certainly not ask a single member of our Association to do that which I am not prepared to do myself. My consumption of phosphate manure—of course, I buy no mixtures or nostrums—is about twenty tons a year; and previous to the formation of our Association I paid to the most respectable makers 6*l*. 10*s*. per ton for manure, containing 25 per cent. of water. The percentage of soluble phosphate was entirely a matter of speculation. According to an elaborate report of Anderson and Way, from an analysis of 171 samples, the average per-centage of soluble phosphate at that time was 15 per cent., and a ton of this manure was valued by these chemists at 7*l*. 5*s*. per ton, Therefore, if a 15 per cent. manure was worth 7*l*. 5*s*. a 26 per cent. manure would be worth 12*l*. 10*s*.; but our Association price for the 26 per cent. manure is now 3*l*. 18*s*. per ton in bulk, delivered free at any station in Lincolnshire, with a further advantage of a watchful system of analysis, free of any cost, to ensure quality and dry condition.

My saving on these calculations would be 8*l*. 12*s*. per ton, or a total of 172*l*. on a consumption of twenty tons yearly. I state facts just as they are recorded by the most eminent chemists, and every farmer will believe me when I say that a very large proportion of the manure sold at that time had little or no value whatever, consisting as it did of *dried mud and road scrapings*, flavoured with a little gas water just to flatter the olfactory nerves of the wise and cautious farmer of that period. A tenth of 172*l*. would be 17*l*. 4*s*. for my contribution, but my requirements are much more modest. I think, therefore, I had better leave every member of our Association to form his own estimate of what he should contribute, suffice it to say that in the first instance the only contribution I ask for is a free and unprejudiced opinion as to the necessity and desirability of what I have in view, viz., the formation of a laboratory, in which agricultural chemistry shall be taught at small cost, in a short time, and in a practical way, to pupils who have received an ordinary education.

"I have only alluded thus far to the material advantage to be derived from a brief course of scientific instruction. Allow me, in conclusion, to quote the language of one of the best and most highly gifted of our chemical philosophers as to its moral influence. The late Dr. Faraday says:—'I do think that the study of natural science is so glorious a school that with the laws impressed on all created things by the Creator, and the wonderful unity and stability of matter, there cannot be a better school for the mind.' Vain and foolish ideas, the fruit of ignorance, cannot be uprooted and destroyed by violence, the natural and more gentle method must be adopted, what in chemistry is called the law of substitution; the mind must be fertilised by knowledge, then truth and useful ideas will take the place of error and ignorant conceits. It is the absence of the exercise of the higher and intellectual faculties that leads so often to vacuity of the human mind, and the consequent indulgence in grosser and more material excitements, injurious alike to body and mind. A better form of education would eradicate the greatest of all human enemies—Ignorance and Intemperance.

### Degrees for Engineering Students at the University of London

IN one of your Notes for May 11 you refer to the failure of a motion which I brought before Convocation of the University of London at its recent meeting, to the effect that it was desirable that Greek should cease to be a compulsory subject at the matriculation examination. I have no wish to trouble your readers with a discussion of this subject, because it has been already so well ventilated in various quarters, and general opinion with regard to it has so nearly crystallised into form in other convocations than that of the University of London, that I have no doubt that the Senate of the University will ere long see the absolute necessity, if the University is to be kept *en rapport* with the scientific culture of the country as it has been hitherto, of adopting the course which I have urged, and the expediency of which has been endorsed by some of the highest educational authorities. The rejection of my motion is not the first illustration that Convocation has given of the highly conservative tendencies of many of its members, and of their incapacity to appreciate the liberal spirit in which the University was founded; and I am quite content to leave the case as it stands, with the remark made by one of old under similar circumstances—

Victrix causa Diis placuit, sed victa Catoni.

I shall, however, be glad if you can favour me with a little space in your columns to air another subject which I also brought before Convocation, with, I am sorry to say, equal want of success, and that is the desirability of modifying the examinations for the degree of Bachelor of Science by omitting the biological subjects, so as to induce engineering students to take it. At present the biological subjects required for the degree, viz., Zoology, Botany, Physiology, and Organic Chemistry, are so entirely foreign to the studies and requirements of such students that in most cases it is scarcely practicable, even if it were desirable, for them to travel so far out of their regular line of work, for the purpose of getting them up for the Bachelor of Science examination. Such a course would be precisely analogous to that which is now prescribed for medical students proceeding to their M.B. degree, who are required to take up those subjects of the B.Sc. examination which are cognate to their routine of study, and who then branch off to those of a purely professional character.

Only two objections were urged in Convocation against this scheme which are worth consideration. The first was that it would tend to lower the standard of the degree by diminishing the comprehensiveness of the examination. In order to meet this objection I suggested that candidates not wishing to take up the biological subjects should be required to substitute for them others of a mechanical nature, such as Applied Mechanics, Engineering and Architectural Construction, and Geometric Drawing, which, as all who have had any experience in teaching them know, are quite as capable of being made efficient educational tests as those which they would replace. The second objection was, that to make such a change would be equivalent to instituting a degree in engineering. That this would be the practical result of the suggested alteration I am prepared to admit, and it is the object which I had distinctly in view in proposing it. What there was in the suggestion to provoke the unconcealed opposition of so many of the members of Convocation, I am a loss to imagine, unless it was the illusion that the profession of engineering is a less scientific one, and the education of its members less worthy of being encouraged, than that of the professions of law and medicine, to which so large a proportion of the London graduates belong.

For my own part, it seems to me a scandal of no mean gravity that, whilst the practice of that profession requires intellectual qualifications of the highest order, and a scientific training of the widest kind, no means should exist in this country whereby either the public should be provided with any guarantee that those who practise it possess either of these qualifications, or its practitioners themselves should be enabled to give evidence of the fact of their own accord. I do not know of any department of education in which the University of London could, at the present time, do more service than in this, and, I trust, there are men in its Senate, who, with more breadth of appreciation than the majority of Convocation, will give the matter their earnest attention. FRANCIS T. BOND

Hartley Institution, Southampton

### Mechanical Equivalent of Heat

I AM afraid your publication, without adding the date, of my letter last week (which I only saw this morning) puts me in a false position in regard to Dr. Joule, inasmuch as it appears to ignore a correspondence of mine with him, which took place between the time that letter was written (now a long time since) and the time of your publishing it.

In that correspondence I allowed that Dr. Joule's theory remained the same in its main features, though I thought he virtually retracted one statement which I had particularly argued against. Dr. Joule, however, did not allow he had made any alteration.

He also informed me that a paper of mine had been read at the meeting of the Manchester Literary and Philosophical Society, in which I showed (as I believe) in a detailed examination that his theory was inconsistent with the results, both of his own and of M. Favre's experiments. Dr. Joule also kindly communicated to me the substance of the reply which he had made, but I have not seen either in print. Of course the question is one of facts; are facts consistent with the new laws of thermodynamics as supposed to have been established during the last twenty years? Tait, in his preface to his Thermodynamics, says: "The subject s one of vast importance, but very few indeed are yet acquainted with even its most elementary facts; and by many of these it is not yet accepted as true." These laws, therefore, can scarcely yet be put on a level with Newton's laws, even if they should be shown to be consistent with facts, which, at least in their present form, I believe to be impossible. H. HIGHTON

May 18

MR. HIGHTON'S letter in NATURE is almost identical with his communication to the *Chemical News*. My answer is similar to that which I sent to the latter publication, viz., that the object of my paper in the Proceedings of the Literary and Philosophical Society was simply to place the theory of the electro-magnetic engine in a form which might prove useful to those who had not worked on the subject, and not in any respect to withdraw the reasonings in what Mr. Highton is good enough to term my "famous paper." Mr. Highton handsomely acknowledged the justice of my note to the *Chemical News* in a letter addressed to me on the 28th ult. JAMES P. JOULE

### Optical Phenomenon

IN reading over Prof. Clerk Maxwell's paper on Colour in NATURE (Vol. iv. p. 13), I was reminded of the following, to me, curious phenomenon which was seen by me on several occasions in the summer and autumn of 1859.

Whilst standing before a black board, making geometrical figures in white chalk, I was struck by one side of each chalk line appearing blue, the remaining half retaining its proper white. The cause was at once evident to me, for I found that the sun shone fully upon one eye, but not upon the other. By closing the eye upon which the sun shone, the chalk marks appeared wholly white. Opening the eye again, the half blue, half white marks appeared; then closing the eye upon which the sun did *not* shine, the whole of the marks appeared a pale blue, scarcely so deep in colour as when in contrast with the white. By squinting, or forcing the eyes to see double, two sets of marks appeared, the one set all blue, the other wholly white.

Subsequently, with the sun upon both eyes, the whole of the marks were blue; whilst upon another occasion, when the sun shone very fully upon both eyes, only the white marks were evident; but shading the eyes by the hand, and allowing a ray to fall upon one eye, the usual half blue half white lines appeared.

On every occasion that I tried the experiment I met with the same results, and when I looked away a beautiful orange-coloured spot—the complementary colour of the blue, I suppose—appeared for some time wherever I looked. What is the cause why only the blue rays were visible? and why blue rather than red or yellow? THOS. WARD

### Yellow Rain

THE following notice will perhaps be of some interest to the readers of NATURE. In December 1870, after a heavy rain at Rosario de Cucuta (New Granada), a great many small round specks of a yellow clayish substance were found on the leaves of plants that had been exposed to the rain. A sample of this substance was sent to Dr. A. Rójas, of this town, who forwarded it to me in order to examine it under the microscope. It proved to be composed almost entirely of a species of *Triceratium*, and another of *Cosmarium*, which must have been carried away by a violent storm from their lacustrian abodes.

Caracas (Venezuela), April 1871 A. ERNST

### The Irish Fern in Cornwall

MY first impulse, on reading the note on this subject in NATURE for the 4th of May, was to apologise to Mr. Dymond for having caused him so much regret by making known a Cornish station for this fern. This first impulse was however checked by the reflection that something is due to the advancement of the study of distributive botany; and I could scarcely have expected even Mr. Dymond to place any very great degree of confidence in my bare assertion, unaided by any reference to localities.

Now that I have done the mischief and made known that the Trichomanes is a Cornish plant, and have been corroborated by Mr. Dymond, it would be interesting to know whether the writer of the note on this fern in the Cheltenham Natural History Society's report found his specimen at the same place, *i.e.* at St. Knighton's. EVERARD F. IM THURN

### Force and Energy

I HAVE been under the impression that the supposed magnetising power of the more refrangible of the solar rays, as first examined by Mrs. Somerville in 1826, had been long ago disproved by the researches of Moser and Riess. This appears, however, to be a mistake, for I see from the report (in a recent number of the *Illustrated News*) of a lecture on Force and Energy lately delivered at the Royal Institution by Mr. Charles Brooke, F.R.S., that the lecturer is stated to have quoted the results of Mrs. Somerville's experiments to "show the interchange of light and magnetic energy."

Is it too much to ask that the editor of a popular treatise on natural philosophy will give us his authority for a statement so contrary to general scientific opinion? EXACTITUDE

### Pangenesis

DOUBTLESS it is owing to a slight misprint in my communication in your number of May 11 that your correspondent, Mr. Meldola, has mistaken the gist of my objection to the theory of Pangenesis. I wrote, "a *seed* borne upon the graft would certainly be affected by the gemmules arising in the root and stem of the stock;" this was printed "a *bud* borne," &c. Now although it seems to me that much has been done to show that the stock will occasionally affect parts of the scion—and this my former letter does not for a moment contest—no evidence whatever has been brought to show that the sexual elements produced upon the scion have ever been affected by the stock without any intermediate change in the parts of the scion which may have borne the affected pollen grains or ovules.* And this certainly ought to be shown before it is assumed that every bud and every sexual element is formed by the aggregation of gemmules from all parts of the parents. Instead of which, in the vast majority of instances, we know that seeds borne upon the scion spring true to the scion. And if any instances to the contrary could be shown, it would then have to be proved that the part of the scion that bore the reproductive element was not a graft-hybrid. I may especially refer your readers to an interesting article by Dr. Masters, in the *Popular Science Review* for April, on "Grafting, its consequences and effects."

A. C. RANYARD

* I should much like to learn if the *Bizzaria orange* can be propagated by seedlings. *Cytisus Adami* is, I believe, always sterile.

## *SIR JOHN HERSCHEL*

FOR nearly one hundred and fifty years Europe has not seen a more accomplished philosopher than the great and good man whose mortal remains were last week consigned to their tomb in the national mausoleum, finding there a significant resting-place close to the grave of Newton. In sorrow and friendly reverence they were followed thither by nearly all that England values as the most eminent in the various domains of those many sciences which he, through a long life, had adorned and advanced.

John Frederick William Herschel was born at Slough, in the early part of 1792, being the only son of that great philosophical astronomer, of whom it were difficult to decide, and one cares not to inquire, whether the father was or was not even more illustrious than the son. Thus the boy was nurtured within sight of that remarkable telescope, wonderful indeed for the day of its construction, which, though in reality among the least of Sir William's achievements, had probably contributed the most to render the name of Herschel famous among men. His education was conducted chiefly at home, or at all events under home influences, and mainly in the society of persons considerably advanced in years; and it is probably to this circumstance that we may attribute much of that singularly retiring, though kindly and affectionate disposition, for which he was so greatly esteemed by all who had the privilege of his acquaintance.

In 1809 he was removed to St. John's College, Cambridge, where there are still retained among a few of its oldest members some curious traditions of his scrupulous attention to the duties of his position. Certain specified selections from the "Principia" of Newton formed of course a portion of the curriculum of study; in that day they came to the student in the form of manuscripts, translated and somewhat modified from the Latin text; John Herschel, however, conceived it his duty to read the entire work just as Newton had left it. We mention this circumstance solely because it furnishes us with an early indication of that staple quality of mind without which no true greatness is ever attained, namely, thoroughness of work. It is not surprising that such a man carried off the highest honours in the University examination, and that in 1813 he graduated as Senior Wrangler of the year; the first among a little phalanx of eminent men, than whom the University of Cambridge has seen nothing superior and not much that is comparable since.

His early lot at Cambridge was cast in times of a scientific transition. To the majority of Englishmen the Continent had long been sealed, and our few men of science were for the most part unacquainted alike with the languages and with the learning of the rest of Europe; indeed, it is scarcely too much to say that the science of mathematics in England had made very little advance beyond what had been known in the later years of Newton. John Herschel, however, possessed the great advantage of living in a house where the chief languages of the Continent were understood, and in which relations with abroad were still maintained. To the late Prof. Woodhouse the honour is due of having introduced to the notice of the Cambridge mathematicians the higher methods of analysis which had long been practised on the Continent, and he was soon ably seconded in his efforts by the young mathematician. In conjunction with his friend Mr. Peacock, who afterwards became the well-known Dean of Ely, John Herschel, in the year 1816, produced a Treatise on the Differential Calculus, for the use of the University, by re-casting rather than by translating a valuable work by Lacroix on that important subject, which hitherto had been studied in England solely to the most meagre extent, and encumbered by the unwieldy garb of the fluxional notation. This work was written in 1816, and before Herschel had taken his master's degree. In 1820 the translation of Lacroix was followed by another and more original work, containing a set of admirable examples and comments on almost all the more important methods of analysis by which mechanical and astronomical science had been so greatly extended by Newton's real successors, such as Euler, Lagrange, and Laplace. In this work Herschel was assisted not only by Mr. Peacock, but also by Mr. Babbage, who wrote that part of it which treated on functional equations. This admirable introduction to the higher forms of analysis is scarcely superseded even at the present day, and in some respects it remains unique. Thus John Herschel was instrumental in the promotion of that great reform in mathematical culture at Cambridge, which has never since ceased to bear most notable and excellent fruit.

It was shortly after his degree that we find the elder Herschel in one of his latest communications to the Royal Society referring with evident satisfaction to the fact that he had a son who was now capable of taking an important part in those astronomical, or rather as they may more properly be called, those cosmical researches which had formed the successful pursuit and the delight of his own life; and before his death he had the pleasure, we might not improperly call it the reward, of seeing his son in the year 1820 become one of the honorary secretaries of the newly-formed Astronomical Society. For fifty years and more he continued to be one of its most constant and loyal supporters, employing some of the last conscious moments of his life in compiling for its service a complete list, or, if we may be allowed the expression, a complete natural history of double stars, commencing with the father's first discoveries, and terminating only with the decease of the son.

Probably the busiest part, where all was busy, in the younger Herschel's laborious life, was passed between the ime of his Cambridge degree in 1813 and the period when he quitted England in order to supplement the exploration of the heavens in the Southern regions, which his father had so ably commenced, if not completed, in the North. Those who have access to the Transactions of the various British scientific societies, and to the learned journals of the day, between 1816 and 1833, will be sure to find at brief intervals some important communication of his, enlarging the boundaries of human knowledge, and bearing the stamp of natural genius, cultivated and developed by honest labour. His fertility in this respect is truly amazing. Partly in conjunction with Sir James South, he re-observed the nebulæ and double stars the existence and the cosmical significance of which had first been brought to light by his father: at the same time adding to the list some thousands of celestial objects which had escaped even his sagacious observation. Like his father also he constructed his telescope with his own hands; an instrument which for many years remained a specimen, unique in its optical capacities and in the efficient simplicity of its mechanical arrangements. Latterly it has been surpassed among amateurs by Mr. Lassell and by Lord Rosse, and among artists by Mr. Grubb; but it was the Herschels who pointed the way and encouraged their successors to stand upon the shoulders of those who preceded them.

Nevertheless astronomy was very far from engrossing his whole attention; we doubt whether it absorbed even the half of it, for those who knew him best knew that the bias of his mind was mainly directed towards chemistry and light, and their cognate branches of physical inquiry. In 1819, when philosophical chemistry in England was perhaps at its lowest ebb, he rediscovered, and for the first time ascertained, the leading properties of the hyposulphite salts, the existence of which had, unknown to Herschel, been previously surmised, and only surmised, by Berthollet. In particular he noted the property of the hyposulphite of soda, whereby, as he says, "chloride of silver newly precipitated is dissolved in this salt almost as readily as sugar." We mention this circumstance because it was owing to this property of the hyposulphite alone, that Daguerre twenty years after was enabled practically to realise the hopes of Davy and Wedgwood, that the photographic pictures which they had already obtained might one day be fixed and preserved, even when submitted to the action of light. Thus, indirectly, John Herschel may, in a strong sense, be regarded as the father of photography; and at subsequent periods perhaps no man has entered more fully and philosophically into the actinic relations of light. It was during this most active period of his philosophical life that, attracted by the marvellous discoveries of Fresnel in connection with the undulatory theory of light, and after having studied and mastered what others had done before him, he set his own original powers to the task, and soon added to our knowledge fresh facts which they, his masters, had themselves overlooked. He discovered, for instance, that the relative positions of the optic axes in certain biaxal crystals were functions of the index of refraction; and he for the first time ascertained certain other actions of crystallised media on polarised light, which placed him at once among the first rank of experimental physicists of his day. The results of these studies he embodied in a most remarkable treatise on Light, published in the "Encyclopædia Metropolitana," which up to the present date may be advantageously consulted by the most accomplished student in this branch of physical inquiry. In the same great work will be found other treatises of his, on Sound, on Heat, and on Physical Astronomy, all of them bearing the stamp of genius and industry, and each one of them containing some specific advance beyond the condition in which he had found the subject.

In 1830 Dr. Lardner induced him to join in the composition of what he designated as the "Cabinet Cyclopædia," and to this Herschel contribute the two most celebrated volumes, viz., the "Preliminary Discourse on the Study of Natural Philosophy," and subsequently the volume on Astronomy. There were but few, if any, men of that day who could have contributed either. The first of them has probably formed the delight, the instruction, and the encouragement of every person who has since pursued or admired a scientific career. In dignity, purity, and pregnancy of language; in profundity of thought, in copiousness of apposite illustration, in a certain indefinable sweetness of persuasion, it, even at this day, captivates every mind that applies itself to its perusal. Here and there indeed its author gives rein to certain metaphysical speculations on Causes and Force, which are now found not exactly to square with the conceptions of later psychological writers. But on such questions as Causation and Force, a man whose mind, like John Herschel's, had been for half a century steeped in the difficult philosophy which embraces and pursues them both, may surely be more safely trusted than other minds, however subtle, whose extent of opportunity and of practical exercise have necessarily been inferior to his. We entertain a strong conviction that when metaphysical science shall, "by taking thought," have arrived at the first cubit of its stature, the deliberate conceptions of Herschel will be found to be in the main correct. A mind like his could have no sympathy with a philosophy which logically admits the thought, that, under some possible state of things, two and two can be equivalent to five. Speculative, he was by nature constrained to be such, but the practical side of his disciplined intellect sufficed to adjust the balance, and to prevent him from going deliberately wrong in his philosophy.

We now reluctantly but necessarily pass over much that is interesting and instructive in the career of the younger Herschel, and approach that crucial period of his life, when, accompanied by his wife and family, he left England for the Cape of Good Hope in 1834. To most of us John Herschel is known chiefly as the most eminent of modern philosophical astronomers; but the pursuit of astronomy was not the voluntary choice nor the chief bias of his intellectual life, it was rather the recollections and the impressions of the happy home of his youthful years, and reverence for the illustrious head of it, which determined him to complete what his father had commenced with such imperturbable diligence, and such wonderful success. He became a great astronomer, rather through filial piety than through the promptings of a natural taste. As in the case of many other great men, some of whom still survive among us, his life-long career was determined by uncontrollable circumstances, while the inborn aptitude has lain in another direction. But passing over such thoughts, suffice it to say that Herschel quitted England for a long sojourn at the Cape of Good Hope, in order to survey those portions of the sidereal heavens which were beyond the reach of his own and his father's instruments. This he did, and wisely and generously did at his own personal expense; for happily, the possession of a moderate fortune enabled him to follow his own bent, and placed him beyond the necessity of the aid and the interference of a patron. How wisely, sedulously, and successfully his time was spent in this happiest of voluntary exiles, may be gathered from the perusal of perhaps the most remarkable volume on philosophical astronomy that has yet appeared.

The publication of this volume was, however, long delayed; he therein unconsciously followed the advice of the Roman poet, "nonum prematur in annum," inasmuch as it was not given to the world as a whole until the year

1847. The truth is that the numerical calculations necessarily entailed for the reduction and the discussion of the observations, occasioned an amount of labour inconceivable to those who are strangers to the requirements of exact astronomical research, and upon all this labour he personally entered. To explain what he required, to such a mind as his, would have been more troublesome and distasteful than to do it himself. As he had done before, so he did now, and so he did again and again while consciousness was accorded to him, he laboured with his own hands. But the book itself, ultimately published by the noble and well-judged munificence of the Duke of Northumberland, is by no means a monument of industry alone; it abounds, in almost every page of its many notes and appendices, with original discoveries, suggestions, speculations, grand and comprehensive conceptions of the distribution of the celestial universe, which will require many a long year to elapse before their significance is exhausted. We may take as an illustration the first instance that occurs to us, in a suggestion, made in a note of Herschel's which might, and for a long time did, escape the reader's notice. He suggests that the main difficulty which occurs in the observation of the sun's photosphere might be removed by viewing its light when reflected from the first surface of a glass prism, which, at the same time, permits the greater part of the heat to escape away from the observer's eye. This simple contrivance, thus rapidly suggested by the way, lies at the bottom of more than one discovery which has since been made relative to the constitution of the solar photosphere; but similar instances abound.

It is hardly necessary to refer to the multiplied and well-earned honours which awaited John Herschel on his return from the Cape of Good Hope. He might have been elected to the Presidency of the Royal Society, but he retired in favour of the Duke of Sussex; and shortly afterwards, not alone for his own sake but for the substantial recognition of an illustrious name among the worthy families of his country, he was made a Baronet of the United Kingdom. Like his great predecessor Sir Isaac Newton, he might have been returned as the representative in Parliament of that noble University where his intellect was nurtured and grew, until it became its brightest and fondest ornament; this honour he declined. Subsequently he was appointed, again like Newton, to the lucrative post of the Mastership of the Mint; but his gentle and unsophisticated nature was ill adapted to cope with the occasional unrealities and difficulties of an official life; it affected his health, and he retired after a tenure of a few years.

Our space forbids us, in this place, to enter upon the more recent portions of this illustrious man's public and scientific career; indeed it cannot fail to be sufficiently known to the great majority of our readers. His true place in the philosophy, and among the great lights of his age, cannot be accurately fixed, until his own generation shall have entirely passed away; for the feelings, the partialities, the prejudices of contemporaneous life, unavoidably warp and incapacitate the judgment, just as too close a proximity to a mass or a multitude is unfavourable to a correct appreciation of its true proportions. Some time after the death of Laplace, the writer of this notice, while travelling on the Continent in company with the celebrated French *savant* Biot, ventured to put to him the question, not altogether a wise one—"And whom of all the philosophers of Europe do you regard as the most worthy successor of Laplace?" Probably no man was better able than Biot to form a correct conclusion, and the reply was more judicious than the question. It was this,—"If I did not love him so much, I should unhesitatingly say, John Herschel." It is from a loving reverence for the memory of a great philosopher and a good man that we now venture to say no more.

Out of the large number of mourning friends who last week in Westminster Abbey gazed with reverential regret at the sorrowful procession which followed the mortal remains of John Herschel, till they were deposited among the best loved and most highly honoured of the worthies of past time, not a few must have recalled to their memories how in their scientific difficulties, or anticipations, or successes, they had betaken themselves to the aged philosopher of Collingwood, and had never failed to meet with the ready aid of a kindly and courteous sympathy.

C. P.

---

## *SIR J. HERSCHEL ON OCEAN CURRENTS*

WE are permitted to publish the following letter (probably one of the last written by Sir John Herschel on scientific subjects) which was addressed by him to Dr. Carpenter, with reference to his paper in the Proceedings of the Royal Geographical Society, "On the Gibraltar Current, the Gulf Stream, and the General Oceanic Circulation," a copy of which had been forwarded to him by Dr. Carpenter on its publication, with a request that he would reconsider the opinions he had formerly expressed as to the inadequacy of differences of temperature and specific gravity to produce great movements of ocean water:—

"Collingwood, April 19, 1871

"MY DEAR SIR,—Many thanks for your paper on the Gibraltar Current and Gulf Stream.

"Assuredly, after well considering all you say, as well as the common sense of the matter, and the experience of our hot-water circulation-pipes in our green-houses, &c., there is no refusing to admit that an oceanic circulation of some sort must arise from mere heat, cold, and evaporation as *veræ causæ*, and you have brought forward with singular emphasis the more powerful action of the polar cold, or rather the more intense action, as its maximum effect is limited to a much smaller area than that of the maximum of equatorial heat.

"The action of the trade and counter-trade winds in like manner cannot be ignored; and henceforwards the question of ocean-currents will have to be studied under a two-fold point of view. The wind-currents, however, are of easier investigation. All the causes lie on the surface; none of the agencies escape our notice; the configuration of coasts, which mainly determines their direction, is patent to sight. It is otherwise with the other class of movements. They take place in the depths of the ocean; and their movements and directions and channels of concentration are limited by the configuration of the sea-bottom, which has to be studied over its whole extent by the very imperfect method of sounding.

"I am glad you succeeded in getting specimens of Mediterranean water near the place of the presumed 'salt spring' of Smyth and Wollaston, making it clear that the whole affair must have arisen from some accidental substitution of one bottle for another, or from evaporation. I never put any hearty faith in it.

"So, after all, there *is* an under-current setting outwards in the Straits of Gibraltar.

"Repeating my thanks for this interesting memoir, believe me, Dear Sir,

"Yours very truly,
"J. F. W. HERSCHEL

"Dr. W. B. Carpenter."

We congratulate Dr. Carpenter on having obtained from so eminent an authority, as one of the last acts of his honoured life, this cordial and well-considered acceptance of the doctrine he had previously opposed; and this distinct recognition of the new aspect in which Dr. Carpenter's own observations and reasonings had placed it. The success of his appeal shows that he did not underrate the noble candour of the great philosopher, to whom, more than thirty years previously, he had dedicated his first scientific treatise, as an expression of his gratitude for the moral and intellectual benefit he had derived from the "Preliminary Discourse on the Study of Natural Philosophy." We shall return to this subject next week.

## *PALÆOZOIC CRINOIDS*

AT the seventh and last of the ordinary monthly meetings of the Montreal Natural History Society for the season 1870-71 a communication on a Mineral Silicate injecting Palæozoic Crinoids was made by Dr. T. Sterry Hunt. The author described a gray granular palæozoic limestone from New Brunswick, which had been examined by Dr. Dawson, and found to consist almost entirely of the comminuted remains of brachiopod and gasteropod shells, crustacea, and the joints and plates of crinoids, cemented with a little calcareous spar. The crinoidal remains were, however, found to have their pores filled with a peculiar silicate, which is exposed in relief when the surface of the limestone is attacked by an acid, and then appears as a congeries of small cylindrical rods or bars, anastomosing and forming a beautiful network which, under a magnifying glass, exhibits a frosted crystalline surface, and resembles the variety of aragonite known as *flos ferri*. This silicate, which also fills small interstices among the other calcacereous fragments making up the limestone, is greenish in colour and forms about 5 per cent. of the rock. Though insoluble in dilute acids, it is completely decomposed by strong acids, and is found to be a hydrous silicate of ferrous oxide and alumina, with some magnesia and a little alkali, closely allied to fahlunite and to jollyte. The results of its analysis will appear in *Silliman's Journal* for May. Dr. Hunt remarked that this process of infiltration, by which the minute structure of these palæozoic crinoids has been preserved, was precisely similar to that seen in the glauconite casts of more modern foraminifera, and in the Eozöon of older times. This ancient calcacerous rhizopod, though most frequently preserved by serpentine, had been shown, both by himself in Canada and by Hoffmann in Bohemia, to be in some cases injected by silicate related in composition to that of these crinoids. The great class of silicates of which serpentine, loganite, pyrosclerite, fahlunite, and jollyte are members, are generally described as the results of pseudomorphic changes of pre-existing silicates or carbonates; but Dr. Hunt maintains them to be original aqueous depositions, similar in their origin to the related mineral glauconite; a view now adopted by such investigators as Naumann, Scheerer, Gümbel, and Credner. These facts have an important bearing on the Eozöon Canadense of Dawson, the organic nature of which, though almost universally admitted by zoologists and mineralogists, is nevertheless still questioned by Messrs. King and Rowney. These gentlemen object that the ancient rocks in which Eozöon is found are what are called metamorphic strata, which have been, according to them, subjected to pseudo morphic changes, and therefore the Eozöon may be the result of some unexplained plastic force, which has fashioned the serpentine and other mineral silicates into forms so like those of foraminiferal organisms as to deceive the most practised observer. This was going back to the notions of those who, rather than admit that mountains had been formed beneath the sea, imagined that the fossil shells which they often contain were not the real shells of animals, but the result of some freak of nature. The argument of Messrs. King and Rowney that the Eozöon rock is a result of pseudomorphic alteration because it contains serpentine, is a begging of the question at issue, by asking us to admit that the presence of serpentine is an evidence of metamorphic change, which is denied. The specimens of this organic limestone, with its injected crinoids, differs from Eozöonal rock only in containing at the same time recognisable fragments of other organic remains, and in presenting in its injected portions the differences which distinguish the minute structure of a crinoid from that of a calcareous rhizopod.

Principal Dawson has verified the observations of Dr. Hunt by microscopic examinations. Crinoids in the fossil state are generally filled with carbonate of lime so as to obliterate their pores. The infiltrating silicate in the present case, however, shows, especially in decalcified specimens, that these ancient crinoids closely resembled in their minute structure the modern forms lately studied by Dr. W. B. Carpenter and Prof. Wyville Thomson, especially *Comatula*. The process of filling up the porous calcareous skeleton of the crinoids has been clearly shown to be prior to the cementing and consolidation of fragmentary limestone.

To this we may add that fragments of the calcareous skeleton of Echinoderms infiltrated with silicates have been detected by Dr. Carpenter, together with *Polystomellæ* and many other foraminifera similarly infiltrated, in Capt. Spratt's dredgings from the Ægean. On placing these fragments in dilute acid, the calcareous network of which Dr. Carpenter nearly thirty years ago showed the skeletons of all Echinoderms to be made up, is dissolved away; and a perfect model is left in green or ochreous silicates, of the sarcodic network, with which, in the living state, the interspaces of the calcareous network are occupied. Dr. Carpenter, however, objects to the term "infiltration" as expressive of the process by which the replacement of the sarcodic substance by silicates has taken place. As this process is going on at the present time on the ordinary sea-bottom, he thinks that it can only be attributed to a process of "substitution," in which the decomposition of the sarcodic substance performs an essential part. Whatever may be regarded as chemically the most probable explanation of the replacement, it will be obviously the same for the ancient as for the modern examples of the process.

## *NOTES*

AT the Anniversary Meeting of the Royal Geographical Society held on Monday last, the address of the retiring president, Sir R. I. Murchison, was read by the secretary, Mr. Clements Markham, Sir Roderick thus closing an occupancy of the presidential chair extending over sixteen years. He is succeeded by Sir Henry Rawlinson. The Founder's Medal was on the same occasion awarded to Sir R. Murchison in recognition of the eminent services he had rendered to geography during his long connection with the society, in the course of which he had been associated with every exploring expedition for the last thirty years. The Patron's or Victoria Medal was presented to Dr. A. Keith Johnston for his long-continued and successful services in advancing geography. We regret to find that the retiring president found it necessary to send a letter to the secretary forbidding any hope that he would be able very soon to take an active part in the proceedings of the society, his progress towards complete recovery being slow. At the annual dinner which followed, the Dean of Westminster expressed a hope that we might yet see the foundation of a professorship of geography at each of the universities.

AT the Anniversary Meeting of the Linnean Society, held yesterday, Mr. Bentham delivered his annual address, which we hope to have an early opportunity of giving to our readers. Mr. Bentham was re-elected to the office of President, Mr. Wilson Saunders of Treasurer, and Messrs. F. Currey and H. T. Stainton of Secretaries, and the following gentlemen, in addition, were elected members of the Council for the ensuing year: Mr. John Ball, F.R.S., Mr. Alfred W. Bennett, Mr. J. J. Bennett, F.R.S., Mr. George Busk, F.R.S., Mr. F. Ducane Godman, Dr. J. D. Hooker, F.R.S., Prof. M. A. Lawson, Mr. Henry Lee, Mr. S. J. A. Salter, F.R.S., Dr. J. Lindsay Stewart, and the Rev. Thomas Wiltshire.

THE Board of Natural Science Studies for the Natural Science Tripos of the University of Cambridge has issued a set of schedules indicating the subjects to which the examination in 1872 and following years will be confined, and also those subjects which are suitable for the questions of the first six papers in the examination, as follows:—(1) Chemistry and certain other branches of Physic; (2) Mineralogy; (3) Geology; (4) Botany, Comparative Anatomy, Physiology, and Zoology, including (A) Morphology; (B) Physiology; and (C) Distribution.

THE Slade Professorship of the Fine Arts referred to in our last number has been established in connection with University College, London.

THE University of London has decided on the appointment of two assistant examiners in Experimental Philosophy at an annual salary of 25*l.* each; and a salary of 30*l.* in place of 25*l.* to each of the assistant examiners in Chemistry; as it is thought expedient to charge them with the superintendence of the practical and laboratory examinations at the preliminary scientific and first M.B. examinations.

DR. C. R. A. WRIGHT has been appointed Lecturer on Chemistry and Practical Chemistry at St. Mary's Hospital, *vice* Dr. Russell, who is now the Professor of Chemistry at St. Bartholomew's Hospital.

A LECTURE was delivered on May 17 by Dr. W. B. Carpenter, F.R.S., in the Comparative Anatomy Lecture Room of the New Museum, Cambridge, on the results of the Deep Sea Explorations during the last summer. After a brief *résumé* of the results of the deep-sea dredging up to the end of 1869, the lecturer gave an account of the configuration of the Mediterranean basin, of the singular difference in the laws of temperature at various depths in it and in the neighbouring Atlantic, of the proof of an outward current flowing beneath the surface in-current in the Straits of Gibraltar, of the additional proof of a great oceanic circulation between the waters of Polar and Equatorial regions, which he considered to have a far greater effect on climate than the Gulf Stream, and upon the fauna of the deeper parts of the Lusitanian seas, concluding with some remarks upon the comparatively azoic condition of the Mediterranean basin and the bearing of this upon some geological questions. The lecture was most attentively listened to by a crowded audience, and at the conclusion a vote of thanks, proposed by the Vice-Chancellor and seconded by the venerable Prof. Sedgewick, was carried by acclamation.

THE number of the members of the French Academy of Sciences is fast diminishing. The late Sir John Herschel was a foreign associate member, which is a very rare honour, as there can only be five such members created. Profs. Faraday and Graham were amongst the foreign associates.

THE distinguished members of the medical profession have mostly deserted Paris, although there are many thousand sick and wounded to be taken care of within the walls of the unhappy city. But there are also sick and wounded by scores of thousands outside. Amongst the distinguished practitioners who are in Paris we see the names of M. Broca, the celebrated anthropologist, Lassergue, Maison Neuve, and Axenfeld. But although some professors of the École de Médecine are to be found amongst these medical gentlemen, the School of Medicine is closed. It appears, however, that an irregular course of lectures is kept up open at Hospital Beaujon, which hospital does not belong to the Government.

M. ELISÉE RECLUS, the newly-appointed director of the National Library, asked from his subordinates to give their adhesion to the Commune. Almost everyone refused, and were instantly dismissed.

THE Annual Conversazione given by the President of the Institution of Civil Engineers will be held on Tuesday evening, June 6th. A collection of Models of Engineering Construction, of small and light pieces of Mechanism, and of Scientific Instruments, as well as of Works of Art, by ancient and modern masters of eminence, depicting some engineering work, object, or matter of interest, as "a bridge, lighthouse, aqueduct, or harbour, &c., set in its appropriate landscape," will be exhibited.

THE following Excursions have been arranged by the Geologists' Association for the ensuing month:—Excursion to Yeovil: Monday, May 29, and three following days, under the leadership of Prof. Buckman and Mr. Lobley, including the following points of interest: Yeovil Junction (Fine Section of Upper Lias Sands); Closeworth (Rectory), inspection of large collection of Mesozoic fossils, belonging to Rev. E. Bower, M.A.; Babylon Hill (Inferior Oolite); Halfway House (Inferior Oolite, very fossiliferous); Sherborne (Inferior Oolite, very fossiliferous); Bradford Abbas (Inferior Oolite); inspection of Prof. Buckman's collection; Handford Hill (Upper Lias Sands); Ham Hill (Inferior Oolite, very large quarries, ancient encampment); South Petherton (Middle and Upper Lias, very fossiliferous); Chard (Chloritic Marl, base of Chalk series). Should time permit, Crewkerne (Inferior Oolite) will be visited on return. Excursion to Ilford: Saturday, June 17, under Mr. Henry Woodward.—On arriving at Ilford, the Mammalian beds in the Newer Pliocene deposits at this place will be inspected, and subsequently a visit will be paid to the residence of Sir Antonio Brady, who has kindly invited the Association to inspect his fine collection of stone implements and mammalian remains. Excursion to Caterham: Saturday, July 1, under the management of Mr. Lobley. Fine Sections of the Upper Chalk are exposed in the neighbourhood of Caterham. Excursion to Warwick: Monday and Tuesday, July 10 and 11, under the Rev. P. B. Brodie.—On arriving at Warwick the party will visit the Museum, in which will be found the finest collection of Triassic fossils in England. The Keuper sections near the town will then be inspected. At Wilmcote very interesting sections of the Insect Bed of the Lower Lias are exposed. Should time permit, visits will be paid to the Permian sections at Kenilworth, and to the fine Lower Lias section at Harbury.

WE learn from the *British Medical Journal* that the Committee of the College of Physicians has produced a scheme of amalgamated examination for consideration by the Joint Committee. Under this scheme, the examination would be a minimum examination, and essential for all the universities and licensing bodies of Great Britain. It would be carried out by examiners appointed by a Joint Committee, with a sole view to the fitness of such examiners. The fee for the joint examination would be one calculated only to cover the expenses—about fifteen guineas. The licensing bodies would not confer any licence except upon those who had passed the examination, and each would fix the fee for its licence. If the College of Surgeons will on its part accept this scheme, it will establish its claim to be considered sincere in the cause of medical reform.

WE have received the first four fasciculi of a new Italian Journal of Chemistry, edited by Prof. Cannizarro, of the University of Palermo. It contains a number of origi[illegible]es by the editor, Dr. U. Schiff, Profs. Lieben and [illegible]r well-known chemists, translations of importa[illegible] and an abstract of the proceedings of the [illegible] Italy, Germany, and England.

THE Scottish Arboricultural Society [illegible] of Transactions for the past year, ed[illegible] The objects of the society are the [illegible] Arboriculture in all its branches [illegible] members for the reading of [illegible] reports on the practical opera[illegible] the same; and by such oth[illegible] and it numbers among its [illegible] culturists, and practical foresters of Scotland. In the present volume are a number of practical essays on various points of tree cultivation, and for the current year no fewer than nineteen prizes are offered, the competition for some being limited to working foresters and woodmen.

REFERRING to the statement of the disappearance of Aurora Island (one of the New Hebrides group), recently printed in the American newspapers, Mr. Tryon exhibited to the Conchological Section of the Academy of Natural Sciences of Philadelphia, at their meeting on January 5th, two species of shells from the collection, supposed to be peculiar to this island, remarking that in the event of the reported submergence of the island being confirmed, these must be classed among the lost species. In his report on the mollusca collected by Wilkes's U.S. Exploring Expedition, we learn from the *American Naturalist*, Dr. Gould gives the following account of Aurora Island :—"The little island of Metia, or Aurora Island, to the northeastward of Tahiti, is one of peculiar interest. It is a coral island which has been elevated two hundred and fifty feet or more, and has no other high island near it. On it were found four small land shells belonging to three genera, viz., *Helix pertenuis*, *Helix Dædalea*, *Partula pusilla*, and *Helicina trochlea*. None of these were found upon any other island. They seem to have originated there, after the elevation of the island, and have a significant bearing upon the question of local and periodical creations in comparatively modern times."

IN these high-pressure days, it is astonishing what a saving in money and temper results from an exact punctuality. One would have thought that in every town which possesses a railway station, precise London time would be kept by the public clocks. This, however, appears to be by no means the case. To remedy this inconvenience, we notice that the Rev. H. Cooper Key is urging on the authorities of Hereford the importance of a daily time signal, preferring a time-gun to the dropping of a ball, as more certain to arrest attention. Certainly every town of the size of Hereford ought to have some means of keeping correct time.

A SLIGHT shock of earthquake was felt in Salvador in Central America on the 24th March, $1^h\ 45^m$. On the night of the 30th there were two shocks, with the sky clear and the moon bright. The Salvador earthquake very nearly coincides with two very severe shocks felt all over the Republic of Chile on the 25th March. Since then other shocks have been felt. In Valparaiso the first earthquake occurred at 11.5 A.M. and lasted about a minute, there being no previous noise. A little after 12 a slight shock was experienced, another shortly after 1, and at 5.30 P.M., a shock as strong as that of the morning ; walls were cracked.

ON the 26th March there were slight shocks of earthquake at Arequipa, in Peru.

WE have been favoured by the president of the Halifax (Nova Scotia) Institute of Natural Science with a report of their most recent meetings, which will be found in another column. We congratulate the Institute on the good work done by its members in illustrating the natural history, past and present, of the colony.

THE *Pioneer* of Allahabad contains a communication on snake bites. The writer is inclined to believe there is no antidote, but he thinks it useful to put on record an experiment. About three years ago he saw a bullock which had been bitten by a snake and was lying prostrate on the ground retching. Having heard from an old Brahmin that aniseed soonf was a remedy, he was induced to try it. He mixed aniseed 2 chittacks, pepper ¼, aniseed leaves 1, aniseed bark 1. This was administered internally with great difficulty down the bullock's throat and externally. In a few minutes the bullock lifted his head, in an hour he stood up and began to chew, and in two hours was all right.

## PROF. WYVILLE THOMSON'S INTRODUCTORY LECTURE AT EDINBURGH UNIVERSITY*

IT is too often the first duty of a professor on taking office, to lament the loss of a predecessor who has lately left a blank in the ranks of literature or of science. I am happily relieved from this sad task, for although my friend, Dr. Allman, has found it necessary to retire from the active duties which he has performed so well for many years, his retirement may be looked upon as in a certain sense a gain to science, since he now enjoys a greater amount of leisure to carry on those admirable researches in one of the most difficult and obscure provinces of biology, which have already placed his name high on the roll of those who have added to the store of human knowledge. Although I sincerely trust it may be long before the inevitable time arrives for summing up the labours of George Allman, I believe I may be pardoned if I say a few words about the nature and method of his work, for there is no sounder example which I can cite for your emulation and my own. While keeping pace with the rapid advance of knowledge, and contributing to the general literature of biology the intelligent commentaries and criticisms of an accomplished teacher, Dr. Allman has steadily pursued for many years one special line of research. Whatever he takes up he works out thoroughly and well. His results are fearlessly quoted in all languages as entirely reliable. His straightforward statements and exact descriptions are warped by no preconceived theories, and need no revision or corroboration, and his beautiful drawings are as true to nature as the objects themselves.

No one appreciates more than I do the value of well-founded generalisations. They are the silken threads on which the pearls of truth are strung, and without them we could never realise the full beauty of the gems, their relative value, and their subtle harmonies in form and lustre and tone of colouring ; but the first thing is to dive for the pearls, and a good pearl-diver is immortal !

There is another matter to which I wish to refer, and I do so with unmixed pleasure—the appointment of my friend Prof. Geikie to a separate Chair of Physical Geology and Mineralogy in the University. You are all aware that it is to the munificence of Sir Roderick Murchison that this most valuable addition to our teaching staff is due. Sir Roderick Murchison is a Scotchman who has done more to advance the knowledge of geological and geographical science than any other man living. It is needless for me to speak in terms of eulogy of this last benefit which he has conferred upon the cause of scientific instruction in his native country, but I could not from feelings of personal gratitude allow this opportunity to pass of saying that it is to Sir Roderick Murchison that I owe my first encouragement and assistance in Natural Science ; and, like all who have received favours at his hands, I have found him a kind and steady friend through life.

We have now in the University three distinct departments of Natural Science, and as it taxes any man's energies to the utmost to keep up with the rapid advance of any one of them, it is of incalculable advantage that their teaching should be in different hands. Broadly speaking, Prof. Geikie now takes the inorganic kingdom of Nature, while Dr. Balfour and I divide biological science between us—Dr. Balfour taking the vegetable kingdom, and I the animal kingdom chiefly. The three subjects, however, meet and inosculate at every point, and the more one branch derives illustration from the other the better. This is especially the case with reference to Physical Geology, and the two departments of biology go between them, and demand full illustration from each. A mass of facts has of late years been developed, which group themselves into a special science of boundless interest—the Science of Palæontology. Still there can be no doubt that Palæontology is simply the biology of the present carried back continuously into the past. I will accordingly, with Prof. Geikie's full concurrence, incorporate pure Palæozoology with my Zoology course, and my colleague, Prof. Balfour, will doubtless do the same by Palæophytology ; and we shall both materially trespass upon the domain of Prof. Geikie for the necessary illustration which his special subject affords, fully aware that he must make even heavier requisitions upon us.

Gentlemen, I have already alluded to the division of the Natural Science group of subjects into three—the study of inorganic nature from a natural history point of view, and the study

* Introductory Lecture to the Natural History Class. By Prof. Wyville Thomson, LL.D., D.Sc., F.R.S.

of the two organic kingdoms. As a certain amount of latitude is allowed in a first lecture, I will crave your indulgence while I direct your attention for a few minutes to a group of forms which are said to belong to none of these kingdoms, and to form a kind of Bohemia of their own.

Prof. Ernst Haeckel of Jena, one of the most profoundly learned naturalists and one of the most sensible thinkers of the day, advocates the separation into a distinct kingdom of an immense series of simple organisms, some of which had been hitherto regarded as plants and others as animals.

Prof. Haeckel's opinion on a matter of this kind is of the highest value, not because he has made a bold and certainly premature attempt to rearrange the universe on Darwinian principles, but because he has been a most sagacious and careful student of the lower forms of life. He has raised for himself a monument in his wonderful monograph of the Radiolaria, which will endure along with Darwin's researches on coral reefs and on the Cirripeds, when the Darwinian theory of modification through Natural Selection may possibly be remembered only as one of the most brilliant of those broken lights which have been shed from time to time by gifted men on the plan of the Divine Creator.

According to Professor Haeckel, the material universe, so far as we at present know it, resolves itself into minerals, protista, plants, and animals. I may say at starting that, along with most of my brother naturalists in Britain, I regard the introduction of this new "kingdom," the Protista, as a mistake; but as the proposal even involves most interesting questions as to the relations between the three recognised kingdoms, it is well worthy of careful consideration. Haeckel ranges among the Protista the Monera, a group of peculiar forms, of which he himself has been the most successful student, and these may be taken as the type of the "Protistenreich;" the protoplasta, containing amœba, difflugia and their allies; the diatoms, the flagellate infusoria; the fungi; the noctiluca; and the rhizopoda.

It is foreign to my present purpose to trace in detail the various steps by which our views of the ultimate process of organisation have been modified during the last few years; how after the publication of the brilliant observations of Schleiden and Schwann, the nucleated cell was almost universally regarded as the physiological unit; how the researches of Max Schultze, Leydig, Beale, and Hofmeister gradually shook our faith in the earlier conceptions of this cell-unit, and did away at all events with the necessity of a cell-wall, proving such a wall, when it existed, to be an excretion, and showing that the vital activity of the cell resided solely in the nucleated spherule of contractile sarcode which forms the cell-contents of every living cell—and how finally Cohn, Max Schultze, Huxley, and Haeckel cast doubts upon the value of the nucleus and upon the necessity of any cell-like limitation, and seemed to render the view highly probable that the vital activity of all organisms, even of the most highly organised, resides essentially and ultimately in a diffused homogeneous "germinal matter," or "protoplasm," of which all formed tissues are modifications or excretions.

It is impossible in the present state of knowledge to subject any view as to the ultimate mechanism of the formation of tissue through the means of protoplasm to direct proof. It seems now to be a very generally received opinion, supported by Huxley, Max Schultze, Hofmeister, Beale, and many others, and notably by Oscar Schmidt, who would seem to bring it almost to demonstration in his beautiful researches on the sponges of the Adriatic, that protoplasm is simply converted, with a certain change of composition, into tissue or "formed material." There are, however, almost insuperable objections to this view. The secondary products of organisation (formed material) are most various in their chemical constitutions, and it involves the admission that protoplasm may change in its chemical composition till it is *almost* carbonate of lime, or silica, or starch, or horn, or cellulose; the last stage of the metamorphosis being its absolute separation as one or other of these bodies. Another view which I have always regarded as more probable is that protoplasm, the substance which is endowed with the peculiar vital property, has always the same composition, and that it acts simply by catalysis, inducing, under certain known laws, decomposition and recombination in compounds which are subjected to its influence, without itself undergoing any change, absorbing the nascent products of combination and decomposition, and recombining them and reserving them with reference to the development or maintenance of the organ to which it gives its life.

The researches of Prof. Haeckel on the Monera have perhaps been of higher value in support of the protoplasm view than any others, for they have given abundant proof that independent beings may exist and may show all the essential phenomena of life without the slightest trace of differentiation of any part of their substance into investing wall or nucleus or distinguishable part of any kind, simply as masses of contractile jelly, particles of albumin endowed with the faculties of nutrition and reproduction.

The positive character to which Prof. Haeckel trusts for the definition of his protista kingdom is the entire absence in all the groups which it contains of sexual reproduction. He contends that all protista are monogenetic, reproducing by gemmation or fission alone. This character he conceives separates them definitely from true animals and true plants. Before passing to the consideration of the general relations of the animal and vegetable kingdoms and the position of these questionable forms, I wish to say that I do not attach much importance to this negative character. Of late years enormous advances have been made in our knowledge of the process of reproduction in lower organisms, and we find that multiplication by gemmation in various forms is infinitely more common than was supposed; that in some cases multitudes of individuals and apparently several generations are reproduced by gemmation alone, without the intervention of sexual reproduction; but at the same time I believe that the tendency of modern research is to make it more and more probable that in all cases conjugation or some other form of sexual reproduction comes in at some part of a definite or indefinite series of broods, and starts as it were an entirely new stock. I am inclined to think that in those cases where we find only monogeny, it is probably from a want of knowledge of the life history, not of an individual, but of a complete cycle of individuals. Besides, the reproductive process in some of these lower forms is very obscure. Not many years ago, accepting Prof. Haeckel's test, all the orders of cryptogamic plants would have belonged to the protista. Who could have anticipated the obscure and beautiful process of fertilisation in ferns? It seems scarcely possible that there should be no equivalent process in fungi, if we could only find it out.

Let us now consider for a moment the characters on which the older kingdoms have been founded, and see how they have stood the test of advancing knowledge. We shall thus be the beter able to judge of the stability or otherwise of the proposed new kingdom.

The consideration of the inorganic kingdom need not, I think, detain us long. Any two groups of things conceivable must have some analogies or resemblances; but it seems to me that any essential relations which have been founded on the resemblances between inorganic substances and organised beings are purely fanciful. Of course, it is impossible to say that a point of continuity may not be discovered, but as yet the boundary line seems sufficiently trenchant.

Inorganic substances never *live*, they are either simple (according to our present state of knowledge) or they may originate from the combination of two or more substances which unite in definite proportions; they may exist in any physical condition from solid to gaseous, but they are homogeneous, that is to say, any portion which may be detached exactly resembles the remainder in composition and in properties; they increase by the addition of like particles from without to the external surface; they may be indefinite in external form or amorphous, but almost universally they tend to assume the form of regular geometric solids bounded by planes, which have a definite relation to one another in position—to crystallise. Internally inorganic substances are at rest, unless their atoms be set in motion, or unless they be otherwise affected by forces acting from without; they initiate no motion nor change. If one could imagine a quartz crystal absolutely isolated from all external influences, it might remain unchanged for ever.

An organised being, on the other hand, either *lives* or has lived during some part of its existence; if living, every part of it is in constant motion and change; it increases by the imbibition of heterogeneous matter from without, by its assimilation, and by the intercalation of the particles of the assimilated food among the particles of the substance already laid down, by molecular intussusception; and old molecules which have undergone change are constantly being removed and replaced by new ones. An organised being always contains a mixture of solids, liquids, and gases; it is never homogeneous nor uniform in structure, but consists of structural elements which are distinct in character, and each of which has its part to play in the production and regulation of the movements and changes which are unceasing; it always contains certain substances in what is called "unstable equilibrium," which become decomposed and reduced to more stable compounds the moment the peculiar vital property is lost. An organised being is not produced by the direct union of definite proportions of two or more simple substances; it arises by the growth of a germ, a portion separated from the body of a pre-existing organised being of the same kind. Finally, organised beings never assume accurate geometrical forms, but under the influence of life each kind of organised being assumes a characteristic, though not absolutely definite shape, which is the resultant of the sum of the shapes of all its structural elements, which has a very close relation to the shape of the organised being from which it was derived as a germ, though it is not identical with it, and which is called its individual form.

I have thus far contrasted inert matter with organised beings possessing life. That the term life indicates a very special property there can be no doubt, but, as yet, an impenetrable veil seems to shroud its ultimate processes. I believe, however, that the veil is at the far end of the labyrinth in which we are now wandering, and that patient observation and guarded generalisation may yet enable us greatly to narrow the limits of the unknown—to approach some steps nearer to the veil. I must premise that, as I am now looking at the subject from a purely physiological point of view, I regard life simply as a condition capable of producing certain perceptible phenomena, and can take no cognizance whatever of that mysterious union between spirit and matter which is broken in passing through "the valley of the shadow of death." Material processes and material changes only are subject to the material instruments of biological research. Those inner mysteries are now and must probably ever remain—in our present condition of existence—beyond the veil.

It becomes daily more manifest with the advance of knowledge that the action of known physical laws—such as chemical affinity and capillarity as manifested by porous media and by colloids—are most intimately interwoven with all organic processes, and it is, as yet, impossible to say how far life may influence, in the sense of modifying or directing, the action of these laws. Life has been called the vital force, and it has been suggested that it may be found to belong to the same category as the convertible forces heat and light. Life seems, however, to be more a property of matter in a certain state of combination than a force. It does no work in the ordinary sense. If a man lift a weight a couple of feet off the ground, many of the so-called vital actions are called into play, but yet every part of the work done can be accounted for by the action of the ordinary physical forces. The act of the will, in regal phrase the "mere motion," which induced the lifting of the weight, can be referred, we can scarcely doubt, to the mechanical action of some part of a large and complicated apparatus, the cerebral hemispheres, and was accompanied by a waste of its substance.

The telegraphic communication to the muscles involved which harmonised their several acts and signalled the contraction of their fibres, was conveyed through a cord whose molecules were set in vibration by a force very probably convertible with the physical forces, generated by chemical change and the waste of tissue; and in the muscle, the organ by which the weight was actually raised, an amount of waste took place—that is to say, an amount of carbon was combined with oxygen precisely equivalent theoretically to the quantity of coal which must have been burned in a perfectly constructed engine to do the same work.

Chemical forces act in living beings under very special circumstances. For a series of years a mass of substances are held undergoing constant change and throughout in the most unstable state of chemical combination. The instant the condition of life is removed, decomposition commences, and the complex constituents of the body are resolved into more simple and stable combinations. But yet it may be fairly questioned whether the chemical relations of the component elements of an organised body are in any way directly affected or controlled by life. It has become quite conceivable, especially through the researches of the late Master of the Mint, that a constant adjustment and re-adjustment of membranous and colloid diaphragms in the presence of powerful catalytic agents may possibly explain the maintenance of almost any chemical conditions however complicated.

The one function of living beings whose explanation it seems at present impossible to imagine except by regarding it as the manifestation of a special property, is what has been called the "moulding of specific form;" the building up of a heterogeneous and complicated organism, which shall repeat, not rigidly but with a certain flexibility, the characters which have been transmitted to it through a germ from a parent, every molecule of every part having thus a direct relation in form, in position, and in composition, to every other molecule of the body. At present, regarding it from a purely material point of view, we are scarcely justified in regarding life as more than that condition of an organised being in which the products of chemical and physical changes taking place within it are stamped with a specific organic form.

(*To be continued.*)

## *SCIENTIFIC SERIALS*

*Journal of the Ethnological Society of London* (January 1871). A paper by Mr. E. B. Tylor on "The Philosophy of Religion among the lower Races of Mankind" gives in a condensed form his views on the development of "Animism," *i.e.* the doctrine of the soul, and of spirit and deity in general, a subject which is treated at length in his recently published work on "Primitive Culture."—Prof. Huxley's address on the "Geographical Distribution of the Chief Modifications of Mankind" is accompanied by an ethnological map, which curators and lecturers will do well to adopt as a wall-map. The principal races of mankind are defined as the Australioid, Negroid, Mongoloid, and the Xanthochroic and Melanochroic (fair and dark whites) Among the special features in Prof. Huxley's scheme of the races of mankind, the following are prominent. The indigenous non-Aryan tribes of Central and Southern India, and less closely the ancient Egyptians and their descendants, the modern Fellahs, are referred to the Australioid type. The Negroid type of Africa is divided between the Negroes proper and the Bushmen of the extreme south, the Hottentots being considered a cross-breed between these two races. The Mongoloid type is made to include not only the brachycephalic Tatar races, but classification by skulls is set aside, and the group is arranged to include the Chinese and Japanese. The "absurd denomination" of "Caucasian" is abandoned, and the nations thus described by ethnologists come under the titles of Xanthochroi, fair whites, who are classed as of special type, and Melanochroi, dark whites, which latter Prof. Huxley is disposed to consider as sprung from intermixture of Xanthochroi and Australioids. In this classification of human types or races, Prof. Huxley rests on physical characteristics, treating language as subordinate. In his remarks on "The Ethnology of Britain" he again states his views as to the great division of European men between the fair whites of the centre and west, and the dark whites of the south. Both types occur in the early population of our islands, the use of Celtic language not corresponding with a racial distinction.—Dr. Nicholas's paper on the "Influence of the Norman Conquest on the Ethnology of Britain" is in strong antagonism to the view that Englishmen are ethnologically "Low Dutch." In his view, the old British race, in great measure, kept its early type, the Saxon, Danish, and Norman invasions affecting language, government, &c., rather than replacing the population itself.—Among the papers on Prehistoric Archæology are Sir John Lubbock's description of the Park Cwm Tumulus, and an account of remains of "Platycnemic Men in Denbighshire," by Mr. W. Boyd Dawkins and Prof. Busk.—Canon Greenwell's paper on "The Opening of Grime's Graves in Norfolk," gives full particulars as to the site of a Stone Age manufactory of implements from the excellent flint of the district. The chalk was systematically mined for the flint, and the so-called "Grime's Graves" are ancient pit-workings of this class. Colonel Lane Fox is disposed to explain in the same way the "Danes' Holes" in Kent, long a puzzle to antiquaries.—Looking at the number of the journal of the Ethnological Society, it is to be hoped that the journal of the new Anthropological Institute will maintain its very high standard of succinctness, solidity, and general interest.

THE *Geological Magazine* for the present month (No. 83) contains only four original articles, of which the first is an account by the editor, Mr. H Woodward, of the objects which more particularly attracted his attention during a recent visit to the Brussels Museum. He notices especially the fossils of the Antwerp crag, and a fine example of the mammoth found at Lierre, in the province of Antwerp, in a sufficiently perfect state to be mounted as a skeleton. Two figures of this interesting specimen are given. Mr. Woodward also refers to a fine series of skulls of *Ursus spelæus* from the Belgian caves contained in the Museum at Brussels.—Mr. Whitaker describes the chalk of the cliffs from Seaford to Eastbourne in Sussex, which he illustrates by a section, and compares with that of the Kentish cliffs.—In a paper (illustrated with a map) on the Denudation of the Coalbrook Dale coal-field, Mr. Daniel Jones endeavours to explain the puzzling arrangement of the coal measures in that locality by demonstrating that the southern portion of it has been largely denuded, and subsequently overlain by coal measures of younger age, so that the deposits are not uniform and persistent.—Mr. W. Davies gives us an alphabetical catalogue of type specimens of fossil fishes in the British Museum, in continuation of the similar lists already published by Sir Philip Egerton and Lord Enniskillen of the type specimens in their collections.—The remainder of this number is occupied as usual by notices, reviews, reports and correspondence.

THE *Proceedings of the Royal Irish Academy*, Series II. No. 2 of vol. i. has just been presented to the members. This Part contains Mr. Andrews's notice of the capture of *Ziphius Sowerbi.* The President's Annual Address. W. Archer "On some new or little-known Freshwater Rhizopods (Plates 12 and 13). Mr. R. C. Tichborne, Laboratory notes. G. J. Stoney "On the Cause of the Interrupted Spectra of Gases." Prof. R. Ball "On the Motion of Vortex Rings in Air." C. E. Burton "On Results obtained by the *Agosta* Expedition to observe the Recent Solar Eclipse." Principal Dawson, Note on *Eozöon Canadense.* Prof. T. S. Hunt, Notes on Messrs. King and Rowney on *Eozöon Canadense.* Prof. Macalister, "On Human Muscular Anomalies." The Appendix contains the minutes of the Proceedings of the Academy, and the Correspondence relative to the Bombardment of Paris.

IN the *Journal of Botany* for May, Mr. C. E. Broome describes a new British fungus *Scleroderma Geaster*, with a lithograph. The contributions to local botany are a continuation of Mr. More's Supplement to the "Flora Vectensis," and Notes of plants of the neighbourhood of Oxford, by Prof. Thistleton-Dyer. We have also a further instalment of Dr. Hance's "Sertulum Chinense," and the usual short notes, reports, reviews, and proceedings of societies.

## SOCIETIES AND ACADEMIES

### LONDON

Zoological Society, May 16.—Prof. Flower in the chair.—The Secretary read a report on the additions that had been made to the society's menagerie during the month of April 1871; and called particular attention to a female of the lately-described Prince Alfred's deer (*Cervus alfredi*), which had been received in exchange, and was stated to have been originally brought from the Philippines.—An extract was read from a letter addressed to the secretary by Dr. R. A. Philippi, Director of the National Museum at Santiago, stating that no species of the tortoise was known to occur in Chili, and that the specimens upon which the so-called *Testudo chilensis* had been based had been received from Mendoza, in the Argentine Republic.—Prof. T. H. Huxley communicated a paper by Dr. P. Martin-Duncan, F.R.S, containing descriptions of the Madreporaria (stony corals) dredged up during the expedition of H.M.S. *Porcupine* in 1869-1870.—Sir Victor Brooke, Bart., F.Z.S., read a paper on Speke's Antelope (*Tragelaphus spekii*) and the allied species of the genus *Tragelaphus*, in which the distinguishing characters of these animals were pointed out, and their synonymy and distribution given.—Mr. P. L. Sclater communicated some notes on a collection of birds made in the vicinity of Lima, Peru, by Prof. W. Nation, of that place, with notes on their habits by the collector.—A second communication from Mr. Sclater contained a continuation of his notes on rare or little-known animals now or lately living in the society's gardens. Mr. Sclater also gave the description of a new parrot, now living in the society's gardens, which he proposed to call *Lorius tibialis.*—Mr. R. B. Sharpe read a note on *Macheirhamphus anderssoni*, a very rare Accipitrine bird from Damara Land, and gave a history of the two species of *Macheirhamphus* now known to science.—Mr. J. Gould exhibited and pointed out the characters of a new humming bird, lately discovered by Mr. H. Whitely in Peru, which he proposed to call *Helianthea osculans;* and likewise characterised five other new species of the same family of birds.

Geological Society, May 10.—Prof. Morris, vice-president, in the chair. Dr. Henry Nyst, of Brussels, was elected a foreign member, and Prof. G. Dewalque, of Liège, a foreign correspondent of the Society. The following communications were read:—1. On the Ancient Rocks of the St. David's Promontory, South Wales, and their Fossil contents, by Prof. R. Harkness, F.R.S, and Mr. Henry Hicks. In the Promontory of St. David's the rocks upon which the conglomerates and purple and greenish sandstone, forming the series usually called the "Longmynd" and "Harlech Groups," repose, are highly quartziferous, and in many spots so nearly resemble syenite that it is at first difficult to make out their true nature. The apparent crystals are, however, for the most part angular fragments of quartz, not possessing the true crystalline form of the mineral. The matrix does not exhibit a crystalline arrangement, and contains a very large proportion of silica, much exceeding that which is obtained from rocks of a syenitic nature. These quartziferous rocks form an E.N.E and W.S.W. course. The arrangement of these rocks, which seem to be quartziferous breccias, is somewhat indistinct. In the immediate neighbourhood of St. David's they have associated with them irregular bands of hard, greenish, ashy-looking shales, much altered in character, but often presenting distinct traces of foliation. In a ridge running from the S.E. of Ramsey Sound in a north-easterly direction, the greenish shales are more compact, and resemble earthy greenstones. The quartziferous breccias and their associated shales form two anticlinal axes, contiguous to each other, and have on their S.S.E. and N.N.W. sides purple and green rocks. The order of the rocks from the quartziferous breccias upwards, when not disturbed by faults, is as follows:—

*Lower Cambrian.*

| | feet. |
|---|---|
| 1. Greenish hornstones on the S.E., and earthy Greenstones on the N.W., forming the outermost portions of the so-called Syenitic and Greenstone ridges. | |
| 2. Conglomerates composed chiefly of well-rounded masses of quartz imbedded in a purple matrix . . | 60 |
| 3. Greenish flaggy sandstones . . . . . | 460 |
| 4. Red flaggy or shaly beds, affording the earliest traces of organic remains in the St. David's Promontory, namely, *Lingulella ferruginea* and *Leperditia cambrensis* . . . . . . . . . . | 50 |
| 5. Purple (sometimes greenish) sandstones . . . | 1000 |
| 6. Yellowish-grey sandstones, shales, and flags containing the genera *Plutonia*, *Conocoryphe*, *Microdiscus*, *Agnostus*, *Theca*, *Protospongia* . . . . . | 150 |
| 7. Grey, purple, and red flaggy sandstones, containing, with some of the above-mentioned genera, the genus *Paradoxides* . . . . . . . . . | 1500 |
| 8. Grey flaggy beds . . . . . . . . . | 150 |
| 9. The true beds of the "Menevian Group," richly fossiliferous, and the probable equivalents of the lowest portions of the Primordial Zone of M. Barrande . | 550 |

The discovery of a fauna specially rich in trilobites, among these rocks of the St. David's Promontory, affords very important information concerning the earlier forms of life of the British Isles. Until the discovery of this fauna, these rocks and their equivalents in North Wales were looked upon as all but barren of fossils. We have now, scattered through about 3000 feet of purple and green strata, a well-marked series of fossils, such as have nowhere else been obtained in the British Isles. In the Longmynds of Shropshire the only evidence of the existence of life during the period of their deposition is in the form of worm-burrows, and in the somewhat indistinct impressions, which Mr. Salter regards as trilobitic, and to which he has given the name of *Palæopyge Ramsayi*. If we assume the purple and green shales and sandstones, with their associated quartz rocks of Bray Head and the drab shales of Carrick M'Reily, county Wicklow, to represent the old rocks of St. David's, they afford only very meagre evidence of the occurrence of life during the period of their deposition in the form of worm-burrows and tracks, and in the very indeterminate fossils which have been referred to the genus *Oldhamia*. One very prominent feature about the palæontology of the ancient rocks of St. David's is the occurrence of four distinct species of the genus *Paradoxides;* and this is in strong contrast with the entire absence of the genus *Olenus*. On a comparison of the palæontology of the St. David's rocks with those of the continent of Europe and of America, which seem to occupy nearly the same horizon, we have like features to a very great extent presenting themselves. With reference to the distribution in time of some of the earlier genera of trilobites, it would appear that the genus *Olenus* is represented in Britain and Europe by twenty-two species, confined to the Lingula-flags and Tremadoc rocks, and not occurring so low as the Menevian group. The absence of this genus from the Menevian group, and its occurrence throughout the whole of the Lingula-flags, and in the Tremadoc rocks, along with the fact that so far as present observations go, no species of *Paradoxides* ranges higher than the Menevian group, have afforded good palæontological grounds for placing the line of demarcation between Upper and Lower Cambrian at this spot, and for including the Menevian group in the Lower Cambrian, to the bulk of which it is intimately united palæontologically. Mr. Hughes bore testimony to the admirable work done by Mr. Hicks, who had, almost unaided, worked out the geology of that district. Allowing that many subdivisions and new specific names had with great advantage been introduced into petrology, he defended the Survey nomenclature by reference to the then received definition of syenite and greenstone, terms still perfectly understood and applicable to the main mass of the rocks in question, though possibly subsequent closer examination and new sections may have rendered some modification of the boundary lines desirable. He was prepared to allow the metamorphic origin of all rocks of the classes under consideration, but did not think there was sufficient evidence to show that the divisional planes in the syenite and greenstones of St. David's were due to original stratification, but might correspond rather to the great joints of most granites. Mr. Hughes pointed out that the conglomerate contained fragments of the hornstone and quartz of this older series, which he considered was probably part of an old ridge or shoal, possibly of Laurentian, but certainly of Pre-Cambrian age, and thought that there were slight differences in the lithological character of the beds on either side, such as might be explained on this supposition. He agreed with Prof. Ramsay in thinking that there was evidence of the proximity of land in early Cambrian times, but was not prepared to refer these red rocks to inland seas or lakes as opposed to open sea; the whole seemed rather the deposit of an open sea encroaching during submergence. He did not attach very much importance to the restriction of genera to limited horizons in these older rocks of St. David's. For, as it was reserved for Dr. Hicks to discover these fossils after so many other observers had examined the district, he anticipated that further researches must certainly result in finding links which will connect together more closely beds, the stratigraphical relations of which seem to indicate so clearly an unbroken though varying series. Mr. Gwyn Jeffreys had been struck by the intercalation of non-fossiliferous beds from time to time among the fossiliferous beds described in the paper. This was the case in beds now in course of formation, and appeared to arise from the great deposits of mud brought down by rivers and redeposited in certain positions in the sea-bed. That this was the case had been proved by recent dredging operations both in the Atlantic, off Spain, and in the Mediterranean. Mr. Boyd Dawkins called attention to the gap which had been filled by the discoveries recorded in the paper, inasmuch as the Molluscan, Annelid, and Crustacean forms were now carried back far into the Cambrian period, and yet without any trace of their convergence, so that the origin of life might be as far removed from that period as was the Cambrian from the present time. The difference in the colours of the rocks he was inclined to refer to the different degrees of oxidisation of the iron they contained, which might supervene in a comparatively short time. The Rev. W. S. Symonds had, in visiting the spot, been much struck by the rocks, at that time termed syenite, which he believed might be an extension of those on the Carnarvonshire peninsula, and which he thought supported the whole series of the Cambrian rocks, so that they might after all be the Laurentian, the same as those of Sutherlandshire and Assynt. If this were the case the nomenclature of the Geological Survey would have to be altered, and the rocks of Pistyl and Holyhead no longer termed metamorphosed Cambrian rocks, but Laurentian. Mr. Hicks, in reply, stated that the quartziferous breccias forming the central ridge contained so many rolled pebbles, and were, moreover, in places so distinctly bedded, that there could be no doubt of their being sedimentary. Other beds, described as greenstone in the maps of the Geological Survey, were also distinctly laminated. The non-occurrence of fossils in the more sandy beds he attributed to their having been deposited in very shallow water. The fossils occurred principally in fine-grained beds of a flaggy nature. "On the Age of the Nubian Sandstone," by Mr. Ralph Tate, F.G.S. The author remarked that the sandstone strata underlying the Cretaceous limestones, and resting upon the granitic and schistose rocks of Sinai, had been identified with the "Nubian Sandstone" described by Russegger as occurring in Egypt, Nubia, and Arabia Petræa. In the absence of palæontological evidence, this sandstone has been referred to the Mesozoic group, having been regarded by Russegger as Lower Cretaceous, and by Mr. Bauerman and Figari-Bey as Triassic, the latter considering an intercalated limestone bed to be the equivalent of the Muschelkalk. The author has detected *Orthis Michelini* in a block of this limestone from Wady-Nasb, which leads him to refer it to the Carboniferous epoch, as had already been done by the late Mr. Salter from his interpretation of certain encrinite-stems obtained from it. The author mentioned other fossils obtained from this limestone, and also referred to the species of *Lepidodendron* and *Sigillaria* derived from the sandstone of the same locality. He regarded the Adigrat Sandstone of Mr. Blanford as identical with the Nubian Sandstone.—3. "On the Discovery of the Glutton (*Gulo luscus*) in Britain," by Mr. W. Boyd Dawkins, M.A., F.R.S. The author in this paper described a lower jaw of the Glutton, which had been obtained by Messrs. Hughes and Heaton from a cave at Plâs Heaton, where it was associated with remains of the wolf, bison, reindeer, horse, and cave-bear. He remarked that he could detect no specific difference between the *Gulo spelæus* Goldfuss, from Germany, and the living *Gulo luscus*, except that the fossil Carnivore was larger than the living, probably from the comparative leniency of the competition for life in postglacial times. He referred to the distribution of the Glutton in a fossil state, and argued that its association with the reindeer, the marmot, and the musk-sheep would imply that the postglacial winters were of Arctic severity, whilst the presence of remains of the hippopotamus, associated with the same group of animals, would indicate a hot summer, such as prevails on the Lower Volga. Mr. Hughes indicated the exact position in which the jaw of the glutton was found, but pointed out that, owing to the excavations of keepers, badgers, rabbits, &c., the earth was so much disturbed in that part that it was impossible to be sure of the original relative position of the bones. He showed that the Plâs Heaton Cave was on a hill rising from the top of the plateau, while the Cefn, Brysgill, and Galltfænan Caves were in the gorge cut through that plateau, and therefore that the Plâs Heaton Cave was probably formed, and might possibly have been first occupied, at a much earlier period than the others. As it appeared to pass under that part of the hill which is overlapped by heavy drift, he thought it quite possible that this may have been a preglacial cave, and that by and by we may find evidence of preglacial fauna in it. The Rev. W. S. Symonds mentioned that in some of the pot holes in the roof of the Cefn Cave he had procured silt containing remains of shells determined by Mr. Jeffreys to be marine. Mr. Hughes explained that these shells had probably been washed in from the superficial drift of the district. Mr. Dawkins, in reply, expressed his belief that though the excavation of the caves in question might have taken place at different periods, yet that their occupation was, geologically speaking, contemporaneous.

Mathematical Society, May 11.—Mr. W. Spottiswoode, president, in the chair. Mr. C. J. Monro, B.A., late Fellow of Trinity College, Cambridge, was elected a member; and Mr. J. Griffiths, M.A., Fellow of Jesus College, Oxford, was proposed for election. The Hon. J. W. Strutt, fellow of Trinity College, Cambridge, was admitted into the Society. Prof. Henrici indicated the method of treatment he had employed in his paper "On the Singularities of the Envelopes of a non-unicursal Series of Curves." Mr. Strutt then read his paper "On the Resultant of a large Number of Vibrations of irregular phase, as applied to the explanation of Coronas." Sir W. Thomson, Prof. Clerk Maxwell, and Mr. Strutt made some further remarks on the subject of the paper. Mr. Maxwell then gave a description of two solar halos he had recently seen, and Prof. W. G. Adams gave some additional particulars in the case of one of the phenomena which had also been noticed by himself. Prof. Cayley then communicated an account of a paper by Mr. J. Griffiths "On the problem of finding the circle which cuts three given circles at given angles." The president next requested assistance in the solution of a "Question on the Mathematical Theory of Vibrating Strings," which he had been unsuccessful in solving. Mr. Strutt mentioned some results he had arrived at in reference to the subject of inquiry. A communication from Prof. Cayley respecting the extension of the Society's sphere of action was laid before the meeting by the president; it was determined that the matter should be discussed at the Society's next meeting. Prof. Maxwell asked for information as to the convention established among mathematicians with respect to the relation between the positive direction of motion along any axis, and the positive direction of rotation round it. In Sir W. Hamilton's Lectures on Quaternions the coordinate axes are drawn, $x$ to South, $y$ to West, and $z$ upwards. The same system is adopted in Prof. Tait's Quaternions, and in Listing's Vorstudien zur Topologie. The positive directions of translation and of rotation are thus connected as in a left-handed screw or the tendril of the hop. On the other hand, in Thomson and Tait's "Natural Philosophy," p. 234, the relations are defined with reference to a watch, and lead to the opposite system, symbolised by an ordinary or right-handed screw, or the tendril of the vine. If the actual rotation of the earth from west to east be taken positive, the direction of the earth's axis from south to north is positive in this system. In pure mathematics little inconvenience is felt from this want of uniformity, but in astronomy, electro-magnetics, and all physical sciences, it is of the greatest importance that one or the other system should be specified and persevered in. The relation between the one system and the other is the same as that between an object and its reflected image, and the operation of passing from one to the other has been called by Listing *Perversion*. Sir W. Thomson and Dr. Hirst stated the arguments in favour of the right-handed system, derived from the motion of the earth and planets, and the convention that north is to be reckoned positive. The right-handed system, symbolised by a corkscrew or the tendril of the vine, was adopted by the society.

### Halifax, Nova Scotia

Institute of Natural Science, March 13.—Mr. J. M. Jones, F.L.S., president, in the chair. D. J. B. Gilpin read a paper on the Mammalia of Nova Scotia, being the ninth part of a series on that subject delivered before the institute. The present paper included the common hare (*Lepus americanus*) and the cariboo (*Rangifer cariboo*) or reindeer of the province. The author stated that whilst Newfoundland and the country around Hudson's Bay were represented by the polar hare (*L. glacialis*) which varied in colour even to pure white, and New England on the south by the wood hare (*L. sylvestris*) which never varied, Nova Scotia had the American hare (*L. americanus*) which varied to a soiled rusty-white, and which had been confounded with both the other species. A specimen of this last species taken early in November, and which might be considered as in summer pelage, was sepia-brown with a yellow wash and coarse black hairs on the back, breast, belly, and inside the legs white, tips of ears black, and pads light rusty. One taken in December of the same year and which may be taken as a winter specimen, was soiled white with rusty streaks on the back and sides; nose and circlet around the eyes rusty; under parts, pure white; a rusty streak on fore arm always, and often upon the thigh. The only parts which remained unchanged were the white of the belly, the black ear tips and the rusty pads, and that all the hair, both, summer and winter, had a lead coloured base. The change of colour takes place during the month of December, and is the result of the summer coat being shed and replaced by the winter one. The American hare abounds in the province, keeps close covert, and is nocturnal. In concluding his remarks upon this the last of the list of rodents found in Nova Scotia, Dr. Gilpin stated that although the equator produced no arctic forms, yet we find equatorial fo rms side by side with boreal ones at the north; and that although the furry foot of the lynx and ermine, and the feathery one of the day owl, the winter falcon, the ptarmigan, and grouse, are the true livery of the north, yet the shrews with satin coats and naked needle-like legs brave cold 20° below zero, and the red squirrel sports with naked palms on snow of similar temperature. Passing by the three orders *Edentata*, *Solidungula*, and *Pachydermata*, one of which, Solidungula, was represented by the horse, an introduced species on Sable Island, and there allowed to assume the feral state, the author arrived at the *Ruminantia*, two genera of which only exist in Nova Scotia—the cariboo or reindeer (*Rangifer cariboo*) and the moose (*Alces americanus*). He stated that the cariboo attain in Nova Scotias the enormous height of four feet ten inches; that the horns differs in every individual, but agrees in certain typical marks. In summer they are in colour rich brown, with white necks and shoulders; in winter, all soiled white; legs brownish, with white fringe on he hoofs extending to the back hoofs. They are seen in droves of seven or eight usually, and now and then of a hundred, but are fast diminishing; not, however, by the hand of man or teeth of wild beasts, but in that noiseless way wild creatures disappear as their range is contracted by new settlements; the does producing fewer fawns, and the males becoming early barren. Nova Scotia is the most southern latitude in which the cariboo is found on the American continent, but there is a "permanent variety," according to Richardson, one third the size of the southern form, with larger horns and no gall bladder, inhabiting the polar region. The President read a paper on the Diurnal Lepidoptera of Nova Scotia, being the second part of a series in process of delivery before the Institute. He remarked how visibly insect faunas differed according to the geological and botanical character of the districts visited by the entomologist, and more particularly alluded to the smaller size of certain insects inhabiting the extreme north-eastern portions of the American continent, compared with individuals of the same species taken farther south. This fact was first brought to his notice by the Rev. C. J. S. Bethune, secretary of the Entomological Society of Canada, three years ago, who while identifying a small collection of *Heterocera* taken in Nova Scotia, observed the smaller size of Nova Scotian forms when compared with those of Western Canada. Since that date the author has compared species of other orders with British types, and found a similar peculiarity, the British being larger than the Nova Scotian. This specific change is probably owing to the difference existing in the botanical character of these separate districts, which is not far removed from each other; but he hopes to be able to pay a second and longer visit to the valley of Annapolis and the slopes of the North Mountain during the coming summer.

### Vienna

Imperial Academy of Sciences, March 9.—Several memoirs were communicated, of which the titles only are given, namely, "On the conversion of formic acid into methylic alcohol," by MM. A. Lieben and A. Rossi, of Turin; "On the structure and development of the earliest plumage observed in the chicken," by Dr. E. Pernitza; "On the solution of algebraic equations of any degrees, even with complex co-efficients, by means of Gauss's scheme for complex magnitudes," by M. A. Raabe; and "On the heat equilibrium between polyatomic gaseous molecules," by Prof. L. Boltzmann. Two sealed papers were also deposited.—Dr. L. Fitzinger presented the sixth section of his critical revision of the family of the Bats (*Vespertiliones*), embracing the genera *Vespertilio* and *Myotis*.—Prof. R. Maly communicated the results of some investigations made in the chemical laboratory of the medical faculty at Innsbruck, including an analysis of the fluid from an ovarian cyst, made by himself, with investigations of the constituents of its ash, by Prof. E. Hofmann; a notice of Trommer's sugar-reaction in the urine, and of a simple mode of preparing muriate of creatinine from that fluid, by himself; and researches upon the bodies containing sulphur in the urine, by Dr. W. Löbisch.—Prof. von Hochstetter communicated some microscopic investigations on opals, by Dr. H. Behrens, in which the author states that most opals are mixtures of various minerals, including a colourless fundamental mass, containing (microscopically discoverable) hydrophane, cacholong, quartz, hydrated and anhydrous oxide of iron, ferriferous silicates, metallic sulphurets and carbonates, and organic substances:—fire-opal, glass-opal, noble-opal, and hyalite are free from admixture, and the first two are structureless. The colours of the noble-opal are interference-colours, caused by their lamellæ, which, however, are not tabular crystals. The double refraction discovered by Schultze in hyalite is caused by differences of elasticity such as occur in dextrin, amber, and compressed glass. The author also noticed the spheroidal structure which frequently occurs in opals.—A memoir on the circum-anal glands of man, by Dr. Gay, of Kasan, was presented by Prof. Brücke. The author describes these glands as having the greatest similarity to the large sudorific glands of the axillary cavity.—Dr. Tschermak presented three memoirs, namely, an analysis of the meteoric iron from the desert of Atacama, by Prof. E. Ludwig, as a further demonstration of its similarity to the meteoric iron of Jewell Hill; a notice of the microscopic constitution of the Lavas of Aden, by M. J. Niedzwiedski, who distinguished three species of rocks:—an obsidian containing sanidine, a trachytic lava containing plagiocuase and algite, and a felspathic basalt; and a contribution of his own to the knowledge of salt-deposits, in which he refers especially to the deposit at Stassfurt, which consists of two stages (rock-salt and kieserite-carmallite), the upper of which appears to be wanting in other salt-deposits. The author notices the minerals sylvine, and kainite, which occur scattered in this upper stage at Stassfurt, and mentions their occurrence in the salt-deposit at Kalusy, in Galicia, and partially at Hallstadt, as indications of the upper stages. He also notices the crystalline forms of the kainite and sylvine of Kalusy, and of the kieserite of Hallstadt.—Prof. L. Ditscheiner presented a memoir on some new Talbotian phenomena of interference, describing the phenomena manifested in the spectrum when the object-glass of the telescope is half-covered with crystalline plates of various thickness, whilst two Nicol's prisms are placed before the fissure and before the eye-glass.—The same gentleman also communicated a paper on a simple apparatus for the production of complementary pairs of colours with Brücke's schistoscope, and a notice supplementary to his determinations of wave-lengths, published some years ago.—M. Franz presented a memoir on the theory of simultaneous substitutions in double and triple integrals; and M. Oskar Simony noticed three mathematical problems, one belonging to the integral calculus and the two others to algebraic analysis.—Prof. A. Bauer presented a memoir on some compounds of lead with other metals, in which he showed that lead combines both with palladium and with mercury to form definite chemical compounds, having the formulæ $Pd^3 Pb$ and $Hg^3Pb^2$. The same gentleman communicated a paper by M. J. Stingl, an analysis of rocks and spring deposits of the Teplitz thermal district.

PARIS

**Academie des Sciences, Morales et Politiques**, April 29.—The French Institute is divided into five branches, of which the Académie des Sciences is considered the senior. All the branches meet in the same hall on different days of the week; the meetings of the Académie des Sciences take place on the Monday, and those of the Académie des Sciences Morales on the Saturday; the other sittings are not public, and the three other sections do not issue a special periodical, although they keep regular records. The Académie des Sciences Morales was not less determined than its elder brother to maintain its sittings, and they were not interrupted up to April 29. But the number of the members, which had been five for the sittings of the 15th and the 22nd, had diminished again to only three, which is the smallest for making a quorum. The presidency was given to M. Naudet, the senior member by age, who is close to his 88th year. The Académie des Sciences Morales et Politiques, which had been suppressed by Napoleon I. as being tainted with "ideology," was restored by Louis Philippe after the revolution of 1830, and M. Naudet is one of the original members, and was during many years perpetual secretary, resigning five years ago as being unable to fulfil the duties of his post. M. Leveque, one of the younger members, acted as perpetual secretary, and read over a short account of the proceedings of the last sitting. M. Pellat, the only third member present, sat on the benches, and held up his hand to approve the record. Then the reading of memoirs was proceeded with. A member of the Académie des Beaux Arts, whose name is not given to us, availed himself of the privilege granted to the academicians of every section, and took his seat by his colleague Pellat. The general public was represented by three persons. One of them was M. Mangin, a literary gentleman attached for years to the editorial staff of the *Patrie*. The *Journal Officiel* of the Commune took no notice of the proceedings, which were reported in the Versailles *Officiel*. It is very likely that the Académie des Sciences Morales et Politiques will be extinguished for the time by the Communist rule, and there is only a faint hope that the Académie des Sciences itself will be able to find the three members required for a quorum. But some academicians propose to advise the five academies to hold a general sitting every week, so that the chance may be increased.

## BOOKS RECEIVED

ENGLISH.—The Sub-Tropical Garden: W. Robinson (Murray).—Horses: their National Treatment, &c., by Amateur (Ballière, Tindall, and Cox).—The Builders of Babel: D. McCausland (R. Bentley).—The Meteoric Theory of Saturn's Rings: A. M. Davies (Longmans).—The Physiological Anatomy and Physiology of Man, vol. i. pt. 2: Todd, Bowman, and Beale (Longmans).

## PAMPHLETS RECEIVED

ENGLISH.—Report of the Observing Astronomical Society, Bristol.—Brown on the Throne.—Biology v. Theology, No. 2, by Julian.—Transactions of the Society of Engineers of Scotland.—Memoirs of the Geological Survey of Ireland, Nos. 104, 113, by G. H. Kinahan.—Report of the Rugby School Natural History Society for 1870.—First Annual Report of the Natural History Society of Derry.—A First Catechism of Botany, by John Gibbs.—On the Physics of Arctic Ice, by R. Brown.—Descriptions of some New Oaks, by R. Brown.—On Double Spectra, by W. M. Watts.—Proceedings of the Bath Natural History Field Club, vol. ii., No. 2.—The Gold Fields of Nova Scotia, by A. Heatherington.—Report of the Palestine Exploration Fund.—Science and Revelation, by R. P. Smith.—Materialistic Theories, by the Archbishop of York.—Transactions of the Clifton College Scientific Society.—Address delivered at the Anniversary Meeting of the Geological Society, by J. Prestwich.—On the Physiology and Pathology of the Lower Animals, by Dr. Lauder Lindsay.—The Historical Difficulties of the Old and New Testament, by Rev. G. Rawlinson.—Positivism: a Lecture by Rev. W. Jackson.—Transactions of the Scottish Arboricultural Society for 1870.

AMERICAN AND COLONIAL.—Third Annual Report of the Noxious and Beneficial Insects of the State of Missouri, by C. V. Riley.—Report of the Fruit-Growers' Association of Ontario.—On the Solar Corona, by Prof C. A. Young.—On a Method of Fixing Photography, and Exhibiting the Magnetic Spectra, by Dr. A. M. Mayer.

FOREIGN.—Plaidoyer en faveur de Paris: W. de Fonvielle.

## DIARY

*THURSDAY*, MAY 25.

ROYAL SOCIETY, at 8.30.—On the Temperature of the Earth as Indicated by Observations made during the Construction of the great Tunnel through the Alps: D. T. Ansted, F.R.S.—Some Remarks on the Mechanism of Respiration: F. Le Gros Clark.—On a New Instrument for Recording Minute Variations of Atmospheric Pressure: W. Whitehouse.—Note on the Spectrum of Uranus, and of Comet I., 1871: W. Huggins, F.R.S.
SOCIETY OF ANTIQUARIES, at 8.30.—Ballot for the Election of Fellows.
ROYAL INSTITUTION, at 3.—On Sound: Prof. Tyndall, F.R.S.

*FRIDAY*, MAY 26.

QUEKETT MICROSCOPICAL CLUB, at 8.
ROYAL INSTITUTION, at 9.—On Bishop Berkeley and the Metaphysics of Sensation: Prof. Huxley, F.R.S.

*SATURDAY*, MAY 27.

ROYAL SCHOOL OF MINES, at 8.—Geology: Dr. Cobbold.
ROYAL INSTITUTION, at 3.—On the Instruments Used in Modern Astronomy: J. N. Lockyer, F.R.S.

*MONDAY*, MAY 29.

ANTHROPOLOGICAL INSTITUTE, at 8.—On the Quissama Tribe of Angola: F. G. H. Price.—On the Races of Patagonia: Capt. Musters.—On Chinese Burials: Dr. Eatwell.

*TUESDAY*, MAY 30.

ROYAL INSTITUTION, at 3.—On the Principle of Least Action in Nature: Rev. Prof. Haughton.

*WEDNESDAY*, MAY 31.

SOCIETY OF ARTS, at 8.—On the Employment of Women: Mrs. Grey.

*THURSDAY*, JUNE 1.

LINNEAN SOCIETY, at 3.
CHEMICAL SOCIETY, at 8.—On Ozone: Dr. Debus, F.R.S.

Oliver, R.A."; p. 45, 2nd column, line 16, for "slow enough to exceed" read "slow enough not to exceed"; p. 47, 1st column, line 28, for "December 29" read "December 15"; same column, 2nd line of footnotes, for "1871" read "1870."

THURSDAY, JUNE 1, 1871

## *SCIENCE LECTURES FOR THE PEOPLE*

IT is the great weakness of Science in this country that its professors are rather a mass of incoherent units than an organised body eager to influence others and themselves enjoying the privileges of such influence.

Each one is apt to work too much by himself, and while he often exhibits the most rare skill in discovering truth, he too frequently leaves to others less able than he the task of bringing his labours before the world at large.

Now, while the man of science complains with much justice that his pursuits have not been recognised by the rulers of our country, he ought not to forget that it is likewise his duty to help others, in doing which he will help himself. Whatever be the faults of our rulers, they are eminently sensitive to public opinion; men of science, therefore, have only to prove to the people that they are a useful class in order to have their services recognised. It is really absurd to suppose that one of the most intelligent and useful bodies of men in this country could not obtain their just demands if they set themselves earnestly and unitedly to the task. They have hitherto tried to prove to our rulers that the promotion of science will benefit the country, but have met with only indifferent success; let them supplement their endeavours by convincing our rulers that to promote it will be for their own benefit, and they are sure to succeed. Success, in fine, will not be attained by a policy of isolation, but by leavening the whole mass of the community with the love of science, and when this is done science will rise to its just place in the councils of the nation.

Many of its chiefs have now begun to perceive this, and we are glad to record the success of one of the best organised attempts that have hitherto been made to extend the knowledge and love of science among the working classes. The Science Lectures for the People, lately delivered in Manchester, have been a very great success, whether we regard the numbers who attended them, or the standing of the lecturers, many of whom came from a considerable distance in order to give their information to the people of Manchester. In the cheap and simple form in which these lectures are now published they constitute an eminently readable and instructive book, suitable for all classes. The titles of the lectures are as follows: (1) Coral and Coral Reefs, by Prof. Huxley; (2 and 3) Spectrum Analysis, by Prof. Roscoe and Dr. Huggins; (4) Coal, by Mr. Dawkins; (5) Charles Dickens, by Prof. Ward; (6) The Natural History of Paving Stones, by Prof. Williamson; (7) Temperature and Life of the Deep Sea, by Dr. Carpenter; (8) Formation of Coal Strata, by Mr. Green; (9) The Sun, by Mr. Lockyer. We are much indebted to Dr. Roscoe for arranging this admirable series of lectures, and also to Mr. T. J. P. Jodrell, who has generously defrayed the heavy expenses connected with their publication. Surely, too, the men of Manchester owe a debt of gratitude to Dr. Roscoe and his friends for this intellectual feast, the elements of which are at once so excellent and so varied. It would be presumptuous in any one man to criticise such lectures, but let it be said no more that the chiefs of science are either unable or unwilling to explain to others the discoveries which they themselves have made. They are at last emerging from their seclusion, and recognise their functions as teachers of truth. "A people," says Dr. Roscoe, "whose masses are without knowledge and without tastes for higher things than the mere struggle for existence can come to no good." These are truthful and noble words, and point to what ought to be the future action of men of science. Their author, we learn, is constantly asked about science lectures, and he thinks that if there were the means of sending lecturers to various localities they might be of the greatest value. But to do this a common action is necessary; for it is surely too much to expect that each large town should independently obtain such lecturers, and publish such a volume as that now under review. Indeed, the question is a more important one than at first sight appears; for a national society, formed with the view of diffusing scientific information among the populace of large towns, would be the beginning of a powerful union capable of forcing the claims of science before the Government of the country. Most of the leaders of science are disposed to admit that such a union is desirable, but many of them object to the formation of a new body. For, curiously enough, in matters of administration we are all of us evolutionists, and dislike very much the appearance of a new organisation that has not been developed by insensible degrees from some previous organisation of a humble character and living under other conditions.

Now, such a nucleus exists at Manchester; and as the necessity for an extended union of scientific men is strongly felt, might it not be desirable to extend the Manchester organisation into one for supplying the scientific wants of the whole community?

We make this suggestion with the view of eliciting the general opinion of the scientific public. This is a transitional age, and the social elements around us appear to be ripe for such a transformation.

## *CROOKES'S CHEMICAL ANALYSIS*

*Select Methods in Chemical Analysis (Chiefly Inorganic).* By William Crookes, F.R.S. Illustrated by twenty-two woodcuts. Pp. 468. (London: Longmans and Co.)

THE title of this book fails to convey any adequate idea of its true province. It is not a mere text-book of quantitative analysis after the manner of Fresenius; nor is it, as one might be inclined to suppose, a collection simply of analytical examples designed to illustrate to students the more important determinative methods, as in the well-known and deservedly appreciated "Handbuch" of Wöhler. It aims rather at being a laboratory *Vade-mecum*—a sort of "Chemists' Constant Companion"—designed alike for the teacher and the taught. It presents in a remarkably clear and well-arranged manner a number of thoroughly reliable methods of analysis—some original, others modifications of older and well-known methods—of which the greater portion have been rigidly tested by the author in his own laboratory. Every working chemist must have repeatedly felt the need of a book such as this, and in its publication Mr. Crookes has rendered an important service to the analytical chemistry of the day. The author's connection with the *Chemical News* has doubtless afforded him great and peculiar advantages in the compilation of the materials for his work; indeed, we notice that not a few of the most valuable processes he describes have already appeared in that journal.

Not the least admirable feature in the book (and herein it differs from the ordinary run of quantitative manuals) is the prominence given to methods for detecting and estimating the so-called "rare" metals. Thus we have methods given for the extraction and quantitative separation of lithium, cæsium, and rubidium; cerium, lanthanum, and didymium; glucinum and yttrium, &c. Bunsen's method of analysing platinum ores is also fully described. The discoverer of thallium may justly say that if investigators were more in the habit of looking for the "rare" elements, they would doubtless turn up unexpectedly in many minerals.

But for fear that some "practical man" has already made up his mind about the character of this book, we hasten to say that by far the larger portion of it is devoted to the analytical processes connected with the more important metals and their ores. The sections on iron and copper are particularly complete, all the newest and best methods being minutely described. We may instance Matthiessen's process for the preparation of pure iron, the Mansfield method of copper assay, and Meunier's methods for the immediate analysis of meteoric iron. Under the article "Soda-ash," attention is very properly directed to the absurdity practised in the alkali trade of at one time using the old atomic weight (24) of sodium, and at another the real number in stating the value of soda-compounds, the manufacturer invoicing the strength of his ash in accordance with the basis of calculation which he knows will be employed in reporting on its quality. This custom in many cases amounts to a positive abuse, and is a constant source of vexatious complaint between buyer and seller. The author quotes an instance in which soda-ash of identical quality has been known to be invoiced, part to one customer as containing 48 per cent., part to another as 49 per cent., and part to a third as 50 per cent.; the actual percentage being $48\frac{1}{4}$; the separate consignments being reported also of these different strengths by the analysts in the different towns to which the goods were sent. Inasmuch as soda-ash is usually valued at so much per cent., this amounts to a fraud on the purchaser. Surely the Alkali Manufacturers' Association would consult their real interest by putting an end to such a petty sham as this. But after all this is only on a par with the iniquitous system of "high" and "low" analyses, which is a scandal to the chemistry of the day. *Apropos* of this we would add that those interested in the agitation which has arisen in certain chemical quarters respecting the proper methods for estimating superphosphates and phosphoric acid generally, will find ample details in this work of the reliable processes which have hitherto been devised to that end. Under the head of carbon the method of assaying animal charcoal is described, and this includes an account of Schiebler's calcimeter and the mode of using it; the account of Heinrich's inquiry into the methods for the proximate analysis of coal, which is here introduced, together with the blowpipe assay, constitute one of the most complete things in the book.

In the midst of so much that is excellent it may seem invidious to seek for real or supposed omissions, but we venture to think that a few addenda in a future edition would add to the value of the book. For example, Bunsen's method of preparing pure platinum tetrachloride from scrap platinum, and his simple and expeditious method of recovering this metal from the residues in the process, might be an advantageous addition to the condensed description by Messrs. Teschemacher and Denham Smith of the ordinary method of estimating potash. Without doubt not a few of the errors to which a potash determination made by this method is liable are due to the use of impure platinum. A chapter devoted to the description of useful or improved forms of apparatus, such as the new filter-pump, would also form a valuable addition. Still we must not forget to add that Dr. Carmichael's neat and ingenious method of analysis receives its due share of attention. Nor do we see the reasonableness of making the selection of methods strictly inorganic; for surely the modifications in the process of ultimate analysis introduced by Mr. Warren cannot constitute the sum of the improvements in organic analysis, proximate and ultimate, which have come under the author's notice.

But we have said enough to indicate the character and scope of this work, and imperfect as our sketch is, it will at least serve to show that the book admits of very general application. It will doubtless attain to the popularity which it merits, and the chemical community will thank the author for the worthy contribution he has rendered to its literature.

T. E. THORPE

## *LETTERS TO THE EDITOR*

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### The Sun

IN NATURE for May 18, I find a review by Prof. Newcomb of my book on the Sun, and I beg leave to give some explanations respecting it. It is a pity that Mr. Newcomb has received my book only so lately (about one year after the printing was finished). On this account the criticism which he makes respecting spectrum analysis and the defects of the work on that head is entirely admissible; but this is no fault of the author. Since the book was written sixteen months have elapsed, and during this time great progress has been made in this branch of science, and nobody knows it better than myself, since I find so many things to add to that chapter.

But the criticism seems not so just when he reproaches the work with appearing to undertake to spare the reader the trouble of having recourse to elementary books. At the time of writing, neither of the valuable books which we have now by Roscoe and Schellen were published or had reached me, and the common treatises are very scanty in this respect, so that it was indispensable then, and perhaps even now, to indicate to the general reader the principles of the new science.

In the rapid progress of discovery, a book becomes old very soon, and a reviewer must not forget that printing requires time, and that this work appeared at the very moment of the breaking out of the war, so that it was shut up in Paris for almost another six months.

But a more serious criticism is that which refers to the temperature of the sun. As this is a repetition of M. Zöllner's critique, I beg to give some explanation. It is true that I have assumed that radiation is proportional to temperature without regard to the law of Dulong and Petit, and to the condition of the surface of the body. I did not, however, ignore that law, and I have taken it into account when speaking of Prof. Kirchhoff's discoveries. But here it was quite out of place to refer to it. Indeed, the consequence of this law is that a body may have a very high temperature, and yet radiate but very little; but the law does not state that a body may radiate more than its own temperature allows. When we judge, therefore, of the temperature from the radiation, we certainly commit an error; but so we always judge the temperature from one part of the effect that it is capable of producing; and taking into account the law of Dulong, we should find even a higher temperature in reality in the radiant body, as is the case with the gases.

The conclusion, therefore, to which I have arrived, after Mr. Waterston, is, I think, by no means-excessive, but if there is an objection possible to be made, it is exactly in the direction opposite to that of my reviewer. Certainly this conclusion is at variance with that of M. Zöllner, but it agrees with the results of other observers. This high temperature besides is really a virtual temperature, as it is the amount of radiation received from all the transparent strata of the solar envelope, and this body at the outer shell must certainly be at a lower temperature.

But this does not prove the incorrectness of my proposition that a thermometer dipped inside the solar envelope in contact with the photosphere, would indicate the enormous temperature that Mr. Waterston has found for the first time.

P. A. SECCHI,
Director of the R. College Observatory

---

WILL you permit me to make a few comments on Prof. Newcomb's review of my treatise upon the Sun.

Soon after the work had appeared, I was informed that the account I had given of Mr. Stone's treatment of the transit observations in 1769 was not such as Prof. Newcomb would admit to be just. Knowing how much attention Prof. Newcomb has given to this subject, and his great skill as a mathematician, I was prepared to learn that I had misapprehended some points of the discussion between himself and Mr. Stone. I do not even now know to what specific statements of mine he objects; but he may rest assured that my sole object has been, and is, to give a just account of the matter. My account is in agreement with that given by Sir John Herschel, and by Admiral Manners when the Gold Medal of the Royal Astronomical Society was presented to Mr. Stone. I had also inferred from the nature of the discussions between Mr. Stone and M. Faye, and between Mr. Stone and Prof. Newcomb, that the truth lay much as in my narrative. At any rate, those who were present at the meetings of the Royal Astronomical Society in 1869 and 1870 will scarcely think that I have been led by any personal prejudices to advocate Mr. Stone's cause with undue favour, for Mr. Stone's strictures on some of my papers, and especially on papers relating to the subject of the transits of Venus, were severe even to bitterness.

I believe that Prof. Newcomb's mastery of this special subject is calculated to prevent him from rightly judging my treatment of it. He sees it from too near a stand-point, and therefore unduly enlarged. I am sure that on a careful reconsideration of the matter he will feel that I could not have given a fuller account of it than I have, without spoiling the symmetry of my book. Already a seventh part of the letter-press and more than a third of the appendix (besides three plates and twenty-four diagrams) have been given to the subject of the sun's distance. I do not think that more space could very well have been spared. It remains yet to be proved that a single statement in these pages is inaccurate. I deny confidently that the distortion of the limbs of Venus and Mercury in transit has been *proved* to be the product of insufficient optical power. Irradiation must produce such effects to a greater or less extent; and I renew "gravely" my proposal to measure the effect, whatever its cause or causes, during the next transit. I would remind Prof. Newcomb that every observer at Greenwich noticed the effect (more or less) during the transit of Mercury in 1868. Now the Greenwich instruments are not commonly supposed to be utterly imperfect, nor the Greenwich observers wholly unskilled. Even if we admitted both these points, I should still adhere to my proposal. For I have shown in the Monthly Notices of the Royal Astronomical Society for 1870, that those two observations which differed most widely are brought into perfect agreement when the relative breadth of the black ligament observed in each case is taken into account.

Prof. Newcomb has misunderstood my remarks about the D line in the spectrum. I have never concluded, and certainly I have nowhere stated, that "the light of the sodium lines proper is reduced." What I have pointed out is that where those lines fall on the spectrum of the electric light, and where, therefore, we should expect an increase of light, there seems to result darkness. In p. 118 I am careful to use in one place the word *seem*, in another the word *appear*.

I must remind Prof. Newcomb that three countrymen of his own, Professors Harkness, Curtis, and (quite recently) Young, have supposed, with me, that the theory *has* been maintained, that the light of the corona is due to sunlight directly illuminating our atmosphere, and that they and Mr. Baxendell have opposed that theory as pointedly as I have.

I have, however, to admit that some passages "indicating personal feeling" would have been better—much better—omitted. I should have remembered that the explanation of such personal feeling would be unknown to most of my readers. Those who know that because I advocated opinions respecting the corona, which are now all but universally admitted to be just, I was spoken of as "simply making myself ridiculous," will at least acquit me of responding as rudely as I had been attacked. But the generality of my readers had heard nothing of this and other assaults upon me.

I take this opportunity of noting that Dr. Armstrong, of the London Institution, has shown me that in my account of the researches of Mr. Lockyer and Dr. Frankland I have not done the former justice. Some alterations must be made also in my narrative of the work of Dr. De la Rue and P. Secchi in Spain in 1860; much more of the credit of the results then obtained being due to Dr. De la Rue than I had judged from the narrative in P. Secchi's "Le Soleil." Also the enunciation of the aurora theory of the corona must be assigned to Prof. Norton of America.

RICHARD A. PROCTOR

[With respect to the penultimate paragraph of the above letter, we need only refer to our own comments on two previous letters from Mr. Proctor, under date July 7 and August 4, 1870, which we now reprint. ED.:—"For an accurate though incomplete statement of Dr. Frankland's and Mr. Lockyer's theory of the Corona, we refer our readers to the first number of NATURE. Many of them will not be surprised to find that it is *not* what Mr. Proctor states it to be. Dr. Frankland and Mr. Lockyer, from their laboratory experiments, have shown that the pressure at the base of the chromosphere is small, and they have therefore stated that it is scarcely possible that a very extensive atmosphere lies outside the chromosphere. Mr. Lockyer has shown, moreover, that the height of the chromosphere as seen by the new method probably falls far short of its real height as seen during an eclipse as it was seen by Dr. Gould. A reference to the same number of this journal will also show that Mr. Proctor has misrepresented Dr. Gould's statements, which endorse the idea put forward by Dr. Frankland and Mr. Lockyer. Dr. Gould has expressly stated 'that there were many phenomena which would almost lead to the belief that it was an atmospheric rather than a cosmical phenomenon.' This is an opinion held by Faye and other distinguished astronomers, and Mr. Lockyer has simply shown that should this turn out to be the case, the continuous spectrum observed may be explained. Astronomers did not require Mr. Proctor to tell them what he has recently been enforcing; but, more modest than he, they have been waiting for facts, and Mr. Proctor surely is old enough to see that by attempting to evolve the secrets of the universe, about which the workers speak doubtfully, out of the depths of his moral consciousness, he simply makes himself ridiculous, and spoils much of the good work he is doing in popularising the science."—"Still holding to our comments, we gladly state that they were not written in the spirit in which Mr. Proctor has read them. He is known to all as an astronomical worker, and our objection to his mathematical result was that it was based upon data among which the principal point at issue was accepted as proved."]

---

## Rain after Fire

IN Paris, on Wednesday the 24th inst., after describing the terrible conflagrations, one of the correspondents writes thus:—

"A more lovely day it would be impossible to imagine, a sky of unusual brightness, blue as the clearest ever seen, a sun of surpassing brilliancy even for Paris, scarcely a breath of wind to ruffle the Seine. Such of the great buildings as the spreading conflagration has not reached stand in the clearest relief as they are seen for probably the last time; but in a dozen spots, at both sides of the bridges, sheets of flame and awful volumes of smoke rise to the sky and positively obscure the light of the sun. I am making these notes on the Trocadéro. Close and immediately opposite to me is the Invalides, with its gilded dome shining brightly as ever."

Another as follows:—"As I drive along the green margin of the placid Seine to St. Denis, the spectacle which the capital presents is one never to be forgotten. On its white houses the sun still smiles; he will not refuse his beams spite of the deeds which they illumine. But up through the sunbeams struggle and surge ghastly swart waves and folds and pillars of dense smoke; not one or two, but I reckon them on my fingers till I lose the count."

Twenty-four hours later, the change has come. "The rain is now falling heavily, has been falling heavily all day, and may do something for burning Paris. The sound of artillery has died away;" and from another writer:—"A heavy smoke hangs over Paris and rain is constantly falling."

I believe it has often been remarked that rain generally follows a heavy cannonading, but in this case there is an almost unexampled artillery fire and tremendous conflagration at the same time, accompanied by a sudden and violent change in the atmospheric conditions. From where I am writing we noticed a remarkable change on Thursday morning, and about 2 P.M., after intense closeness and oppression, a rain of a tropical character set in for twelve hours or more. On many occasions in Queensland, I noticed that in seasons of drought, after extensive grass fires, causing intense heat, heavy thunderstorms generally followed.

GEORGE PEARCE SEROCOLD

Rodborough Lodge, Stroud, May 27

## Alleged Daylight Auroras

SEVERAL letters having appeared in recent numbers of NATURE, giving what the writers consider to have been undoubted instances of aurora visible in the daytime, you will, I hope, allow me to state the reasons why I still adhere to the views expressed in my former communication on this subject.*

And, first of all, I must beg your correspondent Mr. Jeremiah not to think me uncourteous if I dismiss at once, as unworthy of serious criticism, the cases which he has dug out of monkish chronicles. It is likely enough that some of these old records may be imaginative descriptions of nocturnal auroras, and as such they are not without interest, but I cannot admit them as competent witnesses on a point of nicety.

A more modern instance adduced by the same correspondent will be found at p. 7 of NATURE for May 4, under the title "Aurora Borealis, seen in the daytime at Canonmills." In this case it is difficult to know what relation is intended between the title and the account which follows. The account describes the clearing off of the clouds in a mass from the north-west, with the production of an "azure arch," the centre of which "reached an elevation of 20°." If I reply to this that the clearing off of clouds is not an aurora, even though they clear off in a compact body from the north-west, leaving an "azure arch," I may be met by the rejoinder that nobody said it was; and yet I strongly suspect that the writer had some confused idea that he was describing an auroral arch, and I am certain that nine out of ten readers, misled by the heading, would take the same view. Stripped of the cloud-phenomena, all that remains of the Canonmills aurora is the appearance of some "very faint perpendicular streaks of a sort of milky light," which could be traced across the segment of blue sky, but were "extremely slight and evanescent." Considering the probability that the observer regarded the cloud-arch as auroral, which it certainly was not, and considering how his judgment would be likely to be biassed by that idea in the interpretation of "extremely slight and evanescent" appearances, I think we may fairly regard this testimony as particularly weak.

In NATURE for Dec. 8, 1870, Mr. Cubitt describes and figures a double auroral arc which he saw in broad daylight on the 25th October. It was "some 25° above the horizon, and almost due east." In my first letter I expressed a doubt of the correctness of this observation on the ground that auroral arcs are not seen in the east. My criticism has since been challenged on two distinct issues. Mr. Jeremiah insists that an auroral arc may *extend* towards the east, and that what Mr. Cubitt saw may have been the eastern extremity of a northern arc. A reference to Mr. Cubitt's letter and illustration will show at once that if what he saw was any part of an arc, it was the apex and not an extremity. But another correspondent, Mr. Reeks, in NATURE of Dec. 29, 1870, in criticising my remark, makes a statement which is more difficult to answer. He affirms positively that in Newfoundland he has many times seen the arch nearly due east, that is, as he explains, with "the extremities pointing N.N.W. and S.S.E." I would suggest, however, in reply to this statement, that in an extensive auroral display there may be fictitious arches, produced by the accidental correspondence of streamers on either side of the "cupola." An arch of this kind may easily extend from N.N.W. to S.S.E., spanning the entire heavens. It is essentially different from the true auroral arc, which, until much stronger evidence to the contrary is adduced, I shall still believe to be invariably transverse to the magnetic meridian. Obviously, Mr. Cubitt's arc was not of the kind that Mr. Reeks describes.

I pass on to a record of daylight aurora, which, more than any other that I have seen, demands a careful investigation. I refer to "An Account of an Aurora Borealis seen in full Sunshine, by the Rev. Henry Ussher, D.D.," said to be taken from the Transactions of the Royal Irish Academy for 1788, and quoted by the Rev. T. W. Webb in NATURE for May 11. Dr. Ussher's account, it must be admitted, is most particular and complete. He describes "whitish rays ascending from every part of the horizon, all tending to the pole of the dipping needle, where, at their union, they formed a small thin and white canopy similar to the luminous one exhibited by an aurora at night." Nothing can be more precise. But is it not also a trifle too wonderful? Surely, if any part of an aurora is to be seen by daylight, it must be just one here and there of the most vivid beams. That the whole phenomenon should be visible at noon-day in all its completeness, just as at night, even to the faint extremities of the streamers in the magnetic zenith, is to my mind so entirely inconceivable that not even the authority of a doctor of divinity can command my faith in it. I can much more easily believe that the sky presented a remarkably symmetrical arrangement of radiating cirri, and that the observer, impressed by the recollection of the aurora of the previous evening, persuaded himself that the "rays coruscated from the horizon to their point of union." The confirmation by "three different people" is of little value unless their observations were independent.

To those who have no clear conception of the difference between cirrus and aurora, the foregoing arguments will be meaningless. Some persons write very loosely of "luminous cirri," and I have even seen described the transformation of cirrus cloud into aurora as it grew dark. I believe that there is no connection between the two phenomena beyond an occasional and purely accidental similarity of form, and that when the two co-exist, the cirrus, instead of being the seat of the aurora or deriving luminosity from it, only serves to obscure its brightness, and, if dense enough, may appear in the form of dark bands across the auroral light, the latter being, as I conceive, at a very much greater elevation.

I adverted in my former letter to the argument that may be drawn from the non-visibility in the day-time of other lights comparable with the aurora, and I will only now add the following suggestion. If the auroras that occur in this country are occasionally visible in daylight, it might be supposed that the much grander displays of the Arctic regions would be habitually visible in daylight. But is the fact so?

GEORGE F. BURDER

* NATURE, vol. iii. p. 126.

## Aurora Australis

TRAVERSING the Indian Ocean 44° S. 65° E., I observed, September 24th, 1870, 4h. till 13h. Greenwich time, a south polar light of great intensity and splendour. After my arrival at Manado (Celebes) I was just writing a few lines about it for the readers of NATURE, with the purpose of knowing whether at the same time an aurora, or at least disturbance of the magnetic needle, had been observed on the northern hemisphere, when I saw in NATURE (Nos. 49, 50, and 51, 1870), several interesting descriptions of aurora borealis observed September 24 in England, &c. I am not aware whether many observations of southern polar lights have been recorded, but I remember that those which Cook described in the year 1773 were coincident with aurora borealis observed in Friesland, and others observed in 1783 at Rio Janeiro were coincident with polar lights in the northern hemisphere. At all events I believe that the attention of men of science is not sufficiently directed to this coincidence of northern and southern polar lights, at least not as much as it deserves in respect to the theory of polar lights at all; and I should be very glad if, in consequence of this notice, authorities would discuss this highly interesting phenomenon in NATURE.

I shall later, according to my diary, accurately describe the display of this splendid aurora australis, and mention the influence which it perhaps or probably had on the abnormal meteorological phenomena, which I observed during the succeeding days.

ADOLF BERNHARD MEYER

Manado (Celebes), January 9

P.S.—I beg to contribute to the records in NATURE of earthquakes, &c., over the whole globe:—

November 20, 1870, afternoon, an at first vertical, then horizontal, rather heavy shock at Manado.

January 28, 1871, 4h., a slight, very local shock in a part of Manado.

Manado (Celebes), March 5

---

### The Eclipse Photographs

As an ardent and not inexperienced votary of photography, I am fully alive to the value of photographic evidence, and regard with enthusiasm each fresh victory which photography achieves, yet I cannot myself look with any very great degree of satisfaction upon the photographs of the late solar eclipse either as examples of photography or as evidence contributing to our knowledge of solar physics. In saying this I make no reflection whatever upon the ability or efforts of those by whom the pictures were produced. On the contrary, I am aware that when these pictures were taken the first grand requisite of photographic success—a clear view of the object to be represented—was scarcely to be obtained. Briefly; from a technical point of view, the pictures are of but indifferent definition, and the identity of the coronal rifts in the Cadiz and Syracuse photographs not satisfactorily conclusive, in addition to which in the picture by the American observers, the so-called coronal light extends a long way over the lunar disc, which seems to me to preclude the possibility of its being other than a phenomenon of terrestrial meteorology. A few weeks ago, when the sky appeared almost cloudless, I observed a beautiful lunar halo, very much resembling the so-called corona, which I apprehend no one would attribute to anything but atmospheric moisture. Why, then, in the instance of a sky burdened with innumerable clouds, should we attribute the halo of light surrounding the solar disc to other than atmospheric causes, even though there should be something which might be mistaken for a coincidence in two distinct photographs of one or other of the rifts which were characteristic of that halo?

Manchester, May 26 D. WINSTANLEY

### Eozöon Canadense

PERMIT me to state that the presumed "important bearing" on the so-called "Eozöon Canadense," of the principal fact noticed in the communication entitled Palæozoic Crinoids, which appears in NATURE of May 25th, is discussed in a paper by Dr. Rowney and myself, contained in the forthcoming number of the Proceedings of the Royal Irish Academy, now on the eve of publication. The paper referred to is a reply to the articles by Drs. Dawson and Sterry Hunt, which appeared in the last (second) number of the Proceedings.

Glenoir, near Galway, May 29 WILLIAM KING

---

WITHOUT going into the vexed question as to whether Eozöon Canadense is or is not of organic origin, I may be permitted to express some surprise at the new, and, to say the least of it, startling theory broached by Mr. Perry in last week's NATURE, of the vaporous formation of a certain limestone. The only facts brought forward in support of this view are, its occupying pockets, its foliations, and its conformation with irregularities of surface in the pre-existing rock. All these could be as well accounted for on the supposition of deposition from aqueous solution, without doing violence to the fact that carbonate of lime is not volatile at any temperature. E. T. H.

## *THE INEQUALITIES OF THE MOON'S MOTION*

THE following is an abstract of the method of computing the inequalities in the motion of the moon which are due to the action of the planets, proposed by Prof. Newcomb in the paper presented to the Academy of Sciences of Paris on April 3.

When we consider the movements of the sun, moon, and earth, under the sole influence of their mutual attraction, the position of each of these three bodies in space will be given in terms of eighteen arbitrary constants, and of the time. The problems of the relative movement of the moon around the earth, and of the movement of the centre of gravity of the earth and moon around the sun, have been solved with a degree of approximation sufficient at least for the purposes of astronomy. Thus, we have the co-ordinates of any two bodies relatively to a third, or relatively to the centre of gravity of the system, in terms of twelve elements and of the time. It only remains to add the expressions for the uniform movement of the centre of gravity in a straight line, to have the general expressions for the co-ordinates of each body.

We have then only to consider the action of the planet to vary the eighteen elements according to the method of Lagrange, to have the movements of each of the three bodies under the influence of the attraction of the planet. Unfortunately, the expressions thus obtained are at first extremely complicated. We have to compute a coefficient corresponding to each combination of the elements taken two and two. The entire number of the coefficients is, therefore, $\frac{17 \times 18}{2} = 153$. And each coefficient contains eighteen products of the partial differential coefficients of the co-ordinates of the three bodies relatively to the elements. These latter differential coefficients are so complex that the formation of any one product would be a considerable labour. The direct formation of the coefficients required is therefore impossible. The paper in question is principally devoted to an explanation of the simplifications which may be introduced into the problem.

It is first shown that all the coefficients formed by combining any one of the six elements which fix the position of the centre of gravity with any of the twelve elements of the relative motion, vanish identically, while the combinations of those six elements with each other give only the principle of the conservation of the centre of gravity. This leaves only sixty-six combinations. It is then shown that, if the elements are divided into two classes, the first class being the mean longitudes, the longitudes of the perigees, and the longitudes of the nodes of the sun and moon, and the second the mean distances, eccentricities, and inclinations, the coefficients vanish whenever the two elements combined belong to the same class. The number of coefficients is thus reduced to thirty-six, and they are simply the differential coefficients of six functions of the elements of the second class. These functions are formed an extremely simple process when we have the rectangular co-ordinates expressed as functions of the elements and the time.

The remainder of the process is simply one of the development of a very complex perturbative function, and is of no especial interest.

---

## *THE HELIOTYPE PROCESS*

AT one of the recent *soirées* of the Royal Society given by General Sabine at Burlington House, Messrs. Edwards and Kidd exhibited at work the new heliotype process, whereby photographic pictures can be very rapidly copied in by the aid of the printing-press. The process is very inexpensive, and so rapid that if one of the pages of NATURE were sent to the works, it could be copied by photography, and within two or three hours after receipt, pictures could be turned out as fast as the printing-press could work them off. A few days ago I went over the works to examine the process, and a gentleman, who brought an engraving to the proprietors just as I arrived, saw the press printing off very good copies before I left, the interval being about two hours. The works are at some distance out of London, free from the smoke and dust.

The following is an outline of the history of the process:—Mr. Mungo-Ponton, of Clifton, discovered some years ago that if a dried film of gelatine and bichromate of potash be exposed to light, the film is afterwards insoluble in warm water. M. Poitevin afterwards noticed that where light had acted upon such a film, it took greasy ink just like a lithographic stone, whereas those parts on which light had not acted, absorbed water. In the attempt to produce pictures on this principle, he poured a mixture of warm gelatine and bichromate of potash over a lithographic stone, or plate of metal, and when the film was dry he exposed it to light under a negative. Where the light had acted the film became waterproof, and where it had not acted the gelatine swelled up like a sponge. This surface of hills and valleys prevented him from getting good pictures when he attempted to print from it on the lithographic principle.

Messrs. Tesse du Motay and Marechal tried the process just mentioned, and by carefully selecting their subjects, choosing those only in which there was little contrast of light and shade, they reduced the elevations and depressions on the surface of the film to a minimum, and thus obtained some very fair pictures, but after a very few had been printed off, the gelatine printing surface broke up. The next man who took up the process was Albert of Munich. Before his time, whenever a sufficiently thick film of gelatine to stand wear and tear had been used, the elevations and depressions were so great that the film could not be inked. Albert took a plate of glass about half an inch thick, covered it with a thick coating of bichromated gelatine, and after it was dry exposed it all over to light to make it insoluble. Afterwards he covered the surface thus prepared with a very thin coating of sensitive gelatine, on which the picture was printed from the negative. By this process he obtained some exceedingly beautiful and perfect pictures, and he is producing them by this plan at the present time.

Mr. Ernest Edwards took up the process at this point about a year ago. He made a thick leathery film at the outset by adding alum to the warm gelatine solution. He found that films so prepared still retained the lithographic-stone-like property; they will scarcely swell up in water at all. They are insoluble, and they resist the wear and tear of the printing-press very satisfactorily.

The working details of the heliotype process are as follows. The films are prepared upon large sheets of accurately levelled finely ground glass, technically known as "greyed glass"; about 22 inches by 18 inches is a convenient size. The surface of the glass is first polished by means of a clean piece of rag, with a little solution of wax in ether; the exceedingly thin film of wax thus left upon the glass permits the dried gelatine film to come off easily. The glass plates after being waxed are levelled, and then a measured quantity of a warm mixture of gelatine, bichromate of potash, chrome alum, and water, is poured upon each plate from a jug with a piece of muslin tied over its mouth. The temperature of the solution in the jug is about 150° Fahrenheit, and after it is poured over the plate it sets in a very few minutes, but it requires a much longer time to dry. Curiously enough, until it is dry it is not sensitive to light; this fact was found out accidentally, for at first this part of the operations was carefully carried on in yellow light.

After the film has set, the plates are taken into a dark room to dry. If any of the fumes given off by burning gas escape into this room, they act upon the film just as light would do, therefore although a gas stove is used to dry the plates, the products of combustion are very carefully carried off. The gas stove used in the works was invented by Mr. George, a dancing master at Kilburn. It is a closed iron cylinder, into which air is admitted by one pipe coming from outside the house, and the products of combustion are carried off by another. A third iron air pipe enters the bottom of the stove, curves round its sides in a spiral, and then emerges through the iron plate forming the top. Air from outside the house is warmed in this spiral, after which it escapes into the drying-room, which is kept at a temperature of from 90° to 120°. At a temperature of 90° the films take about twenty-four hours to dry. As they dry they contract slightly, and thus separate themselves from the glass. These dried films are technically termed "skins"; they are of an orange colour, and about one-tenth of an inch thick. The picture is printed on them from a negative, and a faintly visible image is formed; when this image is fully out the films are removed to a dark room.

Here each skin is floated in water, and caught upon the surface of a thick plate of zinc; a flat piece of wood, edged with india-rubber is then scraped with considerable pressure over the film, so as to squeeze out all the water between the skin and the zinc. As the film still continues to absorb moisture, it is thus fixed to the zinc with the whole pressure of the atmosphere. After this the zinc with its attached film is left for half-an-hour at least in a large vessel of water, for the superfluous bichromate of potash to soak out, and then the film is no longer sensitive to light. If the film be thus soaked for several hours, or even days, it does not suffer.

The film, upon its zinc plate, is now ready for the printing press. It is damped between each impression, just like a lithographic stone. Then it is inked, and the best roller for the purpose is found to be one made of india-rubber, backed inside with "india-rubber sponge" to give additional softness. Ordinary lithographic ink is used. If stiff lithographic ink be employed, the surface will only "bite" where light has acted most; if thin ink be used, the leathery surface will only bite in the half tones of the picture; hence each picture is produced by at least two inkings, and advantage is taken of this circumstance to use two colours, and get warm shades in the half tones. It is very interesting to see the picture gradually growing under the inking process. By this method double-printing is executed with a single pull at the press. Ordinary Albion hand printing presses are used.

The negatives worked from in this process have to be "reversed," and they may either be reversed at the time they are taken, or afterwards. In the former case, instead of the lens of the camera being pointed direct at the object or picture to be photographed, a mirror, silvered on its front surface, is interposed at an angle of 45°. Another method of reversal is to take an ordinary unvarnished negative, and coat it either with a solution of india-rubber, or a solution of gelatine and alum. When the film is dry the plate is accurately levelled; it is then coated with a pool of collodion as thick as it will hold, and this collodion is then allowed to dry. Next the film is cut through with a penknife near the edges of the picture, and the plate is placed in water, where the negative soon floats off the glass, after which it is dried between blotting paper. The flexible negatives thus obtained are very durable, except when bad india-rubber is used in reversing them.

When a batch of pictures has been printed from any particular skin, the film is taken off the zinc plate, and put away until wanted again. Mr. Edwards says the skins will stand a vast amount of wear and tear, and he showed me one from which he said 1,500 pictures had been printed, the last impression being as good as the first, and the skin ready for further work if necessary.

By this process many of Mr. Nasmyth's lunar pictures have been copied, and while on the premises I saw some work then being executed for Mr. Ruskin, and others known in the world of art and science. Bones, and some descriptions of anatomical specimens, are very easily photographed and printed by this process, which is also well adapted for landscapes and architectural subjects. If it be desired, a glaze is given to the finished prints in a very simple way. A little powdered magnesia is sprinkled over the surface of the print, and it is then placed on a smooth board and rubbed with a pad of flannel. Magnesia belongs to the soapstone family, and when used in this way it very readily gives a surface polish to paper.

WILLIAM H. HARRISON

## *PARIS NEWS*

FOR some time past the Académie des Inscriptions et Belles Lettres has held no regular sitting, almost all the members being refugees in Versailles or elsewhere. A special commission has been given to M. Rénan, one of its most distinguished members, to inspect the ruins of the Parisian monuments which have been destroyed by the Communists. M. Rénan, before publishing his last books on religious matters, had been sent to Mesopotamia to do the same work as Mr. Layard. Private letters received from the distinguished commissioner have been read before a group of members of different academical bodies at Versailles, sitting almost in an official capacity as the Academy for Inscriptions and Belles Lettres. It was stated that the Louvre buildings had escaped, and the bulk of artistic works will be saved from the conflagration. But the private Imperial Library in the old building of the Ministry of State has been destroyed. The value of this collection was chiefly historical, a number of the volumes being of special value from the fact of their having been presented to the several Kings and Emperors of France during the last three centuries. There were also some manuscripts of value, and collections of drawings for the study of art in the Museum. It was intended to open it shortly as a special art library for the use of students at the Louvre. The National Library, formed by Richelieu, was not burned down as has been rumoured; the building has entirely escaped. But it appears that steps had been taken by the insurgents to destroy it like the Serapion was at Alexandria when Omar took possession of the city. The Luxembourg buildings and Museum were saved only by the prompt exertions of the troops, when the insurgents were actually setting fire to them. The Luxembourg holds within its precincts a valuable library, where have been collected parliamentary documents from every nation and of every period. It was said to be the most valuable in the world in this respect. The collection of pictures is the richest in the world for works of living painters belonging to the French school. Courbet, the member of the Commune, had not been admitted to this, esteemed the highest honour by French artists. The Sorbonne is almost entirely saved, the walls only having been pierced by gun-shot or shells. The collections are most valuable, and very serviceable for students. We have no special news from Sainte Geneviève, a library largely used for law purposes on the Place du Panthéon; but it is supposed that the library is safe, as the insurgents were prevented from exploding it, though an immense quantity of powder had been deposited in the cellars, and it was used as an arsenal during the whole of both sieges. The Institute is safe, although it appears steps had been taken for its destruction. The Mazarine Library close to it is most valuable for works of the 17th and 18th century, as well as the library of the Arsenal. But according to every probability this last establishment will be entirely lost, owing to the vicinity of the *Grénier d'abondance*, a place where an immense number of goods were collected, and which was ignited. A commission of the Academy of Sciences will be issued to study the different processes used by the insurgents for burning the Tuileries, Palais Royal, &c. Hay, soaked with petroleum, appears to have been very often resorted to, as well as canisters full of the same substance. In some instances petroleum had been poured from outside into the cellars, and an ignited match thrown into the impregnated air. The stories of firemen throwing petroleum from fire-engines are, we are happy to say, unfounded.

## *DREDGING OF THE GULF STREAM*

WE are much gratified to learn from *Harper's Weekly* that preparations are now being made, under the direction of the Superintendent of the Coast Survey, for a very complete and thorough investigation of the deep-sea bottom, and especially of the channel of the Gulf Stream off the eastern coast of America, with an examination also of the Straits of Magellan and of a part of the Pacific Ocean. A steamer is now being built, which will shortly be launched, with the special object of continuing the deep-sea dredgings which, under the direction of Count Pourtalès, have given the Survey so much reputation.

It is expected that the arrangements will be completed by the end of August, and that the whole matter will be specially in charge of Prof. Agassiz, assisted by Count Pourtalès, whose experience eminently qualifies him for the post.

The plan of operations is, first, to run a line of dredging across the Gulf Stream between New York and Bermuda, and, if necessary, far enough eastward to completely cross the Gulf Stream current. The course will be thence to Trinidad, where a careful examination will be entered into to ascertain whether there is any difference in the deep-sea fauna of the adjacent waters and that of the coast of Florida. The expedition will then probably proceed to San Paulo for the purpose of examining the deepest known portion of the Atlantic, reaching to, at least, five thousand fathoms. From San Paulo it will again cut across the Brazilian current, and after possibly spending some time on the coast between Buenos Ayres and the Straits of Magellan will proceed by a zigzag course to the Falkland Islands, in the neighbourhood of which the expedition will remain for some time, for the purpose of solving certain important problems relating to both the deep-sea fauna and to that of the coast. It is next proposed to spend, at least, a month in the Straits of Magellan during the summer season of that portion of the globe. The work at the Straits being completed, the party expect to pass up along the western coast of Chili, next to the island of Juan Fernandez, and thence across to Callao. From this point the course will be to the Gallapagos, and thence across the Chilian current to some point on the west coast of Mexico—possibly to Mazatlan. The Revillagigedo Islands will next be visited, whence the party will proceed to San Francisco.

The entire exploration will probably occupy ten months, and bids fair to be the most important attempt ever made at determining the character of the fauna of the deep seas. The experience gained in all the former American and foreign expeditions of this kind will be freely used on this occasion; and no pains will be spared in the way of outfit to render the whole undertaking an entire success.

The fact that this expedition is under the direction of the Coast Survey is sufficient guarantee that nothing will be neglected to secure satisfactory results in the way of investigations upon the physics of the ocean, as well as its natural history, as it is intended to make use of the most approved apparatus for the determination of depths, temperatures, specific gravity, and chemical composition of the waters, &c.

## THE SPECTRUM OF URANUS *

IN the paper "On the Spectra of some of the Fixed Stars," † presented conjointly by Dr. Miller and myself to the Royal Society in 1864, we gave the results of our observations of the spectra of the planets Venus, Mars, Jupiter, and Saturn; but we found the light from Uranus and Neptune too faint to be satisfactorily examined with the spectroscope.

By means of the equatorial refractor of 15 inches aperture, by Messrs. Grubb and Son, recently placed in my hands by the Royal Society, I have succeeded in making the observations described in this paper of the remarkable spectrum afforded by the light of the planet Uranus.

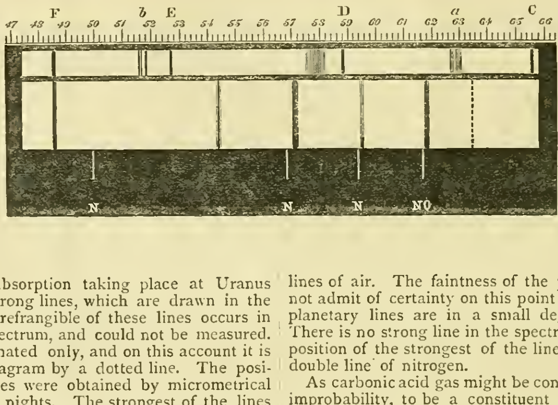
It should be stated that the spectrum of Uranus was observed by Father Secchi in 1869.‡ He says, "Le jaune y fait complétement défaut. Dans le vert et dans le bleu il y a deux raies très larges et très noires." He represents the band in the blue as less refrangible than F, and the one in the green as near E.

The spectrum of Uranus, as it appears in my instrument, is represented in the accompanying diagram. The narrow spectrum placed above that of Uranus gives the relative positions of the principal solar lines, and of the two strongest absorption-bands produced by our atmosphere, namely, the group of lines a little more refrangible than D, and the group which occurs about midway from C to D. The scale placed above gives wave-lengths in millionths of a millimetre.

The spectrum of Uranus is continuous, without any part being wanting, as far as the feebleness of its light permits it to be traced, which is from C to about G.

On account of the small amount of light received from this planet, I was not able to use a slit sufficiently narrow to bring out the Fraunhofer lines. The positions of the bands produced by planetary absorption, which are broad and strong in comparison with the solar lines, were determined by the micrometer and by direct comparison with the spectra of terrestrial substances.

The spectroscope was furnished with one prism of dense flint-glass, having a refracting angle of 60°, an observing telescope magnifying $5\frac{1}{2}$ diameters, and a collimator of 5 inches focal length. A cylindrical lens was used to increase the breadth of the spectrum.



The remarkable absorption taking place at Uranus shows itself in six strong lines, which are drawn in the diagram. The least refrangible of these lines occurs in a faint part of the spectrum, and could not be measured. Its position was estimated only, and on this account it is represented in the diagram by a dotted line. The positions of the other lines were obtained by micrometrical measures on different nights. The strongest of the lines is that which has a wave length of about 544 millionths of a millimetre. The band at 572 of the scale is nearly as broad but not so dark; the one a little less refrangible than D is narrower than the others.

The measures taken of the most refrangible band showed that it was at, or very near, the position of F in the solar spectrum. The light from a tube containing rarefied hydrogen, rendered luminous by the induction-spark, was then compared directly with that of Uranus. The band in the planet's spectrum appeared to be coincident with the bright line of hydrogen.

Three of the bands were shown by the micrometer not to differ greatly in position from some of the bright lines of the spectrum of air. A direct comparison was made when the principal bright lines were found to have the positions, relatively to the lines of planetary absorption, which are shown in the diagram. The band which has a wave-length of about 572 millionths of a millimetre is less refrangible than the double line of nitrogen which occurs near it. The two planetary bands at 595 and 618 of the scale appeared very nearly coincident with bright lines of air. The faintness of the planet's spectrum did not admit of certainty on this point; I suspected that the planetary lines are in a small degree less refrangible. There is no strong line in the spectrum of Uranus in the position of the strongest of the lines of air, namely, the double line of nitrogen.

As carbonic acid gas might be considered, without much improbability, to be a constituent of the atmosphere of Uranus, I took measures with the same spectroscope of the principal group of bright lines which present themselves when the induction-spark is passed through this gas. The result was to show that the bands of Uranus cannot be ascribed to the absorption of this gas.

There is no absorption-band at the position of the line of sodium. It will be seen by a reference to the diagram that there are no lines in the spectrum of Uranus at the positions of the principal groups produced by the absorption of the earth's atmosphere.

WILLIAM HUGGINS

## NOTES

WE understand that the contributors to the next volume of the *Zoological Record* are as follows:—Mammalia, Reptilia, and Pisces, Dr. Albert Günther, F.R.S.; Aves, Mr. H. E. Dresser, F.Z.S., and Mr. R. B. Sharpe, F.L.S.; Mollusca, Molluscoidea, and Crustacea, Dr. Edward von Martens, F.M.Z.S.; Arachnida and Myriapoda, Mr. O. Pickard-Cambridge, C.M.Z.S.; Insecta generally and Coleoptera, Mr. E. C. Rye; Lepidoptera, Mr. W. F. Kirby; Diptera, G. A. Verrall; Neuroptera and Orthoptera, Mr. M'Lachlan; Rhynchota, Mr. John Scott; Vermes, Mr. E. Ray Lankester; Echinodermata, Cœlenterata, and Protozoa, Prof. Traquair. Respecting the work and the association which has been formed to prosecute it, we spoke at some length a few weeks ago, and will only remind our readers that the secretary of the Zoological Record Association is Mr. H. T. Stainton, F.R.S., to whom all applications for further information on the subject should be addressed.

We are glad to see that the higher examination for women at the University of London has this year been successfully taken by one candidate in the department of Natural Philosophy and Chemistry. She is from the Cheltenham Ladies' College.

We have received the Anniversary Address of Sir Roderick Murchison, as retiring President of the Royal Geographical Society, dealing with the history of geographical progress during the past year.

A letter has been received from Dr. Hooker from Mogadore, bringing down the narrative of his journey to April 26. The party had visited Ceuta, Gibraltar, and Casa Blanca, but had found no very striking novelties since the last report.

Mr. Thomas Moore, the Curator of the Chelsea Botanic Gardens, is now delivering in the gardens a course of six lectures on Botany for medical students.

A scientific society has been formed at Middletown, Connecticut, and Dr. John Johnson, of the university, elected president, Prof. Rice, corresponding secretary, and Prof. John M. Van Vleck, treasurer.

Prof. Newton of Cambridge is engaged upon a revised edition of Yarrell's well-known "History of British Birds," which has long been justly regarded as the standard work on the ornithology of these islands. It is now more than thirty years ago since the late Mr. Yarrell began the first edition of this book, and as the literature of the subject has in that time been doubled if not trebled, the editor will have enough to do to bring the work up to the level of the information of the present day. It is announced that the mode of publication will be in monthly numbers, the first of which may be expected in the course of a few days.

At a recent meeting of the Asiatic Society of Bengal, Col. Strachey made a communication to the effect that the Government of India have lately resolved to place four lacs of rupees in deposit, which sum should be available for completing the new Museum building at Calcutta. He regretted the delay which has been caused in the construction of the building, and stated that it was greatly due to the financial difficulty in which the Government of India found themselves a short time ago. Col. Strachey mentioned that the original approximate estimate amounted to about three and a half lacs of rupees. This sum had been sanctioned by Government, and the work for the new building was commenced. Subsequently the regular estimate came up, and it amounted to about seven lacs. After about four lacs had already been spent, a revised estimate was called for, and this rose to about ten lacs. It was, therefore, not surprising that the Government stepped in and inquired into the whole matter carefully, and this caused such a delay that it became impossible to complete the Museum within the appointed time, 23rd March, 1871. However, Col. Strachey hoped that the present action taken by Government in the matter would bring the building to its desired completion at as early a date as possible.

At Plymouth, one of the largest provincial centres of science instruction in connection with the South Kensington department, this year's examinations have just been brought to a close, the arrangements having been carried out under the direction of the School Board for the town, in compliance with the request of the department in their circular of March 7th In accordance with it the School Board appointed their clerk, Mr. Henry Soltan, as the examination secretary, and the assistants were selected principally from the secretaries of the various Science and Art Schools of the town. These gentlemen have been occupied every evening during last month, up to Monday last (22nd), in superintending the conduct of the various examinations which have all been held at the Public Free School, and which have comprised no less than twenty-two subjects in science, besides the four branches of art study, of the second grade, the examinations in which in previous years have been held in March. The details show that a total of 846 papers has been worked, 257 in Art and 589 in Science. The largest numbers of papers in any special subjects were Physical Geography 151, and Freehand Drawing, and Mathematics, stages 1, 2, and 3, each 112.

A considerable portion of modern astronomical literature appears to be designed to bring science into contempt. A paper has been circulated, containing an "extract from a letter addressed to John Hampden, Esq., Chippenham, Wilts," attributing the death of Sir John Herschel to "the chagrin he has for some time evinced at the severe attacks recently made on the astronomical theories with which his name has been so long and prominently associated." It is only the most uncleanly of animals that howl around the bodies of the dead; we should have thought that any "gentleman" receiving such a letter would have consigned it at once to the fire instead of sowing it broadcast over the land.

The Scotch papers report a mirage at the mouth of the Forth on Sunday the 21st inst. The weather was remarkably warm, and in the afternoon there was a dull deceptive haze. The sea presented almost the appearance of a mirror, and the vessels upon it seemed to have a double reflection from the sea and the background beyond. At one time the masts and rigging seemed elongated to four or five times their natural length, and then in the course of a few minutes they were reduced so as to be scarcely visible. At other times the vessels appeared to be sailing double—one ship in sea and one in air. Extraordinary appearances were assumed by the May Island, which rose and fell and changed to all manner of shapes in the course of a few minutes. At one time it appeared a perpendicular wall, rising to the height of several hundred feet, and shortly afterwards it appeared to be flat on the surface of the sea All the other objects which came within the range of the refraction underwent similar changes, and the illusion lasted with varying features for several hours.

Dr. Marshall Hall has contributed to the *Devizes Gazette* a letter, calling attention to the importance, at the present time, of establishing local centres for instruction of farmers in agricultural chemistry and sciences connected therewith. In connection with the circular of Mr. Little's, printed last week, we hope the subject is now at length attracting the attention it deserves.

The *Engineer* of last week contains a drawing of the machinery used in the casting of the Vendôme Column, lately thrown down by the Paris Communists.

At Derajat, in India, a supply of water has been obtained by artesian boring at the depth of 400 feet.

"To the Rt. Hon. Earl Granville, K.G., H.M.'s Secretary of State for Foreign Affairs," &c., &c. Suppose there were addressed to his Lordship a rather pressing letter from the Anthropological Society of Honolulu or Bolivia, requesting him to furnish male and female skulls of each of the tribes of Irish, Welsh, Erse, Lowlanders, Danes, English, &c., inhabiting these islands; a special application made for skulls from St. Giles's, and the Liberties of Dublin; skulls of extinct tribes earnestly sought; and his Lordship expected to supply a consignment of 200 or 300 skulls, besides their flint and other implements, tobacco pipes, pottery, and so forth, ancient and modern. What would be the commotion here, and what the comments in our newspapers! and yet such a request has been made by the zealous Secretary of the Smithsonian Institute to the Government of the United States of Colombia, and he is likely to prefer the same hint here, now that the *Alabama* claims are in happy way of settlement. The Colombian Government has taken the matter coolly, and published the application in the *Gaceta Oficial*, calling to it the attention of the local authorities. How the local authorities will persuade the local Indians to hand over the solicited pair of recent male and female skulls, appears rather doubtful and dangerous, as will be the polite request of the resident magistrate, or other authority, to the tribes of Achill Island or Connemara. Some of the Indian tribes in Colombia are much more likely to place the skulls of the Government or their emissaries in their own local museums.

It is stated from India that a number of experiments have shown that the madar plant, when mixed with opium, is an excellent substitute for ipecacuanha in dysentery.

The Kava or Ava is well known as a favourite intoxicating drink of the South Sea Islanders. The extraordinary and disgusting mode of preparing this beverage, by chewing the root, ejecting the saliva into a bowl and fermenting it, has been the means of giving it a greater amount of publicity than it would have otherwise obtained. Many stories have been told about its uses and effects. It appears that at one time before the intercourse with foreigners the only intoxicating drink known to the natives was the water in which the roots of the kava plant (*Macropiper methysticum*) had been macerated, and this was comparatively little used, except as a medicine, as it was supposed to prevent corpulence. Since the introduction of foreign spirits into the islands the use of kava has much diminished, though intoxication is none the less common, and with many of the natives kava is still much appreciated, and even many of the lower classes of white people are confirmed kava-drinkers. It is said that, if drunk in excessive quantities, it produces numerous cutaneous diseases, but if taken in moderation has no ill effect upon the system. A drink, prepared in a similar filthy manner, is the South American Piwarri, which is produced by first chewing a sufficient quantity of cakes made of cassava meal (*Manihot utilissima*), and then putting the masticated material into a bowl with water, where it is left to ferment for some days, and finally boiled.

So much has been said about the adulteration of butter and the frequent substitute of a compound for that useful article, in which no trace of true butter exists, that the introduction of Australian butter into this country is a matter not only of commercial importance, but must also give general satisfaction to all classes. The butter is of good quality, and arrives after its lengthened voyage in good condition. It is produced in different parts of the Australian colony, so that we may hope to receive large and continuous supplies. It is a fact worth noting that whereas at one time large supplies of butter were exported from Cork into the colonies, one of these same colonies is now sending its produce to us.

The cultivation of the beet in England for the manufacture of sugar seems in a fair way of at last becoming a *fait accompli*. Besides the works already in operation at Lavenham in Suffolk, Buscote in Berkshire, and other places, a new beetroot sugar company has just been formed under good prospects at Sandwich Kent.

## PROF. WYVILLE THOMSON'S INTRODUCTORY LECTURE AT EDINBURGH UNIVERSITY

(*Continued from page* 76)

The distinction between inorganic bodies and organised beings instinct with life seems clear enough. Between the animal and the vegetable kingdoms it is impossible to draw a definite line. It is to solve this difficulty that Ernst Haeckel has proposed his fourth kingdom, and we have now to consider whether or not the solution is satisfactory or legitimate.

Plants have the power of secreting and storing in organs which are specially fitted for its reception, usually the leaves, a substance called "chlorophyll," by means of which, acting probably as a ferment or in some way which is not yet thoroughly understood, the plant can, under the influence of light, absorb carbonic acid from the atmosphere, decompose it, and, while the carbon is in the nascent condition, combine it with the elements of water, or with the elements of water and of ammonia, reduced likewise to the nascent state by the same agency. The plant thus gains from the inorganic world, from the water contained in the soil and the inorganic substances dissolved in it, and from the atmosphere, various elementary substances, chiefly, however, oxygen, hydrogen, carbon, and nitrogen, and these it recombines into ternary, quaternary, and still more complex organic compounds.

The operations which take place within the chlorophyll cell of the plant are briefly these:—

1. Water, $H_2O$, which has been absorbed by the root of the plant from the soil, and pumped up by endosmosis or capillary attraction to the leaf, is decomposed, and its elements are reduced to the nascent condition.

2. Carbonic acid, $CO_2$, which exists as a gas in the atmosphere to the amount of about 1 vol. to 2,500 of air, and which is consequently in contact with the surface of the leaves, is absorbed, and its elements are reduced to the nascent state.

3. Ammonia, $NH_3$, an abundant product of the decomposition of organised bodies, which exists in small quantities in the water of the soil, and much more abundantly as a gas in the atmosphere (in the proportion of about 1 vol. to 1,000,000 of air), is decomposed, and its elements are reduced to the nascent state.

4. The nascent carbon of the carbonic acid is combined with the elements of water in varying proportions, and by the re-combination of the elements of these binary compounds, ternary compounds; for example, cellulose, starch, dextrine, and gum, which have all apparently the same composition, $C_6H_{10}O_5$, or some multiple of these proportions; sucrose or cane sugar $C_{12}H_{22}O_{11}$; dextrose and levulose, grape and fruit sugar, $C_6H_{12}O_6$; the glucosides, such as tannine, $C_{27}H_{22}O_{17}$; the fixed and essential oils, some of which latter, however, as turpentine and its isomers, are binary, $C_{10}H_{16}$; and many like substances, are produced.

5. The nascent nitrogen of the ammonia, sulphur, which is probably derived from a trace of sulphuretted hydrogen in the atmosphere; phosphorus, derived from the decomposition of certain minerals contained in the soil or of vegetable or animal matter, are united to form quarternary, quinary, and more complex compounds, such as vegetable albumen, fibrin, casein, and protoplasm.

| | Albumen. | Casein. | Fibrin. |
|---|---|---|---|
| Carbon | 53·5 | 53·8 | 52·7 |
| Hydrogen | 7·0 | 7·2 | 6·9 |
| Nitrogen | 15·5 | 15·6 | 15·4 |
| Oxygen | 22·0 | 22·5 | 23·5 |
| Sulphur | 1·6 | 0·9 | 1·2 |
| Phosphorus | 0·4 | 0·0 | 0·3 |

and the vegetable alkaloids, for example, nicotine $C_{10}H_{14}N_2$, morphine $C_{17}H_{19}NO_3 + H_2O$, and narcotine $C_{22}H_{23}NO_7$. Under the guidance of the vital property, and through the medium of a peculiar substance called protoplasm, whose exact composition it is difficult to determine, but which seems to be closely related to albumen, which is constantly present where vital actions are going on, and in which alone apparently the peculiar property called life resides, these different substances are adjusted as to their related proportions, and selected and applied each to its destined object in the plant economy, to enlarge the cell or to strengthen the cell-wall, to lay the foundation of a new cell, to be stored up in a special reservoir for future use, to contribute, in short, to the development or maintenance of the special specific form of the organism of which it forms a part.

A plant cannot assimilate pure carbon, or hydrogen, or nitrogen; it seems that it can assimilate no elementary substance except oxygen, unless it be presented to it in the nascent condition. An animal stands in precisely the same relation to the binary compounds, carbonic acid, water, and ammonia. However abundantly, therefore, it might be supplied with these binary compounds which actually contain all the elements necessary for its sustenance, it would surely die of inanition. In order to be capable of affording nourishment to the animal kingdom, these substances must be elaborated to the condition of ternary and quaternary compounds, and this can only be done in the cells of plants. This, then, is the broad and practical distinction between the vegetable and the animal kingdoms. Plants have the power of absorbing, modifying, and organising inorganic substances, while animals are entirely dependent upon the organic substances thus prepared for their support. Taken in this sense, the distinction between the two kingdoms is most marked, and of the highest practical value; but when we set aside this one peculiar property, which is possessed only by some plants, and only by certain parts of those plants at certain periods of their life, and especially when we observe certain minute forms, of low organisation, on the verge of either kingdom, it becomes absolutely impossible to assign any definite distinctive character. The character which is, perhaps, most palpable and universal, is that a mass of vegetable protoplasm is at some time during its existence, inclosed in a cell-wall, which is composed of cellulose, or some very nearly allied ternary compound. Animal protoplasm is rarely, if ever, confined in this way; that is to say, in nucleated cells, with cellulose walls, which are found in all plants, and are not found in the animal kingdom.

The protoplasm of the cells of plants has the power, without developing colour and without the aid of light, of absorbing, decomposing, and assimilating the elements of already prepared organic ternary and quaternary products, whether they be derived from the soil or surface to which the plant is attached, as in the case of fungi; or from sap already elaborated by another part of the same plant, as in the growing root; or even of another plant, as in pale parasites. Most growing points in plants are pale, and the protoplasm in the cells of a pale shoot, or of a colourless plant, has precisely the same vital powers and relations as animal protoplasm. It is only in cells in which protoplasm elaborates and incorporates with itself endochrome, which seems to be a more powerful catalytic agent, capable of disengaging the component atoms of the more stable binary compounds when loosened by the vibrations of light, that the special function of the vegetable cell is performed. The cells of a pale growing point develop the characteristic cellulose wall, but the supply of material is abundant, for the protoplasm of these cells is either confluent, through the porous cell-walls, with the protoplasm of chlorophyll cells, or, as in the seed, it is in connection with a *cache* of preserved food, prepared and stored up by the protoplasm and endochrome of previous leaves.

The difference between the great mass of plants, as represented by their familiar and higher groups, and the higher animals, is very palpable; it is only among the comparatively obscure forms near the limits of either kingdom that a difficulty occurs. The general chemical composition of plants differs markedly from that of animals. A plant consists mainly of ternary compounds, cellulose, dextrine, starch, &c. In an animal, ternary compounds, although some of them—such as oils and fats—are of great importance in its economy, play altogether a subordinate part, and the bulk of the body is made up of substances of the albumen series—albumen, fibrin, and gelatin. Until lately this chemical distinction was regarded as absolute, and still it holds good generally, though glycogen and glucose (animal starch and sugar), and now recognised as being universally present in the tissues of the higher animals whether in health or in disease. A colouring matter apparently undistinguishable from chlorophyll is found in the green bodies of Hydra and Stentor, though there is as yet no evidence that this animal endochrome possesses the power of decomposing carbonic acid; and cellulose, perhaps the most special of the vegetable products, is found in the testa of ascidians. Endochrome is absent in many fungi.

The intimate structure of plants is usually very different from that of animals. Plants and all their parts consist of but one histological element, the cell with a cellulose wall, and its very simple modifications; the texture of plants is therefore to a great degree homogeneous. Animals, on the contrary, consist of many tissues highly differentiated, among which the nucleated vesicle with a definite wall, and tissues simply derived from it, are comparatively rare. The structure test fails also, however, on the borderland, for the most simple animals, such as Amœba and Gromia, are mere minute masses of jelly-like sarcode, which show no structure and no differentiation of tissues, and seem to differ only from the unicellular fungi and algæ in the absence of the cellular wall, while the free amœbiform cell-contents of the myxomycetous fungi are perfectly undistinguishable from such animals without a knowledge of their history.

The general plan of the organs of nutrition is strongly contrasted in the two kingdoms. One of the higher plants absorbs its peculiar food and assimilates it by means of an enormously extended external surface of roots and leaves. An animal, on the other hand, receives its prepared nourishment into the interior of its body by a mouth, and then subjects it to complicated processes of digestion and assimilation in contact with an extended internal absorbing and secreting surface, of which special portions are organised for the performance of the several steps in the process, till at length the unassimilable residue is rejected; but as we descend in the animal series, the digestive cavity becomes more and more simple, and in certain undoubted animal forms, such as the cestoid worms, the gregarinæ, and the foraminifera, it is entirely wanting, and nutrition is effected by absorption through the external surface as in plants.

No special character can be derived from the function of reproduction. Most plants, and many of the lower animals, are multiplied by gemmation and fission, and probably all animals and plants are propagated under certain circumstances by a nearly uniform process of sexual generation. The reproductive elements are produced internally in the higher animals and externally in plants; but even this minor distinction fails very early, for in large groups of the simpler animals ovaries and testes are external.

It is true in the general sense that animals possess organs and functions of relation which are absent in plants. Most plants remain permanently rooted to the ground, and neither the whole plant nor any visible part of it exhibits any spontaneous movements, either voluntary or automatic. It never performs any independent or consequent acts, from which one would deduce the existence of consciousness, intelligence, or will; still, there are certain phenomena even among the higher plants, connected with the habits of climbing plants and with the functions of fertilisation, which it is very difficult to explain without admitting some low form of a general harmonising and regulating function comparable to such an obscure manifestation of reflex nervous action as we have in sponges and in other animals in which a distinct nervous system is absent. The protoplasm in the interior of the vegetable exhibits movements so characteristic and special as almost to be sufficient, were other evidence wanting, to prove its absolute identity with the sarcode of the rhizopods; and when we reach the confines of the two kingdoms, the test of locomotion fails like the others, for the branched and plant-like sponge remains permanently rooted to the ground, while the freed cell-contents of many of the lower plants move actively, either by contractility of the sarcode substances, as in the plasmodia of the myxomycetous fungi, or by circlets or bunches of cilia, as in the zoospores of *Volvox*, *Euglena*, and *Chætophora*.

If we take a water-reed from a pond in summer, and carefully scrape off the slimy matter adhering to it upon a slip of glass and place it under a microscope, we may probably see in the field some minute oval bodies like the small seeds of a plant. These are the bodies of an animal belonging to the genus Gromia, a genus of the Rhizopoda, grouped among Haeckel's Protista, but usually regarded as true animals. If we break up one of them under the microscope, we find it to consist of a little mass of apparently perfectly structureless viscid semi-fluid jelly inclosed in a thin membranous oval shell, with a large opening at one end. This gelatinous mass is under the highest powers destitute of anything which can be called structure. A transparent colourless matrix contains extremely small globules and fine granules scattered through it, and here and there are rounded spaces, which seem to contain a homogeneous liquid. If instead of breaking up the animal we allow it to remain quiet in the water, probably in a few minutes we see a set of very delicate threads protruded from the opening in the test. These threads increase in length, and spread like a branching root in the water. When we examine these closely, we find that they are continuous with the jelly of the animal, that they are, in fact, mere processes of that jelly. When two of the threads touch they flow together, and coalesce, as two streams of treacle might do, showing that they are bounded by no membranous wall; and, when one of the threads comes in contact with an organic particle in the water, the particle sinks into it, and then the thread begins to flow back again into the body of the animal bearing the particle with it, as a stream of treacle might entangle, and carry along a crumb of bread.

The organic particles are introduced into the body, into any part of it, and there they are dissolved and assimilated. I believe that the granules observed in the gelatinous substance are particles of the various products of this assimilation, and that the living matter is perfectly homogeneous and transparent. If the creatures be kept for a few days in water nearly pure, they become less and less granular.

If the thread-like pseudo-podia, as they are called, be rudely touched, they at once contract, and flow rapidly back into their test. The membranous test cannot be truly regarded as a part of the animal, it is a mere excreted defensive covering incapable of any further change, or of manifesting any of the phenomena of life. The body of the animal can be easily squeezed out of it entire, and in that case it shortly begins the excretion of a new shield.

Here, then, we have a homogeneous substance which has the power of inducing and controlling chemical and physical forces, and of moulding into indefinite form the products of the regulated changes taking place within it, which therefore possesses life. The gelatinous matter which in this animal and in the whole sub-kingdom to which it belongs can thus feed and digest without a mouth or stomach, contract without muscles, display irritability without a nervous system—in fact, exhibit all the essential phenomena of living beings without a trace of organisation, is Protoplasm.

If now, laying aside the Gromia, we examine with the microscope the water-plant on which we found it, we find that the whole plant from end to end and in all its parts is honeycombed, that is to say, composed of a congeries of minute chambers separated from one another by well-defined walls, the walls giving the plant its support and consistency.

We place in the field of the microscope a small portion of the growing point of a leaf or stem, and we easily make out that the chambers are minute vesicles each complete in itself, adhering according to a definite arrangement to one another. As these cells have occupied a very prominent position in modern histological and physiological speculation, having been regarded, and being still regarded by many as the units of organisation, the centres and sources of all vital activity, I should wish to sketch distinctly their structure and properties. It is of no consequence whence the cell is selected. All vegetable cells appear to have the same structure at first, during their growth and while their vitality lasts; subsequently most of them undergo great changes, their walls being thicker and their cavities clogged with various secretions. There are some beautiful transparent-beaded hairs at the bottom of the flower cup of the white variety of the Virginian spider-wort. If we place one of these hairs in a drop of water in the field of the microscope, we find that it is simply composed of a row of oval cells attached end to end. The cell is in this case a minute vesicle with an extremely thin transparent wall. This wall consists of cellulose, a substance composed of thirty-six parts of carbon and thirty parts of water. The membrane is perfectly structureless under the highest powers of the microscope, and apparently continuous. It must, however, be minutely perforated, for water and various secretions and excretions pass through it freely. From its composition and structure it is impossible to imagine that vital force should reside in the vegetable cell-wall. We must regard it as an excretion of dead matter moulded as a boundary wall to the cell cavity by some external agent, but incapable of originating any vital action. The cell is full of water or mucous solution, and watching carefully with a proper arrangement of the light, and a moderately high power, we can distinctly trace threads of dense gelatinous matter moving slowly into the inner surface of the cell-wall. These streams commence wider in the region of a nucleus, which was at one time regarded as the heart of the cell, as it were, the centre of its vital activity, and gradually branch and diminish at a distance from it. Under the microscope granules appear in these streams, and with these granules embedded in them, as crumbs are embedded in a stream of treacle, the currents flow round and round the cell, the granules gradually disappearing and being absorbed. The observations of Prof. Max Schultze and of others have, I think, placed it beyond a doubt that this gelatinous substance occurring within the living cell, and forming, at all events, a large proportion of the cell-contents, is identical with the protoplasm which forms the entire substance of such an animal form as *Gromia*.

The necklace-like hair of the spider-wort is, in fact, a chain of cells with dead cellulose walls, and each with a living Gromia body imprisoned within it.

Now, although the power which plants possess of fixing carbon and combining it with the elements of water, is the character which practically distinguishes the Vegetable from the Animal kingdom, I have already shown that we cannot regard this as by any means a universal test. In this respect broomrapes and dodders are animals.

When we pass down by any path we choose, either through animals or plants, we come equally to a great series of very simple forms—mere little masses of protoplasm with a nucleus. Some of these contain peculiarly formed masses of bright colouring matter, green, scarlet, or yellow, and with the possession of such pigment we usually associate the power of decomposing carbonic acid. Many of these bodies have, however, no colouring matter at all, except what is derived from their food. A large number of these simple forms are enclosed in a wall of cellulose, but very many of them are naked or merely covered with a pellicle of firmer protoplasm; while some, such as the plasmodia of the myxogastric fungi are, for some part of their lives, enclosed in a cellulose wall, and for another part, naked. Going still lower, we have Haeckel's Monera, differing from the others merely in the absence of a nucleus and the total want of differentiation of any part. Even these last are sometimes coloured, and from their chemical reactions it seems very likely that they possess some low form of the peculiar vegetable power. Now, the question is, whether all these considerations lead in any way in the direction of establishing a separate kingdom for these simple beings. I think decidedly not, but it seems to me that they prove almost to demonstration that organic nature must be taken as one whole, that the Animal and Vegetable kingdoms are absolutely continuous, and that a tree flinging its green flags into the sunshine and feeding on the winds of heaven, is essentially nothing more than a vast colony of a protozoon, comparable to a gigantic nummulite, only building a cellulose instead of a calcareous shell, and developing a special secretion in special organs for the purpose of enabling it to do so.

## *MR. BENTHAM'S ANNIVERSARY ADDRESS TO THE LINNEAN SOCIETY*

HAVING now for the tenth time the honour of addressing you from this chair on the occasion of your annual gathering, it has been my wish to lay before you a general sketch of the progress making in systematic Biology, the foundation upon which must rest the theoretical and speculative, as well as the practical, branches of the science, to report upon the efforts made further to investigate, establish, and extend that foundation, and to convert the numerous quicksands with which it is beset into solid rock. This subject formed the chief portion of my address of 1862, and again of those of 1866 and 1868; but on the present occasion I have had some difficulties to contend with. Mr. Dallas, to whose kindness I owed the zoological notes I required, has now duties which fully absorb his time, and I have been obliged to apply to foreign correspondents, as well as to my zoological friends at home, for the necessary information. They have one and all responded to my call with a readiness for which I cannot too heartily express my thanks; and if there is some diversity in the extent and nature of the information I have received from different countries, which may prevent any very correct estimate of the comparative progress made in them, it is owing to the questions which I put having been stated too generally, and, though sent in the same words to my different correspondents, they have been differently understood by them. In such a review, however, as I am able to prepare, I propose chiefly to consider the relative progress made by zoologists and botanists in the methods pursued and the results obtained, in the first place as to general works common to all countries, and secondly as to those which are more particularly worked out in or more specially relate to each of the principal states or nations where biological science is pursued, prefacing this review by a few general remarks supplementary to those I laid before you in my first address in 1862.

Since that time systematic biology has to a certain degree been cast into the background by the great impulse given to the more speculative branches of the science by the promulgation of the

Darwinian theories. The great thunderbolt had indeed been launched, but had not yet produced its full effect. We systematists, bred up in the doctrine of the fixed immutability of species within positive limits, who had always thought it one great object to ascertain what those limits were, and by what means species, in their never-ending variations and constant attempts to overstep those limits, were invariably checked and thrown back within their own domain, might at first have been disposed to resist the revolutionary tendency of the new doctrine; but we felt shaken and puzzled. The wide field opened for the exercise of speculative tendencies was soon overrun by numerous aspirants, a cry of contempt was raised against museum zoologists and herbarium botanists, and nothing was allowed to be scientific which was not theoretical or microscopical. But this has been carried, in some instances, too far. If facts without deductions are of little avail, assumptions without facts are worse than useless. Theorists in their disputes must bring forth the evidences they rely upon, and these evidences can only be derived from and tested by sound systematic biology, which must resume and is resuming its proper position in the ranks of science, controlled and guided in its course by the results of those theories, for which it has supplied the basis.* If the absolute immutability of races is no longer to be relied upon, the greater number of them (whether genera, species, or varieties) are at the present or any other geological period, practically circumscribed within more or less definite limits. The ascertaining those limits in every detail of form, structure, habit, and constitution, and the judicious appreciation of the very complicated relations born to each other by the different races so limited, is as necessary as the supplementing the scantiness of data from the depths of Teutonic consciousness by the vivid flashes of Italian imagination, or as the magnifying minute as yet undeveloped organisms, with a precision beyond what is fully justified by our best instruments.

I am, however, far from denying on the one hand how much biological science has of late been raised, since it has been brought to bear through well-developed theories and hypotheses upon the history of our globe, and of the races it has borne; and on the other, how very much the basis upon which it rests has been improved and consolidated by the assiduous use of the microscope and the dissecting knife; but I would insist upon the necessity of equal ability being applied to the intermediate process of method or nomenclature and classification, which forms the connecting link between the labours of the anatomist and the theorist, reducing the observations of the one to forms available for the arguments of the other. All three, the minute observer, the systematist, and the theorist, thus assisting each other, equally contribute to the general advancement of science, and for all practical application, the systematist's share of duty is certainly the most important.

The quicksands to which I have alluded to as besetting thus the foundation of biological science, may be classed as imperfect data and false data, imperfect method and false method. To show what progress is making in removing or consolidating them, it may be useful to consider what these data are, and what are our means of fixing them so as to be readily available for use.

It must, in the first place, be remembered that the races whose relations to each other we study, can only be present to our minds in an abstract form. In treating of a genus, a species, or a variety, it is not enough to have one individual before our eyes, we must combine the properties belonging to the whole race we are considering, abstracted from those peculiar to subordinate races or individuals. We cannot form a correct idea of a species from a single individual, nor of a genus from a single one of its species. We can no more set up a typical species than a typical individual. If we had before us an exact individual representative of the common parent from which all the individuals of a species or all the species of a genus have descended—or if you prefer it an exact copy of the model or type after which the whole species or genus had been created, we should have no possible means of recognising it. I once heard a lecture of a German philosophical naturalist of considerable reputation in his day, in which he thought he proved that the common Clover was the type of Papilionaceæ. His facts were correct enough, but his arguments might have been turned in favour of any other individual species that might have been selected. Suppose two individuals of a species, two species of a genus, two genera of a family, in one of which certain organs are more developed, more differentiated, or more consolidated than in the other, if we agree upon the first question of which is the most perfect, a point upon which naturalists seldom do agree, how are we to determine which represents the common parent or model? whether the perfect one is an improvement upon, or an improved copy, or the imperfect one a degeneracy from or a bad imitation of the other? No direct evidence goes beyond a very few generations, reasoning from analogy is impossible without direct evidence to start from, and the imagining a type without either is the business of the poet, not of the naturalist.

It follows that every such abstract idea of a race must be derived from the observation, by ourselves or by others, of as large a number of the constituent individuals as possible. However fixed a race may be, if fixed at all in Nature, that is not the case with our abstract idea of it, no species or genus we establish can be considered as absolutely fixed, it will ever have to be completed, corrected, or modified, as more and more individuals come to be correctly observed. Hence it is, that a species described from a single specimen, and even a genus established on a single species, always excites more or less of suspicion unless supported by strong reasoning from analogy or confirmed by repeated observation.

Our means of observing and methodising biological facts, of establishing and classifying those abstract ideas we call varieties, species, genera, families &c., consist in the study (1) of living individual organisms; (2) of preserved specimens; (3) of pictorial delineations; and (4) of written descriptions. Each of these sources of information has its special advantages, but each is attended by some special deficiencies to be supplied by one or more of the others.

1. The study of living individuals in their natural state is without doubt the most satisfactory, but very few such individuals can be simultaneously observed for the purpose of comparison, and no one individual, at any one moment, can supply the whole of the data required relating even to that individual. Some additional facilities in these respects are given by the maintenance of collections of living animals and plants, particularly useful in affording the means of continuous observation during the various phases of the life of one and the same individual, and sometimes through successive generations, or in facilitating the internal examination of organisms immediately after death, when the great physiological changes consequent upon death have only commenced. But there are drawbacks and difficulties to be overcome, as well as a few special sources of error to be guarded against, and in this respect, as well as in the progress recently made in their application to science, there is a marked difference between zoological and botanical living collections, or so-called gardens.

The great drawback to living collections, especially zoological, is their necessary incompleteness. At the best it is individuals only, not species, and in a few cases genera that are exposed to observation; genera, indeed, can always be better represented than species, for a few species bear a much larger proportion to the total number contained in a genus, than a few individuals to the total number which a species contains. Whole classes are entirely wanting in zoological gardens, which are usually limited to vertebrata. Of late years means have been found to include a few aquatic animals of the lower orders, but insects, for instance, those animals which exercise the greatest influence on the general economy of nature, the observation of whose life and transformations is every day acquiring greater importance, are wholly unrepresented in zoological gardens. The shortness of duration of their individual lives, their enormous power of propagation, the different mediums in which they pass the different stages of their existence, will long be obstacles to the formation of living entomological collections on anything like a satisfactory scale. The cost also of the formation and maintenance of living collections is very much greater in the case of animals than of plants; but on the other hand zoologists have the advantage of the attractiveness of their menageries to the general unscientific but paying public, and, under judicious management, some sacrifices to popular tastes are far outweighed by the additional funds obtained towards rendering their collections useful to science.

The false data or errors to be guarded against in the observation of living zoological collections are chiefly owing to the unnatural conditions in which the animals are placed. Ungenial climate, unaccustomed food, want of exercise, &c., act upon their temper, habits, and constitution, and confinement materially

* The great importance of morphology and classification, the elements of systematic biology, has been forcibly illustrated by Prof. Flower in his last year's introductory lecture at the Royal College of Surgeons.

modifies circumstances connected with their propagation. Such errors or false data are, no doubt, as yet very few and unimportant compared to those which have arisen from the reliance on garden plants for botanical observations, but, as zoological gardens multiply and extend, they will have to be more and more kept in view.

In my younger days there were already a number of small collections of living animals, but almost all either travelling or local menageries exhibited for money by private individuals, or small collections kept up as a matter of curiosity for the benefit of the public, such as those of the Pfauen-Insel at Potsdam, the park at Portici, or our own Tower menagerie. At Paris alone, at the Jardin des Plantes, in the flourishing days of the Jussieus and Cuviers, was the living zoological collection rendered essentially subservient to the purposes of science. Since then, however, matters have much changed: the Jardin des Plantes, which so long reigned supreme, has, by remaining stationary, sunk into a second rank. She may indeed be as justly as ever proud of her Milne-Edwards, her Brongniart, her Decaisne, and many others, but long out of favour with the Government and the paying public, who transferred their patronage to the high-sounding Jardin d'Acclimatation, now no more, she has been almost abandoned to the resources of pure science, always of the most restricted in a pecuniary point of view. We in the mean time, and after our example several continental states or cities, have made great advances. The formation of our Zoological Society and Gardens opened a new era in the cultivation of the science. After various vicissitudes, the Society had the good fortune to secure the services of one who combined in the highest degree zoological eminence with administrative ability, and thus our great living zoological collection is now raised to the proud relative position which the Jardin des Plantes once held, and which there seems every reason to hope it will long maintain. With an annual income of about 23,000*l.* the Zoological Society is enabled to maintain a living collection of about a thousand species of Vertebrata, and although some portion of the surplus funds is necessarily applied for the sole gratification of the paying public, yet a fair share is devoted to the real promotion of that science for which all the fellows are supposed to subscribe, the accurate observation of the animals maintained, the dissection of those that die, and the publication of the results. Physiological experiments are either actually made in the garden, or promoted and liberally assisted, such, for instance, as those on the transfusion of blood, the effects or non-effects of which were recently laid before the Royal Society by Mr. F. Galton. A very rich zoological library has been formed, and last year's accounts show a sum of about 1,800*l.* expended in the Society's scientific publications.

Zoological gardens, after the example of the London one, have been established not only in several of our provincial towns, but in various continental cities, amongst which the more important ones, as I am informed, are those of Amsterdam, Antwerp, Hamburgh, Cologne, Frankfort, Berlin, Rotterdam, and Dresden; the receipts of the one at Hamburgh, for instance, amounting annually, according to the published reports, to between 8,000*l.* and 9,000*l.* There are also so-called gardens of acclimatisation; but these have not much of a scientific character; their professed object indeed is not so much the observation of the physiology and constitution of animals as their modification for practical purposes, and practically they are chiefly known as places of recreation, and are not always very successful. The great one in the Bois de Boulogne, now destroyed, out of an expenditure in 1868 of about 7,200*l.* showed a deficit of about 1,600*l.*; a smaller one at the Hague is enabled to pay an annual dividend to its shareholders.

Living collections of plants have great advantages over these of animals, they can be so much more extensively maintained at a comparatively small cost. In several botanical gardens several thousand species have been readily cultivated at a comparatively small cost, and species can be represented by a considerable number of individuals, a great gain especially where instruction is the immediate object, the lives of many can be watched through several successive generations, and great facilities are afforded for physiological experiments and microscopical observations on plants and their organs whilst still retaining more or less of life. On the other hand the false data recorded from observations made in botanical gardens have been lamentably numerous and important. A plant in the course of its life so alters its outer aspect that each one cannot be individualised by the keeper of a large collection, and at one period, that of the seed in the ground, it is wholly withdrawn from his observation. He is therefore obliged to trust to labels, these are often mismatched by accident or by the carelessness of the workmen employed, or again, one seed has been sown and another has come up in its place, or a perennial has perished and made room for a sucker or seedling from an adjoining species. The misnomers arising from these and other causes have become perpetuated and sanctioned by directors who, for want of adequate libraries or herbaria, or sometimes for want of experience or ability, have been unable to detect them. Plants have also been so disguised or essentially altered by cultivation that it has become difficult to recognise their identity, and new varieties or hybrids, which, if left to themselves, would have succumbed to some of the innumerable causes of destruction they are constantly exposed to in a wild state, have been preserved and propagated through the protective care of the cultivator, and pronounced at once to be new species. If, moreover, a misplaced label indicates that the seed has been received from a country where no plants of a similar type are known to grow, the director readily notes it as a new genus, and, proud of the discovery, gives it a name and appends a so-called diagnosis to his next seed-catalogue, adding one more to the numerous puzzles with which the science is encumbered. So far, indeed, had this nuisance been carried in several Continental gardens in the earlier portion of the present century, that, excepting perhaps Fischer and Meyer's and a few other first-rate indexes, the great majority, perhaps nine-tenths, of the new species published in these catalogues have proved untenable, and, from my own experience, I am now obliged, *a priori*, to set down as doubtful every species established on a garden plant without confirmation from wild specimens. Fortunately the custom is now abating, and directors of botanic gardens are beginning to perceive that they do not add to their reputation by having their names appended to those of bad species.

Living collections of plants, or botanical gardens, are of much older date than zoological ones, and since the sixteenth century have been attached to the principal universities which have medical schools, that of Padua, dating from 1525, that of Pisa, from 1544, and of Montpellier, from 1597. The Jardin des Plantes of Paris, which in botany, even more than in zoology, so long reigned supreme, was established in 1610, our own first one at Oxford in 1632. These university gardens having been generally more or less under the control of eminent resident botanists, have contributed very largely to the means of studying the structure and affinities of plants, especially in those Continental cities where a milder or more steady climate has facilitated the maintenance of large collections in the open air or with little protection. Continental gardens have also been long and are still made largely available for the purpose of instruction as well as of scientific experiments, of which the recent labours of Naudin and Decaisne are an excellent illustration. For these scientific purposes the arrangement in large and small square compartments is peculiarly suitable, and I confess that I have frequently had greater pleasure in witnessing the facilities afforded to zealous students in following up, book in hand, the straight rows of scientifically-arranged plants in these formal university gardens, than in watching the gay crowds that flock to the more ornamentally laid out public botanic gardens.

I do not think that generally much advance has been made of late years in Continental botanical gardens. Those that I first visited in 1830 appeared to me to be but little improved when I again went over them in 1869. Some have acquired additional space, others have paid more attention to ornament, but most have remained nearly stationary, and a few have even fallen back. In our own country we have made great progress. Kew Gardens had indeed, in former days, rendered assistance to the investigations of Robert Brown and a few other favoured individuals, but they were the Sovereign's private property, and were kept very close, with little encouragement to science at large. But thirty years' unceasing exertions on the part of its distinguished directors, the two Hookers, father and son, have raised them to a point of scientific usefulness far beyond any other establishment of the kind at home or abroad. Of the large sums annually voted for it by Parliament, a portion has indeed to be applied to mere ornament and to the gratification of visitors, but yet, with all the drawbacks of our climate and consequent expenditure in houses, the largest named collection of species ever brought together in one spot, representatives of all parts of the globe, are there maintained, freely exhibited to the public, and submitted to the examination of scientific botanists.

(*To be continued*)

## SOCIETIES AND ACADEMIES

### London

Royal Society, May 25.—"Some Remarks on the Mechanism of Respiration." By F. Le Gros Clark.

The author commences his paper by narrating some experiments on recently slaughtered animals, in the course of which the remarkable tension of the diaphragm was noticed; and the varying condition of that muscle, and of the lungs and pleura, with their mutual relations, are commented on.

The importance of this passive tension of the diaphragm is indicated and exemplified both physiologically and pathologically. It is essential in retaining the supplemental air within the lungs, in restoring the equilibrium of repose, in economising active muscular power, and in maintaining the pericardial space, &c.

The action of the diaphragm in relation to the walls of the chest and to other muscles is next discussed; and the influence of the diaphragm in drawing in the chest-walls, under certain circumstances, is pointed out, and illustrated by cases of injury to the spinal cord.

The action of the intercostal muscles, as necessary adjuncts to the diaphragm and as muscles of inspiration, is insisted on and illustrated by diagrams; and a summary of their action is given.

The agency of the serratus magnus is then discussed; and reasons are advanced, supported by observation and experiment, to show that it is only under special conditions and to a limited extent that it can be regarded as taking any part in the act of inspiration.

The mobility of the different costal regions and of the sternum is exemplified by observation and experiment.

Lastly, the question of abdominal and thoracic breathing, severally in the male and female, is considered; and reasons are adduced for concluding that the received opinions on this subject are erroneous.

"Spectrum of Comet I." By Dr. William Huggins, F.R.S.—On April 7 a faint comet was discovered by Dr. Winnecke. I observed the comet on April 1 and May 2. On both days the comet was exceedingly faint, and on May 2 it was rendered more difficult to observe by the light of the moon and a faint haze in the atmosphere. It presented the appearance of a small faint coma, with an extension in the direction of the sun. When observed in the spectroscope, I could detect the light of the coma to consist almost entirely of three bright bands. A fair measure was obtained of the centre of the middle band, which was the brightest; it gives for this band a wave-length of about 510 millionths of a millimetre. I was not able to do more than estimate roughly the position of the less refrangible band. The result gives 545 millionths. The third band was situated at about the same distance from the middle band on the more refrangiele side. It would appear that this comet is similar in constitution to the comets which I examined in 1868.*

"Researches on the Hydrocarbons of the Series $C_nH_{2n+2}$."—By C. Schorlemmer.

In a former communication I have shown that the paraffins, the constitution of which is known, may be arranged in four groups. The first group, which I called *normal paraffins*, contain the carbon atoms linked together in a single chain. Of these I have obtained some new ones, which I shall describe more fully in a further communication. The normal paraffins which I have so far studied are given, together with their boiling points, in the following table:—

| | From petroleum. | From the acids of the series $C_nH_{2n-2}O_4$ | So-called alcohol radicals. | |
|---|---|---|---|---|
| $C_5H_{12}$ | 37° – 39° | —— | —— | |
| | | | Dipropyl. | From Mannite. |
| $C_6H_{14}$ | 69° – 70° | 69°·5 | 69° – 70° | 71·5° |
| $C_7H_{16}$ | 98° – 99° | 100°·5 | —— | —— |
| | | | Dibutyl. | From methylhexylcarbinol. |
| $C_8H_{16}$ | 123° – 124° | 123° – 124° | 123° – 124° | 124° |

That these paraffins have really the constitution which I have ascribed to them follows partly from their mode of formation; thus dipropyl was obtained from the normal propyl iodide, and dibutyl from normal butyl iodide. The constitution of the others was determined by converting them into alcohols and studying the oxidation products of the latter; thus the hexyl hydride from petroleum, as well as that obtained from mannite, was transformed into secondary hexyl alcohol, which on oxidation yielded acetic acid and *normal* butyric acid.

In the communication above referred to, I placed the hydrocarbon $C_8H_{18}$ from methyl-hexyl carbinol amongst another group; but I have found now that this body is identical with dibutyl and also with the hydrocarbon, which Zinke obtained from primary octyl alcohol. This chemist prepared also dioctyl, $C_{16}H_{34}$, which consequently is a normal paraffin; and it appears probable that dibexyl, which Brazier and Goslett obtained by the electrolysis of œnanthylic acid, belongs to this group too.

We are now acquainted with the following normal paraffins:—

| | Boiling-points. Found (mean). | Calculated. | Difference. |
|---|---|---|---|
| $C\ H_4$ | —— | —— | |
| $C_2H_6$ | —— | —— | |
| $C_3H_8$ | —— | —— | |
| $C_4H_{10}$ | 1° | 1° | |
| $C_5H_{12}$ | 38° | 38° | 37° |
| $C_6H_{14}$ | 70° | 71° | 33° |
| $C_7H_{16}$ | 99° | 100° | 29° |
| $C_8H_{18}$ | 124° | 125° | 25° |
| $C_{12}H_{26}$ | 202° | 207° | 4 × 19° |
| $C_{16}H_{34}$ | 278° | 278° | 4 × 19° |

From this it appears that the boiling-point is not raised 31° for each addition of $CH_2$, as I formerly assumed, but that, as the calculated numbers show, the difference between the boiling-points of the lower members decreases regularly by four until it becomes the well-known difference of 19°.

Chemical Society, May 18.—Prof. Frankland, F.R.S., president, in the chair. Messrs. T. Greenish and J. E. Mayall were elected Fellows. The following papers were read:—"On a new double salt of thallium," by R. T. Friswell. The author wishing to prepare thallic platino-cyanide, mixed hot solutions of thallic carbonate and potassic platino-cyanide, and obtained on leaving the mixture to cool masses of splendid crystals, which appeared by transmitted light of a magnificent crimson red, whilst their reflected colour was a bronzy green of strong metallic lustre. Analysis showed that they are a compound of thallic carbonate with thallic platino-cyanide, $Fl_2\ Pt\ Cy_4$, $CO\ Fl\ O_2$. On treating this salt with acids carbonic acid is set free, and a pale pink residue left, which on examination was found to be thallic platino-cyanide.—The next paper read was "On the action of nitric acid on dichloro-phenolsulphuric acid," by Dr. Armstrong.

Geologists' Association.—The excursion of this Society to Oxford took place on the 12th and 13th inst. On the first day the numbers assembled at the beautiful new University museum at noon, and were introduced to Professor Phillips, who commenced a descriptive lecture on the museum, its arrangement and contents. There is a peculiar double arrangement of the palæontological collection by which the student may with equal ease make himself acquainted with the organisms derived from any one geological formation or devote himself to the study of the fossil remains of a single class or order of the animal or vegetable kingdoms. The museum is not crowded, but contains good specimens of those species which are most typical or characteristic. These, too, with the fossil remains of saurians and mammals are the complete skeletons of analogous living genera, an arrangement most advantageous to the student. The speciality of the Oxford museum is the unique collection of the remains of *Cetiosaurus*. A most interesting description of the enormous bones of this genus was given by Prof. Phillips, who, by means of corresponding crocodilian bones, gave a clear idea of the vast size to which these huge creatures attained. The estimate made by the Professor was that the Cetiosaurus was 40 feet long and 12 feet in height, the femur being fully 60 inches long, while the femur of a crocodile, with which it was contrasted, being no more than nine inches in length. In the afternoon the party proceeded to Shotover Hill, examining by the way the excavations in the Oxford clay near the city, and the exposures of the coral rag and the Kimmeridge clay on the side of the hill. Near the top of Shotover, Portland sands and a thin band of Portland rock are seen, and above these beds and forming the summit of the hill are the "Iron Sands," which have been the subject of much dispute. These highly ferruginous beds were considered to be lower greensand, but the finding of a considerable number of fresh-water species of Mollusca has induced Prof. Phillips to conclude the "Iron Sands" to be of Wealden age. From these sands at the summit of the hill ochre is obtained in large quantities. In the evening a soirée was given by Mr. James Parker, of Oxford, who most hospitably entertained the members of the Association. The magnificent collection

* Phil. Trans. 1868, p. 555; and Proc. Roy. Soc. vol. xvi. p. 386.

of reptilian remains and other fossils from the neighbourhood of Oxford was shown to the visitors, and described by Prof. Phillips and Prof. Morris.—Saturday's proceedings were commenced by an early visit to Merton College, for the purpose of inspecting the very fine collection of fossils which Mr. Earwaker of that college has brought together. Afterwards the party, with Profs. Phillips and Morris, started by carriage for Islip, Enslow Bridge, and Kidlington. At Islip a very fine section of the Forest Marble and Cornbrash is exposed, and the usual fossils of these formations are here found. The village of Islip is, however, interesting to geologists on other grounds, for here lies Buckland. Around the tomb of the great geologist with his distinguished successor at their head the party assembled. The tomb is of polished Aberdeen granite, and the inscription briefly records the fact that there lie the remains of Dr. Buckland, Rector of Islip, Dean of Westminster, and First Reader in Geology in the University of Oxford. The quarries at Enslow Bridge, which have yielded a large number of the Saurian bones in the University Museum, was then visited, and here the visitors were highly gratified to find that during the morning a very fine *Teleosaurus* had been found, and the head, taken out of the bed in which it had lain for untold ages, was exposed to view. This quarry is in the great Oolite, the lower and uppermost strata of which in Oxfordshire yield remains of *Megalosaurus*, while in the middle beds we find *Teleosaurus*. A very remarkable bed of about twelve inches thick occurs a little above the Teleosaurian cave, crowded with *Terebratula maxillata* to the exclusion of every other species. Several other sections of the Great Oolite, Forest Marble, and Cornbrash were examined, and the weather being very fine the drive through the beautiful country was much enjoyed, and the return to Oxford effected in time to allow of the party taking their departure for London by the evening train.

DUBLIN

Royal Dublin Society, May 13.—Dr. J. Emerson Reynolds, analyst to the Society, delivered the concluding lecture for the session 1870-71. The subject of the lecture was the "Chemistry of Milk." The lecturer, referring to cow's milk more particularly, described the constituents of the fluid at considerable length, and showed the precise quantities of butter, casein, sugar, and salts obtained from a known amount of milk of good quality. A number of new facts bearing on the chemical constitution of the different substances present in milk were then stated, and the relations of casein and sugar to the several parts of the animal organism were pointed out. It was proved by a large number of analyses of milk taken from cows fed in various ways in different parts of the country, that milk is naturally subject to very wide variations in the proportions of its constituents, and hence that it is extremely difficult, if not impossible, to state with precision that a given sample of milk had been adulterated with a certain amount of water. Under these circumstances the lecturer suggested that milk should in future be judged according as it might reach or fall below a certain standard quality, fair alike to the vendor and the purchaser, but that milk falling below the standard should not necessarily be stigmatised as adulterated, but simply have a lower commercial value attached to it. Dr. Reynolds stated, as the result of his experience, that milk sold at the present price per quart may fairly be expected to have the following composition in one hundred parts:—

| | |
|---|---|
| Water | 87·0 |
| Butter | 3·5 |
| Casein | 4·0 |
| Sugar | 5·0 |
| Salts | ·5 |

The proportion of fatty matter can be easily ascertained by the rapid methods of Sir Joseph Banks or Dr. Minchin, and the sugar determined in a few minutes by the aid of the polariscope; but it has been hitherto impossible to speedily measure the proportion of the valuable casein of milk without recourse to elaborate chemical analysis. By means of a very simple contrivance, which was exhibited at the lecture, the proportion of casein can, however, now be speedily ascertained; we are, therefore, for the first time in a position to form quickly a sufficiently precise estimate of the nutritive value of a given sample of milk. The lecturer concluded by expressing a hope that the public would now use the means placed in its hands for guarding against imposition on one side, or the hasty condemnation of the honest trader on the other.

May 22.—Prof. Dyer in the chair. Prof. R. Ball read notes on Kater's Pendulum and on a new Hydraulic Press.—Dr. J. Emerson Reynolds read notes of Experiments on the flow of Liquids through Capillary Tubes.—Mr. W. F. Kirby communicated a list of the species of *Papilionidæ* or Swallow-tailed Butterflies in the collection of the Society, and exhibited specimens in illustration. Among these were a long series of *P. cymochles* Gray and *P. idalion* Felder, which Mr. Kirby believed to be sexes of one species. He also called attention to a remarkable variety (?) of *P. polymnestor* Cram., in which the blue colouring of the hind wings was reduced to a band.—Prof. Dyer read a paper on Bud scales, in the course of which he objected to the word mimicry being used for the resemblance borne by a plant belonging to one natural family to a plant belonging to a different natural family, except in such cases as where the plants were found living side by side.—Mr. A. G. More exhibited for Dr. Cartt a number of additions to the museum, and told some of the more remarkable stories known about each species. Among the more interesting specimens exhibited, one of the American Goshawk shot in Tipperary and one of *Cygnus bewickii* may be mentioned.

## DIARY

*THURSDAY*, JUNE 1.

LINNEAN SOCIETY, at 8.—On Some Plants from Northern China: Dr. Hance.—On South American *Hippocrateaceæ*: Mr. Miers.
CHEMICAL SOCIETY, at 8.—On Ozone: Dr. Debus, F.R.S.
ROYAL INSTITUTION, at 3.—On Sound: Prof. Tyndall, F.R.S.

*FRIDAY*, JUNE 2.

GEOLOGISTS' ASSOCIATION, at 8.—On Flint: M. Hawkins Johnson, F.G.S.
ROYAL INSTITUTION, at 9.—Gaseous and Liquid States of Matter: Prof. Andrews.

*SATURDAY*, JUNE 3.

ROYAL SCHOOL OF MINES, at 8.—Geology: Dr. Cobbold.
ROYAL INSTITUTION, at 3.—On the Instruments Used in Modern Astronomy: J. N. Lockyer, F.R.S.

*MONDAY*, JUNE 5.

ENTOMOLOGICAL SOCIETY, at 7.
ROYAL INSTITUTION, at 2.—General Monthly Meeting.

*TUESDAY*, JUNE 6.

ZOOLOGICAL SOCIETY, at 9.—On Dinornis (Part XVII). Containing a description of the sternum and pelvis, with an attempted restoration of *Aptornis defosser*, Ow.: Prof. Owen, F.R.S.—On a Seal new to the British Fauna: Prof. Flower.—On Risso's Dolphin: Prof. Flower.
SOCIETY OF BIBLICAL ARCHÆOLOGY.—On the Early History of Assyria and of Babylonia, from Contemporary Inscriptions (part 1): G. Smith.—On the Date of the Nativity: J. W. Bosanquet.
ROYAL INSTITUTION, at 3.—Least Action in Nature: Rev. Prof. Haughton.

*WEDNESDAY*, JUNE 7.

GEOLOGICAL SOCIETY, at 8.—Notes on the Geology of part of the County of Donegal: A. H. Green, M.A., F.G.S.—On the Persistence in the Deep-seas of the present day of *Caryophyllia cylindracea*, Reuss, a cretaceous coral: Prof. P. Martin Duncan, F.R.S.—Note on an *Ichthyosaurus* (*I. enthikiodon*), from Kimmeridge Bay, Dorset: J. W. Hulke, F.R.S.—Note on a Fragment of a Teleosaurian Snout, from Kimmeridge Bay, Dorset: J. W. Hulke, Esq.
ROYAL MICROSCOPICAL SOCIETY, at 8.
LONDON INSTITUTION, at 2.—Distribution of Prizes and Certificates by Mr. T. Baring, M.P., President.

*THURSDAY*, JUNE 8.

SOCIETY OF ANTIQUARIES, at 8.30.
MATHEMATICAL SOCIETY, at 8.
ROYAL INSTITUTION, at 3.—Sound: Prof. Tyndall.

## THE GENERAL OCEANIC CIRCULATION

AMONG the results of the *Porcupine* Expeditions of 1869 and 1870, there are perhaps none more important than those relating to the Temperature of the Deep Sea. For it is only to such accurate determinations of ocean temperatures as have now been made for the first time, not only at the surface and the bottom, but also at intermediate depths, that a really scientific theory can be framed of that great Oceanic Circulation, which, while it eludes all ordinary means of direct observation, seems to produce a far more important effect, both on terrestrial climate and on the distribution of the marine fauna, than that of the entire aggregate of the surface-currents which are more patent to sight. The latter usually have winds for their prime motors, and their direction is mainly determined by the configuration of the land; so that their course and action will change with any superficial alteration which either opens out a new passage or blocks up an old one. The former, on the other hand, depending solely on difference of temperature, will (to use Sir J. Herschel's apposite language) have its movements, direction, and channels of concentration mainly determined by the configuration of the sea-bottom; and vast elevations and subsidences may take place in this, without producing any change that is discernible at the surface.

The history of the doctrine of the general oceanic circulation has been recently given in the Anniversary Address of the President of the Geological Society, with a completeness which (so far as we are aware) had never been previously paralleled. But this doctrine has hitherto rested on the very insecure foundation of observations which were alike inadequate and inaccurate; and it has consequently been discredited, both by physicists and by physical geographers. It is now impossible to assign a precise value to the older observations upon deep-sea temperatures. For it was shown by the careful experiments which were made by Mr. Casella two years ago, under the direction of the late Prof. W. A. Miller, Dr. Carpenter, and Captain Davis of the Admiralty, that the pressure of sea-water at great depths on the bulb of the thermometer—a pressure amounting to about a ton per square inch for every 800 fathoms—exerts so great an influence on even the very best instruments of the ordinary construction, as to cause a rise of eight or ten degrees under an amount equivalent to that which would be exerted at from 2,000 to 2,500 fathoms' depth;* and the error of many thermometers under the same pressure was two or three times that amount. There is reason to believe that some of the thermometers formerly employed, especially in the French scientific expeditions, were protected against that influence; but no such protection appears to have been applied to the thermometers supplied to Sir James Ross's Antarctic Expedition; and the observations by which he supposed himself to have established the existence of a uniform deep-sea temperature of about 39°, now seem to have been altogether fallacious. So again, Captain Spratt's observations in the Mediterranean, though made with great care, were seriously vitiated by this source of error.

It appears from Mr. Prestwich's exhaustive summary, that as long ago as 1812 Humboldt had maintained that such a low temperature exists at great depths in tropical seas, as can only be accounted for by the hypothesis of under currents from the Poles to the Equator. And this view was adopted by D'Aubuisson, Lenz, and Pouillet; the latter of whom considered it certain "that there is generally an upper current carrying the warm tropical waters towards the Polar seas, and an under current carrying the cold waters of the Arctic regions from the Poles to the Equator." Our Arctic navigators had met with temperatures in the Polar seas as low as 29° at 1,000 fathoms; and these observations have been more recently confirmed by those of M. Charles Martins and others in the neighbourhood of Spitzbergen. Several instances are recorded, on the other hand, in which temperatures of from 38° to 35° were observed at great depths nearly under the Equator; and this alike in the Atlantic, Pacific, and Indian Oceans.

The Temperature-soundings taken in the *Lightning* and *Porcupine* Expeditions, with trustworthy instruments, have shown:—(1) That in the channel of from 600 to 700 fathoms' depth which lies between the North of Scotland, the Orkney and Shetland Islands, and the Faroes, there is an upper stratum of which the temperature is considerably higher than the normal of the latitude; whilst there is stratum occupying the lower half of this channel, of which the temperature ranges as low as from 32° to 29°·5; and a "stratum of intermixture" lying between these two, in which the temperature rapidly falls—as much as 15° in 100 fathoms. (2.) That off the coast of Portugal, beneath the surface-stratum, which (like that of the Mediterranean) is super-heated during the summer by direct solar radiation, there is a nearly uniform temperature down to about 800 fathoms; but that there is a "stratum of intermixture" about 200 fathoms thick, in which the thermometer sinks 9°; and that below 1,000 fathoms the temperature ranges from 39° down to about 36°·5. (3.) That in the Mediterranean the temperature beneath the super-heated surface-stratum is uniform to any depth; being at 1,500 or 1,700 fathoms whatever it is at 100 fathoms, namely from 56° to 54°, according to the locality. To these may be added (4) the observations recently made by Commander Chimmo, with the like trustworthy thermometers, which, in lat. 3° 18½′ S., and long. 95° 39′ E., gave 35°·2 as the bottom temperature at 1,806 fathoms and 33°·6 at 2,306 fathoms. These seem to be the lowest temperatures yet observed in any part of the deep ocean basins outside the Polar area.

It is clear, therefore, that very strong evidence now exists, that instead of a uniform deep-sea temperature of 39°, which, on the authority of Sir James Ross, by whom the doctrine was first promulgated, and of Sir J. Herschel, by whom it was accepted and fathered, had come to be generally accepted in this country at the time when the recent deep-sea explorations commenced, not only is the temperature of the deeper parts of the Arctic basin below the freezing-point of fresh water, but the temperature of the deepest parts of the great oceanic basins, even under the Equator,

* Mr. Prestwich cites Dr. Carpenter as estimating the error from pressure "at 2° or 3° or even more." The error is said by Dr. Carpenter to have been from 2° to 3° on the depths of from 500 to 700 fathoms first explored; but would have been from 8° to 10° at the depths subsequently reached.

is not far above that point. And it seems impossible to account for the latter of these facts in any other mode, than by assuming that Polar water is continually finding its way from the depths of the Polar basins along the floor of the great oceanic areas, so as to reach or even to cross the Equator. And as no such deep efflux could continue to take place without a corresponding in-draught to replace it, a general circulation must be assumed to take place between the Polar and Equatorial areas, as was long since predicated by Pouillet.

Such a vertical circulation, it was affirmed by Prof. Buff, would be necessarily caused by the opposition of temperature between the Equatorial and the Polar seas; and this view was adopted by Dr. Carpenter, in his *Porcupine* Report of 1869, as harmonising with the temperature-phenomena which had been determined in the expedition of that year. It has been since contested, however, not only by Mr. Croll and Dr. Petermann, but also by Dr. Carpenter's colleague, Prof. Wyville Thomson, all of whom agree in regarding the amelioration of the temperature of the Arctic Sea as entirely due to an extension of the Gulf Stream, the underflow of Polar water being merely its complement. And the authority of Sir John Herschel was invoked against the idea that any general oceanic circulation could be maintained by difference of temperature alone; though his statements, when carefully examined, only go to prove that no such difference could produce *sensible currents*.

Such was the state of the question when the *Porcupine* Expedition of last year concluded its work; and the results obtained, whilst confirmatory of previous observations, suggested to Dr. Carpenter a definite Physical Theory, which now comes before us with the express approval of the great philosopher who had been said to be opposed to it.

Having ascertained, as our readers have learned from his report, the existence of an outward under-current in the Strait of Gibraltar, which carries back into the Atlantic the water of the Mediterranean that has undergone concentration by the excess of evaporation in its basin, Dr. Carpenter applied himself to the consideration of the forces by which the superficial in-current and the deep out-current are sustained; and came to the conclusion that, as had been previously urged by Captain Maury, a *vera causa* for both is to be found in excess of evaporation, which at the same time lowers the level and increases the density of the Mediterranean column as compared with a corresponding column of Atlantic water. This conclusion, when scientifically worked out, was found to be applicable, *mutatis mutandis*, to the converse case of the Baltic Sound; in which, as was long ago experimentally shown (with a result that has recently been confirmed by Dr. Forchhammer), a deep current of salt water flows inwards from the North Sea, whilst a strong current of brackish water sets outwards from the Baltic, the amount of fresh water that drains into which is greatly in excess of the evaporation from its surface.

Comparing, then, the Polar and Equatorial areas, it is shown by Dr. Carpenter that there will not only be a continual tendency in the former to a lowering of level and increase of density, which will place it in the same relation to the latter as the Mediterranean bears to the Atlantic; but that the influence of Polar cold will be to produce a *continual descent* of the water within its area; thus constituting the *primum mobile* of the General Oceanic Circulation, of which no adequate account had previously been given. This conclusion, as our readers will have seen, has been most explicitly accepted by Sir John Herschel.

Our limits do not admit of our following Dr. Carpenter through his discussion of the relative shares of the Gulf Stream and of the General Oceanic Circulation in that amelioration of the temperature of the Polar area, of which the industry of Dr. Petermann has collected a vast body of indisputable evidence; and for this discussion we would refer such of our readers as are specially interested in the question to the last part of the "Proceedings of the Royal Geographical Society." But as Dr. Carpenter has now shown a capacity to deal not merely with Physiological but with Physical questions, in a manner which has obtained the approval of some of the ablest physicists of our time, we hope that he will not again be accused (as he was by some of those who opposed his views on their first promulgation) of venturing beyond his depth when he began to reason on these subjects, and of advancing doctrines which his own observations refuted. The exclusive doctrine of the thermal action of the Gulf Stream advocated by Mr. Croll, rests, as Dr. Carpenter has shown, upon so insecure a basis, that a very large body of careful observations must be collected before any reliable data can be obtained as to the heat it actually carries forth from the Gulf of Mexico. And how much of this heat is dissipated by evaporation, as well as by radiation, before one-half of the Stream reaches the banks of Newfoundland (the other half having turned round the Azores to re-enter the Equatorial current), is a question which there are as yet no adequate data for determining. On the other hand, in his conclusion that a great body of Ocean water slowly moving northwards, so as to carry with it a considerable excess of temperature even to the depth of 500 or 600 fathoms, must exert a much greater heating power than the thinned-out edge of the Gulf Stream, Dr. Carpenter seems to us to have both scientific probability and common sense on his side.

## SCIENCE IN ITALY

*Atti dell' Accademia Pontificia de' Nuovi Lincei.*

*Reale Istituto Lombardo di Scienze e Lettere.* Rendiconti.

*Annali di Chimica Applicata alla Medicina.* Compilati dal Dottor Giovanni Polli.

ITALY has become a nation. It is no longer enslaved by the barbarous despotism of a single city, nor divided into mutual throat-cutting republics, nor diplomatically parcelled into heir-looms for royal families. It has at last become the country of its own people. The moral and intellectual laws of Natural Selection are now freely operating, and they will soon show what manner of people these Italians really are.

There are many ways of gauging the civilisation of a community. The consumption of soap has been suggested, and has the advantage, being numerically definite. Thus, let $s$ represent the quantity of soap used, $p$ the population, and $x$ the state of civilisation, we obtain the following equation—

$$x = \frac{s}{p}$$

and thus moral philosophy is brought within the reach of the mathematician. But there is another test which is, I think, even safer than soap, that is, the current literature of the nation, and more especially its periodical literature. The readers of *Reynolds's Weekly Newspaper* and the *Sporting Life* diverge so widely from the subscribers to NATURE, that their differences almost come within the reach of ethnological specification, and I believe that the direction of the growth of Young Italy may best be determined by watching the progress of its periodical and general literature.

It is a very interesting and promising fact that during the last two years the proportion of purely scientific works to those of light literature has been greater in Italy than in either England, France, or Germany. This refers only to original Italian works, and does not include translations. The periodicals named at the head of this article are good examples of the progress of the highest kind of intellectual culture in Italy. The first is published at Rome, the second and third at Milan. "The Transactions of the Pontifical Academy of the New Lynxes" does not belong to Young Italy, as the fasciculi before me are for the twenty-second year of the Academy, and the new Lynceans claim Pontifical patronage, and announce it in their name, which of course is derived from the old classical society of the Lynx-eyed Philosophers of the middle ages; a title which, in spite of its fanciful character, presented one of the earliest formal recognitions of the paramount importance of laborious observation, as opposed to the speculative and disputatious spirit of contemporary philosophy.*

The papers of Father Secchi and Prof. Respighi, on their spectroscopic and telescopic observations on the sun and stars, occupy a considerable portion of these Transactions. Father Secchi's observations are tolerably well known to English readers, but I doubt whether such is the case with Respighi's spectroscopic researches on "Stellar scintillation," the results of which were stated in papers read at the Lyncean meetings of May 10, 1868, and February 14, 1869. The second paper supplemented the first and embraces 720 observations, extending from October 4 to February 12. The primary results obtained by Prof. Respighi were that in the spectrum of a star near the horizon, dark lines and bright bands travel along the spectrum, most frequently from the red to the violet, but sometimes in the contrary direction, and occasionally oscillate from one colour to the other. The nearer to the horizon, the more distinct and definite are these moving lines and bands, and the more slow and regular their movements. The bright moving bands are more rare and less regular than the dark lines, and are only seen when the star is very near the horizon. Further observations brought out the law that in the normal condition of the atmosphere their motion is from the red to the violet in the spectrum of all stars on the west, and from the violet to the red when the star is in the east; while near the meridian, whether on the north or south horizon, the motion is generally an oscillation from one colour to the other; and sometimes the lines appear stationary, or traverse only a portion of the spectrum. In abnormal states of the atmosphere the moving lines are weaker and more irregular in form and motion; this is especially the case during strong winds, which sometimes reduce the movements on the spectrum to mere variations of brilliancy, even in stars very near to the horizon.

Prof. Respighi observes that these appearances are not due to an oscillation of the characteristic spectrum of the star, and that there is no superposition of its colours due to any sensible movement of the image of the star in the normal states of the atmosphere, though he does not deny that there may be such sensible oscillation and superposition, under conditions of abnormal atmospheric disturbance. He has observed that when the moving lines are regular in form and motion, there is usually a continuance of fine weather, and that the phenomena of scintillation are most marked and decided on those nights when there is much humidity in the atmosphere. He believes that by careful study of these phenomena the spectroscope may become an important meteorological instrument.

It would occupy too much space to follow Prof. Respighi through his theoretical reflections on these phenomena, which he attributes to irregularities in the temperature, and distribution of aqueous vapour, &c., in the earth's atmosphere, and the effects of its rotatory movement with the earth, which carries it across the direction of the radiation of the light from the stars.

Besides the above-named, there are some very interesting papers on electro-static induction, and electrical induction or influence in rarefied gases, by Prof. Volpicelli.

The four first numbers of the present year of the Reports of the Royal Institution of Lombardy are remarkably rich in interesting papers, extending over a wide range of subjects. Buccellati on Military Punishment, Lambrosi on the Italian Races, and Ciavarini on the Laws of Human Progress, are the chief essays in the Department of the Moral and Political Sciences. In the Department of the "Mathematical and Natural Sciences" the subjects of the papers are more varied, including, Rovida on the Pulse of the Veins, Barbieri on the Utility of Statistics of Hernia in Italy, Experimental Researches on the Origin of Fibrin, and a new Theory of the Cause of the Coagulation of the Blood, by Mantegazza, and Serpieri on the Probable Relation between the Luminous Cones (*pennacchi*) of the Solar Corona, and the Positions of the Planets.

The author of this paper supposes that the corona is an electrical phenomenon identical with that of our terrestrial aurora borealis, that the sun and all the planets mutually act and react upon each other inductively; that the cones of rays which stretch out from the corona are electrical streamers pointing towards one of the planets; that the curved lines and rays which have been observed

* The original *Academia Lincea* was founded in Rome by Federigo Cesi, the Marchese di Monticelli, in 1603. Cesi was the first president, and Baptista Porta the Neapolitan vice-president. Galileo became a member in 1611. It preceded our Royal Society and the French Academy by about half a century, and combined the functions of these societies with a scheme of philosophical brotherhood and affiliated lodges, somewhat resembling the masonic organisation. Its members were required to be "philosophers eager for real koowledge, who will give themselves to the study of nature, and especially to mathematics." They were to waste no time in "recitations and declamatory assemblies," and to "pass over in silence all political controversies and quarrels of every kind, and wordy disputes, especially gratuitous ones." They are commended to "Let the first fruits of wisdom be love; and sn let the Lynceans love each other as if united by the strictest ties, nor suffer any interruption of this sincere bond of love and faith, emanating from the source of virtue and philosophy."

are other streamers, pointing obliquely to planets or comets; that the zodiacal light is the general stream of electrical influence emanating from the sun and embracing all his planetary children; and that the sun-spots and the hydrogen prominences are due to electrical outbursts. We have had similar hypotheses put forth in England, but not so well argued as by Prof. Serpieri. Like the rest, he fails, however, to supply us with any explanation of the source of such tremendous electric energy. We may have the cylinder, the prime conductors, the insulators, the Leyden jars, and all the apparatus of a fine electrical machine; but we shall get no sparks unless somebody turns the handle. We obtain no electrical force without an expenditure of equivalent mechanical power. In the battery we must oxidise an equivalent of zinc for each equivalent of electricity produced. We know something about the laws of electrical excitation; and those who assume the existence of such huge electrical forces without indicating their origin in accordance with these known laws, only carry the problem of the source of solar energy one stage further back without advancing a single step towards its solution. Among the other papers are Lannetti on Etruscan Crania, and some on Pathology and pure Mathematics.

The Annals of Chemistry, compiled by Dr. Polli, is a carefully collected and valuable record of the progress of Chemistry, in which the subjects are classified under the heads of Pharmacy, Hygiene, Dietetics, Physiology, Toxicology, Pathology, Therapeutics, and Miscellaneous. It is published monthly in octavo fasciculi of sixty-four pages, each containing abstracts of papers from native and foreign journals. It sells at rather less than one shilling. As our *Philosophical Magazine*, with eighty pages of the same size, scarcely pays expenses at 2*s*. 6*d*., we may infer that the *Annali di Chimica*, of Milan, has a better circulation than its old-established scientific contemporary of "London, Edinburgh, and Dublin."

W. MATTIEU WILLIAMS

## SEELEY ON THE ORNITHOSAURIA

*Index to the Fossil Remains of Ornithosauria, Aves, and Reptilia from the Secondary Strata, arranged in the Woodwardian Museum, Cambridge.* By Harry Govier Seeley. 8vo. pp. 144. (1869. Cambridge: Deighton.)

*The Ornithosauria, an Elementary Study of the Bones of Pterodactyles.* By Harry Govier Seeley. With 12 plates. 8vo. pp. 136. (1870. Cambridge: Deighton.)

THANKS to the activity of the "Coprolite" workings in the Upper Greensand around Cambridge, the Woodwardian Museum possesses particularly rich series of interesting reptilian remains, especially those belonging to the *Ornithosauria* or Pterodactyles (Flying Lizards) of the Secondary rocks; to which the second work with its twelve plates is entirely devoted, as is also a large part of the Catalogue first published.

The "Index to the Fossil Remains" is introduced to the attention of the student and anatomist by a prefatory notice from the Rev. Adam Sedgwick, Woodwardian Professor, who, although in his eighty-fifth year, evinces still considerable remains of his wonted fire, when taking up his pen to write of the treasures contained in the Museum of his Alma Mater. The cost of preparing these works has been borne by Prof. Sedgwick, but the printing of both books has been defrayed out of the funds of the Syndics of the University Press.

1. The first book is intended to serve as a guide to the student in the examination of the remains of the extinct birds and reptiles preserved in the Woodwardian Museum, each case, shelf, and bone being numbered so as to correspond with the catalogue in which it is described. The list of specimens from the Cambridge coprolite bed occupies about half the book.

Many new forms are here announced by the author for the first time, as *Enaliornis* (a new bird) several new *Ichthyosauri*, a new Crocodile, 3 species of *Stereosaurus*, 2 new Chelonians; so that we have altogether 70 species from the Cambridge Greensand. There are also Chalk (8 sp.), Gault (2), Wealden (12), Purbeck (7), Potton beds (18), Portland (1), Kimmeridgian (10), Coral rag (3), Oxford clay (8), Oolites (4), Lias (20), foreign reptiles (24), making a total of 187 species.

2. In the second work, that on the Ornithosauria, the author enumerates the materials at his disposal, namely, 500 bones in one collection, and 400 in another, probably representing not fewer than 150 individuals, which well displays the richness of the area.

The bones from the coprolite diggings are much broken, but they retain sufficient character to be readily determined by the comparative anatomist.

Probably, no group of animals have caused more contention between Naturalists than the Ornithosaurians. They have been regarded as bats (Sömmering), as intermediate between birds and reptiles (Goldfuss), amphibians (Wagner), and so on. Herman von Meyer, who has paid more attention to them than any other anatomist, concludes them to be reptiles, though with strong avian affinities. Prof. Owen maintains that they are Saurians.

Mr. Seeley combats these views, and contends that the Pterodactyles were more nearly allied to birds than reptiles, and he refers them all to a new genus, *Ornithocheirus*.

He contends against the cold-blooded view taken of them by Prof. Owen, and asserts that they were warm-blooded, chiefly founding his opinion on the form of the brain. There is a very strong objection to be made against the retention of the terms "cold-blooded," and "warm-blooded," for it seems to us that the heat developed by the animal's body is in direct proportion to the work to be performed. Thus, in aërial locomotion, the efforts of the pectoral muscles to sustain the body in the air, necessitate also a correspondingly more rapid action of the heart and lungs, producing, therefore, more rapid circulation, and an increased bodily temperature. We are therefore inclined to agree with Mr. Seeley on the grounds that, in proportion to the rapidity and the sustained action of the great motor muscles of the body (whether of legs or wing) so will be the rapidity of the action of the heart and lungs, and consequently the acceleration of the temperature of the whole body.

The bones from the Cambridgeshire Greensand are very often so fragmentary that their determination requires the most exact anatomical skill, and we think the plates would have been more useful if in a few instances (perhaps in all) the missing parts and processes had been indicated in outline, so as to help to the better understanding thereof by the student.

H. WOODWARD

## OUR BOOK SHELF

*Handbuch der Systematischen Anatomie des Menschen.* Von Dr. J. Henle, 1 Band, 1 Abtheilung, Knochenlehre, 3 Auflage, pp. 310. (Braunschweig, 1871. London: Williams & Norgate.)

It is unnecessary to commend the work of Prof. Henle, which is on the whole the most full and exact yet published. It shares the richness and accuracy of its illustrations with the last edition (the fourth) of Cruveilhier's great work, and shares with it the serious disadvantage of being incomplete. Indeed, while in the latter the part relating to "Angéiologie" which includes the description of the heart, blood-vessels and absorbents, was published in 1867, preceding the completion of the second volume on visceral anatomy in the following year, the third volume of the German work, with the whole of the nervous system, has not yet appeared. In this respect the only English work on descriptive anatomy which can rival Henle's has a great advantage; each edition of what was originally Dr. Quain's Anatomy has been published complete, and on this ground, as well as that of conciseness, the last edition of this work may, with the help of Prof. Sharpey's masterly introduction on general anatomy, take rank with those of France and Germany.

The department of osteology is not that which Prof. Henle has done best. In minute accuracy of detail it is decidedly inferior to Mr. Ward's treatise, which at least equals the best efforts of the French School of Anatomy. And there is a want of attention to broad views of morphology almost as conspicuous as in M. Cruveilhier's work. Thus the comparison between the upper and lower extremities (pp. 226—229) is very insufficient, giving no account of the important and opposing views which have been maintained on this subject, and admitting the demonstrably false position that the radius answers to the fibula, and the ulna with the olecranon to the tibia with the patella. The difficult subject of the homologies of the cranial and facial bones is also entirely omitted, an omission rendered necessary by the absence of any account of their fœtal development. The rigid specialisation of human osteology so as to exclude all reference to embryology and comparative anatomy on the one hand, and on the other to the mechanism of the skeleton, makes what ought to be the most interesting part of anatomy the most arid and forbidding. In the last edition of "Quain's Anatomy" we have within a shorter compass a good account of the antecedent development, as well as the mere ossification of the several bones, with illustrative diagrams, and a sufficient account of its homologies to awaken interest in this attractive study. On the other hand, there is nowhere to be found so complete an account of Abnormalities as in Prof. Henle's work, a subject of which the importance is only beginning to be recognised in England. The references to observations in this branch of the subject are very full, and include many only lately published. On this, as on other points, the author has added many fresh facts in the present edition. On the whole, however, it differs but little from the first issue in 1855, and the number of woodcuts remains the same. Among the more important additions may be mentioned one on the differences in the skull of the two sexes (p. 216). No mention is made of the little tympano-hyal bone described by Prof. Flower, and even the ordinary variations of the styloid process, which throw so much light on its homology, are scarcely alluded to.

In conclusion, every anatomist will acknowledge the industry and care with which even small advances in knowledge are added in this edition, but will also hope that nothing may delay the appearance of the volume which is to complete the whole treatise, and no doubt complete it worthily of its distinguished author, and of what he has already published.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Science Lectures for the People

Of the justice of your remarks on "Science Lectures for the People" there can be no doubt whatever. The lectures in question are perfect models of what lectures should be, and while reading them I pictured to myself the rich feast that had been prepared for the people who were fortunate enough to hear them—especially for those who had some previous acquaintance with the subjects of which they treat. They are couched in simple language, so that those who run may read. They are strictly to the point, well calculated to excite further inquiry, and in every way adapted for the purpose for which they were intended. It may be, however, doubted, whether lectures on scientific subjects before the general public, however delivered, do that amount of good which they certainly ought to do. A lecture to be thoroughly and lastingly effective presupposes a certain acquaintance with the subject already. To listen even to the most brilliant and never so simply worded address on Spectrum Analysis or Coral Reefs, has a very transient effect, I take it, upon those who have rarely or never heard of such things. However praiseworthy, therefore, every effort to scatter scientific knowledge among our population may be—and it certainly deserves every commendation—my decided opinion, arrived at after large experience with the people in towns and country, especially the latter—is that it will fail, unless we begin with the young. People in masses may be compared with fuel laid in the grate. If you ignite it from the top, a considerable time will elapse before it reaches the whole mass; but if the fire be applied from below, the course is more rapid, and the fuel sooner feels the effect. So with science teaching, or any teaching, we must begin in our schools. Every school, from the primary to the highest, must be opened to its influence. Teachers, I am sure, would welcome the innovation, for it would dispel many a weary hour both for teacher and taught. The everlasting monotony of reading, writing, arithmetic, and scripture, would be enlivened by simple explanations of the human body, plants, &c., and thus children would be taught to take an interest in all matters connected with their future welfare even from their infancy. The same remarks, slightly modified, would apply to many of our middle class and upper schools; for scientific matters, in far too many cases, have still to find a place even here—parents being themselves quite as much, in many instances far more, to blame than the regulations of the school.

It is precisely owing to this want of early training, and consequently to an utter ignorance of the subject, that the lectures on divinity, science, &c., in our universities are of such little real value, and of such little interest to the students. They attend them, it is true, not from any genuine love, but simply because they must attend some for certificates or otherwise. No fault whatever attaches to the lectures themselves; on the contrary, they are of the greatest possible value, and had the students themselves been trained properly and gradatim when at school, the attendance would be vastly increased, a genuine love for the lectures would be engendered, and incalculable results would be the consequence. Or take another instance—our farmers' clubs. With laudable zeal these have been formed all over the kingdom. Lectures on scientific subjects connected with agriculture are delivered from time to time. All very admirable no doubt in its way. The attendance generally is good, but from the vacant stare, the nodding head, and subsequent remarks, nothing can be clearer than that nine-tenths of the lecturer's address on the abstruse niceties of chemical analysis, &c., have been utterly thrown away. What subjects can be more valuable to a farmer than a knowledge of the constituents of the air, the origin of soils, the inner life of plants, the wonderful dependence of animals and plants upon each other, the means of judging artificial manures, &c.; and yet, except among the upper favoured few, utter ignorance of these matters almost universally prevails. It is not from indifference to the subject, far from it, but, as in the former case, from a want of early training in this particular line of thought. The farmer acts just as his father acted before him. He is of all people the most backward in leaving the old routine, and considers such subjects as geology and botany altogether beside the purpose, and a waste of time for his children to learn, though he will praise them in the same breath.

There is nothing more trying for a master's patience—and I speak from experience—than this persistent and short-sighted adherence to what has gone before, just as if the world (the agricultural world particularly) had to jog on to the end of time in the self-same fashion.

Whatever united action, therefore, may be taken by our leaders in science for bringing about a more healthy feeling on this subject, for scattering science and a love for it in every household, depend upon it the readiest and surest way will be to urge on Government to introduce, nay, force, the subject freely and universally into all schools, so that it may grow up with the rising generation, and become a part of their very existence. The task is Herculean, no doubt. An enormous amount of prejudice will have to be overcome, but

Sedit, qui timuit ne non succederet : esto :
Quid? qui pervenit fecitne viriliter?

Lectures on science will thus be not merely listened to as now, but understood and appreciated. Superstition, the child of Ignorance, will be dispelled, and a nation of reasoning and thinking men and women inaugurated as the glorious and inevitable consequence. THOMAS FAWCETT

Blencowe School

### Preponderance of West Winds

I HOPE you will publish this reply to Mr. Laughton's letter in NATURE of May 4, on the Prevalence of West Winds.

He maintains from statistical evidence that west winds occupy a greater portion of the earth's surface than east winds; that their force is greater; and that in the upper regions of the atmosphere the preponderance of west winds is still more decided than at the earth's surface; so that on the whole the atmosphere moves round the earth from west to east.

It is in my opinion certain that this is on the whole proved. I do not question Mr. Laughton's facts but his inferences from them. He thinks this rotation points to some force acting from without—some cosmical cause of a nature quite unlike the sun's heat. I maintain, on the contrary, that all the phenomena of the great atmospheric currents, of which the trade-winds are a part, are to be accounted for by the heat of the sun as the motive power, combined with the rotation of the earth as a modifying influence.

In discussing the question of whether the phenomena point to such a cause as that suggested by Mr. Laughton, the motion of the upper strata of the atmosphere is quite unimportant. It is only the currents at the surface of the earth that can in however infinitesimal a degree increase or diminish the velocity of the earth's rotation; and if the circulation of the atmosphere is due to the sun's heat as its motive power, it cannot have the slightest effect on the earth's rotation; while if it is due to any mechanical force acting from without, as Mr. Laughton thinks—if the Cartesian theory is true, and the circulation of our atmosphere is part of a cosmical vortex—the earth's rotation must be accelerated by its friction. This follows from the simplest dynamical principles. It is true that the acceleration which could be produced in such a way would at the greatest be far too small for us to detect; but it is quite possible for us to ascertain whether or not the currents of air that sweep over the surface of the earth are by their united action capable of affecting its rotation; or, to state the problem more definitely, whether or not the effect of west winds in accelerating the rotation is balanced by the effect of east winds in retarding it. I maintain that such evidence as we have tends to the conclusion that the effects of the two are so balanced.

The separate effect of any wind covering a given area on the earth's rotation = the east and west component of its force × the radius of the parallel of latitude. The latter factor gives leverage. An east wind near the equator has more effect in retarding the rotation of the earth than a west wind of equal extent and force at a higher latitude has in accelerating it, just as a weight at the end of the long arm of a lever outweighs an equal weight at the end of the short arm. Now, the east winds, under the name of trade-winds, are chiefly to be found in the lower latitudes, and for the reason just given they are able to balance the west winds, which are certainly more forcible, and according to Mr. Laughton, occupy a greater area, but being at higher latitudes act at a disadvantage. If it can be shown—and the facts certainly point to it—that the total mechanical effect of the winds is not such as to produce any effect on the earth's rotation, this goes very far to prove that they have no motive power except the sun's heat.

But how is the motion of the upper strata of the atmosphere from west to east to be accounted for? The answer to this will involve the entire theory of the great currents of atmospheric circulation. There is always a current of air towards a heated place along the earth's surface, like the draft towards a fire, and a compensating current of air away from it in the upper regions of the atmosphere. The equatorial latitudes being the hottest, there are currents to them from the higher latitudes, which bring with them the smaller velocity due to the rotation of the higher latitudes, and thus move less rapidly than the earth in those lower latitudes to which they flow. Moving with a less velocity than the earth is the same as moving from the east, and thus are the trade-winds constituted; they are from north-east in the northern hemisphere and from south-east in the southern. This is generally understood and believed; what follows is less generally understood, though I claim no originality for it.

The air rises up over the equatorial regions like a column of smoke over a fire, and flows off towards the poles. Coming from the latitudes where the velocity of the earth's rotation is greatest, it carries that greater velocity with it, and spends the energy of its motion in the form of the west winds of the higher latitudes. The reason, then, that the upper strata of the atmosphere (in all latitudes except on the equator) have a motion round the earth from west to east, is simply that they are at the same time moving from latitudes where the velocity of the earth's rotation is greater to latitudes where it is less. JOSEPH JOHN MURPHY

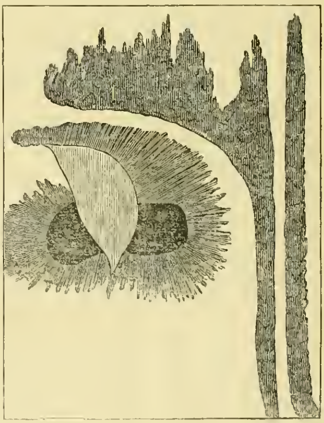
### Remarkable Sun-spots

THE accompanying sketch shows in a rough way the umbræ and a small portion of the penumbra of a sun spot that I observed on the 6th and 7th of this month, and which was made remarkable by the presence of a reddish-brown object like a cloud, that seemed to hang over the nucleus of the principal umbra, apparently dividing it in two. Could this object be seen without the intervention of the dark glass, it would doubtless show a bright red instead of a reddish-brown colour; and from its fog-like aspect, though it was well defined in outline and acuminated at both ends, the impression was inevitable that it hung at a certain altitude above the spot. However, it evi-



dently had no motion distinct from the latter, as on the 7th it occupied the same position as on the day before, but it was much reduced in size. On the 8th it was seen no longer, and the nucleus was now in one, seeming to show pretty clearly that its previous apparent division in two was really caused by the intervention of the brown cloud suspended over it, and that the phenomenon did not consist of two distinct neuclei with the brown object lying between them. I am not aware that anything like this was observed before. J. BIRMINGHAM

Millbrook, Tuam, May 18

## ANNUAL VISITATION OF THE ROYAL OBSERVATORY

ON Saturday last the Board of Visitors of the Royal Observatory made their annual visitation to our National Observatory to examine into the work done, and to receive the Report of the Astronomer Royal. We have not space for the report in full, but this is not to be regretted, for it contains a quantity of minute detail about trivial matters which the ordinary run of mankind would not think worth the printing.

There are, however, several points of great scientific interest in the Report, the new Water Telescope and the instruments for use in the approaching observations of the Transit of Venus having been the lions at Greenwich.

The correction for level-error in the transit instrument having become inconveniently large, owing apparently to a gradual subsidence of the eastern support since the erection of the instrument, about a ton weight of stone was placed on the western pier. Not the slightest change, however, could be traced as due to this; the level-error maintaining its usual value. This plan having failed, the stones were removed, and a sheet of very thin paper, $\frac{1}{270}$ inch in thickness, was placed under the eastern Y, which was raised from its bed for the purpose. The collimators having been observed just before this operation, no difficulty was experienced in adjusting the instrument so as to have very nearly the same error of Azimuth as before. The mean annual value of the level-error appears to be now sensibly zero. This will give some idea of the delicate arrangements necessary for this ponderous instrument.

The usual course of Astronomical observations now carried out for so many years has been adhered to. The list of fundamental stars used for determination of clock-error has been increased to 210. Besides these, Nautical Almanac, circumpolar, and moon-culminating stars have been observed; also refraction stars, stars with large proper-motion, and stars which are required for any special investigation. A few of Bradley's stars which had been inadvertently omitted have been observed in the past year. The Sun, Moon, and large planets have been observed as usual. As the siege and war operations in Paris seriously interfered with the observations of small planets made at the Paris Observatory, observations of them were continued at Greenwich throughout each entire lunation during the investment of the city.

The observations of $\gamma$ Draconis, the star which passes very near the Zenith of Greenwich, with the Water Telescope, made in the spring of the present year, are completely reduced, with the exception of a small correction for the positions of the micrometer-wires, to be determined shortly. As the astronomical latitude of the place of observation is not known (it is not many yards from the transit circle), the bearing of these observations on the question of aberration cannot be certainly pronounced until the autumn observations shall have been made; but, supposing the geodetic latitude to be accordant with the astronomical latitude, the result for aberration appears to be sensibly the same as with ordinary telescopes.

With regard to the Magnetic instruments, the Astronomer Royal states that a plan was arranged last year for photographic impression of hour-lines upon the photographic sheets carrying the records of the three Magnetometers and of the Earth-current Galvanometers: an arrangement already for some time carried out in the new instruments by Dr. Balfour Stewart. The beam of light, constantly directed through a cylindrical lens to fall upon the sheet, emanates from one of the existing lamps, or (in one instrument), from a flame specially mounted for it; it is, however, obstructed by a shade till $2\frac{1}{2}$ minutes before each hour, and acts till $2\frac{1}{2}$ minutes after each hour. The connections of the shades were so arranged that all could be opened and closed by a single wire.

The following numerical results of the magnetic elements for 1870 may be interesting:—

| | |
|---|---|
| Mean westerly declination . | 19° 54′ nearly. |
| Mean horizontal force . . . | 3·865 (in English units).<br>1·782 (in Metrical units). |
| Mean dip . . . . . | 67° 51′ 9″ (by 9-inch needles).<br>67 52 25 (by 6-inch needles).<br>67 53 41 (by 3-inch needles). |

The observations of dip at different hours appear to show a diminution from 9h. A.M. to 3h. P.M.

A small Appendix of great interest is attached to the report. Those who have given attention to the history of Terrestrial Magnetism are aware that Halley's Magnetic Chart is very frequently cited; but the Astronomer Royal could not learn that any person, at least in modern times, had ever seen it. Inquiries were made of nearly all the principal scientific bodies in Europe, and in several of the best continental libraries in vain. At last, by the assistance of Mr. Winter Jones, Principal Librarian of the British Museum, a copy was discovered in the library of the Museum. 600 copies have been taken in a reduced size, for insertion, as an Appendix, in the Magnetical and Meteorological volume for 1869.

On the subject of Chronometers it is remarked, "The performance of chronometers, as depending on their mechanical construction, is very admirable; I have remarked but one point on which I could desire change, namely, that the balance should be struck more lightly, at a greater distance from its axis; the late Mr. Charles Frodsham, at my suggestion, had made experiments on this point, which promised to be successful. The principal errors of even moderately good chronometers are, however, produced by defective compensation, which the most skilful makers cannot perfectly manage. I have long been of opinion that the final adjustment for compensation ought to be made by some more delicate operation than that which suffices for approximate compensation; but the able chronometer-makers whom I have consulted have not yet devised a satisfactory plan."

With reference to Time Signals, we read that a proposal has been made to have a time-ball dropped at Queenstown, and that the report of the Westminster Clock shows that 55 per cent. of its errors are under $1^s$, and 94 per cent. under $3^s$.

In December two attempts were made to determine the longitude of Gibraltar, at the request of Professor Newcomb, but without success, the cable connecting Falmouth and Gibraltar being out of order.

During the year the time of the Astronomer Royal has been partly occupied in preparations for the Transit of Venus, 1874. Measures have been taken for equipping each of five stations with a Transit, an Altazimuth, and an Equatoreal. Some other instruments mounted in temporary observatories were inspected by the visitors. Of Transits there are five new, all mounted on stone piers. Of clocks to accompany them, there are two from the Royal Observatory, three new. Of Altazimuths, one from the Royal Observatory, four new. Of Equatoreals, 6 inches in aperture, and carried by clock-work, there are five, purchased or new. Of clocks of an inferior class, to accompany the two last classes of instruments, one can be supplied, nine must be procured. Fifteen portable observatories must be prepared, of which specimens were exhibited to the visitors. The Royal Observatory can supply three 4-inch detached telescopes, and two more will be desirable.

The report goes on to say:—"My preparations have respect only to eye-observation of contact of limbs. With all the liabilities and defects to which it is subject, this method possesses the inestimable advantage of placing no reliance on instrumental scales. I hope that the error of observation may not exceed four seconds of time, corresponding to about $0''\cdot13$ of arc. I shall be very glad to see, in a detailed form, a plan for making the proper measures by heliometric or photographic apparatus; and should take great interest in combining these with the eye-observations, if my selected stations can be made available. But my present impression is one of doubt on the certainty of equality of parts in the scale employed. An error depending on this cause could not be diminished by any repetition of observations. As, in the event of any national enterprise being promoted in the direction of photographic record, it is probable that the Astronomer Royal may ministerially take an important part, I venture to submit to the Board of Visitors that suggestions on the value and plan of such observations fall entirely within their competence."

All the American observers of the Solar Eclipse, as well as M. Janssen, have visited the Observatory during the past year.

The current reductions of observations, it is remarked, are in a healthy state. Regular reductions give, "in general, great facility for the most advanced inferences; the star-catalogues, and solar, lunar, and planetary errors, lend themselves immediately to investigations of a physical character; the magnetic reductions distinctly, though tacitly, exhibit some of those results (for instance, annual inequalities) which in various observatories have been the subject of special memoirs.

"But from time to time it becomes desirable to unite some of those annual or nearly annual results in groups, so as to exhibit the results justly derivable from masses of observations extending over long periods of years. These operations require new organisations; and, what is worse, they require additional grants of money. I have usually refrained from asking for these, without the distinct approval of the Visitors. I would now submit for their judgment the following subjects:—

"The vigorous prosecution of the Meteorological Reductions (exhibiting the results deducible from the photographic registers) already begun.

"The combination of the results of Magnetic Observations on disturbed days, from the year 1864.

"The discussion of Magnetic Storms, from the year 1858.

"Perhaps, also, the discussion of observations in groups depending on Lunar Declination, or other phases."

The report concludes as follows:—"There is another consideration which very often presents itself to my mind: the waste of labour in the repetition of observations at different observatories. The actual Greenwich system was established when there was little to compete with. Other observatories have since arisen, equipped with and principally using the same classes of instruments, and devoting themselves in great measure to the same subjects of observation (except the unrelenting pursuit of the moon, and perhaps the fundamental elements of the ecliptic). Ought this Observatory to retire from the competition? I think not; believing that there is greater security here than anywhere else for the unbroken continuity of system which gives the principal value to series of observations. Still, I remark that much labour is wasted, and that, on one side or another, that consideration ought not to be put out of sight in planning the courses of different observatories."

This is a very broad hint for some English as well as Foreign Observatories, and it will be well for the cause of Science if the directors of those observatories will take it.

## *THE SCIENTIFIC VALUE OF CHEESE-FACTORIES*

THE American system of cheese-factories was established nearly twenty years ago, and in its present condition of maturity it retains all the essential features which were characteristic of its infancy.* The test of twenty years' experience in a country where apparent improvements are eagerly submitted to a fair trial is amply sufficient to prove the success of the system. Recently the question of its adaptability to English dairy districts has acquired considerable prominence in agricultural circles, and is now passing from the stage of discussion to that of experiment. The two great merits which are claimed for it are, economy in the labour of production, and superiority of quality in the produce. It is evident that if a dozen farmers convey their milk to one building (a factory) to be made into cheese or butter, fewer hands are required to perform the work than if the process were carried on at a dozen different places by as many sets of people. The factory can be furnished with better labour-saving machinery than the farm-dairy, and the former establishment requires no more supervision than the latter. The process of cheese-making, also, occupies practically the same length of time, whether the quantity of milk under treatment be large or small, so that two or three persons whose energies are concentrated at one place will produce as great an economic result as a dozen or more who are necessarily employed at as many different points, each one going through the same routine independently of the other.

The superiority in the quality of the manufactured article may be more difficult of explanation, for the best farm-dairies produce as good cheese as any factory. The reason why the establishment of factories has improved the *average* make of cheese is because fewer first-rate cheese-makers are required under the factory system. But when Mr. Jesse Williams established the first factory twenty years ago, the great bulk of American cheese was extremely poor, and for many years after it was almost unsaleable in the English market. At the present day, on the contrary, it can compete on even terms with all but the very choicest English makes, notwithstanding that it has to undergo the ordeal of a long sea-voyage. The factory-system, therefore, has not only improved the *average* quality of American cheese, but it has very considerably raised the standard of the choicest brands.

Students of nature are perfectly well aware that the most sure and rapid progress is made by means of association and co-operation. The same phenomena are observed from different points of view by workers in the same field; a comparison of their notes leads to the grouping of kindred facts; the apparent exceptions are seen to be the product of attendant variations in the methods or circumstances of observation; and by a process of induction an explanatory theory is arrived at, to be confirmed or rejected by future investigations. In this manner the cheese-factory system has gone far towards the establishment in America of a science of cheese-making. Each factory has been the theatre of exact observations, which have been duly recorded. The results of comparisons of these records have been embodied in papers read before the American Dairymen's Association; and the conclusions of the authors have been frequently put to the crucial test of experiment.

The American Dairymen's Association is only a child of the Factory-system. It is organised on a plan similar to that of the British Association for the Advancement of Science, and like that institution, holds an Annual "Convention," at which papers are read and lectures are delivered. These contributions to the literature of dairying, and the discussions thereon, are published in an annual "Report," which also contains detailed reports from numerous cheese and butter factories, giving the dates of commencing and finishing work, the number of cows supplying the factory, the quantity of milk received, the quantity of cheese made, the percentage of cheese to milk at different periods of the year, and as compared with

* For detailed descriptions of this system, *vide* Journal Royal Agricultural Society, 2nd Series, vol. vi. p. 173, and vol. vii. p. 1.

previous years, as well as other data, including peculiarities in modes of manufacture, which may be useful for comparison with the methods pursued and the results obtained at other factories. There can be no doubt that these efforts must sooner or later result in the formation of a dairy science, and in the establishment of sound theories of dairy management.

But the functions of the American Dairymen's Association are not confined to observation and experiment at home. Already the inquiries of its officers have enabled its members to improve their cheese-making practice by adopting some features of our Cheddar system; and in the last volume of the Report of the Association is an able paper by Prof. Caldwell,* showing some features common to the numerous cheese-making processes followed in Holland, Switzerland, France, and Italy. One of the most interesting points brought out is the intimate connection that exists between the ripening of cheese and the development and growth of *Micrococcus* and other forms of mould. As a matter of commerce it is important to the farmer to ripen his cheese as soon as possible. This is done in various ways, all having for their object the introduction of large numbers of germs of the appropriate fungus. The ripening of Stracchino cheese is thus induced by the introduction of layers of old curd; that of Roquefort by an admixture of mouldy bread, containing germs of *Penicillium*, and that of Brie by packing the thin cheeses between layers of musty hay. Another observation of interest is, that the presence of free ammonia in the curing-room hastens the ripening of the cheese, a fact which may have some bearing on the well-known property of American cheese (which is always packed in boxes) to ripen more rapidly than English makes.

These evidences of a process of scientific investigation induce us, therefore, to regard the factories, or associated dairies, as they are termed, as possessing a scientific value, both as educational establishments and as laboratories. But, it may be asked, why is this not true also of the farm-dairy? Our answer is, that while the manager of a factory makes cheese-making his sole business, his success in which depends entirely on his skill and knowledge, the English dairy-farmer has little or nothing to do with cheese-making, but occupies himself with the management of his farm. With the production of the milk his supervision ceases, and the manufacturing process is either carried on by his wife, who has household cares to occupy her time and thoughts, or by a dairymaid, who has no interest in the matter, and who knows that her services are at a premium.

Thus, with the exception of the additions to our knowledge of the *rationale* of cheese-making, for which we are chiefly indebted to Dr. Voelcker's chemical researches,† the manufacture of dairy products in England can hardly be said to have advanced during the last half century, while it has made enormous strides in America during the last ten years. Let us hope that the establishment of cheese-factories in England, commenced last year at the risk of some liberal-minded Derbyshire landlords,‡ may also be the dawn of an English era of progress in this most important agricultural industry.

## *HYDRAULIC BUFFER FOR CHECKING THE RECOIL OF HEAVY GUNS*

THE ingenious instrument, the name of which stands at the head of this paper, deserves some notice, not only on account of its utility for its purpose, but as an interesting method of meeting and overcoming those violent efforts of nature to which she is provoked by explosion. In the recoil of a heavy gun, we have an example of the greatest force which man attempts to control. The inventions of Captain Moncrieff, which no long ago formed the subject of an article, seek to utilise this force; other gun carriages lead it to expend itself as harmlessly as possible.

The Hydraulic Buffer accomplishes this latter object in a manner very ingenious, and affording some interesting illustrations of Nature's laws; it also possesses several advantages over other methods which have been and are still used. For it the public service is indebted to Colonel Clerk, R.A., F.R.S., Superintendent of the Royal Carriage Department in Woolwich Arsenal. Before the introduction of the Hydraulic Buffer into the English service, and in those cases where it is not yet applied, the method employed to overcome the recoil was the friction of iron plates. To the bottom of the gun-carriage several plates are fixed, which pass between long plates placed along the middle of the slide or platform on which the carriage runs; and the friction of their surfaces in contact overcomes the force of the recoil, and brings the gun and carriage to a standstill. The amount of the friction can be regulated by the compression given to these plates, and requires to be altered for the various charges used. The compression must be taken off to allow the gun to be run forward to the firing position, and must be again set up to meet the recoil.

The Hydraulic Buffer, on the other hand, is always ready for use, and never needs any adjustment. This is one of its advantages, and one which is of special importance in the heat and excitement of action. It consists of a cylinder (A B in figure) placed in the platform, and lying along its length. In the cylinder is a piston pierced with four holes, and the extremity of the piston-rod is attached to the carriage. When the gun and carriage are run out for firing, the piston is moved to the lower end of the cylinder (A), which is filled with water, except a small air-space exceeding slightly the cubic content of the piston-rod, so as to allow for the displacement of the water when the piston is driven to the other end of the cylinder. When the gun is fired, and with its carriage begins to recoil, the piston is driven back into the cylinder. The first effect of this is to compress the air in the cylinder very violently, then the water begins to run through the four holes in the piston, this motion soon attains a very great velocity, and in imparting this to the water, the force of the recoil is soon exhausted. It is spent in transferring the water with very great rapidity through these orifices from one side of the piston to the other.

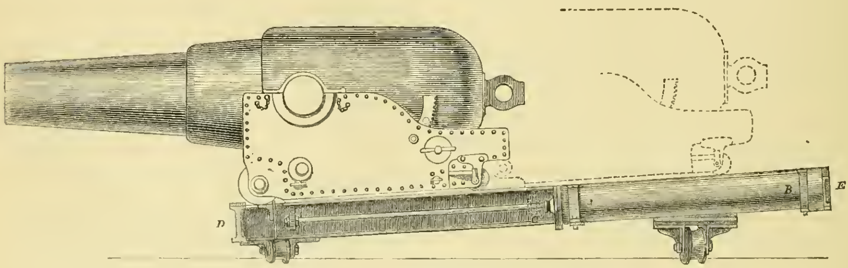
This rapidity depends on the ratio of the area of the piston to the area of the four holes in it. A very small diminution in the area of these orifices would cause the recoil to be checked very much sooner; a correspondingly slight increase would allow the piston to strike with violence against the end of the cylinder. It was found in an experiment with a 20-pounder gun, that when the holes were 0·562 of an inch in diameter, the recoil extended the whole length of the cylinder, 2ft. 9in., and struck violently the end of it; when a piston was used with holes 0·437 in. in diameter, the recoil was only 1ft. 11in., and ended quietly, the same charge being used. In another experiment with a 12-pounder gun in a boat carriage the holes in the piston were five-eighths of an inch in diameter, the recoil was 2ft. 2in.; when the diameter of the holes was increased by one-sixteenth of an inch the recoil was 3ft. 2in.* The proper ratio of the area of the holes to the area of the piston is evidently that which will allow the recoil to expend its force in nearly, but not quite, the whole length of the cylinder. When once this ratio is fixed, it is very remarkable that the amount of the charge, or the slope at which the platform is placed, whether up or down or

* The reason of this is evident from a little consideration: first, every addition to the area of the holes diminishes the area of the piston, which acts on the water; secondly the difference of the work done by the recoil is proportional to the difference of the *squares of the velocities* given to the water in passing through the orifices in the two cases.

horizontal, makes comparatively little difference in the length of the recoil. With a 12-ton (300 pounder) gun a service charge of 30 lbs. of powder gave a recoil of 4 ft. 5 in.; with a battering charge of 43 lbs. the recoil increased only to 5 ft. 1 in.. If the charge is heavy, or if the slope favours the recoil, the carriage will not go much further back than if these conditions are reversed. But it will do so more rapidly. The space travelled over is not much greater with the violent recoil, but it is done in a shorter time. It is also worthy of notice that quick burning powder, such as the rifled large grain, does not give so long a recoil as the slow burning ones, such as the pebble and pellet powders, although it acts much more violently on the gun; the reason is that the recoil is more rapid. Few machines give so striking an illustration of how important an element is time in work to be done, and how much force is to be increased if anything is done more rapidly. The strength of one man is quite sufficient to push in or pull forward the piston of the Hydraulic Buffer, because he does it quietly, "takes his time to do it." The force of a 25-ton gun, recoiling from the discharge of 70 lbs. of powder, and a 600 lb. shot exhausted itself in doing the same, because it does it so quickly.

In fact, the ease with which the hydraulic buffer permits slow motion is one of its disadvantages, and prevents its application to sea service carriages, as it would not keep the carriages from moving as the ship rolled. A modification to obviate this difficulty has been proposed. It consists of a solid piston (without holes), and the back and front ends of the cylinder are connected by a pipe through which the water is driven by the recoil. The motion of the water can be stopped altogether by the stop-cock till the gun is fired, and the area of the orifice through which the water is to pass can also be regulated by it.

The resistance of the water, and consequently the pressure on the cylinder from the recoil, is not uniform. It becomes greatest at the moment when the air receives its maximum compression, before the water attains its highest velocity in passing through the holes in the piston. At this point the force of the recoil is felt as a severe strain upon the cylinder and the platform which holds it. This destructive action of the recoil of heavy guns not only upon platforms, pivots, and racers, but also upon the foundations on which they rest, is one of the great difficulties with which modern military engineering has to grapple. To remedy this disadvantage by causing the recoil to meet with a gradually increasing resistance,



A B cylinder; C end of piston-rod attached to carriage; C′ end of piston-rod after recoil; D E slide or platform. The dotted lines show the position of the carriage and gun after recoil.

so that its force may be felt as a continuous pressure, and not at any point as a shock or blow, the following very ingenious arrangement was proposed by Mr. H. Butter, Chief Constructor in the Royal Carriage Department. It consists in placing along the length of the cylinder and through the holes in the piston four tapering rods, the largest extremities of them being at the rear end of the cylinder, and being of such a size as there to fill completely the piston holes. These orifices and also the whole cylinder must be larger than where the rods are not employed. The effect in this case is that, as the area for the water to flow through the piston is continually diminishing as the holes get further along the rods, the force of the recoil has to impart a continually increasing velocity to the water, and is at no point felt as a shock or blow. The resistance, slight at first, gradually increases throughout the recoil, and so exhausts its force not at any one point, but throughout the whole of its course.

It has been suggested, and it is a consummation most devoutly to be wished, that the Hydraulic Buffer might be applied to railway trains so as to take away the destructive effects of a collision. A train of carriages separated by Hydraulic Buffers would, if suddenly stopped at a high speed, simply close up, the piston being driven in, and the force of the collision would exhaust itself in the motion given to the water in the cylinders. Some practical difficulties stand in the use of this application of the invention; principally, that the length of the piston rods would inconveniently increase the length of the train. But there are none which might not be overcome by a little ingenuity; and the great importance of the object to be gained makes the neglect of any promising means to attain it highly culpable. However, slowness in taking up new ideas (especially if they do not immediately add to dividends), is not altogether a peculiarity of Government departments.

A very interesting pamphlet on this subject has been published by Colonel Clerk, in which Mr. Butter shows the work done in the Hydraulic Buffer, by comparing it with the moment of a similar weight of water falling through such a height as to give it the same velocity as that with which it passes through the holes in the piston. By this ingenious comparison he ascertained that a locomotive engine, weighing 50 tons, and moving at the rate of 30 miles an hour, would be brought to rest in the space of six feet by two Hydraulic Buffers of 12in. diameter. "There are," Colonel Clerk remarks, "two important problems to be worked out by the railway authorities:—(1) to have no railway collisions; (2) if they must sometimes occur, to render them as harmless as possible;" and it is with the second that he deals. The plan which has been so successful in meeting the violence of exploding gunpowder, should, at least, have a trial in a case of far greater importance—security to life in railway collisions. To refuse this, on account of a few difficulties or inconveniences, seems a sin against Nature herself.

## NOTES

IT will be welcome news to astronomers throughout the world to hear that the Board of Visitors of the Royal Observatory have determined to ask the Government to grant the sum of 5,000*l.* to enable *photographic* observations to be made of the approaching Transit of Venus. It is a matter of wonder that now, when the labours of De la Rue and Rutherford have brought this most perfect means of astronomical record to a pitch of perfection which it is scarcely needful to surpass, it is still ignored in official observatories. In the matter of the Transit of Venus, it will more than double the chances of success, and Mr. Rutherford has shown that in other inquiries it enables an only moderately skilled person to do in a month what a Bessel would require years to compass by the old method. There is no doubt that the appeal to Government will be successful. Would that we had a Physical Observatory and a Board of Visitors to look after other phenomena which we are now neglecting, the observation of which is even of more importance in the present state of science than that of any number of Transits of Venus!

AT the conclusion of a recent lecture at the Royal Institution Dr. Carpenter "expressed the earnest hope that the liberal assistance of Her Majesty's Government, which has already enabled British Naturalists to *obtain the lead* in this inquiry, would be so continued as *to enable them to keep it for the future.* In particular he called attention to the suggestion lately thrown out by M. Alex. Agassiz that an arrangement might be made by our own Admiralty with the naval authorities of the United States, by which a thorough survey, Physical and Biological, of the North Atlantic should be made between the two countries, so that British and American explorers, prosecuting in a spirit of generous rivalry labours most important to the science of the future, might meet and shake hands on the mid-ocean." We fear that if we do not bestir ourselves the credit which has been won by British scientific enterprise will pass elsewhere. The United States Government is not only preparing the Deep-sea Exploring Expedition, of which we gave an account in our last issue, but is also fitting out a similar expedition to the North Pacific. The German Government is about to send a like expedition to explore the depths of the Atlantic to the west of Portugal, where the *Porcupine* Expedition of last year met with its greatest biological successes; and the Swedish Government has already despatched two ships expressly fitted for deep-sea exploration, to Baffin's Bay; the Natural History part of the work being under the charge of Mr. Lindape, who acted as assistant-naturalist in the last *Porcupine* Expedition. What are our Scientific men as a body, what is our Government doing? We grieve to say that up to the present time we have heard of no general appeal to the Government for the required help. And thus, having shown other nations the way to the treasures of knowledge which lie hid in the recesses of the ocean, we are falling from the van into the rear, and leaving our rivals to gather everything up. Is this creditable to the Power which claims to be mistress of the seas? Is it fair to the eminent men who have freely given their best services to the nation, and obtained for it a glorious scientific victory? If their success is regarded by other countries as so distinguished that they are vieing with each other for a participation in it, surely we ought at least to *hold our own.*

A PARAGRAPH has appeared in several papers to the effect that the lime light is to be displayed on the great clock tower at Westminster during the sitting of Parliament. We are glad to announce that the light in question will not be the lime light, but a much more brilliant one—the magneto-electric. Such a light has now for some time past shone from the Capitol at Washington, and was under the consideration of Lord John Manners some few years ago. Mr. Ayrton, we learn, has expressed great interest in the matter, an estimate has been called for, and as there is already steam power available, we may hope that, under Dr. Tyndall's direction, the new light will soon brightly shine.

THE Educational Lectures delivered at the London Institution during the past session by Prof. Huxley, Dr. Odling, and Mr. R. A. Proctor, were followed by examinations, and on Wednesday last the prizes and certificates obtained by the students were distributed by Mr. Thomas Baring, M.P., F.R.S., the president of the Institution. In Chemistry, the first prize was awarded to Frederick Garrett, and the second prize to A. J. Richardson. In Biology, Miss Dora Harris gained the first prize, while A. Percy Lloyd and Miss F. L. Tolmé obtained second prizes. In Astronomy, the first prize was gained by A. J. Wallis, and second prizes fell to Miss Annie Piper and Edward Garrett.

W. T. THISTLETON DYER, Esq., commenced last Monday a course of six lectures on the Natural History of a Flowering Plant, at the Royal College of Science for Ireland, St. Stephen's Green. The lectures will be continued on the following Monday and Thursday evenings.

THE Society of Arts has this year conferred its Albert Gold Medal upon Mr. Cole, C.B. It seems agreed on all hands that without Mr. Cole we should have had neither the South Kensington Museum nor any of those Science and Art classes which are now either in full work or are springing up throughout the country, and are doing an incalculable amount of good. If this be so, then certainly Mr. Cole has done more for the spreading of Science and Art in this country than any other man of his time; and our scientific and artistic bodies should join with the Society of Arts in acknowledging his services.

THE Royal Commission on Scientific Instruction and the Advancement of Science recommenced their sittings on Tuesday last, and will meet again to-morrow.

PROF. HUMPHRY, of Cambridge, will hold classes for instruction in Practical Anatomy on Tuesdays, Thursdays, and Saturdays at half-past twelve during the Long Vacation, commencing July 4. There will also be classes for instruction in Practical Histology on Wednesdays and Fridays at half-past twelve, commencing July 5. This, together with a course of instruction in the Physiological Laboratory, under the direction of Dr. Michael Foster, will constitute a course of Practical Physiology. Gentlemen who have entered to the Anatomical Lectures will be at liberty to attend these classes without additional fee.

THERE will be an election to a Science Fellowship at Corpus Christi College at the beginning of Michaelmas Term. Candidates must have passed all the examinations required by the University for the degree of B.A., and must not be in possession of any benefice or property which would disqualify for retaining a Fellowship. This examination will commence on Monday, October 9, and will be specially in chemistry. Candidates are requested to communicate with the president, either personally or by letter, at their convenience, before the end of Act Term.

THE Sheepshanks Astronomical Exhibition at Trinity College, Cambridge, has been awarded to Horace Lamb, Scholar of the College. The Exhibition is open to all members of the University, the only conditions being that the person elected shall become a member of Trinity College.

AT a recent Court of Governors of St. Bartholomew's Hospital, Mr. Paget, F.R.S., was appointed consulting surgeon to the hospital. At a Court held last Thursday, Mr. Callender was elected surgeon. There is now, therefore, a vacancy for the office of assistant-surgeon to the hospital.

WE greatly regret to hear of the alarming illness of Mr. Grote, the Vice-Chancellor of the University of London. His long and useful life has been devoted to the cause of higher education in this country, and since the foundation of the University he has been one of its staunchest and most unwearied friends.

We observe that Miss Esther Greatbatch, who has just passed the second (special) examination for women at the University of London in French and in Harmony and Counterpoint, also took the second prize at the examination which followed Prof. Guthrie's Lectures on Physics at the London Institute, in February, 1870, and out of seventy-four candidates, the first prize for the examination in Physical Geography, which followed Prof. Huxley's lectures on that subject in 1869. In 1868 Miss Greatbatch passed as a Junior with first class honours, and gained a prize for Mathematics at the Cambridge Local Examination. In December, 1870, she passed as a Senior, with first class honours, gaining the Mill-Taylor Scholarship and a prize for Political Economy. Miss Greatbatch did not take up the Mill-Taylor Scholarship, which can only be held at Cambridge. She is a pupil of the North London Collegiate School for Girls, where she has received the whole of her education. The lady to whom we alluded last week is not the first who has gained a special distinction of proficiency in Natural Philosophy and Chemistry at the examinations of the University of London, that honour having been conferred on Miss Orme in 1870.

Prof. Huxley's "Elementary Lessons in Physiology" are about to be translated into Hindostanee.

The Paris correspondent of the *Daily News* states that the chateau of the Marquis Laplace at Arcueil Cachan, which escaped the Prussians, has been plundered by a band of housebreakers from the Mouffetard district. The manuscripts of the celebrated astronomer were thrown into the Bièvre, from which the original of "The Mechanism of the Heavens," in the author's handwriting, has subsequently been fished out. The library, which was rich in rare books, souvenirs, and works of art, has been looted and devastated.

The medal given by the Royal Geographical Society to Dr. Keith Johnston is in acknowledgment of the services of the devotion of more than forty years of an unusually active life to purely geographical pursuits. He has done more for popularising geography than almost any other living author. The publication of his "Physical Atlas" in 1847 gave an unexampled impetus to the study of Physical Geography in Britain, and his publications since then, of great utility and importance, have been very numerous.

We learn from the *Journal of Botany* that the well-known cryptogamist Fries accompanies the Swedish Arctic expedition as botanist, and MM. Lindahl and Nauckhoff as zoologist and geologist. The expedition intends to visit Baffin's Bay, and to return in October.

A new botanical magazine has just appeared at Lund in Sweden, "Botaniska Notiser," edited by Otto Nordstedt. It will be specially devoted to Scandinavian botany, and to a review of all botanical papers published in Sweden, Norway, Denmark, and Finland.

The yearly part, just issued, of the Natural History Transactions of Northumberland and Durham contains, as usual, many valuable contributions to scientific literature. The first paper is a Revision of the Catalogue of Coleoptera of Northumberland and Durham, by Mr. T. J. Bold, including 1,520 species, about one half the number hitherto found in Great Britain. Dr. W. C. M'Intosh contributes a short Report on the Collection of Annelids dredged off Northumberland and Durham, and Mr. George Hodge a Catalogue of the Echinodermata of the same counties, forty-three in number, accompanied by interesting remarks on each species, and illustrated by four plates. From Messrs. W. Kirby and J. Duff we have some elaborate Notes on the Geology of part of South Durham, the lower coal measures in the neighbourhood of the village of Etherley, embellished by diagrams showing the position of the coal-seams. Then follow five papers on remarkable fossils of the carboniferous series by Mr. Albany Hancock, in conjunction with Messrs. T. Atthey and R. Howse; viz., On the Labyrinthodont Amphibian, *Loxomma Allmanni*, being its first occurrence in the neighbourhood; On a new generic form of the same order, to which the name *Batrachiderpeton lineatum* is given; On another new form from the magnesian limestone, *Lepidotosaurus Duffii*; A description of a specimen from the marl-slate of the oldest known reptile, *Proterosaurus Speneri*, and of a new species, *P. Huxleyi*; and A description of four specimens from the same formation of *Dorypterus Hoffmanni*; these papers are illustrated with six well-executed plates. The last paper is on *Saccamina Carteri*, a new foraminifer from the carboniferous limestone of Northumberland (with one plate), by Mr. H. B. Brady; and the volume closes with an admirable address from the president of the Tyneside Naturalists' Field Club, Mr. G. S. Brady, in which he gives a sketch of the work of the society during the past year, and of the general additions to natural history literature during the same period, especially in the departments of "Spontaneous Generation" and the "Origin of Species." The president for the present year is Mr. G. C. Atkinson.

The last number of the "Bücher-verzeichniss," published by Friedländer and Son, of Berlin, is a valuable and copious catalogue of astronomical literature in English, French, German, Latin, and the other European languages.

A third edition of Prof. Brünnow's "Lehrbuch der Sphärischen Astronomie" has just been published in Berlin.

We are favoured by Mr. Login with a photograph representing the produce of one grain of wheat grown on the Egyptian system in India, which gave off 160 shoots, and has produced 105 ears of corn; another, $4\frac{1}{2}$ ft. high, which produced 45 ears from $4\frac{1}{2}$ in. to 5 in. in length; and another $3\frac{1}{2}$ ft. high, with about 50 ears. These are represented as about average results from this system, and are contrasted with a single plant grown on the native broad-cast system, assisted by irrigation, producing seven ears from each grain, and another without irrigation, producing from five to fifteen ears, and also represented as average results. We congratulate the Indian authorities upon having a man of Mr. Login's wide grasp in their service. This is by no means the first time we have referred to his labours.

With reference to the alleged disappearance of Aurora Island, one of the New Hebrides group, to which we alluded some weeks since on the authority of a paper read before the Academy of Natural Sciences of Philadelphia, a correspondent of the *Shipping and Mercantile Gazette* affirms that the whole story is a fable. The original statement rested on a notice by Captain Plock, of the French ship *Adolphe*, bound from Iquique to London, that he passed over the position of the Iles de l'Aurore, as marked on his French chart of the South Atlantic, and saw nothing of them, from which he concluded that they had disappeared. It appears, however, that the Iles de l'Aurore (Aurora Islands) never existed. They were formerly placed between lat. 52° 38′ and 53° 15′ S., and between long. 47° 43′ and 47° 57′ W. of Greenwich. The first reporters of the islands probably saw icebergs in the given locality, and mistook their character. Aurora Island, in the New Hebrides group, has been confounded with the Aurora Island in the Paumotu, Tuamotu, or Low Archipelago. Aurora, Makatea, or Metia Island, lat. 15° 50′ S., long. 148° 13′ W., one of the Low Archipelago, has not been visited for some time, but its elevation would lead to the inference that it could not disappear suddenly; it is fertile and inhabited. This is the island visited by Wilkes, and on which the unique specimens of mollusca were found. It is upwards of 2,500 miles eastward of the New Hebrides.

## *AMERICAN NOTES* *

THE official report of the geological explorations prosecuted during the past summer by Prof. F. V. Hayden, under the authority of the Department of the Interior, has just been published by the Government in a well-printed volume of over five hundred pages, containing a full account of the geology and natural history of the region traversed. It embraces an article by Prof. Hayden upon the physical character and local geology of the different sections of his route, which extended from Cheyenne, by way of Fort Fetterman, South Pass, Fort Bridger, the Uinta Mountains, to Green River, and back again, *viâ* Bridger's Pass, to Cheyenne. This is followed by an account of the Geology of the Missouri Valley from Omaha to Salt Lake Valley, with observations on the mines, ores, coals, and salts. An appendix contains an article by Prof. Cyrus Thomas upon the agricultural possibilities of the country, with a list of the orthopterous insects, including a number of new species, followed by a number of special reports—as one by Prof. Meek, on the invertebrate fossils; on the Tertiary coals of the West, by Prof. Hodge; on the ancient lakes of Western America, by Prof. Newberry; on the vertebrate fossils of the Tertiary formation, by Prof. Leidy; on the fossil plants of the Cretaceous and Tertiary formations of Kansas and Nebraska, by Mr. Lesquereux; on the fossil reptiles and fishes of the Cretaceous rocks of Kansas, the fossil fishes of the Green River group, and the recent reptiles and fishes, by Prof. Cope; and on the industrial resources of Western Kansas and Eastern Colorado, by Mr. Elliott. Lists of the mammals, molluscs, and birds, of the coleoptera, hemiptera, and plants, are also included, together with an account of the general meteorology of the expedition. A large number of new species of different kinds are described, and the whole work forms a very important addition to our information relative to the geology, geography, and natural history of the West.

The second and third annual reports of the Peabody Academy of Science of Salem (for 1869 and 1870) have just been published, giving a gratifying account of the activity of that young and energetic society, which, although only in the third year of its existence, already ranks among the best establishments of the kind in the country, and which, in the number of excellent working naturalists associated with it, is rapidly making its mark. The donations to the museum of the academy during 1870 alone amounted to 195, received from 148 different persons. The identification of the specimens presented has been accomplished by the officers of the academy, aided by specialists in other parts of the country. The reports embrace references to several exploring expeditions instituted in the interests of the academy in different parts of the United States, as well as in Central America. The second number of the first volume of the Memoirs of the academy has also just appeared, and closely resembles typographically, as well as in size and other features, the well-known Memoirs of the Boston Society of Natural History, and of the Museum of Comparative Zoology. This part is occupied entirely by a paper upon the embryology of certain neuropterous and other insects, by Dr. A. S. Packard, jun., the Secretary of the Council.—Attention is called by the Panama papers to the extraordinary meteorological conditions that have lately prevailed throughout Central and South America, especially in the falling of large quantities of rain where previously such an occurrence was almost unknown. This unusual amount of precipitation is understood to have first occurred on the Isthmus of Panama, and to have resulted in disastrous floods at Aspinwall and elsewhere, of which an account has already been given. The climatic change seems to have travelled southwardly from that region, and to have involved successively a large portion of the chain of the Andes in its operations. The latest advices from Peru show that in localities hitherto perfectly rainless torrents have fallen to such an extent as to produce very great disasters. These have occurred at Payta, San José, Lambayeque, &c. The villages on the western slope of the Andes in Chili and Peru are not prepared for such an occurrence (of which many of the inhabitants had never had any practical experience), the sites and material of the buildings being alike unsuited to resist storms. The town of Lambayeque, containing seven or eight thousand inhabitants, is reported to have been entirely destroyed by the rain. The most southerly point reached by the rain at last dates seems to be the valley of Canete, which was inundated to the great damage of the sugar and other plantations. Much land has been totally ruined by the washing out of its soil, leaving behind a mere collection of gravel and stones. Vessels passing along the western coast at a distance of hundred miles and more experienced heavy rains where previously nothing but fog had been met with. The electric phenomenon visible around Mount Tacora, to which we recently referred, seems to have been a part of this same system of atmospheric disturbance, and connected with it was a widely extended arrangement of the telegraph lines in Chili, an event of extreme rarity.

* Communicated by the Editor of *Harper's Weekly*.

## *SCIENCE IN VICTORIA*

ONE or two interesting subjects were discussed at a recent meeting ot the Royal Society of Victoria, and we are favoured by a correspondent with the following particulars:—Notes on the working of the great Melbourne telescope, which some time ago was inconsiderately pronounced to be a failure, which were read by Mr. Faric MacGeorge, who has had charge of the instrument since Mr. Le Sueur left. It was stated that the speculum polished by Mr. Le Sueur had worked very satisfactorily, and some fresh discoveries with regard to Sirius and the star *d* were thus described by Mr. MacGeorge:—"On 9th Dec. 1870—indifferent evening—I noted all the faint stars near Sirius for future identification. On the 18th Jan. 1871, for the first time, I chanced upon Lassell's observations of Sirius in the 'Memoirs of the Royal Astronomical Society,' 1867. Mr. Martin there mentions having suddenly found a very faint star in the neighbourhood of Sirius which had, until then, escaped keen observers like Struve, Lassell, and himself, in the exquisite 4ft. equatorial at Malta. On comparing the position of this faint star—now called Lassell's Companion—with the faint stars noted by me on 9th December, it evidently corresponded with one noted on that date, so that with our great equatorial my eye, unbiassed by previous knowledge, detected at the first inspection on an indifferent evening an object which had long escaped these careful and experienced observers in the great Malta equatorial, an instrument of acknowledged excellence and equal aperture to our own. Several still fainter stars have since been seen near Sirius, two of them between Lassell's Companion, the star *d*, and Sirius. So far as I have yet seen, any want of definition is evidently due to atmospheric defects, not instrumental ones, the power of definition being at all times in direct ratio with the goodness of the evening." Prof. Wilson made a suggestion to the society respecting an expedition to Cape York, in a steamer, to witness the Total Eclipse of the Sun on the 12th December next, the eclipse being visible along a portion of the northern coast of Australia. The proposal was favourably entertained, and an understanding arrived at that it should receive fuller consideration at the next meeting. The annual meeting of the Acclimatisation Society of Victoria was held on the 10th March, Dr. Black, the President, occupying the chair. In their customary report to the subscribers, the council, while regretting the smallness of their numbers, stated that under the management of the new secretary Mr. A. C. Le Sœur, the society bade fair to again become extensively useful. It was mentioned that four ostriches which had been received from South Africa had been taken charge of by Mr. Samuel Wilson, of Longerenong, and had now increased to sixteen, and there was every reason to suppose that their numbers would be considerably augmented in the course of this season. So far the experiment had been a marked success. Ostrich farming was a profitable occupation at the Cape colony, and it was hoped it wou d ultimately become so here. The climate of the Wimmera district, it was remarked, appeared to be well adapted to their habits; as a proof of which, the young Australian birds were now taller than the parent stock. It was stated, amongst other subjects dealt with in the report, that the society had done and was doing all in its power to encourage sericulture in the colony, and to this end had, in conjunction with Dr. Von Mueller, sent white mulberry cuttings and plants to all parts of Victoria. Some months ago a box of silkworm eggs was sent by the Governor of India to his Excellency the Governor, who kindly handed them to the society for d's ribution, and lately a supply of very superior Japanese eggs, such as were seldom sold to foreigners, had been forwarded by Dr. Bennett, the hon. secretary of the Acclimatisation Society of New South Wales. The Silk Supply Association of London, it was mentioned, in one of their reports recently published, recognised no less than 36,000 square miles of country in Victoria as well suited to the growth of silk; and when the numerous young plantations came into bearing a great stimulus would be given to this industry, which in all probability would, before many years, add materially to the wealth of the colony.

## *MR. BENTHAM'S ANNIVERSARY ADDRESS TO THE LINNEAN SOCIETY*

(*Continued from page* 94)

PRESERVED specimens have the great advantage over living ones, that they can be collected in infinitely greater numbers, maintained in juxtaposition, and compared, however distant the times and places at which they had been found. They are often the only materials from which we can obtain a knowledge of the races they represent; although still consisting of individuals only, they can, by their numbers, give better ideas of species and other abstract groups than the almost isolated living ones; and their careful preservation supplies the means of verifying or correcting descriptions or delineations which have excited suspicion. Their great drawback is their incompleteness, and the impossibility of deriving from them all the data required for the knowledge of a race or even of an individual. It is owing to the frequency with which characters supplied by preserved specimens, although of the most limited and unimportant a nature, have been treated as sufficient to establish affinities and other general conclusions which have proved fallacious, that the outcry I have alluded to has been raised against museums and herbaria by those very theorists whose speculations would fall to the ground if all the data supplied by preserved specimens were removed from their foundation.

In respect of these deficiencies, as well as in the means of supplying them, there is a great difference between zoological and botanical museums. Generally speaking, zoological specimens show external forms only; botanical specimens give the means of ascertaining internal structure;* and as a rule the characters most prominently or most frequently brought under the observer's notice acquire in his eyes an undue importance. Hence it is that external form was for so long almost exclusively relied upon for the classification of animals, whilst the minutiæ of internal structure were at a comparatively early period taken account of by botanists, while palæontologists are still led to give absolute weight to the most uncertain of all characters—outline and external markings of deciduous organs. External form is, however, really of far greater importance in animals than in plants; the number, form, size, and proportions of limbs, the shape and colour of excrescences, horns, beaks, feathers, hair, &c., in animals may be reckoned almost absolute in species when compared with the same characters in the roots, branches, and foliage, and, to a certain extent, even in the flowers of plants. In plants, local circumstances, food, meteorological conditions, act readily in modifying the individual, and producing more or less permanent races of the lowest degree (varieties); whilst animals in these respects are comparatively little affected, except through those slow or occult processes by which the higher races, species, or genera in all organisms are altered in successive ages or geological periods. Even relative position of external parts, so constant in animals, is less so in plants. Animals being thus definite in outline, and a very large proportion of them manageable as to size, their preserved specimens, carcases, or skins can be brought together under the observer's eye in considerable numbers, exhibiting at once characters sufficient for the fixation of species; whilst, with a few rare exceptions, a whole plant in its natural shape can never be preserved in a botanical museum. And, although good botanical specimens have a general facies, often sufficient to establish the species if the genus is known, yet the most experienced botanists have often erred in their determinations where they have been satisfied with external comparison without internal examination.

Identification of species is, however, but a small portion of the business of systematic biology, and for higher purposes the classification of species, and the study of their affinities, the pre-eminence of ordinary zoological over botanical specimens soon fails, those characters distinguished by Prof. Flower as adaptive are proportionately more prominent, and the essential ones derived from internal structure are absent; and not only do the former thus acquire undue importance in the student's eyes, but arguments in support of a favourite theory have not unfrequently been founded on distortions really the result of bad preparation, although supposed to be established on the authority of actual specimens, and therefore very difficult to refute. Mounted skins of vertebrata, showy insects in their perfect stage, shells of malacozoa, corals, and sponges, necessarily form the chief portion of a museum for public exhibition; but science and instruction require a great deal more; museum collections really useful to them should exhibit the animal as far as possible in all its parts and in all the phases of its life. This necessity has been felt in modern times, and has resulted in the establishment of Museums of Comparative Anatomy, amongst which that of our own College of Surgeons has certainly now taken the lead. But I have nowhere seen, except on a very small scale, the two museums satisfactorily combined. The idea, however, is not a new one; several zoologists have expressed their opinions on the desirableness of such an arrangement, which it is to be hoped will be duly considered in the formation of the new National Zoological Museums about to be erected at South Kensington, for the double purpose of exhibition and science. The requirements of the gazing public are sure to be well provided for, and there is every reason to believe that the exertions of scientific zoologists will not have proved useless, that we shall in the portion devoted to science and instruction see the skins of vertebrata preserved without the artist's distortions, accompanied, as far as practicable, by corresponding skeletons and anatomical preparations, as well as by the nests and eggs of the oviparous classes; insects with their eggs, larvæ, and pupæ; shells with the animals which produce them, &c., always with the addition, as far as possible, of the collector's memoranda as to station, habits, &c., in the same manner as herbarium specimens are now frequently most carefully completed by detached fruits, seeds, young plants in germination, gums, and other products.

Here, however, will arise another source of false data to be carefully guarded against—the mismatching of specimens, which in botany has probably produced more false genera and species than the misplacing of garden labels. The most careful collectors have in good faith transmitted flowers and fruits belonging to different plants as those of one species—the fruits perhaps picked up from under a tree from which they were believed to have fallen, or two trees in the same forest with similar leaves, the one in flower the other in fruit, supposed to be identical, but in fact not even congeners, and the mismatching at the various stages of drying, sorting, distributing, and finally laying in the specimens, have been lamentably frequent. Collectors' memoranda, if not immediately attached to the specimens or identified by attached numbers, have often led the naturalist astray, for collectors are but too apt, instead of noting down any particulars at the time of gathering, to trust to their memory when finally packing up their specimens. And so long as reasoning by analogy was never allowed to prevail over a hasty glance at a specimen and the memoranda attached to it, false genera and species arising from these errors were considered indisputable. *Magallana* of Cavanilles was, till recently, allowed materially to invalidate the character of Tropæoleæ, overlooking the strong internal evidence that it was founded upon the fruit of one natural order carefully attached to a poor flowering specimen of another.

Zoological museums and botanical herbaria differ very widely in the resources at their disposal for formation, maintenance, and extension of their collections. Zoological museums are by far the most expensive, but on the other hand as exhibitions they can draw largely on the general public, whilst herbaria must rely mainly upon science alone, which is always poor; both, however, may claim national assistance on the plea of instruction as well as of pure science, and for practical or economic purposes the herbarium is even more necessary than the museum. The planning the new museums so as best to answer these several purposes for which they are required, has, we understand, engaged the attention of the Royal Commission on Scientific Instruction and the Advancement of Science, and our most eminent zoologists have been consulted; any further observations on my part would therefore be superfluous. If our Government fail in their arrangements for the promotion of science, it will not be for want of having its requirements laid before them.

I am unable to say what progress has been made of late years in zoological museums, my notes on Continental ones were chiefly taken between the years 1830 and 1847, and would therefore be now out of date. It would, however, be most useful if some competent authority would undertake a tour of inspection of the more important ones, as in the great variety of their internal arrangements many a useful practical hint might be obtained, and we much want a general sketch of the principal zoological and botanical collections accessible to science, showing in what branch each one is specially rich, and where the more important

* By *internal structure* is here meant the morphology of internal organs or parts, usually included in the comparative anatomy of animals, not the microscopical structure of tissues, which is more especially designated as vegetable anatomy.

typical series are now respectively deposited. In herbaria a few changes have recently taken place which it may be useful to record. Paris, I mean of course the brilliant Paris of a twelvemonth back, had lost considerably. Of the many important private herbaria I had been familiar with in earlier days, two only, those of Jussieu and of A. de St. Hilaire, had been secured for the national collection, Webb's had gone to Florence, J. Gay's, which would have been of special value at the Jardin, was allowed to be purchased by Hooker and presented by him to Kew. The celebrated herbarium of Delessert is removed to Geneva, whilst his botanical library, one of the richest in existence, is locked up within the walls of the Institut. These are but partially replaced by M. Cosson's herbarium, which has much increased of late years, and to which he added last spring the late Schultz Bipontinus's collection rich in Compositæ. The national herbarium of the Jardin des Plantes is still one of the richest, but no longer *the* richest of all. The limited funds at the disposal of the Administration have allowed of their making but few acquisitions; their staff is so small and so limited in the hours of attendance, that the increase of the last twenty years remains for the most part unarranged, and their library is most scanty. Science has been out of favour with their governments of display. It would be out of place for me here to dwell upon the painful feelings excited in my mind by the dreadful ordeal through which a country I have been so intimately associated with for more than half a century is now passing, feelings rendered so acute by the remembrance of the uniform kindness I have received from private friends as well as from men of science, from Antoine Laurent de Jussieu and his colleagues to the eminent professors of the Jardin, who have now passed through the siege; but I may be allowed to express an anxious hope that when the crisis is passed, and the elasticity of French resources will have restored the wonted prosperity, the new Government may at length perceive that, even politically speaking, the demands of science require as much attention as popular clamour.

The Delesserian herbarium has been well received at Geneva, where it has been adequately deposited in a building in the Botanic Garden, very near to the Natural History Museum now erecting. At Paris it had been for some time comparatively useless, owing to the attempt to class it according to Sprengel's Linnæus, but now an active amateur committee, Messrs. J. Mueller, Reuter, Rapin, and others, under the presidency of Dr. Fauconnet, have already made great progress in distributing the specimens under their natural orders; and Geneva, already containing the important typical collection of De Candolle, and Boissier's stores rich especially in Mediteranean and Oriental plants, has become one of the great centres where real botanical work can be satisfactorily carried on; and as she has had the good sense to level her fortifications, she may accumulate national treasures with more confidence in the future. Munich has lost much of the prospect she had; the Bavarian Government failed to come to terms with the family of the late von Martius, his botanical library has been dispersed, and his herbarium removed to Brussels, where it is to form the nucleus of a national Belgian collection. At Vienna the Imperial herbarium is now admirably housed in the Botanical Garden, and is in good order, with the advantage of a rich botanical library in the same rooms. At Berlin, where the Royal Herbarium, like the Zoological Museum, has always been kept in excellent order, want of space is greatly complained of since it has been transported to the buildings of the University. At Florence, as we learn from the *Giornale Botanico Italiano*, the difficulties with regard to the funds left by Mr. Webb for the maintenance of his herbarium have been overcome, and it is to be hoped that the liberal intentions of the testator who made this splendid bequest for the benefit of science will no longer remain so shamefully unfulfilled. To the above six may be added Leyden, Petersburgh, Stockholm, Upsala, and Copenhagen, as towns possessing national herbaria sufficiently important for the pursuit of systematic botany; but when I visited them, now many years since, they were all, more or less, in arrear in arrangement. I know not how far they may have since improved. In the United States of America, the herbarium of Asa Gray, recently secured to the Harvard University, now occupies a first rank. That of Melbourne in Australia, founded by Ferdinand Mueller, has, through his indefatigable exertions, attained very large proportions; and that of the Botanical Garden of Calcutta, under the successive administration of Dr. Thomson and the late Dr. T. Anderson, had recovered in a great measure its proper position, which, I trust, it will henceforth maintain. Our own great national herbarium and library at Kew is now far ahead of all others in extent, value, and practical utility; originally created, maintained, and extended by the two Hookers, father and son, their unremitting and disinterested exertions have succeeded in obtaining for it that Government support without which no such establishment can be really efficient, whilst their liberal and judicious management has secured for it the countenance and approbation of the numerous scientific foreigners who have visited or corresponded with it. Of the valuable botanical materials accumulated in the British Museum during the last century I say nothing now, for the Natural History portion of that establishment is in a state of transition, and my own views as regards Botany have been elsewhere expressed. I have only to add that we have also herbaria of considerable extent at the Universities of Oxford, Cambridge, and Edinburgh, and at Trinity College, Dublin, and to express a hope that the necessity of maintaining and extending them will be duly felt by these great educational bodies, if they desire to secure for their professorial chairs botanists of eminence.

3. Pictorial representations or drawings have the advantage over museum specimens, that they can be in many respects more complete, they can represent objects and portions of objects which it has been impossible to preserve, they can give colour and other characters lost in the course of desiccation, they preserve anatomical and microscopical details in a form in which the observer can have recourse to them again and again without repeating his dissections, and although, like a museum specimen, each drawing represents usually an individual, not a species, yet that individual can by exact copies be multiplied to any extent for the simultaneous use of any number of naturalists, whilst specimens of the same species in different museums are corresponding only, not identical, and imperfect comparison and determination of specimens supposed to be authentic (*i.e.*, exactly corresponding to the one originally described) have led into numerous errors. Drawings, moreover, of diagrams and other devices can represent more or less perfectly the abstract ideas of genera and species, they can exhibit the generic or specific character more or less divested of specific or individual peculiarities.

Drawings on the other hand are, much more than specimens, liable to imperfections and falsifications arising from defective observation of the model and want of skill in the artist, and errors thus once established are much more difficult of correction than even those conveyed by writing. A pictorial representation conveys an idea much more rapidly, and impresses it much more strongly on the mind, than any detailed accompanying description by which it may be modified or corrected, and is but too frequently the only evidence looked into by the more theoretical naturalist. This is especially the case with microscopical and anatomical details of the smaller animals and plants, the representations of which, if very elaborate and difficult to verify, usually inspire absolute confidence. Drawings are also costly, often beyond the means of unaided science, who here again, as in the case of gardens and museums, is obliged to have recourse to the paying public; the public in return require to have their tastes gratified, artistic effect is necessarily considered, thus increasing the cost and removing the pictures still further from the reach of the working biologist. It appears to me, however, that collections of drawings systematically arranged have not generally met with that attention which they require from directors of museums, and that their multiplication in an effective and cheap form ought to be a great object on the part of Governments, Scientific Associations, and others who contribute pecuniarily to the advancement of science.

To be effective, the first requisites in a zoological or botanical drawing are accuracy and completeness; it is a faithful representation not a picture that is wanted. Many a splendid portrait of an animal or plant, especially if grouped with others in one picture, has been rendered almost useless to science by a graceful attitude or an elegant curve which the artist has sought to give to a limb or to a branch, and those analytical details which are of paramount importance to the biologist are neglected, because they spoil the general effect. We next require from an illustration, as from a description, that it should be representative, or to a certain degree abstract, and this requires that the artist, if not himself the naturalist, should work under the naturalist's eye, so as to understand what he delineates. Great care should be taken, in the selection for the model of an individual in a normal state, as to health, size, &c., and in the selection and arrangement of the anatomical details, so as to represent the race rather than the individual, all of which requires a thorough acquaintance with the questions to be attended to. It is true that the artist working independently and copying mechanically may serve as a check on the naturalist, who in minute microscopic examinations may be apt to see too much in conformity to preconceived theories; but that is not often the case, the most satisfactory analytical drawings I have always found to be those made by the naturalist's own hand, and I have long felt how much my own inability to draw has detracted from the value of botanical papers I have published. And thirdly, when we consider that the great advantage of an illustration over a description is, that the one gives us at a glance the information which we can only obtain from the other by study, we require that each drawing or plate should be as comprehensive as is consistent with clearness and precision. Outline drawings or portraits without structural details often omit the essential characters we are in search of; where details are unaccompanied by a general outline, we miss a great means of fixing their bearing on our minds. Structural details may also equally err in being too numerous or too few, or too large or on too small a scale. If the plate is crowded with details of little importance, or which may be readily taken from the general outline, they draw off the attention from those which it is essential should be at once fixed on the mind, and if enlarged beyond what is necessary for clearness, they require so much the more effort to comprehend them, unless indeed they be destined to be hung up on the walls of a lecture-room. I believe it to be the case with some drawings of the muscles of vertebrata, or of the internal structure of insects, as I know it to be with those of ovules and other minute parts of flowers of the late Dr. Griffith and others, that with their very high scientific value, their practical utility is much interfered with by the large scale on which they are drawn. A great deal depends also on the arrangement in the plate, always keeping in mind that the object is not to please the eye, but to convey at one view as much as possible of comparative information without producing confusion.

Biological illustrations in general have much improved in our time. It is true that some of the representations of animals and plants dating from the middle of last century will enter into competition with any modern ones as to the general outlines and facies, but analytical details were almost universally neglected, and colouring when attempted was gaudy and unfaithful. At present I believe we excel in this country in the general artistic effect, as unfortunately also for the naturalist in the costliness, of our best zoological and botanical plates; the French are remarkable for the selection, arrangement, and execution of the scientific details, and as a model I may refer to some of the publications of the Paris Museum, such as the Malpighiaceæ of Adrien de Jussieu, and also for the excellent woodcuts illustrating their general and popular works; the Germans and some Northern states for the admirable neatness of microscopic and other minutiæ executed at a comparatively small cost, owing partially at least to the use of engravings on lithographic stone.

4. Written Descriptions are what we must chiefly rely upon to convey to the general or to the practical naturalist the results of our studies of animals and plants; but descriptions are of two kinds—individual descriptions and descriptions of species, genera, or other races. The former are like preserved specimens or delineations, materials for study, like them they require in their preparation little more than artistical skill guided by a general knowledge of the subject; but abstract descriptions, whether specific or relating to races of a higher degree, require that study of the mutual relations of individuals and races and their consequent classification which constitute the science of systematic biology, and this distinction should be constantly kept in view for the just appreciation of all descriptive works. Any tyro can with care write a long description of a specimen unimpeachable as to accuracy, but it requires a thorough knowledge of the subject and a keen appreciation of the bearings of the points noticed to prepare a good description of a species. For the latter to be serviceable it must be accurate, it must be full without redundancy, it must be concise without sacrificing clearness, it must be abstractive not individual, and lastly, the most difficult qualification of all and that which constitutes the main point of the science, the abstraction must be judicious and true to Nature.

The paramount importance of accuracy is too evident to need dwelling upon. We are all liable to errors of observation. Imperfect vision or instruments, optical deceptions, accidentally abnormal conditions of the specimen examined, hasty appreciation of what we see from preconceived theories, are so many of the causes which have occasionally led into error the most eminent of naturalists, and require to be specially guarded against by repeated observation of different specimens and constant testing at every step by reasonings from analogy. Errors once established on apparently good authority are exceedingly difficult to correct, and have been the source of many a false theory. Where loose examination and hasty conclusion have been frequently detected, we can at once renounce all confidence in an author's descriptions—in his genera and species—unless confirmed from other sources, but an accidental oversight on the part of a naturalist of established reputation is the most difficult to remedy, notwithstanding the eagerness with which some beginners devote themselves to hunting them out. No botanist was, I believe, ever more careful in verifying his observations over and over again, and in submitting them to the tests supplied by the extraordinary methodising powers of his mind, than Robert Brown, no one has ever committed fewer of what we call blunders, or established his systematic theories on safer ground, yet even he has been detected in a few minor oversights, eagerly seized upon by a set of modern speculative botanists, lovers of paradoxes, as justifying them in devoting their time and energies to the disputal of several of his most important discoveries and conclusions.

The value of a description as to fulness and conciseness is practical only, but in that point of view important. A description, however accurate, is absolutely useless if the essential points are omitted, and very nearly so if those essential points are drowned in a sea of useless details; the difficulty is to ascertain what are the essential points; and hence one of the causes of the superiority of monographs and floras over isolated descriptions, such as those of Zoologies and Botanies of exploring expeditions, which I insisted on in my address of 1862; in the former the author must equally examine and classify all the allied races, and thus ascertain the essential points; in the latter case he is too easily led to trust to what he believes to be essential. My own long experience in the using, as well as in the making, of botanical descriptions, has proved to me how difficult it is to prepare a really good one, how impossible it is to do it satisfactorily from a first observation of a single specimen. However carefully you may have noted every point that occurs to you, you will find that, after having comparatively examined other specimens and allied forms, you will have many an error to correct, many a blank to fill up, and much to eliminate. I have more than once had to verify the same species in two authors, the one giving you a character in a few lines which satisfies you at once, the other obliging you to labour through two or three quarto pages of minute details, from which some of the essential points are omitted.

But the great problem to be solved at every stage in systematic or descriptive biology, and that which gives it so high a scientific importance, is the due detection and appreciation of affinities and mutual relations, and in this respect the science has made immense progress within my own recollection, and especially during the last few years the gradual supplanting of artificial by natural classifications has been too often commented upon to need repetition. It is now, I believe, universally admitted that a species consists of individuals connected together by certain resemblances or affinities the result of a common descent. It is also acknowledged that for scientific purposes these species should be arranged in groups according to resemblances or affinities more remote than in the case of species, although here commences the great difference of opinion as to the meaning of these remote affinities, whether they also are the result of a common descent, or of that supposed imitation of a type which I have above alluded to. For those, however, who have once connected affinity with consanguinity, it is difficult to recede from so ready an explanation of those mysterious resemblances and differences, the study of which must be the ruling principle to guide us in our classifications. All this has now been fully explained by more able pens than mine; my only object in repeating it is to point out clearly the need of treating all systematic groups from the order down to the genus, species, or variety, as races of a similar nature, collections of individuals more nearly related to each other than to the individuals comprising any other race of the same grade, and of abolishing the use of the expression *type* of a genus, or other group, in any other than a purely historical sense, as a question of nomenclature.* If a genus has to be

* For the purposes of instruction some one species is often named as *a* type of a genus, that is to say, as fairly representing the most prevalent

divided, our laws of nomenclature require the original name to be retained for that section which includes the species which the founder of the genus had more specially observed in framing his character, and therefore, and for that reason only, it becomes necessary to inquire which was or which were the so-called typical species—the biologist's or as it were the artist's, not Nature's type.

I need not repeat what I said in 1862 of the comparative value of monographs and faunas or floras over miscellaneous descriptions, observing only that the immense progress made in the accumulation of known species henceforth diminishes still more the relative importance to science of the addition of new forms when compared to the due collocation and correct appreciation of those already known. Much has been done of late years in the latter respect, but yet some branches of biology, and perhaps entomology more than any other, are very much in arrear as to supplying us with available data for investigating the history of species and their genealogy ; their origin, progress, migration, mutual relations, their struggle, decay, and final extinction. It is to be feared that in insects as in plants, but too large a proportion of the innumerable genera and sub-genera have been founded rather on the sortings of a collector than on the investigation of affinities ; and, indeed, that must in a great measure be the case so long as a large proportion are only known from their outward form at one period only of their varied phases of existence.

The days of a Systema Naturæ, or single work containing a synopsis of the genera and species of organised beings, are long since passed away. Even a Species Plantarum, now that their number at the lowest estimate exceeds 100,000, has become almost hopeless. The last attempt, De Candolle's Prodromus, has been nearly forty years in progress, the first portion has become quite out of date, and all we can hope for is that it may be shortly completed for one of the three great classes of plants. Animals might have been more manageable were it not for the insects. Mammalia estimated at between 2,000 and 3,000 living species, birds at about 10,000, reptiles and amphibia under 2,000, fishes at about 10,000, crustacea and arachnida rather above 10,000, malacozoa about 20,000, vermes, actinozoa, and amorphozoa under 6,000, would each by themselves not impose too heavy a tax on the naturalist experienced in that special branch who should undertake a scientific classification and diagnosis of all known species. In one important branch, indeed, the fishes, this work has been most satisfactorily carried out in Dr. Günther's admirable Genera and Species of all known fishes published under the misleading title of "Catalogue of the Fishes in the British Museum," and recently completed by the issue of the seventh volume. The sound philosophical views expressed in his preface to that volume (which, by some strange inversion, bears a signature not his own) can be appreciated by us all, and zoologists are all agreed as to the care with which they have been worked out in the text. Insects are, however, the great stumbling-block of zoologists. The number of described species is estimated by Gerstaecker at above 160,000, viz. : Coleoptera, 90,000 ; Hymenoptera, 25,000 ; Diptera, 24,000 ; Lepidoptera, 22,000 to 24,000. Mr. Bates thinks that, for the Coleoptera at least, this estimate is too high by one-third, but even with that deduction the number would exceed that of plants, and it is probable that the number of as yet undiscovered species in proportion to that of the described ones is far greater in the case of insects than of plants. We can therefore no longer hope for a Genera and Species of insects, the work of a single hand, or indeed guided by a single mind. The great division of labour, however, now prevalent among entomologists may procure it for us in detail, with one drawback only, that the smaller the portion of the great natural class of Arthropoda to which the entomologist confines his attention, the less he will be able to appreciate the significance of distinctive characters, and the more prone he will be to multiply small genera—that is to enhance beyond their due value the races of the lowest grades—to the great inconvenience of the general naturalist who has to make use of the results of his labour.

A Genera Plantarum is still within the capabilities of a single botanist, although he must, of course, trust much to the observations of others, and it therefore cannot be so satisfactory as if he had examined every species himself. The last complete one was Endlicher's, the result of several years' assiduous labour, but now thirty years old. Dr. Hooker and myself commenced a new one, of which the first part was published in 1862, and which might have been brought nearly to a close by this time had we not both of us had so many other works on hand to deter us, although the researches necessary for these other works have proved of great assistance to the Genera. As it is, the part now nearly ready for press carries the work down to the end of Compositæ, or about half through the Phænogamous plants. In regard to works of a still more general description, the exposition of the families or orders of plants, we have nothing of importance since Lindley's "Vegetable Kingdom," dated 1845, but republished with some additions and corrections in 1853, and Le Maout and Decaisne's "Traité Générale," mentioned in my address of 1868, and of which Mrs. Hooker is now preparing an English translation, under the supervision of Dr. Hooker. Dr. Baillon has also commenced a "Histoire des Plantes," containing a considerable number of useful original observations, and illustrated by excellent woodcuts, but as a general work, one portion is of too popular a character, and in some cases too diffuse to be of much use to science, and the generic character too technical for a popular work without any contrasted synopsis, and its great bulk in proportion to the information conveyed will always be a drawback. I cannot believe that the author can have been a party to the unblushing announcement of the French publisher, that it is to be completed in about eight volumes. If carried out on the plan of the first one, it must extend to four or five times that number. In Zoology, Bronn's most valuable "Klassen und Ordnungen der Thierreichs," continued after his death by Keferstein and others, which I mentioned in my address of 1866, has advanced but slowly. The Amorphozoa, Actinozoa, and Malacozoa, forming the first two volumes, were then completed, and Gerstaecker has since been proceeding with the Arthropoda, commencing with the Crustacea for the third volume, of which only the general matter and the Cirripedia and Copepoda are as yet published, and three or four parts of a sixth volume for birds have been issued by Selenka, treating the anatomical and other matters in great detail. Another general work of merit, although on a smaller scale, has been proceeding as slowly. Of Carus and Gerstaecker's "Handbuch der Zoologie," the second volume, containing the Arthropoda, Malacozoa, and lower animals, had been already published in 1861, and to this was added in 1868 the first half of the Vertebrata for the first volume, with a promise that the remainder should appear in the autumn, but which promise has not yet been fulfilled. Among the other recently published systematic zoological handbooks of which I have memoranda as published in various Continental states, the most important are said to be Harting's, published at Kiel, in the Netherlands, of which up to 1870 only three volumes had appeared, containing the Crustacea, Vermes, Malacozoa, and lower animals ; A. E. Holmgren's "Swedish Handbook ;" Zoology, of which Mammalia were published in 1865, and Birds in 1868 to 1871 ; and Claus's "Grundzüge," and Troschel's "Handbook" (7th edition) for University Teaching in Germany.

In a comparative sketch of the more partial monographs, faunas, and floras, I had wished to direct my attention more especially to the means afforded us of comparing the plants and animals of different countries ; and with this view one of the questions I addressed to foreign zoologists was—"What works or papers are there in which the animals (of any of the principal classes) of your country are compared with those of other countries?" The answers to this query have not been generally satisfactory. Where the zoology has been well investigated, we have popular handbooks, elaborate memoirs, and works of high scientific value, or splendidly illustrated. But short synoptical faunas, so useful to the general naturalist and corresponding to the floras we now possess of so many different countries, are very few ; the statement of the general geographical range of each species, so prominent a feature in many modern floras, is still less thought of, and indications of allied or representative races in distant countries are equally rare. We have indeed several excellent essays on the geographical distribution of animals ; I had occasion to allude to several of them in my address of 1869, but they are in general chiefly devoted to discussion, with statements of such facts only as bear upon the author's conclusions, not records of facts which may be useful to the geographical or general biologist. These must be collected from a great variety of separate works and papers, of which I have received long lists from Denmark, Sweden, Germany, Switzerland, Italy, France, and the United

character ; but to prevent any confusion with *the* imaginary type, it would surely be better to call it an "example," as, indeed, is often done. In geographical biology the word "type" is used again in another sense, which, however, does not lead to any misunderstanding.

States. As yet I only have had time to refer to a few which appeared to bear more immediately on the objects I had in view, but I hope on some future occasion to return to the subject. In the meantime I must content myself with glancing rapidly over the different countries, taking them in the order adopted in my former addresses, and endeavouring to show the progress making in supplying our deficiencies. Towards these deficiencies I would particularly call the attention of entomologists and terrestrial malacologists, for insects and land shells are of all others the animals whose life and local stations are the most closely dependent on vegetation. In the following notes I am further precluded from entering into details as to the zoological works or memoirs mentioned, by the consideration that they would be superseded by the analysis given in the annual reviews inserted in *Wiegmann's Archiv*, and more especially in our own admirably conducted *Zoological Record*, which so strongly claims the support of everyone interested in the promotion of Zoological Science.

(*To be continued.*)

## *ZOOLOGY*

### Note on Transversely Striated Muscular Fibre among the Gasteropoda.*

IN studying the radula of a species of *Acmæa* (probably *A. Borneensis* Rye), obtained by Prof. A. S. Bickmore at Amboyna, I noticed, on placing the structure under a power of 100 diameters, that certain of the muscular fibres which adhered to it, when torn from the buccal mass, had a different appearance from the others. On increasing the power to some 800 diameters, it was at once evident that the different aspect of these fasciculi was caused by fine, but clearly defined, transverse striation. Suspecting that it was an optical delusion, caused by a very regular arrangement of the nuclei of the fibres, I subjected the muscle to various tests and to still higher magnifying powers. I also introduced under the same glass some of the voluntary dorsal muscles of a small crustacean for comparison. The structure of the ultimate fibres in both appeared to be similar. These seemed to be composed of a homogeneous tube or cylindrical band of translucent matter, with nuclei interspersed at irregular intervals. In neither was there any appearance of separation into transverse discs, as is seen in the striated muscles of vertebrates. That the striated appearance was not due to contraction and folding of the muscle, was evident upon taking a side view of one of the fibres, when the striæ on each side, as well as the intervening elevations, were seen to correspond exactly to each other. The only perceptible differences between the muscles of the crustacean and the striated muscles of the mollusk, appeared to be that the latter were much more finely striate; the striæ being six to eight times as numerous as in the former in the same space. No difference between the striated and nonstriated muscles of the *Acmæa* could be observed, except in the fact of the striation. In both the nuclei were irregularly distributed. The appearance of the striated fibre reminded one of a string of rhombic beads, which bore no relation to the position of the true nuclei. The striated fibres appeared, after a careful dissection of the parts in a number of specimens, to be the retractors of the radula; they were longer and in narrower bands than the nonstriated fibres, and comparatively much fewer in number. The striation was most evident toward the middle of the fibres, and became evanescent toward their extremities.

Lebert and Robin (Müller's Arch. f. Anat. and Phys., 1846, p. 126) state that the primitive muscular fasciculi of invertebrates often have the nuclei and intervening clear spaces "arranged in such regular order that they might, at the first glance, be mistaken for transversely striated muscular fibres. The latter, however, are actually found in one acephalous mollusk, *Pecten* (and probably in *Lima* also), and some annelids," and are constantly present in the voluntary muscles of *Crustacea* and *Insecta*. In the further researches of M. Lebert (Annales Sci. Nat., t. xiii. 1850, p. 161), he observes that there is nothing extraordinary in the discovery of transversely striated muscular fibre in *Polyzoa* (*Eschara*) by Milne-Edwards, and in *Actinia* by Erdl, since "the further we have pursued the study of the comparative histology of muscular fibre, the more convinced we have become that transversely striated muscular fibre is to be found in a large number of animals of very inferior organisation, without regard to their more or less advanced position in the animal kingdom."

Striated muscular fibre has lately been shown to exist in the "tail" or appendix of *Appendicularia* by Moss (Trans. Lin. Soc., vol. xxvii. p. 300). It was already known to exist in *Salpa*, (Eschricht, ov. Salperne), in the articulated brachiopoda (Hancock, Tr. Roy. Soc., 1857, p. 805), and in *Pecten* (Lebert, Annales Sci. Nat. 1850, 3rd ser. t. xiii. p. 166; and Wagner, Lehrb. d. vergleich. Anat., t. ii. p. 470, 1847), as well as in *Eschara* (Milne-Edwards, Annales Sci. Nat., series ii. t. iv. p. 3). I believe, however, that this is the first instance in which it has been shown to exist in the class *Gasteropoda*; and this, as well as the rarity of such cases among the lower invertebrates, is a sufficient apology for bringing forward such an isolated fact. Other duties have not yet permitted me to determine whether this phenomenon is constant throughout the genus, or whether it does or does not occur among allied genera. W. H. DALL

* Communicated by the author, from the "American Journal of Science and Arts," vol. i., Feb. 1871.

## *SCIENTIFIC SERIALS*

IN the first paper in the *American Naturalist* for May, Prof. C. F. Hartt opens out quite a new field for investigation in the rock-inscriptions of Brazil, and illustrates it with nine plates of very great interest. The inscriptions occur on the rocks in various districts, and are many of them very rude, representing human and other figures, the sun, moon, and stars, and others very difficult to decipher. Prof. Hartt mentions as a curious circumstance that the hands and feet are always represented by radiating lines, usually only three digits being drawn for each hand and foot; the number rarely reaches four, and never five. This, he thinks may be explained by the fact that many tribes of Brazil are unable to count beyond three or four. The antiquity of these rock paintings and sculptures is undoubted, being mentioned by many ancient writers, as well as by Humboldt and others in more recent times. There can be no doubt that they ante-date the civilisation of the Amazons, and there is a strong probability that some of them, at least, were drawn before the European discovery of America. A short paper, by Dr. F. R. Hoy, on Dr. Koch's *Missourium tetracaulodon*, made by Prof. Owen into a Mastodon, points out several particulars in which Dr. Koch's account of the discovery of the fossil is not to be relied on, especially the inference of the great antiquity of man deduced from it. Mr. J. H. Emerton gives an account of the so-called "Flying Spiders," which are merely blown about by the wind. Among the "Miscellany" is an interesting note by Mr. A. Garrett, on the Distribution of Animals in the South Seas, especially in the Viti Islands. The number is altogether one of unusual interest.

*Archiv für Anthropologie*, 1870, Heft 3. An essay on "Theories of Sexual Generation," by Prof. His, of Basel, is rather historical than speculative, tracing the two principal lines of opinion represented in early science by Hippocrates and Aristotle, as to the respective functions of the two parents, and the mode of transmission of their bodily characteristics to the offspring. Among modern writers Prof. His dwells especially on Harvey's views. A paper by Dr. Welcker, "On the compressed feet of Chinese ladies," contains careful drawings, showing the shoe, the foot, and the abnormal position of the bones. As complete an account is given as the subject needs from an anatomical point of view. Dr. Jensen, occupied in studying the proportions of the brain in the insane, arranges for this purpose, a "stereoscopic-geometrical drawing apparatus," by the aid of which to produce geometrical drawings on which measurements can be made. Dr. Schaaf hausen's dissertation on "Cannibalism and Human Sacrifice," is a valuable, though somewhat undigested contribution to the subject. Among the motives assigned for cannibalism, the principal are hunger, revenge, superstition, such as induces savages to devour a brave warrior to obtain his courage, and lastly, the gluttonous longing for a kind of flesh which is described as appetising. Human sacrifice may sometimes be a relic of early cannibalism, an offering to deities who devour human flesh, or it may be an act of propitiation. There is evidence of the ancient or modern existence of cannibalism in most countries of the world, Great Britain being distinctly included. Even in modern times it occasionally breaks out in the civilised world, but on the whole its frequency among savages, and its general disappearance under improved social conditions, enable the writer, who argues in favour of a steady progression in the civilisation, to put it fairly into his argument.

## SOCIETIES AND ACADEMIES

### London

Geological Society, May 24.—Prof. John Morris, Vice-President, in the chair. Messrs. Mosley, Colvin, Noble, F.R.A.S., and Davey, were elected Fellows of the Society. The following communications were read:—(1) "On the principal Features of the Stratigraphical Distribution of the British Fossil Lamellibranchiata." By Mr. J. Logan Lobley, F.G.S. In this paper the author showed, by means of diagrammatic tables, what appears to be the present state of our knowledge of the general stratigraphical distribution of the fossil Lamellibranchiata in Britain. As a class, the Lamellibranchs are sparingly represented in the Lower, and more numerously in the Upper Silurian group, and fall off again in the Devonian; they greatly increase in number in the Carboniferous, become scanty in the Permian and Trias, and attain their maximum development in the Jurassic rocks. They are also largely represented in the Cretaceous and Tertiary series. The stratigraphical distribution of the two great subordinate groups, the Siphonida and the Asiphonida, corresponds generally with that of the class; the Siphonida predominate over the Asiphonida in Tertiary formations, whilst the reverse is the case from the Cretaceous series downwards. Nearly all the families of Lamellibranchs are represented in the Jurassic and Carboniferous rocks, and in the former very largely. The author remarked especially on the great development of the Aviculidæ in Carboniferous times. Mr. Etheridge, after noticing the importance of the paper, remarked that possibly the great difference observed in the proportions of Lamellibranchiata in different formations might to some extent be due to our want of knowledge. Of late years, in the Caradoc and Lower Silurian series, the number of species had been nearly doubled, principally through the persevering industry of one single observer, Lieut. Edgell. The same was to some extent the case in the Carboniferous rocks, owing to the collections of Mr. Carrington. Much was also being done for the Oolitic series, in connection with which the names of Mr. C. Moore, Mr. Sharp, and Dr. Bowerbank ought to be mentioned. Mr. Griffiths and the Rev. Mr. Wiltshire were doing the same work for the Gault. What the late Mr. S. P. Woodward had done as to the distribution of the different species of molluscs through time, Mr. Lobley was doing on a larger and more extended scale. Prof. Ramsay was glad to find that Mr. Lobley was, to some extent, doing the same for the Lamellibranchiata as Mr. Davidson had done for the Brachiopoda. He did not know how the case might be with the Silurian and Devonian formations, but in the Carboniferous strata the Lamellibranchiata were obtaining a preponderance over the Brachiopoda. He accounted for their comparative absence in formations of other ages, especially between the Upper Silurian and Rhætic beds, by the best known areas of those periods having been mainly continental, or containing principally freshwater or inland sea remains, so that the true marine fauna was absent. In Carboniferous times possibly the true relative proportions of the two forms had been preserved in the deposits. Mr. Judd was doubtful as to the safety of placing too great reliance upon figures. He questioned whether some of the conclusions as to the great increase of Lamellibranchiates between the Carboniferous and Jurassic periods could be substantiated. Much depended on the amount of the rocks present in different countries, and the study bestowed on each. The conditions also for the preservation of the fossils might be more favourable at one time than another. Mr. Carruthers considered the tables as of the greatest value, as indicating the present state of our knowledge. He called attention to the difference of conditions under which deposits had accumulated, which must have to some extent affected the proportion of Lamellibranchiates preserved in the different formations. Mr. Charlesworth remarked on the occurrence of *Trigonia* in the Australian seas, and on there being varieties of form among specimens of existing species so great that if they were found fossil they might be regarded as of several species. Mr. Hughes considered that the data were too incomplete to justify the generalisations of some of the previous speakers. It had been pointed out that whenever the tables showed a very large number of Lamellibranchs from any formation, that formation had been carefully worked out by local observers; and therefore he would like to know in each case the proportion the Lamellibranchiata bore to the total number of fossils found. It had been shown also that a larger proportion of Brachiopoda had been found in the older rocks, and of Lamellibranchiata in the newer. But in the older rocks whole genera of Lamellibranchs are confined to horizons and localities which are not cut off by stratigraphical breaks, such as would allow us to think it at all probable that they can be characterised by peculiar genera. He thought the scarceness and irregular occurrence of Lamellibranchs in the older rocks could be best explained on the supposition that those portions of the older deposits which were least favourable to Lamellibranchs happened to be those now chiefly exposed to our search, and that those few portions are only in part worked out. Mr. Jenkins observed that in thick deposits there was a far greater likelihood of numerous forms being present than in thin, for thickness meant time, and time meant variation. Prof. Morris dissented from this view, as in thin littoral deposits an enormous number of shells might be present, while in beds formed of deep sea they might be almost entirely absent.—2. "Geological Observations on British Guiana," by Mr. James G. Sawkins, F.G.S. In this paper the author gave a general account of his explorations of the Geology of British Guiana when engaged in making the geological survey of that colony. He described the rocks met with during excursions in the Pomeroon district, along the course of the Cuyuni and Mazuruni rivers, on the Demerara river, on the Essequibo and its tributaries, on the Rupununi river, and among the southern mountains. The rocks exposed consist of granites and metamorphic rocks, overlain by a sandstone, which forms high mountains in the middle part of the colony, and is regarded by the author as probably identical, or nearly identical, with the sandstone stretching through Venezuela and Brazil, and observed by Mr. Darwin in Patagonia. Prof. Ramsay remarked upon the barrenness, from a geological point of view, of the district investigated by Mr. Sawkins, and especially called attention to the absence of fossils in the stratified rocks. He referred briefly to Mr. Sawkins's labours in Trinidad and Jamaica, and to his discovery of metamorphosed Miocene rocks in the latter colony exactly analogous to the metamorphic Eocene rocks of the Alps. He was glad to see that the author had brought forward examples of cross-bedding in metamorphic rocks, and considered that the results adduced were favourable to those views of the metamorphic origin of granite which he had himself so long upheld. Mr. D. Forbes, on the contrary, considered that the facts brought forward by Mr. Sawkins were confirmatory of the eruptive nature of the granites observed. He added that cross-bedding was common in igneous rocks and even in lavas. Mr. Tate remarked that in the country to the north of the district described in the paper metamorphic rocks abound. He considered that the series of metamorphosed Jurassic rocks extends across the whole north of South America, and perhaps into California. Similar sandstones to those described occur in the basin of the Orinoco, and contain fossils which show them to be of Miocene age. Mr. Tate did not consider these sandstones as the equivalent of the Patagonian sandstones, as from the shells contained in the latter they would appear to be Pliocene or Pleistocene. Mr. Sawkins, in reply to a question from Mr. Tate, stated that the only gold found in the country had probably been carried down from the well-known gold district of Upata. He also entered into a few additional details connected with the chief points in his paper, dwelling especially upon the physical features of the country, in illustration of which several landscape drawings were exhibited.

Royal Institution of Great Britain, June 5.—Sir Frederick Pollock, Bart., M.A., vice-president, in the chair. Silas Kemball Cook, Miss Elinor Martin, Dr. Charles Bland Radcliffe, and Mrs. Radcliffe were elected members of the Royal Institution. The special thanks of the members were returned for the following donation to "The Fund for the Promotion of Experimental Researches":—Sir Henry Holland, Bart. (thirteenth annual donation), 40*l*.

Anthropological Institute, May 29.—Prof. Busk, F.R.S., vice-president, in the chair. George Latimer of Puerto Rico was elected a member. Mr. F. G. H. Price read a paper "On the Quissama Tribe of Angola," inhabiting that portion of Angola situated on the south bank of the Quanza river. The country had lately been visited by Mr. Charles Hamilton, well known for his travels among the Kaffirs. The Quissama bear the reputation of being cannibals, but cannibalism, although undoubtedly practised by them to some extent, does not largely prevail. The men are well formed, and average about five feet eight inches in height, they are copper-coloured, have long, coarse, and in some instances, frizzled, hair; their heads are mostly well developed, and the Roman nose is not unfrequently met with.

Their weapons are spears, bows and arrows, and occasionally guns, the latter being rude copies from the Portuguese article. Mr. Hamilton was well received by the chief, who told him that he was the first white man that had seen the tribe at home. The men and women of the Quissama are addicted to hunting; they are virtuous, practice monogamy, marry young, and are very prolific. The men largely preponderate in numbers over the women, the result, it is supposed, of infanticide, but of that practice Mr. Hamilton had seen no evidence. The Quissama believe in the existence of a Supreme Being.—A paper was read by Lieut. George C. Musters, R.N., on the races of Patagonia inhabiting the country between the Cordillera and the Atlantic, which the author had traversed during the years 1869 and 1870. The Patagonians consist of three races distinctly differing in language and physique, and partially differing in religion and manners, Tehuelches or Patagonians, Pampas, and Manzaneros, the latter being an offshoot of the Araucanians of Chile. The Tehuelches and Pampas are nomadic tribes subsisting almost entirely by the chase. The proverbial stature of the Patagonians was so far confirmed by the observation that the Tehuelches give an average height of five feet ten inches, with a corresponding breadth of shoulders and muscular development; the Manzaneros come next in order of height and strength, the Pampas being the smallest of the three races. The Manzaneros are remarkable for their fair complexions, whilst the Tehuelches are, literally speaking, Red Indians. Lieut. Musters had visited all the various tribes of those races, from the Rio Negro to the Straits of Magellan, for political purposes, and he estimated the population, which he described as diminishing, as follows:—Tehuelches 1,400 to 1,500, Pampas 600, and the remainder Manzaneros, amounting in all to about 3,000.—Dr. Eatwell contributed a communication on Chinese burials.—Mr. Josiah Harris announced the arrival from the coast of Peru of various pieces of rag, of wooden images, pottery, and other articles of great interest; and the chairman stated that the specimens would be exhibited and described at the next meeting of the Institute.—Mr. George Harcourt exhibited a flint implement found near a stream flowing from Virginia Water, and a bronze Celt discovered in the root of a tree in the parish of Thorpe, Surrey.

### Paris

**Academy of Sciences**, May 1. M. Chasles contributed a rather long but very important paper on Conic Sections. The illustrious mathematician gives the theorems rather than the mode of demonstrating them. It is a reminiscence of the old academy in the golden age of the seventeenth century. The theorems are very numerous.—M. Trécul read a rather long account of the analysis of the juices which can be extracted from aloes.—M. Decaisne read a memoir, which is printed at full length, on the Temperature of Children when they are taken ill.—M. Delaunay presented the second number of his monthly meteorological report for the month of April. It is to be noticed that April expired on a Sunday, and that M. Delaunay spared not a single hour, as his *résumé* was ready on the following day. The observatory had suffered scarcely any injury up to the end of the second siege. No delegate of the Commune had presented himself either to take possession of it or to blow it up.

May 8.—It was only at this late date that M. Longuet's death was officially made known to the Academy. M. Delaunay, who presided over the proceedings, gave expression to a few becoming sentences of regret at the loss the Academy had experienced. M. Longuet was a physiologist of much ingenuity and ability.—M. Duchartre, member of the Botanical Section, read a rather long paper on our knowledge of Liliaceæ.—M. Sedillat, the learned Arabic scholar, read a paper on the etymology of French words having an Arabic origin. Their number is immense, and M. Littré, in his great "Etymological Dictionary," supposes it to be even much larger. The intercourse with Arabs was very active even in mediæval times, as is proved by the history of the University of Paris, which so long defended Averrhoes. M. Sedillat gives many instances chosen from an immense number of others.—M. Stanislas Meunier sent a very interesting paper on meteorites. The experiments were made by him according to the precepts given by M. Daubrée, to whom M. Stanislas Meunier is assistant. M. Daubrée is now a refugee at Versailles. The museum where these experiments were executed is said to be safe, contrary to previous assertions. M. Stanislas Meunier explained by what process serpentine mountains can be changed into tadjerite. Tadjerite is found in some meteorites which belong to the museum collection. Specimens are also to be found in the British Museum, Yale College, U.S., &c. M. Boilot, the scientific editor of the *Moniteur*, read a paper which was written to show astronomers that they must study carefully the different kinds of combustion on the surface of the earth, natural or artificial, to gain some quasi-experimental knowledge of the celestial phenomena of the origin and variations of star light. The doctrine was illustrated by some interesting observations.—M. Quesneville, editor of the *Moniteur Scientifique*, presented a set of his papers.—M. Tremeschini presented three drawings representing one large solar spot seen on the 6th, 7th, and 8th of May at noon. These drawings are inserted in the *Comptes Rendus*. M. Tremeschini lives at Belleville, the spot where the rebellion fought its last desperate struggle. It is to be hoped that he escaped safe, though up to this moment nothing has been heard from him.

## BOOKS RECEIVED

English.—A Memoir of the Indian Survey: C. R. Markham (India Office).—Light Science for Leisure Hours: R A. Proctor (Longmans).—At Last, 2 vols.: Rev. Canon Kingsley (Macmillan and Co.).—The Modes of Origin of Lowest Organisms: Dr H. C. Bastian (Macmillan and Co.).

Foreign.—(Through Williams and Norgate)—Lehrbuch der Mechanik: Dr. Wernicke.—Le Soleil: Padre Secchi

## DIARY

*THURSDAY*, June 8.

Society of Antiquaries, at 8.30.—On the important Excavations in Rome during the present season: J. H Parker, F.S.A.

Mathematical Society, at 8.—On Plücker's Models of Certain Quartic Surfaces: Prof. Cayley.—On the Motion of a Plane under certain Conditions: Mr. S. Roberts.

Royal Institution, at 3.—Sound: Prof. Tyndall.

*FRIDAY*, June 9.

## *PRIMITIVE CULTURE* *

I.

WHEN the commencement of Mr. Buckle's great "Introduction" appeared, some fourteen years ago, no small controversy arose as to the possibility of constructing a Science of History. On the one hand it was argued that for two or three centuries past every generation had demonstrated certain events to be regular and predictable, which previous generations had considered irregular and unpredictable; had generalised facts which it was supposed were incapable of being generalised; and had indicated the existence of order, method, and law, in events which earlier ages had regarded as regulated only by the fitful vagaries of a blind chance, or the inscrutable decrees of a supernatural interference. On the other hand, it was asserted that, even supposing the universal prevalence of law and order to be proved, our necessary nescience would still remain so totally unenlightened with regard to the operation of the law and the sequence of the order, that no ingenuity could achieve such a classification of human motives and actions as could justly be dignified with the name of a science. Since then we have passed through what amounts to a scientific revolution. Not only has archæology vastly extended the limit of its domain, but the doctrine of evolution—itself the most striking generalisation deduced from a comparison of the world's present with the world's past—points decisively to archæology as the most fruitful province of inquiry to the student of the science of History. Before Buckle wrote, archæology had indeed already discovered more than one new world for the conquest of modern science. In the last generation, the archæology of organic nature, brought to light by geology, had afforded a sure basis for the science of Comparative Anatomy; and in a precisely analogous manner the archæology of language and religious worship, revealed in the early literary monuments of India, Assyria, and Egypt, had more recently altogether regenerated the science of Comparative Philology, and created that of Comparative Mythology. But the value and importance of archæological research in other directions had not yet been understood and appreciated. It was not until the discoveries of human implements and remains in the drift and cavern deposits had directed attention to the multifarious problems presented by primitive culture, that investigators began to regard the sciences of Language and Religion as merely departments of the more general and comprehensive science of Comparative Civilisation, and to recognise the fact that the science of Comparative Civilisation is the very corner-stone of any real science of History. As indicating the direction of scientific research, it is significant that Mr. Darwin's last work, which surely should have been entitled the "Ascent" rather than the "Descent of Man," should be so closely followed by the volumes of Mr. Tylor on Primitive Culture. The main argument, indeed, of both writers is fundamentally the same. The difference between them is that Mr. Darwin traces it out in connection with what man *is*, Mr. Tylor in connection with what man *does*. One applies the theory of evolution to man in relation to organic nature, the other to man in relation to human culture. Both, too, have pursued the same method. It was no part of Mr. Darwin's design to write an exhaustive physical history of mankind, or of Mr. Tylor's to detail the history of civilisation. Each has selected the most salient and significant points to illustrate his argument, and has instanced only sufficient facts to supply a reasonable proof of the propositions enunciated.

It is not, however, merely as an exponent of the theory of development that Mr. Tylor has taken his work in hand. Leibnitz long ago pointed out the supreme importance of a study of mankind in connection with that of what he terms the natural history of the world, in order to ascertain what ought to be introduced and what banished from among men. This principle Mr. Tylor has recognised throughout, and the facts he brings forward have quite as often been selected for the light they throw on vexed questions of the day as for the illustration they afford of the theory of evolution.

One great stumbling-block in the way of the student of culture is the extreme imperfection of the only records to which he has access. The comparative anatomist, however, who is perhaps even more closely beset by the same difficulty, has pointed out the means by which it may to a great extent be effectually overcome. If analogy be as trustworthy in the one case as in the other, the historian of culture can study the past in the present with the same confidence as the anatomist, and can as readily reconstruct the shape of human society in primeval ages as his fellow-worker can restore the outward form of an extinct flora and fauna from their fossil remains. But is this analogy to be trusted? Can it be demonstrated that any such vital connection exists between antique and modern barbarism as will enable the inquirer to study prehistoric culture in that of still-existing races, savage, barbaric, or semi-civilised? Can it be proved that savage, barbaric, and civilised life are really correlated as various stages of growth and development? To these questions Mr. Tylor's work supplies a satisfactory answer. Carefully reviewing a number of the most important departments of culture, he proves the existence in all of innumerable relics—the fossils, as it were, of primeval thought and life—traces the modes of connecion of one age with another in progress, degradation, survival, revival, and modification, and demonstrates the utter inadequacy of any theory but one of development to explain the complex and varied phenomena of civilisation. Survival in culture, the origin of language, the art of numbers, mythology, religion, rites and ceremonies, are each in turn discussed, and it is not too much to say that the extent of research, the rare felicity of illustration, the breadth of view and signal originality which Mr. Tylor has brought to bear on these subjects really render the appearance of his work an epoch in the annals of the philosophy of history.

To follow Mr. Tylor through his entire argument, and the evidence he produces in support of it, would be to write a somewhat larger work than his own. We can here only indicate the general method he has pursued, and comment briefly on a few facts which he has collected. Commencing with a general survey of the science of culture, he proceeds to give a rough outline of the course of its development. In so doing, he necessarily touches

* "Primitive Culture: Researches into the Development of Mythology, Philosophy, Religion, Art, and Custom." By Edward B. Tylor, author of "Researches into Early History of Mankind," &c. Two vols. 8vo. (London: Murray, 1871.)

on the controversy between the upholders of the two theories of development and degradation, of whom Sir J. Lubbock and the Duke of Argyll are among the latest representatives. "The master-key," he well observes, "to the investigation of man's primeval condition is held by pre-historic archæology. This key is the evidence of the Stone Age, proving that men of remotely ancient ages were in the savage state." While he shows, however, that the study of archæology has gradually cut away the ground under the feet of those who, like Archbishop Whately and the Duke of Argyll, appear to consider that civilisation was originally created in a state of happy mediocrity, from which it has since more frequently fallen than risen, he is careful at the same time to recognise the agency of degradation as secondary only to that of progress. One circumstance in connection with this argument has perhaps hardly been sufficiently considered by the advocates of either side. The distribution of mankind over the face of the globe is an event for the most part belonging to pre-historic ages, but it is quite clear in some cases, and strongly probable in many others, that the occupation of new territories widely divided by the sea from the earlier inhabited portions of the world, was the result of seafaring disaster; that, in fact, the first denizens of many islands, and perhaps of some continents, were the shipwrecked crews of primeval canoes, cut off from further intercourse with their countrymen, destitute of all the materials and appliances of such rude culture as they may once have possessed, and ignorant of even the primitive industrial arts necessary to utilise them even if they were at hand. Under such circumstances—and a consideration of the actual distribution of mankind in historic times countenances the supposition that the contingency must have occurred over and over again—the march of degradation must have been certain and swift; and even allowing that in the case of mariners belonging to a somewhat advanced tribe, the degradation might be only temporary, the event would account for at least some portion of the diversity which is only less striking than the uniformity perceptible in the various civilisations of the world. Be this, however, as it may, the entire evidence available on the subject fully bears out Mr. Tylor's conclusion, that "throughout the whole vast range of the history of human thought and habit, while civilisation has to contend not only with survivals from lower levels, but also with degeneration within its own borders, it yet proves capable of overcoming both and taking its own course. History within its proper field, and Ethnology over a wide range, combine to show that the institutions which can best hold their own in the world gradually supersede the less fit ones, and that this incessant conflict determines the general resultant course of culture.

The next two chapters are devoted to "Survival in Culture," the strange permanence in the midst of a higher civilisation of certain customs, arts, opinions, &c., long after the real and earnest meaning has died out of them, which in a lower stage commended them to acceptance. Among these metamorphic remains of an earlier world are many, if not most, of the games, rhymes, proverbs, riddles, and minor social customs of civilised peoples. A notable instance is to be found in archery. "Ancient and widespread in savage culture, we trace the bow and arrow through barbaric and classic life and onward to a high mediæval level. But now, when we look at an archery meeting, or go by country lanes when toy bows and arrows are 'in' among the children, we see, reduced to a mere sportive survival, the ancient weapon which, among a few savage tribes, still keeps its deadly place in the hunt and the battle." In another passage Mr. Tylor remarks: "the practice of poisoning arrows after the manner of stings and serpents' fangs is no civilised device, but a characteristic of lower life, which is generally discarded, even at the barbaric stage." Perhaps one of the most striking instances of linguistic survival is to be found in the word "intoxication," derived from "toxicon," the material employed for poisoning the arrow. Among other instances of survival, Mr. Tylor quotes the custom of casting lots. It is noteworthy that both Wesley and Whitfield in certain cases employed this means of ascertaining what they considered the Divine will, and that even yet many Englishmen are to be found who attach under certain circumstances the old sacred significance to the process. That the theory of survival suggested by Mr. Tylor does really account for nearly all the otherwise utterly unaccountable customs and ways in vogue among civilised nations, will not be doubted by anyone who has taken the trouble to trace their history in any considerable number of cases. It is not, for example, many years since the present Lord Leigh was accused of having built an obnoxious person—one account, if we remember right, said eight obnoxious persons—into the foundation of a bridge at Stoneleigh. Of course so preposterous a charge carried on its face its own sufficient refutation; but the fact that it was brought at all is a singular instance of the almost incredible vitality of old traditions. The real origin of a story such as this dates from a time when the foundations of bridges, palaces, and temples were really laid upon human victims, a practice the tradition of which is handed down to us in the Romance of Merlin, and a thousand other legends old and new, to be finally embalmed for the benefit of posterity in Mr. Tylor's volumes. The most telling, however, of all Mr. Tylor's instances of survival are those which bear upon the history of modern spiritualism.

"Beside the question," he observes, "of the absolute truth or falsity of the alleged possessions, manes-oracles, doubles, brain-waves, furniture movings, and the rest, there remains the history of spiritualistic belief as a matter of opinion. Hereby it appears that the received spiritualistic theory of the alleged phenomena belongs to the philosophy of savages."

This conclusion may possibly astonish and even "exercise" the spirits of some of the faithful; but assuredly it is abundantly borne out by the evidence adduced, which parallels with most afflicting minuteness the various phenomena of spiritualism from mediæval story and tales of witchcraft, from classic fable and ecclesiastic miracle, from Chinese divination and Indian divinity, from the feats of North American mountebanks, the hocus-pocus of the angekoks in Greenland, the juggleries of the Siberian shamans. Even this array of evidence, however, is but a fraction of what might be produced. Mr. Tylor quotes Lucian's Hyperborean, who flew and walked on the water clad in undressed leather breeks, and who by the way is possibly only an allotropic form of our own Regnar Lodbrok; but he spares us that other

Hyperborean, Abaris, "the air-walker," to whom Pythagoras, the Miss Kilmansegg of antiquity, displayed his precious leg. In fact here, as elsewhere, Mr. Tylor has acted on the principle that the half is greater than the whole. He selects enough for his purpose, and resolutely declines to overburden himself with superfluous testimony. Fortunately there are two sides to the theory of survival. If on the one hand we have survivals of the type of modern spiritualism, we have on the other survivals of ideas, which, first broached in a stage of civilisation when they are considered foolish or mischievous, become in a higher stage the dominant influences which direct human opinion. To take a single case :—It is now near upon two centuries since Balthazar Bekker, a D.D. of Amsterdam, corrupted, may be, by certain impious notions propounded by the arch-infidel Descartes, published his "Monde Enchanté," a crime for which he was at once deprived of his benefice ; since, as a learned Englishman remarked in reference to the case :—

> Dæmonas ex mundo quisquis proscripserit audax,
> Esse brevi nullum dicet in orbe Deum.

If the English reader of to-day will take the trouble to read this work—and it is worth the trouble—he can scarcely fail to be struck with the remarkable survival of the ideas contained in it, expanded, corrected, developed as they are in these chapters by Mr. Tylor. Not that Mr. Tylor has borrowed anything from Bekker, but simply that Bekker was the first, as Mr. Tylor is the last, to apply science systematically to the phenomena of sorcery, witchcraft, and spiritualism of his age. Survivals of this kind are indeed proofs as decisive of the vitality of civilisation as survivals of the other kind are of the vitality of barbarism.

In the following chapters on Language, emotional and imitative, Mr. Tylor makes out a strong case in favour of what Prof. Max Müller, with a felicity worthy of a better cause, has nicknamed the "pooh-pooh" and "bow-wow" theories. "It may be shown," he says, "within the limits of the most strict and sober argument, that the theory of the origin of language, in natural and directly expressive sounds, does account for a considerable fraction of the existing *copia verborum*, while it raises a presumption that, could we trace the history of words more fully, it would account for far more." Among other matters touched on in this inquiry, Mr. Tylor refers to the language employed in addressing beasts, particularly dogs and horses. Some curious samples of dog-language are to be found in the Book of St. Alban's, and, indeed, in almost every old treatise on hunting. Sir Tristram, however, the hero of the Arthurian cycle, who is generally considered the *rédacteur en chef* of this particular dialect, appears to have thought plain Norman French best adapted to the intelligence of greyhounds, and is very sparing in his use of mere "brutish interjections." Of horse-language one of the best examples is to be found in "The Enterlude of John Bon and Mast Person," a tract belonging to the middle of the sixteenth century. This is how John Bon addresses his team :—

> Ha, browne done ! forth that horson crabbe !
> Ree, comomyne, garlde, with haight blake hab !
> Have agayne, bald-before, bayght ree who !
> Cherly boy, cum of, that whomwarde we may goo !

One branch of inquiry into which Mr. Tylor partly enters in these chapters and the following one on the Art of Numbers, appears to deserve closer attention than it has yet received. Considering the important part which gesture plays in all the lower languages, it is a fair hypothetical inference that, as language gradually became more and more developed, a number of words and phrases would creep into it, formed on the principle of translating gesture into phonetics. Thus, for instance, the universal gesture for "likeness" or "sameness" is to hold out both hands together. If, in several different languages, the words meaning "likeness" or "sameness" have an etymological connection with the word meaning "together," a strong presumption would be raised that they were translated from the gesture ; and if any large number of correspondences of the same kind were detected, the presumption would be raised into a theoretical certainty. Whether such evidence exists of the translation of action into sound in general language, none could determine better than Mr. Tylor himself, whose essay on the gesture-language in one of his earlier works, forms really almost a complete handbook on the subject. That it does exist in language, as applied to numbers, is clearly shown in his chapter on the art of counting, where he traces the quinary, decimal, and vigesimal systems to their origin in the fact that the average man possesses five fingers on each hand, and as many toes on each foot. He perhaps, however, has not sufficiently noticed the further strong probability that the duodecimal system owes its origin to the circumstance that, in addition to his fingers and toes, a man possesses two hands and two feet—a consideration not without its bearing on the obscurity attending the numerals eleven and twelve in certain languages.

## *LEA'S UNIONIDÆ*

*A Synopsis of the Family Unionidæ.* By Isaac Lea, LL.D. 4th edition. 4to. (Philadelphia, 1870.)

THIS work, by a veteran American conchologist, contains 184 pages, and is a memorial of his labour and zeal during a period of more than forty years. The *Unionidæ* are generally known as "fresh-water mussels." Their variability is notorious ; for almost every river, lake, and pond yields different forms, which some writers call species and others call varieties.

> Non nostrum est tantas componere lites.

But while giving Dr. Lea ample discretion to make as many species as he pleases, and full credit for his honest wish to keep down the number, it certainly strikes one as somewhat singular that he admits only "seven or eight species of the family *Unionidæ* living in Europe," when he enumerates 720 species as North American, of which latter number he has himself described no fewer than 582 ! According to Kreglinger's catalogue, which is the newest on the land and fresh-water shells of Europe, fifteen species of this family inhabit Germany. We have but five, including one debateable species of *Anodonta.* The total number of living species recognised by Dr. Lea is 1,069, besides 224 unknown to him or doubtful. To distinguish varieties from species is one of the great difficulties which perplex the naturalist ; but the rule which I have adopted may serve the purpose to a considerable extent, viz., "that all distinct groups of individuals living together and having a common feeding-ground, and which are not connected or blended with each other by insensible gradations, are *primâ facie* entitled to the rank of species." (British Conchology, vol. i., Introduction, p. xix). Now we may see several species of *Rissoa* living under the same stone between tide-marks, several species of *Limnæa* in the same stream or ditch, and more than one species of *Helix* feeding together on the same leaf. In such cases there is no fusion or confusion of species; each has its own definite limits, and retains its own peculiar characters. I say nothing of genera and more comprehensive groups which form communities in a still more diversified fashion, but are equally free from intermixture.

J. GWYN JEFFREYS

## OUR BOOK SHELF

*Echinides du Département de la Sarthe, considérés au point de vue zoologique et stratigraphique.* Par Cotteau et Triger. (Paris: Baillière, 1855-1869. London: Williams and Norgate.)

WE fear that some time must elapse before science will resume its place in unhappy France; but in the meantime its professors, who are innocent of the mischievous and insane acts which have caused so much ruin, demand our heartfelt sympathy. M. Cotteau, of Auxerre, whose work we are about to notice, is well known to English geologists, and is highly esteemed by them for his long and conscientious labours in the field of Mesozoic echinology. His coadjutor, M. Triger, died during the progress of the work. It consists of two royal octavo volumes, one containing an account of Echinoderms found in the Jurassic and Cretaceous formations in the Department of the Sarthe, the other having sixty-five well-executed plates of species, besides several charts to show their geological and stratigraphical distribution. It appears from the preface that this most creditable production of French palæontology was commenced in 1857, and finished in 1869. We therefore regret to observe that M. Cotteau was not aware of Dr. Wright's admirable monograph on British fossil Echinodermata, which was published by our Palæontographical Society in 1856, and which goes over a great deal of the same ground as M. Cotteau. Had the latter author consulted it, he would probably have avoided some mistakes, *e.g.* in attributing the specific name of *Pseudodiadema hemisphæricum* to Desor instead of to Agassiz. A comparison of the figures of this and other species given in both works is decidedly favourable to the British artist (Mr. Bone) as regards accuracy and completeness, although MM. Levasseur and Humbert are deservedly eminent in their style of lithography.

The Echinoderms found in the Jurassic and Cretaceous formations must have inhabited a soft bottom in seas of considerable depth, judging from the present habits of allied species; and their variability was not less in those remote periods of the world's history than it was in the epochs which preceded and followed.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### The Paris Observatory

HAVING read only yesterday the agonising account written by M. Marie-Davy and countersigned by M. Delaunay, descriptive of the Communists having made the Paris Observatory one of their chief strategical points, of the domes of the observatory having five hundred bullet-holes through them, and of the rabid attempts made by the citizens in arms, before retiring on the approach of the Versaillists, to burn or blow up the whole building, I am not a little surprised to find in NATURE of June 8, received here this morning, a statement to the effect "that the Paris Observatory had suffered scarcely any injury up to the end of the second siege. No delegate of the Commune had presented himself either to take possession of it or to blow it up."

I presume that you wrote in ignorance of the real facts, and perhaps not without some intention of whitewashing the poor Communists from the exaggerated denunciations which have been poured on them since their fall; yet neither they nor you should object to true accounts of what they actually did while in power appearing before the world without menace and without favour.

The mere showing of the Commune during this second siege, and still more its international organisation, seems to have surprised most persons; yet the character of the association, and its imminence under the feet of all the Governments of Europe, was duly noted in the section on Metrological Legislation of my report presented to the Board of Visitors of the Royal Observatory, Edinburgh, in June 1870; the association, though political, having obtained mention there on account of its having adopted the scientific metrical system of weights and measures, and professing to find it a most efficient agent for assisting in breaking down the barriers between nations, and rooting up traditional customs and beliefs. I must confess, however, that I was not prepared for these revolutionaries taking up so very early in their outward career, as this their first and just-concluded essay in Paris, the chronological department of the metrical system, thereby repudiating, as the order found on General Delescluze indubitably shows, both the Christian Era and the accustomed months, for decimal periods of days and the era of the first French Revolution. In my book, "Our Inheritance in the Great Pyramid," published in 1864, I did indeed remind that that most revolutionary method in chronology was originally a part of the metrical system, and though deposed under Napoleon Bonaparte, might be expected to reappear when the present promoters of French metrology in this country had acquired more boldness; but here is the accomplished fact upon us at this very moment, and it would be well for all those metrical agitators who were so loud at the British Association last summer in Liverpool in their outcries to Government to make the metrical system compulsory throughout this country, now to declare honestly whether they are inwardly with the Communists in desiring ultimately the abolition of the Christian era and the destruction of the week of seven days.

### Science Lectures for the People

IT is all very well to say, Let our children be taught science in the schools; but that does not meet the need of a large section of the nation, the product of the schools of a former generation. Many hard-worked men who had no scientific teaching whilst at school, have now acquired the wish to know more of nature's mysteries, but know not whither to turn for aid. Books are plentiful, but it is very tiresome to wade through dry pages, scientifically dried of their sap by the use of terms which are not commonly understood—especially after the wearying labours of the day. Experimental lectures, like those at the Royal Institution, but a little more specialised, are wanted for popular use; the question is, How are we to get them? Are we to go to Government for aid, or shall we bestir ourselves and voluntarily endow these lectures?

Surely Huxley or Tyndall would be quite as much sought after as Spurgeon if they came forward and announced a series of lectures; St. James's Hall would be as crowded as the Tabernacle if they held a weekly lecture; pew-rents would be as certain of collection from scientific as from religious devotees. Those busily engaged professors can indeed hardly be asked to undertake such a task as this; but any competent man of science, able to explain the facts of science in popular language, might reckon on public support if he made such a venture as this. Let him, for example, give a series of twelve lectures on Biology, as it affects our daily existence; not wandering into the remote regions of extraordinary phenomena, but simply expounding ordinary life laws. Here would be a subject refreshingly new and interesting to thousands of City-born and bred toilers.

The lectures, if on week days, must be after office hours—from nine o'clock to ten, say; and in some hall easily accessible, as St. James's.

GEORGE FRASER

169, Camden Road, N.W.

### The Eclipse Photographs

IT would have given me much pleasure to have shown Mr. Winstanley the original negatives of the photographs of the late eclipse of the sun if he had called on me to see them, and by so doing he would have avoided falling into the mistakes which his letter contains.

At the time when the last photograph was taken the sky was perfectly clear, and unless Mr. Winstanley is in possession of exclusive information he has no right to assume that the American photograph was not taken under equally favourable conditions. Some of my photographs (which Mr. Winstanley cannot have seen) were taken through the edges of a cloud, the whole of which could be covered by the hand when held with the arm extended; and there was a perfectly cloudless sky near the sun excepting towards the east.

The imperfection in my No. 5 picture, which Mr. Winstanley's experienced eye detects, arose from the shaking of the telescope, caused by the high wind blowing at the time. Probably a single gust during the eight seconds while the plate was exposed caused the mischief, and this defect would never have been seen but for the extremely actinic power of the red prominences which leave their impression on the sensitive plate instantaneously. The moon's limb is perfectly sharp, excepting where the red prominences appear.

Let it be clearly understood that this "indifferent definition" refers to the moon's limb only; the details of the corona do not appear to have suffered; after the gusts of wind the telescope has returned to its proper position, and Mr. Winstanley must know from experience that the image of an object giving off feeble light would not be materially injured by a slight blow given to a firmly mounted camera.

Mr. Winstanley says that "the identity of the coronal rifts in the Cadiz and Syracuse photographs is not satisfactorily conclusive." Assertion is not proof. In NATURE of March 9 I gave evidence which appeared to me to be conclusive (I need not here refer to the opinions of others who are equally satisfied), and up to the present time no counter-evidence has been produced.

It is not for me to defend the American photograph. In due time we shall know all about how that was produced. But has Mr. Winstanley failed to notice that the light on the moon's disc does not extend all round and all over it as it would do if caused by our atmosphere? It is chiefly on the east and west sides. We may expect the explanation of this defect when we hear how it happens that the corona in this photograph is cut off instead of extending as in all the other photographs.

I fail altogether to see the connection between the solar corona and a lunar halo—the phenomena bear no resemblance to each other. The solar corona comes close up to the perfectly black disc of the moon. I never saw a lunar halo close up to the moon's limb. When seen through a mist or in a "sky burdened with innumerable clouds," there can be no doubt that the lunar surface is obscured by the moisture in our atmosphere.

### Ocean Currents

HAVING had occasion in the spring of 1868 to consider the subject of Ocean Currents as discussed by Captain Maury and Sir John Herschel, I was led to certain views respecting the origin of the oceanic circulation, which are briefly touched upon in a paper which appeared in the *Student* for July, 1868. At that time an experimental test of my theory (or rather of that portion of the theory I advocated, which was, as I judged, novel) occurred to me. The experiment might, I conceive, be very readily tried. It somewhat resembled that by which Dr. Carpenter illustrated lately at the Royal Institution his views respecting the influences of evaporation and polar cold; but as I wished specially to show how the westwardly equatorial current came about, the experiment was somewhat more complex. Let the circumference of a large and shallow cylindrical basin represent the equator and the central part the north polar regions. Within this cylinder let solid matter be so placed as to represent the northern halves of the continent, in such sort that the resulting configuration would correspond to that of a map of the northern hemisphere (say on the equidistant projection). Let sea-water be poured in to represent the northern portions of the terrestrial oceans. Now to represent the Arctic ice-fields, let lumps of ice be placed at the centre of the cylindrical vessel (they should be circled round by a wire-guard); and to represent the effects of equatorial heat, let a stout iron ring round and above the rim of the cylindrical vessel be heated. In this state of things the process of circulation, which actually took place in Dr. Carpenter's experiment, would take place after such modified sort as the contour of the continent masses permitted. Now suppose that the cylindrical vessel is set in steady and somewhat slow rotation about its axis. It is clear that on the currents flowing from the pole and polewards, effects will be produced which precisely resemble those due to our earth's rotation. If I am right in regarding these effects as the true cause of the direction in which the equatorial currents, the Gulf Stream, and in fact all the currents in open ocean are observed to flow, abundant evidence to that effect will be obtained. If no such evidence be obtained, the westwardly direction of the equatorial currents must, I imagine, be ascribed to the trade winds, as Franklin and Sir J. Herschel have maintained.

In the summer of 1868 I suggested to Prof. Pepper that such a contrivance as the above, if it worked as I judged (and still judge) that it would, would form an interesting and instructive addition to the models exhibited at the Polytechnic Institution. Dr. Carpenter has already proved that the vertical circulation takes place in an experiment of this sort. If the eastwardly and westwardly circulation takes place as I expect, the expe imental illustration of oceanic circulation would be singularly complete. The circulation in the southern hemisphere could be illustrated in like manner.

I may note here that the vast distance separating the polar from the equatorial regions must not be overlooked in theories respecting oceanic circulation. The influence of arctic cold may be paramount in very high latitudes; but equatorial evaporation must, it should seem, be the prime moving cause in tropical and sub-tropical regions.

RICHARD A. PROCTOR

Brighton, June 6

### Day Auroras

I HAVE read attentively the numerous letters which have appeared in your columns on this subject; but so far as I can discern it seems not to have occurred to any of your correspondents that the auroral force, whatever it may be, affects every kind of cloud as well as the cirrus. On June 15, 1870, at 9 A.M., I witnessed here as complete a display of auroral motions in the cirrus cloud as ever I beheld in a midnight sky; and from that date I dismissed in my own mind all doubt as to the identity of auroral force, whether seen by day affecting the cirrus cloud or appearing as streams and rays of light at night. On Thursday and Friday last I witnessed a configuration of cirro-stratus cloud, evidently the result of magnetic polarisation, which I have no hesitation in characterising as auroral. There were on Thursday two poles, both in the line of the magnetic meridian; but on Friday night, at nine o'clock, only one pole in the direction of the true meridian. The phenomenon to which I refer is of very frequent occurrence, especially before a track of fine warm weather; and without at present offering a theory on the subject of auroras, I venture to class polarisations of clouds, whether cirrus or not, as arising from the same cause as luminous aurora. The transverse or dia-magnetic lines are generally as well marked in cloud auroras, and it is an interesting task to watch the transformation of cirrus cloud from the meridional to the equatorial direction. I have also noted that when these auroral lines converge towards the magnetic pole, a steady barometer and fine weather ensue; but that when the transverse or equatorial lines predominate and continue long visible, rain soon follows. These transverse lines of cloud are always lower and seem to be dia-magnetic.

D. LOW

Burntisland, May 22

PERHAPS you will allow me to add my mite to the discussion which has been going on in your pages on the question of the visibility of the aurora in daylight.

On the 3rd of September in last year, when at Nairn in the north of Scotland, I witnessed an aurora, such as I never heard or read of, or saw before; and strangely enough it was not noticed, as far as I am aware, in any of the newspapers. I had gone down to the beach at about 10 15 P.M., and immediately noticed what appeared at first to be a kind of haze over the whole sky, which slightly dimmed the light of the stars.

For a few minutes I thought no more about it, but, happening to turn my eyes towards the zenith, there was a sight I never shall forget. A number of sheets of whitish light were constantly darting with a flickering motion from the surrounding haze of similar light, and meeting in the zenith; the length of their course was as much as 15° to 18°; they appeared to proceed indiscriminately from all points in azimuth.

I immediately became aware that the whole sky, down to the very horizon, was illumined by a white, colourless aurora; but I was so fascinated by the incessant play of the streamers overhead, that for some time I could notice nothing else. At last I turned away in order to observe accurately the full extent of the aurora in all directions. I found that it reached quite down to the horizon all round, except in one place, viz., in the S.S.E., and at that point there was a symmetrical arc (of a great circle, as far as I could judge) the summit of which was about 7° or 8° above the horizon. This arc was perfectly well defined; within it was blue sky, and above and around, over the whole heavens, nothing but the auroral light, except in the gaps between the darting streamers in the zenith. I carefully took the bearings of this remarkable arc, and found by means of a compass the next day, that it was bisected by the magnetic meridian. The phenomena underwent no diminution during the time (an hour and a half) I was watching it. The sky appeared to be quite free from cloud.

I have often witnessed fine displays of aurora; one in the winter of (I think) 1848, in this county, the colours and streamers of which were magnificent, far finer than those I saw on the 24th and 25th of last October at Edinburgh; but I never before observed the stars to be so much dimmed as they were at Nairn in September, notwithstanding the light on that occasion was colourless. On other occasions, I have always thought the stars quite unaffected by the auroral light, both to the naked eye and in the telescope, but on this they were obviously dimmed as by a haze.

My impression is, that no aurora that I ever saw could be visible in daylight, with the exception perhaps of this last, and the only portion of this that could possibly be seen in daylight was the well-defined arc low down in the S.S.E. I think it is just possible that in a clear and cloudless sky such an arc as this might be visible. HENRY COOPER KEY

Stretton Rectory, Hereford, June 6

## Red and Blue

I WAS much interested by the letter of Mr. T. Ward (NATURE, vol. iv. p. 68) describing the appearance of a blue colour when looking at white chalk marks on a black board while the sun was shining in the eyes, as I have frequently noticed a precisely complementary phenomenon.

While walking along the chalky roads of East Kent in bright sunshine, and reading under an umbrella, I have frequently noticed that the letters appear of a deep blood-red colour; the black colour of the type reappearing immediately on passing over the shadow of a tree on the ground, or on allowing the sun to shine directly on the book. This was so striking when first seen that I had to convince myself that the page was not printed in red ink. This is obviously the exact converse of the observation of Mr. Ward, who saw a blue colour from white marks on a black surface, while I saw a red colour from black marks on a white surface. A short time since I observed a precisely similar colour when looking down on the platform of a railway station with the setting sun shining on the eyes, the cracks between the boards also appearing red. HERBERT M'LEOD

## Influence of Barometric Pressure on Ocean Currents

A LOW barometric pressure and an increased height of the ocean was, I believe, first assumed to stand in the relation of cause and effect by Mr. Piddington. The abnormally high tidal waves that sometimes rushed up the Hooghly during Calcutta hurricanes were ascribed to the low pressures which accompanied them. There is no doubt that unequal pressure is a true cause of currents in the ocean. But I think it, as well as difference in specific gravity, may be regarded as infinitesimal in amount, compared to the influence of the winds.

The high tidal waves at the mouth of Hooghly are not experienced during the first stage of the hurricane, or so long as the wind blows from a northerly quarter. The waters in the Bay of Bengal are then propelled towards the south. It is only after the wind changes to the south and the barometer is rising that the waters are driven against its northern shores. It is when the wind happens to change to the south at the time of the flow of the tide that great inundations occur in the Delta.

On the coast of the United States, however, there is apparently an intimate relation between low pressures and high tides. In general, so long as the barometer remains low, easterly winds are blowing on the coast and heaping up the waters in every bay. During the second stage of the storms the winds generally blow violently from the west or north-west, often at a right angle to the whole coast. These high westerly gales cause very low tides along the United States when the barometer is rapidly rising. But low tides are not experienced with high pressures if the air is calm.

High tides only occur on the coast of Europe after westerly winds have been blowing for some days in the Atlantic. It is a well-recognised fact among the fishermen on the east coast of Scotland that high tides are due to this cause. I think Hugh Miller was right in maintaining that the friction of the south-west winds on the wide surface of the Atlantic must be quite as powerful in maintaining the flow of the stream through the Florida Channel as the action of the Trade winds in forcing the tropical waters into the Gulf of Mexico.

Owing to the great rapidity with which barometric disturbances are propagated in our temperate latitudes, it is difficult to conceive how barometric pressure of itself can have an appreciable influence on the currents of the ocean. The rate of their propagation in winter is from thirty to sixty miles an hour. In the fourth number of the "Board of Trade Weather Report" an instance is given, in which the rate is affirmed to be upwards of seventy miles an hour. The velocity in this case, however, as I may try to show on another occasion, is estimated about ten miles an hour too high. But let us suppose that no winds accompanied these rapidly propagated depressions and elevations of the barometer. A difference of an inch of pressure existing between places on the ocean two or three hundred miles apart would create only a very slow moving current, even though the diminished area of pressure were stationary. But these low pressures pass so rapidly onwards that the *vis inertiæ* of the waters of the ocean would hardly be overcome before they were again subjected to the opposite influence of an increase of pressure.

The effect of barometric pressure on the level of inland seas, like the Baltic and Mediterranean, must be still less than in the open ocean. Winds are often localised, but great depressions of the barometer extend over immense areas; in most cases far larger than the area of the Baltic. Any higher level from this cause would be brought about by the flow of the waters from either end, as the pressure might be assumed to be the same on both sides of that narrow sea. The mere effect of changes of barometric pressure, it will be admitted, would be quite inappreciable in any inland lake in Britain. But any one who is in the practice of fishing in the smallest of our lakes may always observe that there is an under current or "drag" created when the wind blows strongly towards the shore, in consequence of the accumulation there of its waters. The Niagara is sometimes suddenly raised two feet by strong west winds blowing over lake Erie. It is long since M. Volney, as regards the Mediterranean, stated that east winds caused a rise or flood of from two to three feet in the harbour of Marseilles, and that westerly winds produced opposite effects. It was by a careful deduction of effects produced on a small scale that this acute observer was enabled to give a consistent outline of the causes which produced the ocean currents in general. The currents of the ocean may be regarded as coinciding very closely with the average force and direction of the winds over its surface. Since, however, Humboldt assures us that the surface water of the Gulf Stream in the Florida Straits is sometimes reversed by the force of the winter "northers," it does seem vain to attempt to trace permanent surface currents in any part of the North Atlantic, vexed as its surface is by winds so inconstant in their force and direction.

Pitmuir, Leven, Fifeshire R. RUSSELL

## St. Mary's Loch, Selkirkshire

To the student of Nature it may seem easy to decide whether the water of any given lake is good for domestic uses. But as regards St. Mary's Loch, where the question has to be settled by dint of a squabble in the Auld Reekie municipality, with all its complementary dust, smut, and heat, the true aspects of Nature are liable to misrepresentation.

Although not resident in Edinburgh, nor subject to its prejudices and ratings, your correspondent has taken considerable interest in the subject as discussed both locally and in Parliament. Last week he visited St. Mary's Loch, and took pains to compare it with its very various reputation. He was prepared to find it an oozy swamp, fed by a moorland drainage of bogs and peat mosses.

A true poet is credited with seeing clearer and telling better than other people can, and in this case the credit is fairly earned by Sir Walter Scott, poet laureate of Scottish scenery. In the "Lay of the Last Minstrel" we read of "Fair St. Mary's silver Wave." In "Marmion,"

> Nor fen nor sedge
> Pollute the pure lake's crystal edge.
> Abrupt and sheer the mountains sink
> At once upon the level brink,
> And just a line of pebbly sand
> Marks where the water meets the land.

In plain prose your correspondent saw as follows:—St. Mary's Loch, a practically inexhaustible natural reservoir; in a district pastoral, not moorland. The surface of surrounding hills and flats, formed of loose rock, shingle, or gravel, with sprinkling of light earth, the very type of natural draining to prevent or exterminate bog, morass, and swamp. Not a trace of peat, except peat-reek odour from Tibbie Shiell's chimneys. Tibbie burns peats got from exceptional points high among the hills. The various feeders of the loch run in pure as water can be. That the loch, bedded in a shingly, gravelly flat, and surrounded with bare, smooth, lawn-like hill-slopes, should *appear* to contain brown-tinted water, arises from three concurrent causes. First, the extreme purity of the water; second, the tawny-brown hue of aquatic growths, enveloping the shingle under water, by transmission; third, the pipe-clay whiteness of the dry shingle on the beach, by contrast. From the first-stated cause the water varies in apparent tint according to the bottom hues. Aside from chemical analyses, the relative physical features at once decide St. Mary's Loch to excel the famous Loch Katrine as a water source.

The Edinburgh people are about to celebrate the centenary of Sir Walter Scott. His evidence, before cited, and the occasion, may serve to excuse the spontaneous testimony of

A STUDENT OF NATURE

---

### Sun Spots and Earth Temperatures

I NOTICED lately the deduction by Mr. Stone of a connection between Wolf's solar spot periods and the earth temperatures at the Cape of Good Hope: and now Professor Smyth, at Edinburgh, recalls to our attention the fact that his own investigations had, a year ago, led him to a similar conclusion.

Will you permit me to call attention to a further discussion of this subject, as contained in a short article, published in Silliman's "American Journal of Science." The compilations were mostly made in February, 1869, and afford interesting confirmation of the results, which I suppose to have been deduced by Messrs. Smyth and Stone.

CLEVELAND ABBE,
Director Cincinnatti Observatory,
Meteorologist to the Signal Office

Washington, May 6

---

### Bessemer Bombs

ALLOW me through the medium of your columns to call the attention of scientific men to the significant inference which, it appears to me, is to be drawn from the formation of "bombs" in the Bessemer process, incidentally described by Mr. Williams in a recent number of NATURE.*

These "bombs" are minute hollow spherules; the smaller are for the most part perforated. These minute hollow spherules are formed of liquid incandescent matter, the smaller showing the true form—perforated spheres.

The point to which I wish to direct the attention of Mr. Williams and other scientific men is this:—May we not have here an experiment which supplements those ingenious ones of M. Plateau on revolving liquid spheres? Mr. Williams will perhaps kindly examine some of the most perfect of these bombs, and let us know whether he sees trace of revolution in their formation. I believe he will find such evidence, and that the revolution is about the perforation. C. E.

Brighton

* See NATURE, vol. iii. p. 410.

## THE STRASBOURG MUSEUM

A BRIEF notice of this Museum may not at this time be devoid of interest. It occupies ten large rooms in the Academy House of Strasbourg. Two rooms are devoted to Comparative Anatomy, and eight to the Zoological, Geological, and Mineralogical collections. One large hall is exclusively devoted to a collection of species indigenous to Alsace, and here its flora and fauna, both fossil and recent, will be found well represented. The large hall of Mammals contains about 2,000 specimens belonging to between 600 and 700 species, among which may be noticed a fine series of Felidæ, including two specimens of the rare *Felis pardina* of Portugal. Among the Ruminants are a grand specimen of the *Ovis nivicola* of Kamtschatka; four specimens of Tragelaphus from the mountains of Constantine, a large series in all stages of growth of the *Antilope rupicapra* from Switzerland, the Carpathians, and the Pyrenees; *Capra semlaica* of the Nilgherries; six specimens of *C. ægagrus* from Kurdistan, of which two are magnificent adult males and the others females and young; *C. walee* from Abyssinia, male and female; nine specimens of *C. hispanica* from the Sierra Nevada; seventeen of *C. ibex*, representing it in all its ages and in all states of wool; not to mention excellent specimens of *C. pyrenaica*, *C. caucasica*, *C. altaica*, and *C. sinaica*; indeed, it may be doubted if there is in any Museum a more complete collection of this interesting group. Of the Antelopes the Museum also possesses a grand series, and the attention in this corner of the hall will be at once attracted by the case of Reindeer, containing eight perfect specimens, representing the wild race of Norway, the domesticated animal of Lapland, and the varieties from Siberia, Greenland, and Labrador. There are also beautifully stuffed specimens of the European and American Bison, and among the Cervidæ we noticed a most interesting little variety from Corsica of *Cervus elaphas*.

Among the Rodents the Collection of Hares and Rabbits from all parts of the world is very fine. The Collection of Madagascar Lemurs is nearly complete. There are also fine specimens of *Colobus ursinus* and *C. vallerosus* from the Gaboon, and a skeleton of the female Gorilla; one of the largest specimens known of the Walrus, and an immense series of Phocidæ from the North Seas. We have omitted to mention two nice specimens of *Chlamydophorus truncatus*.

The Bird Galleries are very extensive, and contain upwards of 5,000 species and nearly 14,000 birds. The Collection of Vultures is very rich; *Gypætus barbatus* from Switzerland, Pyrenees, Sierra Nevada, the Atlas, and Abyssinia; *Aquila pelagica* from Kamtschatka. Of Strix there are about 200 specimens and 60 species. The Birds of Paradise are represented by perfectly fresh specimens of *Semiophora Wallacei*, *Paradisea alba*, *Craspedophora magnifica*, male and female; *Astrapia nigra*, male and female; good specimens of both species of *Cephaloptera; Turacus giganteus; Anas Stelleri*, male and female; *Alca impennis*, a very old specimen. Passing by the grand series of Pelicans, of Grouse we record magnificent specimens of *Oreophatis derlyanus*, *Lophalector Macartneyi*, male and female, *Balaniceps rex*, &c.

The Reptiles and Fishes occupy two large halls.

The Entomological Collection is very fine; a portion of it is exposed to the public in one of the halls; but the greater part is kept in the Cabinet Room. Nothing can surpass the beauty and freshness of the collection of Alsace Insecta. The collection of Coleoptera numbers about 8,000 species.

The Palæontological Collection is arranged according to the geological formations; and one must remark a magnificent example of *Teleosaurus Chapmani*, 12 ft. long; a grand mass of *Pentacrinus fascicularis*, 5 ft. by 3, and containing 15 individuals established on a mass of oysters.

The fossil plants are, as might be expected, very numerous, and many of them are well known through the memoirs, as well as the fine monograph on Fossil Plants, by Dr. Schimper.

In thus noticing some of the chief objects which attracted our attention during a visit to this Museum in January last, it is well also to remember that this grand collection owes its very existence to the life-long labours of Dr. Schimper. Since 1838 he has been the Director of the Museum, which before that time existed only in name. Throughout the terrible bombardment the Museum escaped almost without any damage, and has now become one of the most valuable prizes of war gained by the conquerors. The thanks of the world of science are due to the excellent director of this collection, for all that he has done for it and for science, and we hope we are not wrong in here expressing the wish that, should Prof. Schimper, having been all his life a Frenchman, find it impossible to change his nationality and so continue to reside in Strasbourg, that that new rule which knows so well when it likes how to appreciate the man of science, will not forget to whose care it is indebted for the magnificent prize which it has won.

E. P. W.

---

## *DUST AND SMOKE* *

AFTER a few preliminary experiments illustrative of the polarisation of light, Prof. Tyndall adverted to the polarisation of light by fine dust, by the sky, and by the coarser particles of smoke. In the former the direction of maximum polarisation, as in the case of the sky, is at right angles to the illuminating beam. In the latter, according to the observations of Govi, the maximum quantity of polarised light was discharged obliquely to the beam. Govi's observation of a neutral point in such beam, on one side of which the polarisation was positive and on the other side negative, was also referred to. The additional fact was then adduced that the position of the neutral point varied with the density of the smoke. Beginning, for example, with an atmosphere thickened by the dense fumes of incense, resin, or gunpowder, and observing the neutral point, its direction was first observed to be inclined to the beam *towards* the source of illumination. Opening the windows so as to allow the smoke to escape gradually, the neutral point moved down the beam, passed the end of a normal drawn to the beam from the eye, and gradually moved forward several feet down the beam. The speaker did not halt at these observations, they were introduced as the starting point of inquiries of a different nature, and after their introduction the discourse proceeded thus :—

But what, you may ask, is the practical good of these curiosities? And if you so ask, my object is in some sense gained, for I intended to provoke this question. I confess that if we exclude the interest attached to the observation of new facts, and the enhancement of that interest through the knowledge that by-and-by the facts will become the exponents of laws, these curiosities are in themselves worth nothing. They will not enable us to add to our stock of food or drink or clothes or jewellery. But though thus shorn of all usefulness in themselves, they may, by leading the mind into places which it would not otherwise have entered, become the antecedents of practical consequences. In looking, for example, at this illuminated dust, we may ask ourselves what it is. How does it act, not upon a beam of light, but upon our own lungs and stomachs? The question at once assumes a practical character. We find on examination that this dust is organic matter—in part living, in part dead. There are among it particles of ground straw, torn rags, smoke, the pollen of flowers, the spores of fungi, and the germs of other things. But what have they to do with the animal economy? Let me give you an illustration to which my attention has been lately drawn by Mr. George Henry Lewes, who writes to me thus :—

"I wish to direct your attention to the experiments of von Recklingshausen should you happen not to know them. They are striking confirmations of what you say of dust and disease. Last spring, when I was at his laboratory in Würzburg I examined with him blood that had been three weeks, a month, and five weeks, out of the body, preserved in little porcelain cups under glass shades. This blood was living and growing. Not only were the Amœba-like movements of the white corpuscles present, but there were abundant evidences of the growth and development of the corpuscles. I also saw a frog's heart still pulsating which had been removed from the body (I forget how many days, but certainly more than a week). There were other examples of the same persistent vitality or absence of putrefaction. Von Recklingshausen did not attribute this to the absence of germs—germs were not mentioned by him; but when I asked him how he represented the thing to himself, he said the whole mystery of his operation consisted in keeping the blood *free from dirt*. The instruments employed were raised to a red heat just before use, the thread was silver thread and was similarly treated, and the porcelain cups, though not kept free from air, were kept free from currents. He said he often had failures, and these he attributed to particles of dust having escaped his precautions."

Prof. Lister, who has founded upon the removal or destruction of this "dirt" great and numerous improvements in surgery, tells us of the effect of its introduction into the blood of wounds. He informs us what would happen with the extracted blood should the dust get at it. The blood would putrefy and become fetid, and when you examine more closely what putrefaction means, you find the putrefying substance swarming with organic life, the germs of which have been derived from the air.

Another note which I received a day or two ago has a bearing particularly significant at the present time upon this question of dust and dirt, and the wisdom of avoiding them. The note is from Mr. Ellis, of Sloane Street, to whom I owe a debt of gratitude for advice given to me when sorely wounded in the Alps. "I do not know," writes Mr. Ellis, "whether you happened to see the letters, of which I enclose you a reprint, when they appeared in the *Times*. But I want to tell you this in reference to my method of vaccination as here described, because it has, as I think, a relation to the subject of the intake of organic particles from without into the body. Vaccination in the common way is done by scraping off the epidermis, and thrusting into the punctures made by the lancet the vaccine virus. By the method I use (and have used for more than twenty years) the epidermis is lifted by the effusion of serum from below, a result of the irritant cantharadine applied to the skin. The little bleb thus formed is pricked, a drop of fluid let out, and then a fine vaccine point is put into this spot, and after a minute of delay it is withdrawn. The epidermis falls back on the skin and quite excludes the air—and not the air only, but what the air contains.

"Now mark the result—out of hundreds of cases of re-vaccination which I have performed, I have never had a single case of bloodpoisoning or of abscess. By the ordinary way the occurrence of secondary abscess is by no means uncommon, and that of pyæmia is occasionally observed. I attribute the comparative safety of my method entirely, first, to the exclusion of the air and what it contains; and, secondly, to the greater size of the apertures for the inlet of mischief made by the lancet."

I bring these facts forward that they may be sifted and challenged if they be not correct. If they are correct it is needless to dwell upon their importance, nor is it necessary to say that if Mr. Ellis had resigned himself wholly

* Lecture delivered at the Royal Institution, Friday evening, June 9, 1871.

to the guidance of the germ theory he could not have acted more in accordance with the requirements of that theory than he has actually done. It is what the air contains that does the mischief in vaccination. Mr. Ellis's results fall in with the general theory of putrefaction propounded by Schwann, and developed in this country with such striking success by Prof. Lister. They point, if true, to a cause distinct from bad lymph for the failures and occasional mischief incidental to vaccination; and if followed up they may be the means of leaving the irrational opposition to vaccination no ground to stand upon, by removing even the isolated cases of injury on which the opponents of the practice rely.

We are now assuredly in the midst of practical matters. With your permission I will recur once more to a question which has recently occupied a good deal of public attention. You know that as regards the lowest forms of life, the world is divided, and has for a long time been divided, into two parties, the one affirming that you have only to submit absolutely dead matter to certain physical conditions to evolve from it living things; the others, without wishing to set bounds to the power of matter, affirming that in our day no life has ever been found to arise independently of pre-existing life. Many of you are aware that I belong to the party which claims life as a derivative of life. The question has two factors: the evidence, and the mind that judges of the evidence; and you will not forget that it may be purely a mental set or bias on my part that causes me throughout this discussion from beginning to end, to see on the one side dubious facts and defective logic, and on the other side firm reasoning and a knowledge of what rigid experimental inquiry demands. But judged of practically, what, again, has the question of Spontaneous Generation to do with us? Let us see. There are numerous diseases of men and animals that are demonstrably the products of parasitic life, and such disease may take the most terrible epidemic forms, as in the case of the silkworms of France in our day. Now it is in the highest degree important to know whether the parasites in question are spontaneously developed, or are wafted from without to those afflicted with the disease. The means of prevention, if not of cure, would be widely different in the two cases.

But this is by no means all. Besides these universally admitted cases, there is the broad theory now broached and daily growing in strength and clearness—daily, indeed, gaining more and more of assent from the most successful workers and profound thinkers of the medical profession itself—the theory, namely, that contagious disease generally is of this parasitic character. If I had heard or read anything since to cause me to regret having introduced this theory to your notice more than a year ago, I should here frankly express that regret. I would renounce in your presence whatever leaning towards the germ theory my words might then have betrayed. Let me state in two sentences the grounds on which the supporters of the theory rely. From their respective viruses you may plant typhoid fever, scarlatina, or small-pox. What is the crop that arises from this husbandry? As surely as a thistle rises from a thistle seed, as surely as the fig comes from the fig, the grape from the grape, the thorn from the thorn, so surely does the typhoid virus increase and multiply into typhoid fever, the scarlatina virus into scarlatina, the small-pox virus into small-pox. What is the conclusion that suggests itself here? It is this:—That the thing which we vaguely call a virus is to all intents and purposes a *seed*: that in the whole range of chemical science you cannot point to an action which illustrates this perfect parallelism with the phenomena of life—this demonstrated power of self-multiplication and reproduction. There is, therefore, no hypothesis to account for the phenomena but that which refers them to parasitic life.

And here you see the bearing of the doctrine of Spontaneous Generation upon the question. For if the doctrine continues to be discredited as it has hitherto been, it will follow that the epidemics which spread havoc amougst us from time to time are not spontaneously generated, but that they arise from an ancestral stock whose habitat is the human body itself. It is not on bad air or foul drains that the attention of the physician will primarily be fixed, but upon disease germs which no bad air or foul drains can create, but which may be pushed by foul air into virulent energy of reproduction. You may think I am treading on dangerous ground, that I am putting forth views that may interfere with salutary practice. No such thing. If you wish to learn the impotence of medical science and practice in dealing with contagious diseases, you have only to refer to a recent Harveian oration by Dr. Gull. Such diseases defy the physician. They must burn themselves out. And, indeed, this, though I do not specially insist upon it, would favour the idea of their vital origin. For if the seeds of contagious disease be themselves living things, it will be difficult to destroy either them or their progeny without involving their living habitat in the same destruction.

And I would also ask you to be cautious in accepting the statement which has been so often made, and which is sure to be repeated, that I am quitting my own *métier* when I speak of these things. I am not dealing with professional questions. I am writing no prescription, nor should I venture to draw any conclusion from the condition of your pulse and tongue. I am dealing with a question on which minds accustomed to weigh the value of experimental evidence are alone competent to decide, and regarding which, in its present condition, minds so trained are as capable of forming an opinion as on the phenomena of magnetism and radiant heat. I cannot better conclude this portion of my story than by reading to you an extract from a letter addressed to me some time ago by Dr. William Budd, of Clifton, to whose insight and energy the town of Bristol owes so much in the way of sanitary improvement.

"As to the germ theory itself," writes Dr. Budd, "that is a matter on which I have long since made up my mind. From the day when I first began to think of these subjects, I have never had a doubt that the specific cause of contagious fevers must be living organisms.

"It is impossible, in fact, to make any statement bearing upon the essence or distinctive characters of these fevers, without using terms which are of all others *the most distinctive of life*. Take up the writings of the most violent opponent of the germ theory, and, ten to one, you will find them full of such terms as 'propagation,' 'self-propagation,' 'reproduction,' 'self-multiplication,' and so on. Try as he may—if he has anything to say of those diseases which is characteristic of them—he cannot evade the use of these terms, or the exact equivalents to them. While perfectly applicable to living things, these terms express qualities which are not only inapplicable to common chemical agents, but as far as I can see actually inconceivable of them."

Once, then, established within the body, this evil form of life, if you will allow me to call it so, must run its course. Medicine as yet is powerless to arrest its progress, and the great point to be aimed at is to prevent its access to the body. It was with this thought in my mind that I ventured to recommend, more than a year ago, the use of cotton-wool respirators in infectious places. I would here repeat my belief in their efficacy if properly constructed. But I do not wish to prejudice the use of these respirators in the minds of its opponents by connecting them indissolubly with the germ theory. There are too many trades in England where life is shortened and rendered miserable by the introduction of matters into the lungs which might be kept out of them. Dr. Greenhow has shown the stony grit deposited in the lungs of stonecutters. The black lung of colliers is another case in point

In fact a hundred obvious cases might be cited, and others that are not obvious might be added to them. We should not, for example, think that printing implied labours where the use of cotton-wool respirators might come into play; but I am told that the dust arising from the sorting of the type is very destructive of health. I went some time ago into a manufactory in one of our large towns, where iron vessels are enamelled by coating them with a mineral powder, and subjecting them to a heat sufficient to fuse the powder. The organisation of the establishment was excellent, and one thing only was needed to make it faultless. In a large room a number of women were engaged covering the vessels. The air was laden with the fine dust, and their faces appeared as white and bloodless as the powder with which they worked. By the use of cotton-wool respirators these women might be caused to breathe air more free from suspended matters than that of the open street. Over a year ago I was written to by a Lancashire seedsman, who stated that during the seed season of each year his men suffered horribly from irritation and fever, so that many of them left his service. He asked me could I help him, and I gave him my advice. At the conclusion of the season this year he wrote to me that he had simply folded a little cotton-wool in muslin, and tied it in front of the mouth; that he had passed through the season in comfort and without a single complaint from one of his men.

The substance has also been turned to other uses. An invalid tells me that at night he places a little of the wool before his mouth, slightly moistening it to make it adhere; that he has thereby prolonged his sleep, abated the irritation of his throat, and greatly mitigated a hacking cough from which he had long suffered. In fact, there is no doubt that this substance is capable of manifold useful applications. An objection was urged against the use of it: that it became wet and heated by the breath. While I was casting about for a remedy for this, a friend forwarded to me from Newcastle a form of respirator invented by Mr. Carrick, an hotel-keeper at Glasgow, which meets the case effectually, and, by a slight modification, may be caused to meet it perfectly. The respirator, with its back in part removed, is shown in Fig. 1. It consists of the space under the partition of wire-gauze *q r*, intended by Mr. Carrick for "medicated substances," and which may be filled with cotton-wool. The mouth is placed against the aperture *o*, which fits closely round the lips, and the air enters the mouth through the cotton-wool, by a light valve *v*, which is lifted by the act of inhalation. During exhalation this valve closes; another breath escapes by a second valve, *v'*, into the open air. The wool is thus kept dry and cool; the air in passing through it being filtered of everything it holds in suspension.*

We have thus been led by our first unpractical experiments into a thicket of practical considerations. In taking the next step, a personal peculiarity had some influence upon me. The only kind of fighting in which I take the least delight, is the conflict of man with nature. I like to see a man conquer a peak or quench a conflagration. I remember clearly the interest I took twenty years ago in seeing the firemen of Berlin contending for mastery with a fire which had burst out somewhere near the Brandenburger Thor; and I have often experienced the same interest in the streets of London. Admiring as I do the energy and bravery of our firemen, and having heard that smoke was a greater enemy to them than flame itself, the desire arose of devising a fireman's respirator. But before I describe what has been done in this direction, let me draw your attention to the means hitherto employed to enable a man to live in dense smoke. Thanks to the courtesy of Capt. Shaw, I am enabled to show you the action of the "smoke-jacket," known abroad as the "Appareil Paulin," from its supposed inventor. The jacket is of pliable cowhide. It has arms and a hood, with eye-glasses. With straps and buckles the jacket is tied round the wrists and waist, and a strap which passes between the legs prevents it from rising. On the left side of the jacket is fixed a screw, to which the ordinary hose of the fire-engine is attached, and through the hose air instead of water is urged into the space between the fireman's body and the jacket. It becomes partially inflated, but no pressure of any amount is attainable, because the air, though somewhat retarded, escapes with tolerable freedom from the wrists and waist. Hence the fireman, when his hose is long enough, can deliberately walk into the densest smoke or foulest air. But you see the use of the smoke-jacket necessitates the presence of several men; it also implies the presence of an engine. A single man could make no use of it, nor indeed any number of men without a pumping engine. Its uses are thus summed up in a communication addressed to me by Captain Shaw:—

"This smoke-jacket is very useful for extinguishing fires in vaults, stopping conflagrations in the holds of ships, and penetrating wells, quarries, mines, cesspools, &c.—any places, in short, where the air has become unfit for respiration.

"The special advantages of this jacket are its great simplicity, its facility for use, and the rapidity with which it can be carried about and put on; but its drawback is that it requires the use of an engine or air-pump, and consequently is of no service to one man alone. For this latter reason smoke-jackets, although very effective for enabling us to get into convenient places for extinguishing fires, have very rarely proved of any avail for *saving life*."

Now it is that very want that I thought ought to be supplied by a suitable respirator. Our fire-escapes are each in charge of a single man, and I wished to be able to place it in the power of each of those men to penetrate through the densest smoke into the recesses of a house, and there to rescue those who would otherwise be suffocated or burnt. I thought that cotton wool, which so effectually arrested dust, might also be influential in arresting smoke. It was tried; but, though found soothing in certain gentle kinds of smoke, it was no match for the pungent fumes of a resinous fire, which we employ in our experiments in the laboratory, and which, I am gratified to learn from Captain Shaw, evolves the most abominable smoke with which he is acquainted. I cast about for an improvement, and in conversing on the subject with my friend Dr. Debus, he suggested the use of glycerine to moisten the wool, and render it more adhesive. In fact, this very substance had been employed by the most distinguished advocate of the doctrine of spontaneous generation, M. Pouchet, for the purpose of catching the atmospheric germs. He spread a film of glycerine on a plate of glass, urged air against the film, and examined the dust which stuck to it. The moistening of the cotton-wool with this substance was a decided improvement; still the respirator only enabled us to remain in dense smoke for three or four minutes, after which the irritation became unendurable. Reflection suggested that in combustion so imperfect as the production of dense smoke implies, there must be numerous hydrocarbons produced which, being in a state of vapour, would be very imperfectly arrested by the cotton wool. These in all probability were the cause of the residual irritation; and if these could be removed, a practically perfect respirator might possibly be obtained.

I state the reasoning exactly as it occurred to my mind. Its result will be anticipated by many present. All bodies possess the power of condensing in a greater or less degree gases and vapours upon their surfaces, and when the condensing body is very porous, or in a fine state of division, the force of condensation may produce very remarkable effects. Thus, a clean piece of platinum-foil placed in a mixture of oxygen and hydrogen so squeezes the gases together as to cause them to combine; and if the experiment be made with care, the heat of combina-

* Mr. Ladd, of Beak Street sells these respirators.

tion may raise the platinum to bright redness, so as to cause the remainder of the mixture to explode. The promptness of this action is greatly augmented by reducing the platinum to a state of fine division. A pellet of "spongy platinum," for instance, plunged into a mixture of oxygen and hydrogen, causes the gases to explode instantly. In virtue of its extreme porosity, a similar power is possessed by charcoal. It is not strong enough to cause the oxygen and hydrogen to combine like the spongy platinum, but it so squeezes the more condensible vapours together, and also acts with such condensing power upon the oxygen of the air, as to bring both within the combining distance, thus enabling the oxygen to attack and destroy the vapours in the pores of the charcoal. In this way, effluvia of all kinds may be virtually burnt up, and this is the principle of the excellent charcoal respirators invented by Dr. Stenhouse. Armed with one of these, you may go into the foulest-smelling places without having your nose offended. Some of you will remember Dr. Stenhouse lecturing in this room with a suspicious-looking vessel in front of the table. That vessel contained a decomposing cat. It was covered with a layer of charcoal, and nobody knew until told of it what the vessel contained.

I may be permitted in passing to give my testimony as

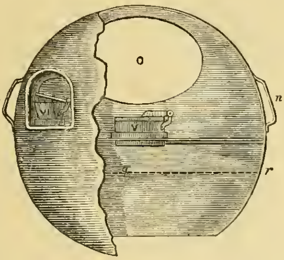

FIG. 1.

to the efficacy of these charcoal respirators in providing warm air for the lungs. Not only is the sensible heat of the breath in part absorbed by the charcoal, but the considerable amount of latent heat which accompanies the aqueous vapour from the lungs is rendered free by the condensation of the vapour in the pores of the charcoal. Each particle of charcoal is thus converted into an incipient ember, and warms the air as it passes inwards.

But while powerful to arrest vapours, the charcoal respirator is ineffectual as regards smoke. The particles get freely through the respirator. In a series of them tested downstairs, from half a minute to a minute was the limit of endurance. This might be exceeded by Faraday's method of emptying the lungs completely, and then filling them before going into a smoky atmosphere. In fact, each solid smoke particle is itself a bit of charcoal, and carries on it, and in it, its little load of irritating vapours. It is this, far more than the particles of carbon themselves, that produces the irritation. Hence two causes of offence are to be removed: the carbon particles which convey the irritant by adhesion and condensation, and the free vapour which accompanies the particles. The moistened cotton-wool I knew would arrest the first, fragments of charcoal I hoped would stop the second. In the first fireman's respirator, Mr. Carrick's arrangement of two valves, the one for inhalation, the other for exhalation, are preserved. But the portion of it which holds the filtering and absorbent substances is prolonged to a depth of four or five inches (see Fig. 1). On the partition of wire gauze *qr* at the bottom of the space which fronts the mouth, is placed a layer of cotton-wool, *c*, moistened with glycerine; then a thin layer of dry wool, *c'*; then a layer of charcoal fragments; a second thin layer of dry cotton wool, succeeded by a layer of fragments of caustic lime. The succession of the layers may be changed without injury to the action. A wire-gauze cover, shown in plan below Fig. 2, keeps the substances from falling out of the respirator. In the densest smoke that we have hitherto employed, the layer of lime has not been found necessary, nor is it shown in the figure; in a flaming building, indeed, the mixture ot

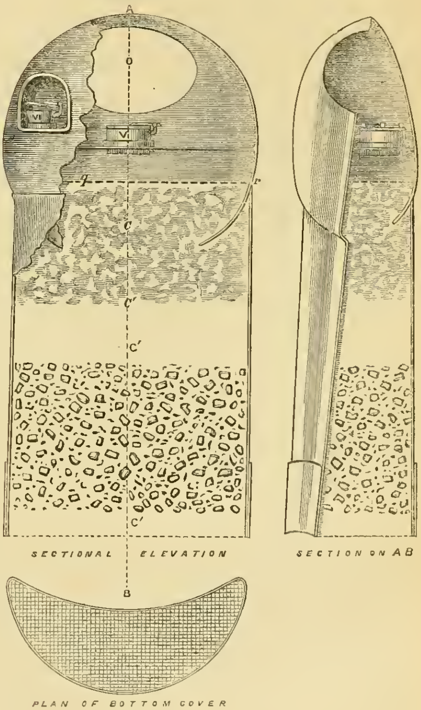

FIG. 2.

air with the smoke never permits the carbonic acid to become so dense as to be irrespirable. But in a place where the gas is present in undue quantity, the fragments of lime would materially mitigate its action.

In a small cellar-like chamber downstairs, with a stone flooring and stone walls, the first experiments were made. We placed there furnaces containing resinous pine-wood, lighted the wood, and placing over it a lid which prevented too brisk a circulation of the air, generated dense volumes of smoke. With our eyes protected by suitable glasses, my assistant and I have remained in this room for half an hour and more, when the smoke was so dense and pungent that a single inhalation through the undefended mouth would be perfectly unendurable; and we might have prolonged our stay for hours. Having thus far perfected the instrument, I wrote to Captain Shaw, the chief officer of the Metropolitan Fire Brigade, asking him whether such a respirator would be of use to him. His reply was prompt; it would be most valuable. He had, however, made himself acquainted with every contrivance of the kind in this and other countries, and had found none of them of any practical use. He offered to come and test it here, or to place a room at my disposal in the City. At my request he came here, accompanied by three of his men. Our small room was filled with smoke to their entire satisfaction. The three men went successively into it, and remained there as long as Captain Shaw wished them. On coming out they said that they had not suffered the slightest inconvenience; that they could have remained all day in the smoke. Captain Shaw then tested the instrument with the same result. From that hour the greatest interest has been taken in the perfecting of the instrument by Captain Shaw himself. He has attached to the respirator suitable hoods. The real problem is practically solved, and I can only say that if a tithe of the zeal, intelligence, and practical skill were bestowed on the cotton-wool respirator that Captain Shaw has devoted to the fireman's respirator the sufferings of many a precious life might be spared, and its length augmented.*

The lecture was concluded as follows:—"Thus have we been led from the actinic decomposition of vapours through the tails of comets and the blue of the sky to the dust of London, from the germ theory of disease down to this fireman's respirator. Instead of this trivial example, I could, if time permitted, point to others of a more considerable kind in illustration of the tendency of pure science to lead to practical applications. Indeed those very wanderings of the scientific intellect which at first sight appear utterly unpractical, become in the end the wellsprings of practice. Yet I believe there is a philosophy embraced by some of our more ardent thinkers (who I fear on many points commit the well-intentioned, but fatal mistake of putting their own hopeful fancies in the place of fact) that would abolish these wanderings of the intellect and fix it from the outset on practical ends alone. I do not think that that philosophy will ever make itself good in the world, or that any freedom-loving student of nature could or would tolerate its chains."

---

A short time before the lecture I had an opportunity of inspecting the apparatus of Mr. Sinclair, which has been tested and highly spoken of by the superintendent of the Manchester Fire Brigade. The original idea is due to Von Humboldt, who proposed it for the Hartz mines. Galibert constructed the apparatus in an improved form, and it has been still further improved by Mr. Sinclair, who has purchased Galibert's patent. It consists of an air-tight bag, from which issue two tubes that unite on a single one with a respirator mouth-piece. The bag is filled with air, and the wearer inspires through one valve and expires through another. The expired breath is carried to the bottom of the bag, and is stated to remain there in consequence of the chilling experienced in its passage downwards. A bag of not inordinate size is stated to be sufficient to supply a man with air for twenty minutes. Mr. Sinclair's apparatus was exhibited during the lecture.

J. T.

* Mr. Ladd has also proposed a form of mouth-piece which promises well, and Mr. Cottrell has attached to it an ordinary fencing-mask. This will probably be the form of apparatus finally adopted.

## NOTES

We are able to state that the Council of the Royal Astronomical Society are considering the steps necessary to be taken to insure observations being made of the Total Solar Eclipse visible in Ceylon next December. We need scarcely remark that there is no subject which is at present engaging the attention of scientific men more important than that of the nature of the Corona, and it will be a disgrace to the science of the age if the next eclipse is allowed to pass over without every effort being made to increase our knowledge.

The Astronomer Royal requests us to state that he will be obliged for the loan of any unpublished observations made during the recent total eclipse. Communications to be addressed to him at the Royal Observatory, Greenwich.

We are glad to learn that the Right Hon. Mr. Robert Lowe has been elected a Fellow of the Royal Society. We have before in these columns stated our belief that Science has every reason to expect a favourable recognition of her claims from him as Chancellor of the Exchequer if proper claims are put forward in a proper manner, and we reiterate the assertion. It was unfortunate that the first grant of public money for which Mr. Lowe was asked, for scientific purposes, was allocated in a way which made Mr. Lowe somewhat indignant, a feeling which was however shared by many men of science. It was also unfortunate that the requirements of science in the matter of the Eclipse Expedition were not properly put before the Government in the first instance, but it is now a matter of history that Mr. Lowe was satisfied with a semi-official statement of the claims of Astronomy, and not only at once granted the required aid, but threw all the power of the Government into completing the necessary arrangements. The same may be said of the Dredging Expeditions. The willingness of a Chancellor of the Exchequer after all, however, is not the only thing requisite for State recognition of the claims of Science. We want a proper scientific organisation, and proper scientific representation. That Science here is in a chaotic state, is the well-founded opinion of many of our scientific men; and if this condition of things is allowed to continue, students of Science must expect that their wishes shall be ignored or lost sight of in the rush of other more emphatically asserted claims.

The official statements made under the head of "University Intelligence" in the daily papers have been lately very remarkable. We noticed, not very long ago, that Prof. Max Müller was called Professor of Comparative Physiology! What will Dr. Rolleston say to this? A few days afterwards it was announced that Mr. Reinold, the Lee's Reader of Physics at Christ Church, would give a course of lectures on Statistical Electricity!! Surely no one but Mrs. Malaprop herself could have made such blunders; while to cap all, a day or two ago we were informed (again in the official "University Intelligence") that the Commemoration at Oxford was an "interesting event!" Surely this is rather hard on Alma Mater!

Astronomy, may we say astrology, like many other things, is being put on a new footing at Constantinople. For many years the chief functionary in this department of science has been the Sultan's chief astrologer, but we believe he is now little called upon by Abdul Aziz to cast horoscopes for a lucky time, as the Sultan starts at a punctual hour, and the astrologer has chiefly to cast the ephemerides for the Salnameh, or official almanack, a periodical growing in respectability. Lectures in Physical Science are given in Turkish by Mussulman Professors at the Darul Funoun, or University, though there are godly men in Islam who maintain that such teaching is contrary to scripture. The time in Constantinople is a sore puzzle. As the day begins at sunset, and has to be divided into twenty-four hours, at sundown begins a general setting of watches, because steamboat departures and other incidents are regulated by Turkish time. The chief object for which expensive clocks and watches are bought by the Turks is for working out the canonical hours of prayer. Now a reform is setting in, H. E. Halil Pasha, Director-General of Arsenals, brought up at Woolwich, the Rev. Mr. Gribble, F.R.A.S., H.M. Chaplain, and Mr. Coumbary, Director of the Meteorological Observatory, have set up a noon-gun at the Tophaneh Arsenal.

WE regret to have to record the death of M. Payen, Professor of Chemistry at the Conservatoire des Arts et Métiers. Although seventy-six years of age, he had enjoyed very good health, and died suddenly of apoplexy. He had been a member of the Academy for twenty-nine years. An address was delivered at the grave by M. Decaisne, and another in the Academy by M. Chevreul.

DURING the last siege of Paris many learned Frenchmen experienced heavy losses through the firing of private houses. M. Bertrand lost the manuscript of the third volume of his great Treatise "On the Differential and Integral Calculus." The amount of labour required for writing it a second time is immense. M. Bertrand had calculated many formulæ from new methods of his own invention. Many instances of similar misfortunes could be given, but altogether it is astonishing that the amount of mischief done was not even larger. During the whole of the rebellion the Academy, with only one exception, held its meetings regularly. No fact more honourable for the members can be written in the eventful history of the learned society.

WE congratulate Marlborough College on the determination of the head master, the Rev. F. W. Farrar, to introduce an adequate amount of natural science as a part of the school work; as well as on the selection he has made of Mr. G. Farrer Rodwell as Science Master, by whose appointment to Marlboro' a vacancy is occasioned in the post of science master at Clifton College.

THE Examiners for the Johnson Memorial Prize Essay at Oxford have awarded it to Mr. James S. Gamble, B.A., Magdalen College. *Proxime accesserunt:* Mr. J. P. Earwaker, Merton College; and the Hon. F. A. Russell, Christ Church. This prize is only awarded every four years, the subject this year being—"On the Laws of Wind; (1) with regard to Storms, (2) with regard to average Periodical Phenomena at given places on the Earth's Surface."

MESSRS. H. N. READ, SOLLAS, and YULE have been elected to exhibitions of 10*l*. each for merit shown in the annual college examination in natural science at St. John's College, Cambridge, in addition to the usual prizes in books conferred upon all of the first class in that examination.

HERBERT MOGG, from Clifton College, Bristol, and S. Cook, private tuition, have been elected to scholarships for Natural Science at Pembroke College, Cambridge.

A NATURAL SCIENCE DEMYSHIP, of the annual value of 80*l*. for five years, will be given in October next at Magdalen College, Oxford. The limit of age is twenty years, and a sufficient knowledge of classics to pass the College Matriculation Examination is also required. At the same time, and with the same papers, a Natural Science Postmastership, of the value of 80*l*. for five years, will be awarded at Merton. Each candidate will be considered as standing in the first instance at the college at which he has put down his name, and unless he has then given notice to the contrary will be regarded as standing at the other College also. The Examination will commence on October 3.

PROF. LIVEING gives notice that the chemical laboratory of the University of Cambridge will be open during the long vacation, as in Term time. The demonstrator (Mr. Liversedge) will attend to give assistance to students on mornings and afternoons alternately during July and August. Dr. Michael Foster also gives notice that the physiological laboratory will be open, and that, under his superintendence, Mr. Martin will give a course of instruction in practical physiology.

ON Wednesday, the 7th inst., a grace passed the Senate of the University of Cambridge, granting 200*l*. from the Worts' Fund to Mr. G. R. Crotch, who is about to proceed in the autumn to the United States of America, *en route* for the Sandwich Islands, New Zealand, and Australia, for the purpose of enabling him to collect and transmit to Cambridge specimens illustrative of the natural history of those parts of the world, and of any others he may visit, with the understanding that such specimens shall be the property of the University, and be accompanied by reports from time to time, which may hereafter be published, of the investigations he has made and the objects he has collected. Though Australia will be the basis of Mr. Crotch's operations, he does not intend to confine his researches to that continent, and should the opportunity offer itself of visiting from its northern settlements the Island of New Guinea, it is to be hoped he will be able to avail himself of it.

THE following have been elected honorary members of the Cambridge Philosophical Society:—Sir B. C. Brodie, Dr. W. B. Carpenter, Capt. Clarke, R.E., Prof. Huxley, Prof. Bartholomew Price, Mr. W. Spottiswoode, Prof. Argelander (Bonn), Prof. Clebsch (Göttingen), Prof. Des Cloiseaux (Paris), Prof. Helmholtz (Berlin), Prof. Wöhler (Göttingen).

IN the *Times* of last Monday Mr. F. Galton calls attention to the small extent to which the great public schools have availed themselves of the opportunity of competing for the medals offered by the Royal Geographical Society for the best candidates in physical and in political geography, and to the very unprepared state in which those candidates who do go up present themselves. He believes it is the Universities that stop the way of reform, and suggests that one branch of geography be included as a necessary subject in a matriculation examination before admission to the Universities.

ON Trinity Monday, according to ancient custom, the Provost and Senior Fellows of Trinity College, Dublin, proceeded to the election of a fellow and of fifteen scholars. Eight candidates had presented themselves for the Fellowship Examination. Mr. William F. Burnside was declared elected as fellow, Mr. G. S. Minchin obtained the Madden Premium; Mr. F. Purser was only half a mark below Mr. Minchin. The following were elected classical scholars:—Tyrrell, Hewitt, Wilson, Barry, Hill, Baker, H. W. White, Butler, and Roberts; and as science scholars:—Graham, Fitzgerald, Downing, Hackett, Byrne, and Adair.

AT the annual meeting of the Royal College of Surgeons of Ireland, held on Trinity Monday, Dr. J. H. Wharton was elected President, Dr. F. Kirkpatrick Vice-President, Mr. William Coles, Secretary; and on the Council:—Messrs. R. Adams, W. Colles, A. Carte, M.D., J. Denham, W. A. Elliott, A. H. Jacob, G. W. Hatchell, E. Hamilton, M.D., W. Hargrave, H. Irvine, W. Jameson, H. Labatt, E. Ledwich, R. Macnamara, J. Morgan, M.D., R. M'Donnell, M.D., F.R S., B. M'Dowel, M.D., G. H. Porter, M.D., and A. J. Walsh. There was a severe contest for the Vice-Presidentship, in which Dr. Kirkpatrick defeated Dr. Mapother by a few votes.

THE *Gardener's Chronicle* publishes more recent intelligence of Dr. Hooker and his party under date "Camp, Atlas Mountains, May 19th." They had succeeded in reaching the top of the crest of the Atlas, nearly due south of Morocco, at an altitude of about 11,500 feet, the upper 3,000 feet of which were very steep indeed, very rocky and stony, with a good deal of snow, and the temperature 24° Fahr. The flora of this upper region appears to be excessively poor; they did not find a single really Alpine plant, "and few plants of any kind; no gentians, primroses, anemones, ranunculi, or other types of an Alpine flora. The rocks were chiefly a very hard porphyry, red, black, and grey, with granite here and there, and beds of limestone, all hard and obnoxious to plants. Moreover, these steep upper cliffs of the Atlas are alternately roasted by a blazing sun, or parched by a Sahara sirocco, or swept by moist north-west Atlantic gales, which bring heavy snowstorms such as we experienced, probably throughout the year. The flora up to 7,000 feet, on the contrary, is exceedingly rich, varied, and beautiful;" and Dr. Hooker thinks that their collections will prove of very great interest and considerable extent. Many English plants find their southern limits here, and there is an abundance of roses, bramble, elder, honeysuckle, ivy, ash, poplar, &c.

A French physician, Dr. Brierre de Boismont, has discovered a new disease, a form of contagious mental alienation, from which, he states, the members of the Commune suffered during the late insurrection in Paris, and which he terms the *morbus democraticus*.

We have received during the past week *Les Mondes* for March 23, and the *Moniteur Scientifique* for May 1 and 15, together with the *Comptes Rendus* to May 29, we trust an earnest of the re-opening of the scientific intercourse with Paris which has for long been so lamentably interrupted.

We learn that the celebrated collection of Egyptian antiquities made by the late artist antiquary, Robert Hay, of Linplum, recently exhibited at the Crystal Palace, has been purchased by a well-known banker in Boston, U.S.A., and it is now being shipped for that city. We regret that so valuable a collection should be allowed to leave this country, and congratulate America on the acquisition of so important and in many instances unique an addition to its antiquities.

On Saturday, June 10, the boys belonging to the Geology Class at Christ's Hospital went to some pits at Woolwich and Charlton, under the care of Professor Tennant. Unfortunately the rain detained them for an hour, but, notwithstanding the inconveniences caused by the wet, some interesting specimens were discovered, and a somewhat better idea of what geology really is was obtained from the practical work that they did.

In a note in a recent number of the *American Naturalist*, Prof. Dawson repeats his assertion that his *Prototaxites Logani* of the Erian formation of Canada is a true exogenous tree, with bark, rings of growth, medullary rays, and well-developed, though peculiar woody tissue; and not, as Mr. Carruthers has maintained, a gigantic alga.

Mr. F. G. Sanborn has been appointed instructor in Practical Entomology in the Bussey Agricultural Institution of Harvard University.

Congress recently appropriated 40,000 dols. for the annual expenses of the U.S. Geologist, Dr. F. V. Hayden, who is surveying the Rocky Mountain region of Colorado.

Prof. Henry, of the Smithsonian Institution, has received the decoration of "Commander of the Order of St. Olaf," from Charles, King of Sweden and Norway. A joint resolution has been offered in Congress to enable the Professor to accept the honour.

Dr. Wills de Hass is about to start on an extended visit of exploration in the Valley of the Mississippi, with a view of determining the character of certain ancient works in the vicinity of St. Louis.

At a meeting of the New York Lyceum, held on May 15, the president, Prof. Newberry, of Columbia College, gave a summary of what was being done in the line of geological exploration throughout America—a task he was well qualified to perform, from his intimate acquaintance with the subject, and from his own connection with one of the most important of these enterprises. He congratulated the Lyceum upon the prospect that what he called the Chinese puzzle of New England geology is in a fair way to be worked out during the present season by means of the concurrent labours of several eminent geologists. Among these he mentioned Sir William Logan, late director of the Geological Survey of Canada; Prof. C. H. Hitchcock, the State Geologist of Vermont; and Profs. Shaler and Hyatt, of Eastern Massachusetts. Prof. Dana also proposes to carry a geological section from the valley of the Connecticut to that of the Hudson. The following additional items were mentioned in the communication of Prof. Newberry: the geological survey of Canada will be continued under the direction of Mr. A. R. C. Selwyn, who succeeded Sir William Logan in its chief direction.

We learn from *Harper's Weekly* that Prof. Winchell has resigned the directorship of the geological survey of Michigan; but the work will be carried on by the board of trustees, Major Brooks devoting himself to the iron region. Prof. Pumpelly declines to continue the survey of the copper district, and asks that the small appropriation may be turned over to Major Brooks. The current surveys of Indiana, Illinois, and Missouri are to be continued during the year, and a new survey has been authorised in Arkansas. No positive appointment of director for this work has yet been made, although the place has been offered to Prof. Orton, of the Ohio geological corps, and declined by him. Bills providing for surveys of Pennsylvania and West Virginia were introduced into the Legislatures of those States during the past winter, but failed to become laws.

A laboratory for the use of students in practical inorganic chemistry having been opened last September at the Oldham School of Science and Art, twenty-two *artisan* students presented themselves for examination by the Department on the 4th of May, and fourteen of them have passed.

## ON THE NECESSITY FOR A PERMANENT COMMISSION ON STATE SCIENTIFIC QUESTIONS*

THE duty of the Government with respect to Science is one of the questions of the day. No question of equal importance has perhaps been more carelessly considered and more heedlessly postponed than this. And now that a hearing has been obtained for it, neither the governing class nor the masses are qualified to discuss it intelligently. The governing class, because it is for the most part composed of men in whose education, as even the highest education was conducted thirty to fifty years ago, science occupied an insignificant place; and the masses, because they may be taken to be virtually destitute of scientific knowledge. Those who wield, and those who confer, the powers of government being alike incapable of dealing with this question, it devolves on another section of the community to urge its claims to attention.

The section qualified to do this is composed of scientific men, properly so called, of professional men, such as engineers, and certain manufacturers who are engaged in applying science practically, and of a limited number of officers in the naval and military services. This section is without much political influence, but its intellectual power is enormous, and this power has never been so strongly exerted, or so decidedly acknowledged, as at the present time.

A tangible acknowledgment of the claims of science consists in the recent appointment of a Royal Commission "on Scientific Instruction and the Advancement of Science," which is now sitting. The problem which this Commission is expected to solve is one of very great complexity, delicacy, and difficulty. It has to survey the whole world of scientific thought, and to construct a chart on which the districts that it is the duty of the State to occupy shall be clearly delineated, with boundary lines so drawn as not to trench upon tracts which may be best left to individual or corporate management. It has then to devise a form of government of which not a trace at present exists, fitted

* Abstract of a paper read at the Royal United Service Institution, by Lieut.-Colonel Strange, F.R.S.

to administer the affairs of the newly-acquired territories. Instruction in science is one thing, and, I admit, an indispensable thing, without which there can be no foundation for future scientific progress; scientific investigation is another and perfectly distinct thing, constituting the end to which instruction is the means. Each may be pursued separately and solely. But if instruction be scanty, investigation will be unsound; if investigation is neglected, progress must be impossible. It will be for the Royal Commission now sitting to point out the relation of instruction to investigation, and to decide how far and by what agency the Government may beneficially aid each.

The first report of the Royal Commission has been published. It deals with certain limited matters of detail only, relating to the occupation of some new buildings at South Kensington. Possibly the settlement of these details may have claimed immediate attention with reference to the arrangement of the buildings in question. This first report has therefore not touched the great problems above adverted to, which await the deliberation of the Commission, and an authoritative solution of which at its hands is anxiously expected by the scientific world.

It may be asked why, as a Royal Commission is investigating the relation of Science to the State, the subject of the present paper should be brought forward independently of that body. The reply is, first, that discussions of any of the questions on which the Royal Commission is deliberating can hardly fail to afford light and assistance useful to the inquiry; secondly, that the problem submitted to the Royal Commission is, "How should the State aid Science?" whereas the question on which I am to address you is totally different, namely, "How can Science aid the State?" Although this latter question may be considered by the Royal Commission, it is certainly not necessarily a part of their programme, and as it is a question of at least equal importance with the former one, it is most undesirable that it should be overlooked.

To the question, "How can Science aid the State?" I reply, "By means of a permanent scientific commission or council, constituted for the purpose of advising the Government on all State scientific questions."

In order to apprehend the aim of this proposal, its practical operation and probable results, it must be examined systematically and in detail. I propose to do this under the following heads:—

I. The scope implied by the term State scientific questions, and the importance of those questions.

II. How are such questions at present dealt with, and with what results?

III. What should be the constitution and functions of the proposed Council of Science?

IV. What objections can be alleged against the proposed council? . . . .

[On the second point we quote the following:—]

II. *How are such questions at present dealt with, and with what results?*—I wish to preface my remarks on this head by saying that they are not intended to apply to any particular party in politics. In speaking of the shortcomings of the Government, I mean to include ALL administrations, whatever political principles they may have represented. I cannot perceive any difference worth noting between different Cabinets as regards science. All have, in my opinion, displayed, in the most elaborate manner, their incapacity to grasp science as a national matter. I am not aware of a single attempt on the part of any Government that has ever existed in England to define its duties with regard to science, or to model any administrative agency for dealing with it in a rational, efficient, and comprehensive manner. It would be invidious and unjust to single out any set of Ministers as having been more negligent in this matter than others, where all have been to all intents and purposes equally indifferent to it.

How then are State scientific questions now dealt with? The answer is, desultorily, capriciously, inefficiently, irresponsibly, when they are dealt with at all, but in many instances of the greatest moment they are absolutely neglected. The number of questions involving science on which Government has to decide, are innumerable and never ending. Every day adds to their number and their urgency. This vast increase of such questions has taken place within a period which, in the life of a nation, is very brief. . . . . Our official scientific arrangements are substantially the same now as they were in the pre-scientific era —they may be more extensive in degree, but they are the same in kind—the butter may be spread further, but there is not more butter. The enormous scientific activity of the last 30 or 40 years does not seem to have struck the official world as a fact having a bearing on the humdrum routine of the Departments—more secretaries—more clerks—more subordinates of various kinds have been appointed to prevent accumulation of arrears; more committees of inquiry have sat, more scientific witnesses have been examined, more reports published, if not read. But not a single step has been taken towards the creation of an *organisation* capable of concentrating and directing all this scattered effort.

The example of foreign nations, the pressure of the public, and the demands of inventors, daily set before the Government scientific puzzles, which they are often, if not generally, at their wits' end to solve. It never seems to occur to them that these puzzles will never cease, and that they will increase in difficulty as a matter of absolute certainty. The attempt is made to stave off by temporary expedients work of a permanent character. The puzzles are guessed at, and the guess is oftener wrong than right. Problems too deep for guessing are either pushed out of sight or submitted to methods of investigation that end in a blunder, perhaps a catastrophe.

I do not wish either to declaim or to exaggerate. I will briefly indicate the provision that does exist for the solution of State scientific questions. It is of three principal kinds. First, official subordinates in various departments. Second, temporary and special Committees. Third, consultation with individuals eminent in science, or with scientific bodies. I omit debates in Parliament, because no scientific question ever was or will be solved by such an assembly, and I omit also the press, which is so influential in other respects, as altogether unreliable for such inquiries.

The objections to the first kind of provision, viz., official subordinates, are, that such persons have almost invariably other duties of an executive nature to perform, and have not therefore the leisure necessary for scientific investigation. Science, moreover, is now in a stage in which scarcely any one problem can be adequately grasped by a single mind; this remark particularly applies to State scientific problems, which are invariably of a mixed order, requiring a great variety of attainments for their perfect comprehension. Lastly, subordinates are disqualified for the office of advisers by the very fact that they are subordinates. No inferior can be expected to urge distasteful counsels on a powerful superior, and no superior can be expected to abandon his own preconceived ideas in consequence of the timid and feeble remonstrances of an inferior under his orders. Subordinates then are unfitted to be counsellors, because they must in the majority of cases be deficient in leisure, attainments, and independence.

One clear, decided example of the inadequacy of this source of scientific advice is as good as a thousand. [The loss of the *Captain* was then referred to.]

The second expedient—temporary Committees, has been very largely employed for the purpose of guiding the Government through their scientific difficulties. There are very serious objections to this expedient. First, there seems to be no rule, either for their appointment or for their composition. If the Government is much pressed by public opinion (which on such subjects is not over-well informed), or if it sees a difficulty ahead, which, however, it often fails to do, a Committee is the result. But there is no guarantee for the proper composition of the Committee. There always lurks about some of the names a suspicion either of incompetence, or of leaning towards the supposed foregone conclusion of the Government. But, passing by such suspicions, there remains the fact, that the members are selected either by some Minister who, not being a scientific man, probably knows nothing about the qualifications necessary for conducting the proposed inquiry, or by some outside and irresponsible person to whom the Minister has applied for help. It is quite overlooked that the selection of the proper persons for conducting any given inquiry can only be made by some one having a knowledge of the subject of the inquiry, or of subjects cognate thereto; the selection is in itself a scientific question. Though some temporary Committees have done good service, it may be safely declared that on the whole they have failed to give reasonable satisfaction.

A second objection to such Committees consists in the fact itself that they are temporary. As such they necessarily commence their labours, however well they may have been selected, with but a partial and confused knowledge of the question at issue, and much time is lost in gaining some insight into it. After much work and expense, they reach a certain stage in the inquiry at which a report is possible. Perhaps by that time the public pressure, or other cause that led to their appointment, has died out, or action is necessary,—in either case the Committee is considered to have served its purpose, and is broken up; the members disperse, take up other duties, the knowledge of a particular subject which they gained in the course of their inquiry is lost to the country, and a scientific problem is left half solved, until at some future day it must be taken up again for completion, and the old work gone over *de novo*. The system of temporary Committees, in fact, implies a belief that finality is attainable in those mixed scientific problems in which chiefly the State is interested, or that such problems can advantageously be taken to bits and studied piecemeal; whilst the fact is, that no one such problem that can be mentioned ever has, or ever will, as long as human ingenuity survives, come to an end. Permanent arrangements alone can deal with the unbroken continuity and unceasing change of scientific development.

A third objection to such Committees consists in the fact that much of the investigation carried on by several Committees may be common to each. This involves the repetition of the same work, and great consequent waste of time, effort, and money. . . . .

I come now to the third source from which the Government draws its scientific inspiration, namely, individuals eminent in science, and scientific bodies. Recourse is had to such sources without any system whatever; there exists no rule, for instance, defining what cases should be submitted to an individual, what cases to a scientific society, and what cases to a temporary Committee. Nor is it possible to assess the degree of responsibility attaching to an individual or to a scientific society advising the Government. If the advice so obtained is rejected, nothing about it is known publicly; if it is adopted and turns out unsound, the right to blame the adviser is absent. It is impossible to ascertain when such consultations have occurred, and with what results. The probability is that they are not frequent. During the two years that I served on the Council of the Royal Society, I only remember one application from Government for advice. It was on some point connected with coppering ships. A committee was formed of the most competent persons, and probably very sound counsel was afforded. But it is evident that this is an expedient that cannot be frequently employed, as it would occupy too much of the time of the Society, which should be devoted to its legitimate objects. Advising the Government is certainly not one of these, nor should the Government of a great, powerful, and opulent nation like England be reduced to such makeshifts as private societies for direction in matters of such tremendous national moment.

Having shown, I trust, that Government is without recognised scientific advisers, I proceed to discuss:

III. *What should be the constitution and functions of the proposed Council of Science?*—The ground requires to be cleared before approaching this question. I have heard it urged that the various departments of the State should be complete in themselves, each with its own consultative element, as distinct from its executive. This appears at first sight a plausible arrangement, but it will not bear examination. Many of the scientific inquiries that devolve on the Government affect several departments, and in such cases it would be wasteful to have numerous repetitions of the same investigation when one would do; and if, under the supposed arrangement, one investigation of a given class of subjects was decided on, the selection of the particular department to which it should be referred would cause endless bickerings and jealousies,—the co-operation of departments being, like universal peace, a somewhat remote hope. Again several departments would require identical scientific advisers. . . . .

For these reasons I discard this suggestion, and revert to the proposal which forms the subject of this paper, namely, that there should be one permanent great council for advising and assisting the Government on all State scientific questions. This council should be purely consultative, not executive. All departments should equally be entitled to its assistance. The Council should not be expected to initiate questions, though it might occasionally see fit to propose certain investigations to the Government, without whose sanction, however, they should not be undertaken. The Government should not be bound on all occasions of scientific difficulty, either to resort to, or be guided by, the opinion of the Council; but it would of course become in either case absolutely responsible for all consequences. . . . .

The duties that would devolve on this Council, stated broadly, would be—

1st. To advise the Government on all questions arising in the ordinary routine of administration, submitted to it by the various departments.

2nd. To advise the Government on special questions, such as the founding of new scientific institutions, and the modification or abolition of old ones; the sanctioning of scientific expeditions, and applications for grants for scientific purposes.

3rd. To receive, consider, and decide upon inventions tendered to Government for the use of the State.

4th. To conduct or superintend the experiments necessary to enable it to perform the above duties.

As to the first branch of its duties little need be said. The number and variety of questions involving scientific considerations entering into the current work of the different departments are almost unlimited. A large proportion of them could be answered at once by competent persons, but there would remain many that require investigation, discussion, and often experiment.

The second branch, special questions, would not perhaps be so extensive, but it would be exceedingly important. At present there exists literally no provision for dealing with such questions. Sometimes one person, supposed to have a knowledge of the matter at issue, sometimes another is consulted, sometimes no one. At present the Royal Commission now sitting is probably dealing with the subject of existing and required scientific institutions. But supposing this body settles all such matters in the most satisfactory manner at the present time, a reconsideration of them will very soon be demanded by the rapid advance of science, and the perpetually changing relations of different lines and modes of physical inquiry. But the Royal Commission is a temporary body. Its functions will sooner or later cease, whilst the mutations and permutations of scientific thought are incessant. Questions relating to State scientific institutions require ceaseless watching,—never-ending modification. A permanent body, such as I propose, alone can preserve the national scientific establishments in a condition of vigorous efficiency on a level with the existing state of physical knowledge.

The sanctioning of special scientific researches and expeditions will be a very important duty, which there is at present no one qualified to perform. . . . .

Sanctioning of grants of money for aiding scientific objects comes under the same head as sanctioning expeditions. At present £1,000 per annum is granted by Government for such purposes, and it is distributed by the Government Grant Committee of the Royal Society. As a member of this committee I can testify to the extreme care, fidelity, and impartiality with which it performs this gratuitous duty, The amount of the grant might with advantage be much increased, as at present only small sums can be given out of it to each applicant; these are often quite insufficient, and as they must unavoidably be small, no application for aiding extensive and costly researches can expect efficient aid from so narrow a source. The proposed council would be a public body, precisely qualified to perform the duty now imposed on private individuals.

The third branch of duties devolving naturally on the council would be the dealing with inventions tending for the use of the State. . . . .

The fourth class of duties which the Council would have to perform would relate to the experiments and investigations necessary to enable it to perform the duties previously enumerated. Regarding the necessity for providing the Council with the agency, appliances, accommodation, and funds requisite for these purposes, there can hardly be two opinions. They are absolutely indispensable. I need not here attempt to define what would be wanted. Such details would follow naturally the affirmation of the great principle involved in the creation of the Council.

I come now to a question on which opinions may differ—namely, the question whether the Council should be a paid or an unpaid body. I say, unhesitatingly, that it should be handsomely paid. If the heads of duties to be performed, of which I have given but an outline, be duly considered, it will be seen that they will be laborious, responsible, and beneficial in the highest degree; and that they can only be adequately performed by highly qualified persons. It is idle to expect that such men as will be necessary, will devote themselves almost exclusively, as they will have to do, to such labour from pure love of science and of their fellow-creatures. The delights of philosophical speculation are one thing, carrying with them their own reward—a reward beyond any money consideration; downright official routine work is quite another thing. In no other professional field is it unpaid; nor is it ever worth much if not paid for. It has hitherto been too much the custom to treat men of science as exceptions to all other professions; to assume that whilst it is quite proper to enrich and ennoble soldiers who fight for pay, lawyers who evade or apply the law according to circumstances; physicians who kill or cure as seemeth best to them; and even divines, whose mission to save souls might be deemed a sufficient privilege: the man of science who contrives the arms with which the soldier wins his fortune and his coronet, who surrounds the lawyer, the physician, and the divine with the luxuries which their superior privileges enable them to command, should work for love, and die, as he too often does, in poverty.

If the Council, the creation of which I now advocate, does its duty, it will confer benefits untold on every member of the community, from highest to lowest; from the military and naval appliances necessary to protect our unequalled national wealth, down to the smallest and least regarded necessaries of our ordinary life, the influence of this Council will be felt; and is it either just or wise to expect such benefits for nothing? . . . .

[The author then gives some indication of the mode of constituting the Council.]

IV. *What objections can be alleged against the proposed Council?*—Difficulties innumerable can of course be conjured up in this as in every case of reform, but I have only heard three definite objections raised that seem to me to deserve any notice. They are:—

1st. That this is a system of centralisation, and therefore objectionable.

2nd. That it will be liable to jobbery.

3rd. That it will be too costly.

I will touch on each of these briefly.

As to centralisation, I admit the impeachment, but claim it as an advantage, not an evil. Those who are scared by centralisation forget that it constitutes the very basis of civilisation and of stable efficient government. In primitive savage life there is no centralisation, no united effort for a common purpose. Each individual struggles single-handed for his rights. Civilisation teaches us to set apart certain members of the community for purposes beneficial to the whole, to form them into distinct bodies, having definite duties to be executed, under the direction of a head central authority. The army, the navy, the police, the post-office, are examples of such bodies, the animating and ruling law of which is centralisation. In the case of the police, we have local, in the other cases imperial, centralisation. The body we are considering will have to perform duties of a strictly imperial character, contributing directly to the efficiency of the defensive power of the empire, and to the security and well-being of every member of the community. It is a body which not only would not be effective, but which could not exist but in a centralised form.

As to the second objection, that the arrangement I have proposed would be liable to jobbery, I must own that, as I contemplate the employment of human beings only, I do certainly expect to see the operation of human motives. But if jobbery be a fatal objection to the scheme, then on the same principle we ought to have no army, navy, church, bench, magistracy, municipalities, or Parliament, for in each of these the discovery of some traces of jobbery will probably reward a diligent scrutiny. It is not apparent why a degree of purity not dreamt of in regard to any other profession should be insisted on when science is in question; nor is it clear why men of science should, *a priori*, be deemed more corrupt than their neighbours. Of course every precaution should be taken against corruption in so important a body, and the rest must be left to that sense of honour to be found in all other professions, and of which even men of science are perhaps not entirely devoid.

The third objection, undue costliness, is, in my opinion, as invalid as the other two. My proposal has two main objects—to increase efficiency, and to diminish blunders. Both are in the strictest sense economical objects. If it does not seem calculated to attain these objects, it should on no account be adopted. If it gives satisfactory promise of their attainment, no expenditure that it is likely to occasion will be too great in order to secure them. Let any one who is terrified by the cost, visit our ports, dockyards, and arsenals, and there see the ships that have been built which should not have been built, the cannons made that should never have existed, and the useless arms and equipments of the pre-scientific ages. Let him count the cost of these, and compare it with the probable cost of substituting for the reign of haphazard ignorance a reign of systematic intelligence. To take one example—that of Her Majesty's ship *Captain*. This vessel, with her armament and stores, probably cost the nation three or four hundred thousand pounds. Who shall assess in money the value of the 500 noble lives that perished with her? Would not the nation willingly give a million to have them back? If so, we have as the cost of one single blunder committed by one Department something like a million and a half of money, a sum that would go a long way to permanently endow a body which, had it existed a year ago, must have prevented that blunder. But if I dwelt on the preservation, prolongation, and increased comfort of civil life which such a Council would tend materially to secure, the cost of its maintenance would appear absolutely insignificant in comparison with the blessings it would shower on the nation. Against the cry of costliness I oppose the assertion, easily established, that nothing is so ruinous as disregard of the laws of nature, and nothing so profitable as intelligent obedience to them. Science, looked at in the dryest commercial spirit, must, in the long run, *pay*.

I must guard myself against the supposition that the proposal I have here advocated comprises all that is necessary for the efficient administration of scientific State affairs. It is only one part of a great system that has to be created. Other parts of the system will, no doubt, receive due attention from the Royal Commission now considering them. But there is one part so important that I feel called on to name it; I mean the appointment of a Minister of Science. He need not necessarily be exclusively devoted to science; he might, perhaps, with advantage, have charge of education and the fine arts also; but some one in Parliament directly representing the scientific branches of the national services has become absolutely indispensable. . . .

When we have all Scientific National Institutions under one Minister of State, advised by a permanent, independent, and highly qualified consultative body—when we have a similar body to advise the Ministers of War and Marine in strategical science—then the fact that, in accordance with our marvellous constitution, these Ministers must almost necessarily be men without pretension to a knowledge of the affairs which they administer, need cause us no alarm. When these combinations have been, as they assuredly will be, sooner or later, effected, the wealth, resources, and intelligence of the nation, having due scope, will render us unapproachable in the arts of peace, and unconquerable in war—but not till then.

In conclusion, I must claim for the proposal I have advocated that there is nothing revolutionary in its character.

I aim at creating no new principle. We have already, as an integral part of our administration, a body constituted on the very same principle as that now advocated. I allude to the Council of India. . . .

My proposal, therefore, I maintain aims at the creation of no new principle,—but only at the extension of one already existing, and universally approved after long experience. Nor do I aim at creating new labours. The work of which I have been speaking is now being done, or suppposed to be done, and it is paid for heavily by the nation, but it is not well done. I propose to improve its quality by improving the agency to which it is assigned. I propose to substitute concentration for scattered effort, system for chance, organisation for disorder. I propose neither to exact from the Queen's advisers new duties, nor to fix upon them new responsibilities. The end and aim of my proposal is to lighten their labours and anxieties by putting into their hands better arms than those with which they now vainly strive to uphold the power and glory of the nation.

A. STRANGE

## *SCIENTIFIC SERIALS*

THE last part of the *Sitzungsberichte* of the Isis Natural History Society of Dresden contains the proceedings of the Society for the months of July, August, and September, 1870. In the section of Prehistoric Archæology, Dr. Mehwald described kitchen-middens on Zealand and Jutland, and on the Andaman Islands, and stated that M. Lorange of Fredrikshald, in Norway, has investigated a grave in that neighbourhood which he believes to have been a family grave, in which the bodies were deposited one above the other, the one first buried being probably at a depth of 600 to 700 feet.—Prof. Geinitz explained Delesse's Geological Map of the Department of the Seine, and remarked upon the occurrence in that district of the bones of extinct animals associated with artificial products and the remains of man. He also glanced at the well-known phenomena of the same kind at St. Acheul and Schussenried, and gave a list of articles received by the Museum of Dresden from the pile-buildings of Robenhausen, in the Pfaffikon Lake. Prof. Geinitz also noticed the contents of some recent anthropological publications.—M. Klemm exhibited a ring of serpentine, measuring about two inches in diameter, found in the year 1835, in an urn in Lower Lusatia. —In the mineralogical and geological section, M. C. Bley noticed the occurrence of roestone in the neighbourhood of Bemburg, and ascribed the peculiar structure of the stone to the great amount of salt contained in the water from which the carbonate of lime for its formation was precipitated.—Prof. Geinitz referred to the discovery of a well-preserved molar of *Elephas primigenius* in the bed of the Elbe below Kötschenbroda, and also exhibited a great number of marly concretions and transported blocks from the loam pits between Strehlen and Mockritz. He also noticed some of the localities in which fossils are to be found in the Loess. M. H. Engelhardt communicated notices of some plants from the brown coal of Saxony, namely, *Anona cacaoides* Zenk. sp., *Gardenia pomaria* Schl. sp. (=*G. Wetzleri* Heer), *Livistona Geinitzi* n. sp., *Glyptostrobus europæus* Brongn. sp., and a species of *Carpolithes*.—Prof. Geinitz communicated a list of some corals from the Lower Pläner of Plauen, which had been determined by Dr. W. Bölsche ; eleven species are enumerated of which six are indicated as new, namely, *Montlivaltia* (?) *tourtiensis*, *Thecosmilia* (?) *Geinitzi*, *Latimæandra*, *Fromenteli*, *Psammohelia granulata*, *Thamnastræa tenuissima*, *Dimorphastræa Dunkani*, and *Astrocœnia tourtiensis*.—M. Engelhardt communicated a paper on the Loess in Saxony, in which he described the general nature and mode of occurrence of the deposit, and the special peculiarities presented by it in particular localities. In connection with this paper and the concretions from the Loess exhibited by Prof. Geinitz at a previous meeting, M. Klemm presented a memoir on concretions and on the globular forms occurring in the minerals and rocks.—Dr. O. Schneider noticed the minerals occurring in the granite of the Königshayner mountains, and in the Zechstein of Niederludwigsdorf near Görlitz, and described some crystals of zircon received from Haddam in Connecticut.—Prof. Geinitz reported upon some fossils from a sandy deposit of Cretaceous age at Château de Meauene near Angers. The predominant form is *Siphonia pyriformis* Goldf. Three species of *Palmacites* are noticed, and one of them is described as a new species under the name of *P. Boxbergæ*— In the mathematical, physical, and chemical section, the only paper of which particulars are given is a description by Prof. Klein of an apparatus invented by him to enable the magnetic needle to be employed on board of armour-plated ships. The arrangement consists of a compass placed at the mast-head and connected with an electro-magnetic apparatus, by which an index is moved.—In the Zoological Section Prof. Günther gave a short exposition of the comparative anatomy of the brain in mammalia. —M. Engelhardt exhibited some corals and shells obtained from Guano.—Dr. Ebert remarked upon Huxley's *Bathybius*.—M. C. F. Seidel described the excrescences and other deformities produced on the stalk of the common cabbage by a small weevil, *Baris cuprirostris*.—Dr. Ebert referred to the support afforded to the theory of the evolution of organic types by the discovery of the curious lizard, *Hatteria punctata*, upon the anatomy of which Dr. Günther has given us such interesting information. Dr. Ebert tabulates the characters of the orders of reptiles to show in what a singular manner *Hatteria* combines their peculiarities.— Dr. Schneider noticed the scorpions collected by him in Egypt.— Dr. Mehwald noticed the occurrence of a snake (*Coronella lævis*) and of a lizard (*L. agilis ?*) as far north as 62° and 63° in Norway ; and M. Kirsch gave some account of experiments with vipers and the common snake. According to the latter the bite of a new-born viper, five inches long, killed a mouse in a short time ; snakes killed by decapitation exhibit irritability by galvanism for a very much longer time than those destroyed by poison ; and the common snake (*Tropidonotus natrix*) is the only snake indigenous to Bavaria that attacks frogs.—The Botanical Section received from M. C. Wilhelmi an account of those Australian plants which may furnish nourishment to man. The abstract of this paper here published enumerates a considerable number of plants, parts of which are used as food chiefly by the natives.— The rest of the communications to this section require no mention, except a report by M. F. A. Weber upon Hildebrand's work on the sexual relations of the Compositæ.—At one of the general meetings Prof. Hartig reported upon the applicability of various kinds of wood to the manufacture of paper.

## SOCIETIES AND ACADEMIES

### London

Zoological Society, June 6.—Mr. G. Busk, vice-president, in the chair. Prof. Owen, F.R.S., read a paper on Dinornis, being the seventeenth of his series of communications on these extinct birds. The present paper gave a description of the sternum and pelvis, and an attempted restoration of the whole skeleton of *Aptornis defossor*.—Prof. Flower, F.R.S., gave a description of a specimen of the so-called Risso's Dolphin which had been taken in a mackerel-net near the Eddystone Lighthouse, and of a second specimen of the same dolphin subsequently purchased in Billingsgate Market. After a searching investigation of the history of this supposed species, Prof. Flower came to the conclusion that the differences usually held to separate it from the *Delphinus griseus* of Cuvier were untenable, and that the species should be correctly designated *Grampus griseus*.—A second paper was read by Prof. Flower on a specimen of the Ringed or Marbled Seal, which had been obtained on the coast of Norfolk, being the first certain instance of the occurrence of this seal in the British seas. To this was added some remarks on the difficult questions presented by the synonymy of this species, which, after full consideration, Prof. Flower came to the conclusion ought to be called *Phoca hispida*.—A paper was read by Prof. W. Peters, giving a description of the Bats collected by Mr. F. Day, in Burmah. The collection contained a very interesting new form of *Rhinolophi*, which Dr. Peters proposed to call *Phyllorhina trifida*.—A communication was read from Dr. A. Günther, F.R.S., containing the description of a new species of Teius (*Teius rufescens*) from Mendoza, founded on five specimens of this lizard living in the Society's Gardens.—Mr. A. G. Butler communicated a Monograph of the Lepidoptera hitherto included in the genus *Elymnias*.—A second communication was read from Mr. Butler, containing a revision of the species of Butterflies formerly included in the genus *Terias* (*Pierinæ*).—A paper by Dr. J. E. Gray was read, containing a reply to Mr. Theobald's observations on Dr. Gray's paper on the families and genera of Tortoises, printed in a recent part of the Society's "Proceedings."

Chemical Society, June 1.—Prof. Frankland, F.R.S., president, in the chair.—The following gentlemen were elected Fellows : H. Adrian, H. Durham, G. Martineau, E. Neison.— Dr. Debus, F.R.S., delivered a lecture "On Ozone." The first who had observed that the passage of electric sparks through oxygen brings about a change in the properties of this gas was Van Marum. The next to take up the subject was Schönbein, in 1840. He ascribed the peculiar odour and the more energetic oxidising properties of the altered oxygen to a substance which he termed ozone. He also found that ozone may be prepared by many other methods. His experiments, however, led to no positive results, as regards the nature of ozone. It was through the researches of Marignac and De la Rive that ozone was shown to be nothing but an allotropic modification of oxygen. Dr. Debus then discussed the question whether there existed another modification of oxygen, called antozone, and answered the proposition negatively—the substance called antozone was only peroxide of hydrogen. The lecturer concluded by calling special attention to one of the characteristic reactions of ozone, viz., the decomposition of potassic iodide, which reaction is differently explained by the various observers. Schönbein has shown that potassic iodide protects free iodine against the action of potassic hydrate. It may be assumed that potassic hydrates and an iodine solution react upon one another thus :

$$KHO + I_2 = KIO + HI, \text{ and then } KHO + HI = KI + H_2O ;$$

if now an excess of potassic iodide be added, the potassic hypoiodite and potassic iodide produce again potassic oxide (which becomes in its turn a hydrate) and iodine, and the excess of iodide prevents the action of KHO on the iodine, but not that of the latter on starch.

Society of Biblical Archæology, June 6.—Mr. Samuel Birch, LL.D., F.S.A., president, in the chair. The following ladies and gentlemen were proposed by the council for ballot at the next meeting :—Rev. A. H. Sayce, Queen's College, Oxford, E. R. Hodges, late of Jerusalem, Mrs. J. W. Bosanquet, and Miss Dorothy Best, of Maidstone. Mr. George Smith (British Museum) read an elaborate and interesting paper "On the Early History of Babylonia." Commencing with a *résumé* of facts already ascertained by the labours of Sir Henry Rawlinson and other *savans*, he proceeded to describe seriatim the principal localities where excavations had been already undertaken, and to identify them with many of the cities mentioned in the older Books of the Pentateuch. A chronological list of kings and a brief account of the military and political changes, including several new facts from contemporary inscriptions, concluded the first part of the paper. In its second division, the theology, the arts, the social and moral characteristics of the ancient Chaldeans were examined, and the examination was further illustrated by the exhibition of sundry casts of ancient bricks and cylinders, translations of which were also given.—Mr. J. W. Bosanquet, F.R.A.S., treasurer, read a paper "On the Date of the Nativity."

Linnean Society, June 1.—On the nomination of the President the following members of the Council were elected vice-presidents for the ensuing year:—Mr. J. J. Bennett, F.R.S., Mr. George Busk, F.R.S., Dr. J. D. Hooker, F.R.S., and Mr. W. Wilson Saunders, F.R.S.—The following papers were read:—"On some plants from North China," by Dr. Hance; "On South American *Hippocrateaceæ*," Mr. J. Miers, F.R.S. The history of this family shows the widely divergent opinions of numerous botanists in regard to its affinities, the absolute want of knowledge to guide these opinions at last culminating in the extinction of the *Hippocrateaceæ* by the authors of the new "Genera Plantarum," who have reduced it to a mere tribe of the *Celastraceæ*; and not only so, but have amalgamated the several genera previously established into 2, viz.: *Hippocratea* and *Salacia*. The large amount of evidence here presented will, however, show its right to stand as a distinct natural order, having in fact little connection with *Celastraceæ*. The chief characters in its floral structure consist in having five sepals, five alternate petals imbricated in æstivation, and only three stamens (very rarely five); the most important feature is the hypogynous disc, variable in shape, but constantly placed between the stamens and petals; the ovary is always superior, usually 3-locular, with definite anatropous ovules fixed in the axis. The mode of growth of the ovary varies greatly, dividing the family into three separate tribes. 1. *Hippocrateæ*, where, in the progress of growth, the axis of the ovary never lengthens, remaining completely atrophied, the cells growing upwards vastly, sometimes to 100 times the length of the axis at the maturity of the flower, thus producing three distinct capsules from a single ovary, which sometimes open 2-valvately, and have winged seeds, or are indehiscent with nuciform seeds borne upon a carinated ovular support; upon such differences five several genera are established. 2. *Tontelieæ*, distinguished by a drupaceous fruit, often a large size, the growth of an ovary wherein the axis lengthens commensurately with the cells, the fruit being thus 3-locular, with several seeds, which in most cases are covered by an *arilline*, a fleshy complete coating, resolving itself into a mucilaginous pulp that envelopes the seeds; this tribe consists of eight genera. 3. *Kippistieæ*, remarkable for a floral development hitherto unknown among Dicotyledones, but long ago described by Robert Brown in Monocotyledones; here the stigmata, instead of alternating as usual with the stamens and standing opposite to the cells of the ovary, are opposite to the stamens and alternate with the cells of the ovary; the fruit is drupaceous, variable in the position of the seeds, but with characters resembling those of *Tontelieæ*; this tribe consists of three genera. There are thus seventeen genera in all, with well-marked characters, which are separately illustrated by as many drawings, each amply explained by analytical figures. The numerous facts here shown in regard to structure are, for the most part, hitherto undescribed, many being derived from analyses made of plants in the living state. In summarising these details, the author points out the many salient points of distinction in the structure of *Hippocrateaceæ* and *Celastraceæ*. 1. In the former the stamens are generally anisomerous in regard to the petals (three to five); in the latter they are constantly isomerous with stamens equal to, or double the number of, the petals. 2. In the former the stamens are distinctly inserted *inside* the disc; in the latter they are invariably inserted *outside* of the disc. 3. In the former the anthers, generally of a peculiar form, are constantly *extrorse*; in the latter they are of the usually normal structure, and always *introrse*. 4. In the former the disc is generally elevated, and presents a free wall of separation between the stamens and more external parts; in the latter it is a mere expansion of the torus, intervening between the ovary and all other floral parts. 5. In the former the sepals, petals, stamens, and disc are persistent at the base of the fruit, and are never seen in such position in the latter family. 6. In the former, the superior ovary is always elevated above the torus and quite free from it; in the latter it is always more or less partially imbedded in the disc and half agglutinated with it. 7. The atrophied condition of the axis of the ovary, though not a constant feature, is one quite peculiar to the *Hippocrateaceæ*, and on the other hand, in *Celastraceæ*, we find no growth at all approaching the several kinds of large drupaceous fruits seen in the *Hippocrateaceæ*. 8. In the development of the seeds there is a constant distinction. In *Hippocrateaceæ* they are invariably without albumen, in the *Celastraceæ*, without exception, the embryo is enveloped in albumen, usually copious. In the former the cotyledons are often closely conferruminated in a solid mass, a circumstance quite unknown in the latter. 9. In the *Hippocrateaceæ* no trace of an arillus can be seen, in *Celastraceæ*, though not universal, a distinct arillus, in most cases, partially surrounds one extremity of the seeds. In the former, in one tribe, the seeds exhibit a greater or smaller expansion of the testa, in the shape of a large membranaceous wing, or a narrower alar keel, while in the two others they are invested by an *arilline*, an entire fleshy coating, the nature of which was explained many years ago, a feature seen in some other families, though too often unnoticed by botanists. 10. In the *Hippocrateaceæ*, the leaves, but more particularly the branches of the inflorescence, the pedicels, sepals, and petals, contain numerous white elastic threads, which hold the parts together when broken, and these spiral threads often extend to the pericarps, to the integuments of the seeds, and even occasionally to the fleshy cotyledons. Nothing of this kind has yet been observed in *Celastraceæ*. Any one of these peculiarities, by itself, would tend little to support any separation of these two families, but the sum of the whole tells powerfully to mark a great distinction in their organisation. The only arguments that have yet been urged for their near affinity are that both generally consist of arborescent plants with evergreen leaves, an axillary inflorescence, petals and sepals with imbricated æstivation, a three-celled ovary, a simple style and stigma; but these are all characters common to many other families distantly related, and wholly insufficient by themselves to establish any near affinity. The more probable inference is that these two families should be separated by a long interval.

### DUBLIN

Natural History Society.—Prof. E. Perceval Wright, M.D., in the chair. Dr. A. W. Foot read a paper on a small collection of Hymenoptera, named for him by Mr. F. Smith. None of the species referred to were rare, and they had, for the most part, been collected in the counties of Wicklow and Kildare.—Mr. W. Andrews read "Notes on some Irish Saxifrages." Fine living specimens were exhibited of *Saxifraga geum*, and of its varieties *umbrosa*, *hirsuta*, and *elegans*. A coloured drawing by the late Mr. Du Noyer was also shown of a remarkable variety found at the Great Blasquet, in which the flowers presented a glandular disc surrounding the base of the pistil. Specimens of *S. Andrewsii* were also laid on the table. Mr. Andrews stated that he had lately given Mr. A. G. More the exact locality of this rare form, supposed by some to be a hybrid, and he fully expected that in the course of this summer Mr. A. G. More would be able to verify this as well as he had done other of his discoveries. He believed, judging from the structure of its ovaries, that this species had strong affinities with *S. nivalis*. Lastly Mr. Andrews exhibited some very remarkable specimens of *S. stellaris*, which very much resembled in shape *S. leucanthemifolia*, and indeed Mr. John Ball appears to regard this latter form as but a variety of the former.—A resolution was passed that Mr. R. J. Montgomery, Mr. R. P. Williams, Mr. A. Andrews, and Dr. A. Wynne Foot be a committee to have the museum of the society catalogued and arranged for sale, and that the committee be requested to report to the society in November as to any offers they may receive for it. The museum is very rich in Irish birds, containing some unique specimens; but the society not having a house of its own, and holding its meetings in the Royal Irish Academy House, has considered it advisable to dispose of its collections.

Royal Geological Society, May 12.—The Rev. Maxwell Close in the chair. Prof. Traquair exhibited a collection of Carboniferous Ganoid fishes, found in nodules of clay ironstone from Wardie near Edinburgh.—Mr. G. H. Kinahan read a paper on the Geological Drift of Ireland.—Rev. Prof. Haughton read some analyses made by the late M. H. Ormsby of the Geological Survey of India of Granitic Rocks and their Constituent Minerals, found in Lower Bengal and Ceylon. These analyses were made by Mr. Ormsby in 1868, and in expressing his sense of their importance Prof. Haughton also expressed his deep regret, shared in by the Society, at the loss geological science had sustained by the untimely death of so promising a geologist and mineralogist as Mr. Ormsby.—Mr. Edward T. Hardman read a paper on an Analysis of a Trachyte porphyry from Tardree Quarry near Antrim. The paper gave tha result of a careful analysis of one of the two specimens of trachyte known to exist in the British Islands, and from it Mr. Hardman was able to come to such conclusions with regard to the age and altered state of the rocks as led him to controvert the theories of Cotta and Richthofen on the relative ages of basalts and trachytes. Prof. Haughton, who had seen the rock *in situ*, was able to endorse the view taken by Mr. Hardman as to the altered condition of it.

Royal Irish Academy, May 8.—Rev. President Jellett in the chair. Prof. J. M. Purser read a second report on the researches of Prof. Cohnheim on inflammation and suppuration, which was referred to the Council for publication. The secretary read a paper by Mr. Hyde Clarke, on the ancient name Hibernia. This paper was very severely criticised by several members of the Academy, the impression apparently being that the author had no true scientific basis for the conclusion at which he had arrived, and further that the method adopted by him was helping—if it had not already done so—to bring discredit upon this branch of Ethnology.

May 22.—Rev. President Jellett in the chair. The president read a paper on Saccharometing, with special reference to an examination of specimens of sugar beet grown in Ireland.—Prof. Sullivan read a paper on the comparative composition of ancient Bronzes in connection with the ethnology of the ancient people of Europe; also, one on the Great Dolomite Bed of the North of Spain in connection with the Lithonic stage of opal.

### Paris

Academy of Sciences, May 5.—M. Delaunay in the chair. M. Roulin, a member of the Institute, delivered an address, discussing the last communication from M. Ledillot on Arabic Etymology. The learned member contends that M. Ledillot is deceived by superficial and casual analogies, and gives too large a credit to the Arabic language in the formation of French. He frequently quoted the great Etymological Dictionary written by M. Littré, who is now a representative of Paris in the Versailles Assembly, and attempted to vindicate M. Littré's various etymologies.—M. Elie de Beaumont read a letter from M. Bertrand, now at Tours, where he is a delegate for teaching the pupils of the National Polytechnic School. M. Bertrand has worked out theoretically the assertions of M. Navier on the flight of birds. He asserts that the clever mathematician was deceived in supposing the birds exerted an immense force in flight. M. Navier's assertions, which were supposed correct for upwards of thirty years, were very often assailed on practical grounds, and almost generally supposed worthless. But it was necessary to revise his mathematical analyses. M. Bertrand's communication will be welcomed by people engaged in the construction either of flying machines or of apparatus for guiding aërostats.—M. Martins, director of the Montpellier Botanic Gardens, sent a communication on the extraordinary frost of last December. He showed by reliable observations that the temperature at Montpellier was lower by 4° C., than the temperature at Paris. If the Paris minimum is supposed to have been −12°, the Montpellier minimum must have been −16°. M. Martins explains the circumstance by the influence of the Gulf Stream, which diminishes the coldness of the air at Paris more than at Montpellier, owing to the greater distance of that southern station from the ocean.—M. Charles Emmanuel read a paper on certain movements of floating bodies, which he attributes to some electrical influences unnoticed and consequently unexplained hitherto.

May 29.—M. Marié Davy, director of the Meteorological service at the Observatory, read a paper on the effects of the two great atmospheric currents of the atmosphere; one of them north-east, and the second, opposite to the first, south-west. To recite the history of the struggle between these two primary currents would be to recite the eventful history of temperature. Judicious balloon ascents would greatly help meteorologists in executing useful work.—M. Yvon Villarceau gave some most interesting details on the state of things at the Observatory during the night of May 22. The Communists tried to set fire to the establishment, but succeeded only in burning down the wood casements, used to protect the instruments from shelling during the Prussian investment. One circle constructed by Rigault was destroyed. This circle was intended to be used as a mural circle for observations connected with the next international geodesic congress to be held at Vienna, in order to revise the determination of the earth's radius. M. Yvon Villarceau declares that in spite of this misfortune, the French Republic will be able to hold its ground on that pacific battle-field.—M. Chevreul read the speech delivered on his behalf at the funeral of the lamented M. Payen. The learned orator reviewed at full length the different processes resorted to in order to render edible different substances during the first investment of Paris. M. Payen was the originator of these ingenious processes. One of them will be largely used in naval expeditions for procuring fresh albumine for crews and passengers. Ordinary albumine, as it is used by dyers and photographers, is melted at a temperature of 100° C., and can be used for all the cooking purposes. Distant marine expeditions will always remember with gratitude the exertions of M. Payen and his associates for feeding 2,500,000 people surrounded during months by an hostile overpowering force.—M. Chevreul gave some interesting details on the protection of the Museum, and the losses experienced by the great Gobelins' conflagration.

## BOOKS RECEIVED

English.—Hours of Exercise in the Alps: Prof. Tyndall (Longmans)—Astronomy Simplified for General Reading: J. A. S Rollwyn (Tegg and Co.)

Foreign.—Verhandlungen der k.k. zoologisch-botanischen Gesellschaft in Wien: Trübner.

## DIARY

*THURSDAY*, June 15.

Royal Society, at 8.30.—On the Fossil Mammals of Australia. Part V. Genus Nototherium.—Contribution to the Fossil Botany of the Coal Measures. II.: Prof. W. C. Williamson, F.R.S.—On Cyclides and Sphero Quartics: Dr. Casey.—On a Law in Chemical Dynamics, and other Papers: Dr. Gladstone, F.R.S., and A Tribe.

Society of Antiquaries, at 8.30.—On a Reliquary of Sculptured Ivory of the Sixth Century: A. Nesbitt, F.S.A.

Linnean Society, at 8—On British Spiders: Rev. O P. Cambridge.—On a Luminous Coleopterous Larva: Dr. Burmeister.

Chemical Society, at 8.—An Experimental Inquiry as to the Action of Electricity upon Oxygen: Sir B. C. Brodie, Bart.

*FRIDAY*, June 16.

Royal Institution, at 9—On the Esquimaux and Ice of Greenland, illustrated by Drawings and Photographs: Mr. William Bradford, Artist, of New York. (Extra meeting.)

*MONDAY*, June 19

Anthropological Institute, at 8.—Mode of Preserving the Dead among the Natives of Queensland: Albert M'Donald.—Forms of Ancient Interments in Antrim: Dr. Sinclair Holden.—Analogies and Coincidences among Unconnected Nations: Hodder M. Westropp.—Peruvian Antiquities: Josiah Harris.

*TUESDAY*, June 20.

Zoological Society, at 9.—Report on Additions to the Society's Menagerie in May: The Secretary.—On some Arachnida, collected by Cuthbert Collingwood, M.D., during rambles in the China Sea: Rev. O. P. Cambridge.—Notes on some Rodents from Yarkand: Dr. J. Anderson.

*WEDNESDAY*, June 21.

Meteorological Society, at 7.—Anniversary Meeting

Royal Society of Literature, at 8.30.—On the Life and Writings of William of Malmesbury: Mr. W. Birch.

Geological Society, at 8.—Notes on the Geology of Part of the County of Donegal: A H. Green, F.G.S.—On some Supposed Vegetable Fossils: W. Carruthers, F.R S., F.G.S—Memoranda on the Most Recent Geological Changes of the Rivers and Plains of Northern India, to show the Practical Application of Mr. Login's Theory of the Abrading and Transporting Power of Water to effect such Changes. T. Login, C.E.

## STATE MEDICINE

AMONG the duties which the State owes to Science, none are of more practical and vital importance, and none are more urgent, than those which concern the care exercised, or that should be exercised, over the public health by properly appointed State Medical Officers. The essays of Dr. H. W. Ramsay have so fully explained the term "State Medicine" that we do not feel it necessary here to do more than allude to the subject in very general terms. It will readily be acknowledged that some sort of a medical polity is a necessity for a State; but while in this country certain laws and regulations exist for the improvement of the public health, still there has been but little or no effort made to establish these laws on a scientific basis.

In the recently issued Second Report of the Royal Sanitary Commission, the true relations of the State towards the public in these matters are thus admirably enforced:—"Every person should be entitled to such reasonable public protection in respect of his health as he is in respect of his liberty and his property. For instance, he should no more be liable to have the water of his well poisoned by the neglect of his neighbour, than to be robbed with impunity. And he should be under this protection, as far as it is reasonably attainable, everywhere and at all times. The first principle, therefore, of sanitary administration is, that no member of the community shall wilfully or for profit damage another man's supply of the three absolute essentials of life, food, water, and air; and therefore that it is the duty of the State to secure, as far as possible, that these essentials shall be supplied in sufficient quantity and the greatest attainable purity in all circumstances in which these objects cannot be attained by individual care and resources. In this point of view it may appear a question whether the State should allow that any man, even by prescription, shall be held to have acquired the right to pollute, for his own advantage, another man's food, water, or air, or in any manner poison him. At any rate care should be taken that no one shall acquire such right in future."

The second requirement is laid down with equal clearness, viz.:—"Universality, through constant supervision by public health officers in every part of the country. The efficiency of the agents in sanitary administration is as important as their ubiquity. They must be well instructed and capable, without the pedantry or officiousness of sciolists. Ignorance, pretentiousness, or overmeddling on the part of the agents, would bring into disrepute any sanitary system. In a free country disrepute would bring about failure. Fitness in the agents is the third requisite in sanitary legislation."

When, however, the Commission comes to apply these principles to the existing state of things, the only practical suggestion offered is that the supervision of the public health be entrusted to the Poor Law Medical Officers, of whom there are in England alone about 4,000. The Commissioners have evidently a suspicion that this suggestion will not be favourably received by the country. And we have no hesitation in saying that it is miserably inadequate. When we look at the value of the examinations to which alone medical students are compelled to submit themselves before they obtain a license to practise, or when we look (must we say it?) at the life of the average medical student attached to any of our great hospitals, no two conclusions are possible on this subject. It is notorious that, as a rule, it is not the most competent of the London students who ultimately arrive at the position of general practitioner in a country village; and the Poor Law authorities, however discriminative their choice, can only select from the material to their hand. To effect the objects arrived at by the Sanitary Commission, a far more highly educated class of men is required.

That medical men should be educated in a knowledge of State medicine will probably not be denied, and that the State for its own good should encourage such knowledge will probably also be granted; but it is not easy to persuade a State to adopt even approved of principles, if these principles require a wholly new machinery for the effectual carrying of them into practice. The Universities are, however, engaged in the work of education, and upon them, we think, devolves the duty not only of keeping up the standard of education, but of endeavouring to push this standard ever a little advance of the day.

The training necessary for the medical profession is very different from that required to qualify one to be an authority on State medicine; it most certainly assists in this qualification, but a man might be a most excellent surgeon or a most skilled physician, and yet not be able to pronounce an opinion on many of those subjects on which his advice would be required by the State.

In a medical school belonging to a college which holds out considerable rewards to those students who distinguish themselves as classical or science scholars, there is always a probability that some of the students in medicine will have also been distinguished students in arts. Experience has proved that this is the case in Trinity College, Dublin; and experience has proved the incalculable advantage of a high training in art-subjects to the future medical man. What better combination of knowledge, indeed, could there be to form a model officer of State medicine than that of a thorough knowledge of science (using the term as it is generally understood at the Universities) and of an equally thorough knowledge of medicine? We are glad, therefore, to find that, acting on the suggestion of Dr. Stokes, their Regius professor of physics, the University of Dublin has determined to hold a yearly examination for a diploma on State medicine, the first of which was held on the 12th inst. This examination was open to all doctors of medicine of the Universities of Oxford, Cambridge, and Dublin.

The course is a long but a highly interesting one. It resolves itself into the following among other subjects:—1. Law: The legislation relative to sanitary measures, to the conduct and duties of medical men, to vaccination, inoculation, lunatic asylums, &c. 2. Engineering: This chiefly in connection with the construction of hospitals, barracks, troop ships, prisons, and the sewerage and waterworks of cities. 3. Vital and Sanitary Statistics, including the science of statistics as applied to man, and the practical application of statistics to medicine. 4. Meteorology, including a knowledge of climates, &c. In addition the candidates will be examined in Pathology, *i.e.*, the laws of epidemics, of contagion and infection, influence of hereditary disposition, &c.; in Chemistry, under the heads of—1, air; 2, water; 3, gaseous poisons; 4, principal deodorising and disinfecting agents; and in Medical Jurisprudence under the divisions of Hygiene and Forensic Medicine. This course has been evidently selected with great care, and appears well calculated to test the qualifications of the candidates. The medical men who successfully pass it and obtain the diploma, ought certainly to be able to assist in establishing on a scientific basis the laws relating to the public health.

One very serious omission we observe in the list of subjects to be examined in, and it is one we would have least expected, viz., the Microscope and Spectroscope. It is perfectly astonishing to find the number of well-educated men in the medical profession who are unable to understand the ordinary manipulation of an ordinary microscope, or of a spectroscope in connection with the microscope. The medical men who pass this examination will, we believe, take rank at once as medical experts—but fancy one qualified to act as a medical expert and yet not knowing how to manage an achromatic condenser!

At present this movement of the Dublin University can but be regarded as an experiment, but it is an experiment in the right direction, and one that has been, and we hope for years will be, conducted under the watchful eye of a most able physician, who thoroughly understands the subject of medical education, and who, throughout his whole life, has laboured to elevate the profession that he adorns.

---

## *PRIMITIVE CULTURE**

### II.

THE chapters on mythology, which naturally follow those on language, form an admirable summary of the history of myth from its vigorous infancy in the earlier ages of human thought through the various stages of growth and maturity onwards to second childhood, death by ossification of the heart, and final post-mortem existence through millenniums of disembowelled mummydom. Myth, in fact, is as ubiquitous, as multiform, as language. Nay, it is perhaps more ubiquitous, more multiform. The spaniel, who fawns on his master or flies at a beggar, who bays at the moon or cowers from the thunder, has evidently framed to himself some simple dog-theory in connection with certain phenomena, which is closely analogous to, if it be not absolutely identical with, a rudimentary myth. It is, indeed, probably not too much to say that wherever a phenomenon is stated or explained, whether with or without the intervention of language, there exists a myth, though a higher knowledge than that which creates the myth is always requisite in order to recognise its mythic character. The Ptolemaic system of astronomy, for instance, has been long ago conclusively demonstrated to be a myth, although a myth belonging to an advanced stage of culture, and a thousand and a thousand others are everywhere around us only waiting for the extension of knowledge to effect the metamorphosis requisite for their recognition. It is evident that if this theory of myth be even approximately correct, the statement or explanation of any phenomenon in language is in effect merely the creation of another phenomenon out of which myth may be evolved *ad infinitum*; in short, that myth is essentially the outcome of the complex action, reaction, interaction, and counteraction of human thought on the one hand, and the sensible phenomena of the universe, including those of language, on the other. The sensible phenomena of the universe may thus not inaptly be regarded from the standpoint of Democritus or Lucretius as continually throwing off films or likenesses of themselves, which films or likenesses, once seized and appropriated by language, become additional phenomena, with a vitality, so to speak, and reproductive power of their own. On the other hand, if, in accordance with the spirit of Scandinavian philosophy, we regard philosophy itself, art, poetry, science, morality, and religion—all the products of human thought—as a single living organism, we may then consider myth as the former substance of the organism, the physical atoms which have been gradually eliminated and replaced in the process of growth and development. Or, not to complicate matters by the introduction of evolution,—civilised knowledge, as a whole, may be likened to an old canoe, of which no plank nor nail is the same as when she started on her first voyage, and myth to the old timbers and metal which once formed a part of her, but have now been some lost, some metamorphosed into wholly different shapes, some utilised again in the construction of other vessels. We can thus understand how every department of thought has absorbed and assimilated more or less of myth,—how myth has absorbed and assimilated more or less of every product of the human intellect. It is, in fact, the non-appreciation of the true place of myth in human knowledge, which has led so many earlier students of mythology astray. One school looked on all mythology as crystallised poetry; another as indurated chronicle; a third as frozen philosophy; a fourth as petrified religion, and so forth;—each school doing something towards really making mythology what it believed mythology to be, and all, as a net result, extracting from one of the most vitally-interesting investigations a mere *caput mortuum* of doubly-distilled platitude, and quintessential commonplace. So long as "mythology" meant simply an acquaintance from without with the Greek and Roman Pantheon, such a result was, perhaps, inevitable. Unfortunately the doctrines of these schools are not even yet by any means universally recognised as being themselves mythic; and many of them are still to be found reproduced in contemporary works of no inconsiderable learning, to supply future students with illustrations of Mr. Tylor's theory of survival. It must be admitted, too, that even the late brilliant achievements of more scientific inquirers still leave a vast field untouched for classification and comparison. Nor is this task an easy one. A myth is always the statement or explanation of a phenomenon, and myths may thus be classified according to the phenomena to which they refer; but first of all "to catch your myth," and then to determine the phenomenon to which it refers, are feats, for the most part, beyond the skill of ordinary students. An amusing instance of these difficulties is afforded by Mr. Tylor himself. "No legend," he observes, "no allegory, no nursery rhyme, is safe from the her-

* "Primitive Culture: Researches into the Development of Mythology, Philosophy, Religion, Art, and Custom." By Edward B. Tylor, author of "Researches into Early History of Mankind," &c. Two vols. 8vo. (London: Murray, 1871.)

meneutics of a thorough-going mythologic theorist. Should he, for instance, demand as his property the nursery 'Song of Sixpence,' his claim would be easily established: obviously the four-and-twenty blackbirds are the four-and-twenty hours, and the pie that holds them is the underlying earth, covered with the over-arching sky; how true a touch of nature it is that when the pie is opened—that is, when day breaks, the birds begin to sing; the King is the Sun, and his counting out his money is pouring out the sunshine, the golden shower of Danae; the Queen is the Moon, and her transparent honey the moonlight; the Maid is the 'rosy-fingered' Dawn, who rises before the Sun, her master, and hangs out the clouds, his clothes, across the sky; the particular blackbird, who so tragically ends the tale by snipping off her nose, is the hour of sunrise. The time-honoured rhyme really wants but one thing to prove it a Sun-myth, that one thing being a proof by some argument more valid than analogy." This is exquisitely ingenious; but what if the rhyme should turn out to be, after all, only a quite genuine nursery riddle, of the type which Mr. Tylor has so admirably illustrated elsewhere? An archetypal clock, presented as a *haute nouveauté* to some Edward III. or Richard II. would satisfy all the conditions of the enigma. The large circular face would represent the pie;—the four-and-twenty hours duly figured thereon, in accordance with the liberal notions of archaic horology, would correspond to the four-and-twenty blackbirds; the striking, possibly with chimes, to the song of the birds; the king in his counting-house, counting out his money, would felicitously symbolise the hour-hand counting out the time, which is money, in majestic solitude, unaccompanied as yet by any fussy revolutionary minute-hand; the queen in the pantry, eating bread and honey, would typify the stealthy activity of the fine wheel-teeth of steel and brass; the maid in the garden, hanging out the clothes, would appropriately allegorise the wooden drum on which the weights were suspended by lines, at a distance from the works; while the magpie, which seems a preferable heading to "black-bird" who snaps off the maid's nose, would probably be none other than the ingenious mechanist who wound up the instrument, and, having done so, removed the key from the nozzle of the drum. Whatever may be thought of this interpretation, it seems exceedingly probable that the rhyme is really a riddle, and, indeed, many other unintelligible jingles are most likely referable to the same category. One of them, if a riddle, does also unquestionably enunciate a sun-myth. In the immortal Jack and Jill who went up a hill to fetch a pail of water, we may clearly recognise the sun and moon under an enigmatic, not to say riddle-iculous exterior, and after satisfying ourselves as to their identity, we may further admire the curious felicity with which the difference of sex between Hêlios and Selênê—etymologically identical with the difference between *leôs*, a lion, and *leaina*, a lioness—is indicated in the English ditty. To return, however, from the precincts of the nursery, Prof. Max Müller, with a natural bias in the direction of his own brilliant researches, seems to ascribe the origin of myth somewhat too exclusively to the influence of language, just as in his interpretation of myth he appears to pay a rather too marked attention to the Dawn-Goddess to do full justice to the claims of other less seductive divinities. The Professor himself, however, will probably be among the first to recognise the value of Mr. Tylor's distinction between material and verbal myth, and to acquiesce in the classification which considers the former as primary, the latter as secondary in the order of evolution.

In his account of eclipse-myths, Mr. Tylor quotes sundry remarks of Mr. Samuel Davies eighty years ago with regard to the struggle between ecclesiastical authority and science in India. "The learned Pundits," says Mr. Davies, "reject the ridiculous belief of the common Brahmuns, that eclipses are occasioned by the intervention of the monster Rahoo, with many other particulars equally unscientific and absurd. But as this belief is founded on explicit and positive declarations contained in the 'Vedus' and 'Pooranus,' the divine authority of whose writings no devout Hindoo can dispute, the astronomers have some of them cautiously explained such passages in those writings as disagree with the principles of their own science; and where reconciliation was impossible, have apologised as well as they could for propositions necessarily established in the practice of it by observing that certain things, as stated in other Shastrus, might have been so formerly and may be so still, but for astronomical purposes astronomical rules must be followed." It is, perhaps, not a mere accidental coincidence that in 1760, a few years before this was written, the following "Declaratio" appeared at the end of the third volume of the Jesuit edition of Newton's works, published at Geneva:—"Newtonus in hoc tertio libro telluris motæ hypothesem assumit. Autoris propositiones aliter explicari non poterant, nisi eâdem quoque factâ hypothesi. Hinc alienam coacti sumus gerere personam. Cœterum latis a summis pontificibus contra telluris motum decretis, nos obsequi profitemur." Fortunately for Mr. Tylor and his fellow-workers, the difficulties which beset the scientific inquirer from this source have probably almost reached their minimum in England. Ecclesiastic thunder itself has lapsed into mere survival, and roars, if it roars at all, only after the fashion of Snug the Joiner's lion.

The remainder of the work, occupying part of the first and the whole of the second volume, is devoted to a discussion of "Animism," in other words, of the philosophy of religion in relation to early and barbaric civilisation. The subject is one of almost equal interest, importance, and difficulty, and Mr. Tylor's treatment of it is eminently original and masterly. Tracing the origin of a belief in spiritual beings to the result of primæval thought on the problems presented by the difference between the dead and the living body, by sleep and waking, trance, disease, and death, he follows the course of its development upwards into the existing religions of the most civilised races. Showing how the doctrine which teaches a possible continued existence after death of the souls of individual creatures really supplied a theory adequate to explain the phenomena to the barbaric intellect, he calls attention to the process by which this belief in a ghost-soul became expanded into a belief in other spirits, who were held to control the events of the material world, and hence became the objects of worship and propitiation, until Animism reached its full development in a system inculcating a belief in controlling deities and subordinate spirits, in souls separable from bodies and a future state of existence, morality being incorporated into religion only in the later stages of culture. One of the most striking points in the whole work is Mr. Tylor's identification of the theory of "images" generally ascribed to Democritus with the savage theory of object-souls. Democritus explained the fact of perception by declaring that things are always throwing off images of themselves, which images, assimilating to themselves the surrounding air, enter a recipient soul and are thus perceived. This theory, Mr. Tylor adduces evidence to prove, is merely an application to the phenomena of thought of one of the most characteristic doctrines of savagery, the doctrine that every object, inanimate as well as animate, possesses a soul of its own. "Nor is the correspondence," says Mr. Tylor, "a mere coincidence, for at this point of junction between classic religion and classic philosophy the traces of historic continuity may be still discerned. To say that Democritus was an ancient Greek is to say that from his childhood he had looked on at the funeral ceremonies of his country, beholding the funeral sacrifices of garments and jewels and money and food and drink, rites which his mother and his nurse could tell him were performed in order that the phantasmal images of these objects might pass into the possession of forms shadowy like themselves, the souls of dead men. Thus Democritus, seeking a solution of his great problem of the nature of thought, found it by simply decanting into his metaphysics a surviving doctrine of primitive savage animism." No more pregnant identification of philosophic tenets with those of earlier religion has been achieved since Comte traced back to fetishism the conception of a soul of the universe as held by certain pantheistic schools.

In describing the nature of the soul as understood by the lower races—well indicated by the way in J. Amos Comenius's "Orbis Sensualium Pictus," where he figures *anima hominis* as a dotted outline of a man—Mr. Tylor calls special attention to the spirit-voice, which is conceived as a murmur, chirp, or whistle—as it were the ghost of a voice. Among the Algonquins souls chirp like crickets; among the New Zealanders, Polynesians, and Zulus, they squeak or whistle. Nicolaus Remigius, whose "Dæmonolatreia" is one of the ghastliest volumes in the ghastly literature of witchcraft, cites Hermolaus Barbarus as having heard the voice *sub-sibilantis dæmonis*, and, after giving other instances, adduces the authority of Psellus to prove that the devils generally speak very low and confusedly in order not to be caught fibbing. The idea of ghosts whistling is still far from extinct in England. In Leicestershire and elsewhere it is reckoned "very bad" to hear "the Seven Whistlers," though strict inquiry about them only elicits the suggestive fact that "the develin"—or common martin—"is one on 'em."

In his account of the doctrine of transmigration of souls, Mr. Tylor forbears to touch on one circumstance, which probably exercised some considerable influence on its development. When two systems of mythology, both originally derived from the same source, came into close contact after long separation, both the difference and the similarity between them could hardly escape attention. If the names of certain deities common to the two systems had been changed while their history and attributes had remained substantially unaltered, the theory of transmigration would, in some cases, satisfactorily account for the phenomenon. In fact, mythologically, the doctrine of transmigration is simply true. Mythology is just now demanding of history the extradition of William Tell, on the plea that his ghost is one which has transmigrated from her domain; and the scientific detective who falls in with Robin Hood or King Arthur will hardly fail to recognise in the one the transmigrated soul of Phœbus Apollo, in the other, the wandering spirit of the Bear-ward in Böotes, returned from his long sojourn in the northern sky.

Tempting, however, as are the inquiries suggested in this profusely suggestive work, the reviewer's limit has already been transgressed. We have not yet, we cannot have for years, or for ages, anything approaching to a complete science of history or exhaustive philosophy of religion, but the scientific student of Primitive Culture will at least admit that in these volumes the foundation of both has been "well and truly laid."

## BOOK SHELF

*Dr. Dobell's Reports on the Progress of Practical Medicine in different Parts of the World.* Vol. ii. (1871, Longmans.)

In these reports Dr. Dobell aims at obtaining from the natives of different countries concise statements of the advances made in medicine and the allied branches of knowledge, which have appeared in foreign journals, or in a more permanent form. He has obtained more or less full and detailed reports from America, Australia, California, China, France, Germany, Iceland, India, Italy, Java, Newfoundland, New Zealand, Portugal, Prince Edward's Island, Shetland Isles, Turkey, and the United Kingdom. The idea is a good one. The flood of periodical literature is so great that it is most difficult to keep up with the weekly journals of this country alone, and it becomes almost hopeless to do so with those of France and Germany. Such reports as those before us materially lighten labour, and the only objection to them is that a man who is working at any given subject cannot rely upon their being complete. The report on French progress by Prof. Villemin is a good one. That on German advances, by Dr. Alhaus is much too short. It might, with great advantage, have been extended at the expense of the excerpts from English writers. Everyone has access to the leading English journals, and, moreover, this part of the work is already well done by Braithwaite and Ranking, but comparatively few have access to Virchow's Archiv, the Deutsch Klinik, and the Wiener Medizinische Zeitung. Many of the English abstracts might have been condensed. We miss a Russian report. Yet both Russian naturalists and Russian physicians have journals of their own. On the whole the book is a useful one, and we can recommend it to our readers as containing a considerable mass of information which they will not elsewhere easily find.

*Geometrische Seh-Proben zur Bestimmung der Sehschärfe bei Functions-prüfungen des Auges.* Von Dr. Boettcher. (Berlin, 1870. London: Williams and Norgate).

This little book, with its test objects, is intended as a substitute for Snellen's test types to be used by those who are unable to read, and has been drawn up by Dr. Boettcher, with especial reference to the testing of the vision of recruits. Besides the ordinary types, it contains a number of figures of squares and rectangles, variously disposed in regard to one another at different distances, and it need scarcely be added of various sizes. The very smallest require good vision to enumerate their number and disposition at the ordinary distance of eight inches, whilst the largest should be seen at two hundred feet. They afford a good means of determining the existence of Hypermetropia, Myopia, Astigmatism, and other affections of the retina of the eye, and seem to us to be well adapted for the purpose for which they are intended. H. P.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Thickness of the Earth's Crust—Mr. Hopkins and M. Delaunay

In your numbers for March 16 and 23, 1871 (pp. 400, 420) you give brief notices of the proceedings of the Academy of Sciences in Paris on the 6th and 13th of that month, from which it appears that Mr. Hopkins's method of determining whether the crust of the earth is thick or thin has been again under discussion there. In the latter of these notices M. Delaunay observes that he had been anticipated in his objections by Mr. Hennessy.

It so happens that Mr. Hopkins sent to me in Calcutta in 1858 a copy of Mr. Hennessy's paper (which was published in the *Philosophical Transactions* of 1851) with his remarks in writing in the margin; and I think it will be interesting to your readers if I give Mr. Hopkins's opinion of the paper.

Mr. Hennessy remarks (p. 546) that Mr. Hopkins's "result was founded on the hypothesis of the non-existence of friction and pressure from molecular causes at the surface of contact of the shell and nucleus." On which Mr. Hopkins writes:—"This is not correct. My hypothesis is the absence of friction between the fluid particles themselves."

Again, Mr. Hennessy considers, as a result of his calculation, "that we are entitled to assume that the motion of rotation of both shell and nucleus takes place nearly as if the mass were entirely solid." On which Mr. Hopkins observes: "Nothing could justify the assumption of a mechanical impossibility." And he traces this erroneous conclusion to the fact that Mr. Hennessy has made two assumptions in the course of his calculations which vitiate it throughout, viz., (1) that the axes of instantaneous rotation of the shell and nucleus would coincide (which is implied in the last formula in par. 2. p. 514), "which," wrote Mr. Hopkins, "they certainly would not," and (2) that "the shell (or crust) is rigid" (p. 519, 525) so as to resist, without change of form, the internal pressure which arises from the inner surface, that is, the surface of the nucleus, ceasing to be a surface of equilibrium, which Mr. Hopkins very reasonably considers to be quite inadmissible, and that accordingly the results deduced from these assumptions are "valueless."

2. I will take this opportunity of reverting to my letter to you of April 10, 1871. I there point out that what Mr. Hopkins did consists of two parts—(1) his conception of the idea that as the crust is not solidly connected with the fluid nucleus the amount of precession must depend in some measure upon the thickness of the crust; and (2) his *calculation* of the amount of precession this idea would lead to, so that by comparison with observation the thickness might be approximately found. In this way he discovered that if the crust and nucleus were homogeneous, and of the same density (which they are far from being), the inner and outer surfaces of the crust being similar and similarly situated spheroids, the internal pressure of the fluid would act so as to leave terms in the precession depending on the thickness of the crust, only of the second order of small quantities; whereas, in the case of the earth where the mass is heterogeneous, the mean density being double of the superficial density, the thickness is involved in terms of the first order in the expression for the precession, and by a comparison with observation leads to Mr. Hopkins's result, viz., that the thickness is very great, something like 800 or 1,000 miles at least.

Calcutta, May 24 John H. Pratt

### The Duties of Local Societies

It is undoubtedly the work proper to local natural history societies to study well the productions of their own immediate neighbourhood, to catalogue all the fossils, plants, and animals, and to note any peculiarities regarding them. In the settlement of the great questions still under discussion, much will depend upon their faithfully performing this duty. All naturalists will cordially endorse whatever has been said in regarding such societies from this point of view, and will agree in declaring that it is far better they should be occupied in such labour than in the discussion of theories and abstruse general questions, which are better left to larger and more influential bodies. It is their office to collect facts upon which individual minds may generalise. This of course applies to such bodies in their collective capacity, and not to the members as individuals; it is very probable that such individuals may make use of the facts collected by the society.

But it should also be remembered that local societies have another duty to perform, and one, too, of hardly secondary importance, and that is the inculcation of the love of natural history in other minds. Indeed, it will often be found that for a time at least this must take precedence of the work already mentioned. It is well known to all who have taken any active part in field clubs and the like, that the real work devolves upon two or three members, sometimes fewer still, and it is totally beyond the power of these two or three to work up the whole natural history of the district by themselves; they may have the will and the ability, but neither the time nor the means. We have known societies numbering above a hundred members where this was the case; the great majority could not be called working members at all; they joined for various reasons, some merely because it was rather "the thing" to do in the town or village; the greater number probably because they were interested in seeing specimens, hearing pleasantly-written papers at meetings, highly delighted at microscopical conversations, &c., &c., but did not care about working in the subjects for themselves. It is very evident that in such cases the first and foremost aim should be to induce as many as possible to become students of nature, at least to enable them to make intelligent notes of what they observe. Hence we find that the reports of provincial societies occasionally appear with little addition to what is already known, very little local information in them, and though this is to be greatly regretted (and in reality is so by the editors), it should not be regarded, as it often is, merely as matter of reproach by others more advanced. Local magazines and reports are issued mainly for the perusal of the members and others living in the locality, and such persons naturally wish to see the best of the papers that have been read; and the matters that interest them most are not always new discoveries, wherever they may be made.

But besides the ordinary method of reading papers at meetings principally, if not solely, attended by members, there are others to be followed by way of inducing outsiders to join the society. One is that of "Penny Rambles," which has been very successful in some localities. These should be conducted by some one not only well versed in natural history, but gifted with the not common ability to impart his knowledge in an attractive and popular way. There should be a change of conductors as often as possible, but care ought to be taken always to secure good ones, as one disappointment lasts a long time; this implies that some competent person or committee should have the control over the arrangements. Sometimes it will be found that one man makes himself so well understood, and consequently so attractive, that he is preferred to others, and here the *vox populi*, within due limits, should have weight. As for subjects, no naturalist will ever be at a loss: the geology of the neighbourhood, some quarry, sand pit, or sea beach; the botany, some of the rarities and their peculiarities; entomology also, and an occasional chat about some interesting antiquity in the vicinity. No abstruse theories should be taken up, they may be intensely interesting to the real naturalist, but are in a general way unknown, and if known, unappreciated by the multitude.

The science lectures, lately so admirably carried out at Manchester, and already referred to in these pages, will occur at once to every one; they might well be taken up in all large towns. But could not Museum Lectures also be started? The duty of every local society to establish a museum has been ably argued by another pen—a museum not for its own sake merely, but with this secondary idea before them, the good of the town or village in which they may be located; one in which the labouring man shall find displayed specimens of the wealth of his own neighbourhood, as well as typical forms from far off lands. Prof. Huxley has well said in one of his "Lay Sermons" that there is a general impression among people that every event of importance happened a long time ago; it is equally true that they fancy any natural object worth looking at must be sought for a long way off; it is our duty to eradicate both impressions. If some plan could be adopted of giving penny lectures in the Museum, it would greatly add to the interest excited; it would assist people to understand what they see, and tend to the destruction of that languid curiosity so painfully evident in the faces of sightseers. The contents of one case would serve for one or two lectures, and those who listened would necessarily carry away a few new ideas.

We have been viewing the question solely from its popular side, being convinced that it is of great importance; other plans may occur to the reader, and may be well worthy of ventilation.

HENRY ULLYETT

### Colour

SINCE the publication in NATURE of my paper on "Colour," I have received several inquiries for references on the subject. These I should have given at the time, only that I wrote away from books; perhaps on the principle of "better late than never," the publication in NATURE of the following selection may save trouble to some interested in the matter.

Helmholtz: "Ueber die Theorie der zusammengesetzten Farben;" "Poggendorff's Annalen," lxxxvii. p. 45; "Philos. Magazine," (4) iv. p. 519.

Maxwell: "Experiments on Colour perceived by the Eye, with Remarks on Colour Blindness;" "Edinburgh Transactions," xxi. p. 275.

Maxwell: "On the Theory of Compound Colours, and the Relations of the Colours of the Spectrum;" "Phil. Trans.," 1860.

Maxwell: "Account of Experiments on the Perception of Colour;" "Phil. Mag." (4), xiv. p. 40.

Müller: "Zur Theorie der Farben;" "Pogg. Ann" vol. 139, p. 411.

These are the principal original memoirs. Of books on colour there are very few that can be trusted. Benson's "Principles of the Science of Colour" is recommended by Prof. Maxwell. There is also a tolerably complete exposition of the subject in Helmholtz's "Physiologische Optik," of which excellent work a French translation has, I believe, been published.

Have any of the readers of NATURE tried a double image prism for exhibiting the mixtures of two colours? By the aid of a Nicol the proportions of the components may be varied at pleasure, and the combination is, in my experience, more effective than the plate of glass referred to in the books. However, on account of the texture of the coloured papers or wafers, the mixture is not so perfect as that obtained by rotation.

J. W. STRUTT

### A Hint to the Longsighted

A SMALL optical expedient which has been of service to me may be new to some of your readers, and useful, on occasion, to those among them whose sight is as long as my own. The focal length of the convex lens I require for my right eye in reading is twelve inches, and I find that by holding a lens of 30-inch focus about a foot from this eye I am enabled to see distant objects not only with singular distinctness, but also perceptibly magnified. I can read moderate-sized print at the distance of twelve feet, and make out the details of a church tower half a mile off nearly as well as with a small opera glass magnifying two and a half times. The greater the distance of the lens from the eye the greater is the magnifying power; but beyond a certain point (depending on the focus of the lens and the distance of the object) the gain is more than neutralised by the loss of distinctness with eyes that deviate but slightly from the normal standard, the lens employed must be so weak that the gain is inappreciable.

I presume that a lens thus held at a distance from the eye, like the German "Stöpfel Linse" described by Sir John Herschel, "realises the notion of Descartes as to the mode of action of a telescope, which he regarded as an enlargement or prolongation of the eye. For the natural cornea we substitute an artificial one, which is more remote from the retina, and so forms there a larger image."

W. T. RADFORD

### Lignite and Selenite

WILL you kindly allow me to inquire whether any of your readers can inform me if there exists any connection between lignite and selenite when found together, and, if so, in what way the lignite assists in the formation of the crystals of calcium sulphate.

I have recently found selenite in three or four different places, and in each case associated with lignite, viz., in the Bracklesham Beds near Stubbington, in the Woolwich Beds at Dulwich, and in ochrey clay near Lewisham Chalk Pits.

June 19 AN AMATEUR

### Arctic Auroras

IN answer to your inquiry, I send you the following information on a Northern Light observed at Kooltook, S.W. end of the Baikal Lake, by Dr. Dyhoffsky. It is taken from a source doubtless not at your disposition (Bulletin of the Siberian section of the Geographical Society, 1871, No. 2):—

"On October 24 (1870) evening a northern light was observed at Kooltook. It began at 9 P.M. with a red light, which appeared more and more distinctly from behind the mountains that border the landscape on the north. It was a little towards the east from the magnetic meridian. This light now increased in the form of a column, now diminished, and at times seemed to vanish entirely. After nearly an hour of such waverings, the light gradually began to increase and get broader; at midnight it reached its utmost intensity and development.

"Its least limits on the horizon were included between N. 59° E. and N. 45° W. Six columns were distinctly visible at midnight, reaching half the distance between the horizon and the zenith, the middle column was the brightest and highest, but at the same time the narrowest, and bordered with reddish-yellow. The other columns were less brilliant but far broader. When the middle column decreased, the western one began to increase, though it never reached the intensity of the middle column. The other columns also increased and diminished by turns; then the phenomenon gradually fainted away, and at three o'clock there remained but a ruddy light, which now, as at the beginning, was brighter towards the east of the meridian."

The same aurora was observed at different localities of Europe.

P. KROPOTKINE

Catherine Channel, Petersburg, May $\frac{13}{25}$, 1871

### Day Auroras in the Arctic Regions

I CAN now answer Dr. Burder's question regarding the appearance of the Aurora Borealis in the Arctic Regions. The other evening (last Thursday) I had a conversation with a distinguished magnetician and Arctic explorer, and he informed me that he has often seen the Aurora in *broad daylight* in those regions, the colour invariably being crimson. This, I hope, will once for all settle the apparently vexed question (*pace* Dr. Burder) of "alleged" daylight Auroras. Not to repeat the entire "crusher" of Dr. Burder's, I think many will now discard as "unworthy of serious criticism" his cirrus-cloudy arguments. He must pardon me for being so unceremonious, and remember his own interesting way of confuting—or, better, his attempt.

JOHN JEREMIAH

## *SCIENCE IN PLAIN ENGLISH*

### I.

IN tracing the development of public opinion, no period is more instructive than the last three hundred years; and at present the review is particularly important, for we seem to be in a position analogous to the state of Europe just before the Revival of Classical Learning. We are evidently on the eve of great changes in principle, and one vital question is to consider the value of classical culture as compared with the study of science.

The distinctive work of the thirty years (1820-1850) was to "diffuse useful knowledge" among the middle classes. Beside the establishment of mechanics' institutions throughout the country, the London University was founded in 1828; and the British Association for the Advancement of Science held its first annual meeting at York on September 27, 1831, under the presidency of Earl Fitzwilliam.

Another agency has been brought into action, more especially directed to the practical arts, and bringing into friendly competition the various nations of Europe. The International Exhibition of 1851 had a remarkable influence upon the application of science and art to trade and manufactures, calling forth a memorial from the leading manufacturing and commercial towns as to the importance of establishments for instructing workmen in the principles of science and art, on which their respective industries depend. It was stated that unless this was speedily done the country would run serious risk of losing that position which hitherto had been its strength and pride.

This foreboding was confirmed by the Exhibition at Paris in 1867, which showed an advance made by Continental nations even in some departments in which England had been considered supreme. The conclusion was received with surprise in some quarters, and vexation throughout the country.

There was no doubt that remarkably rapid progress in manufactures had been made by some of the Continental nations; and this rapid improvement was attributed, in a great measure, to the scientific training of proprietors and managers in France, Belgium, Germany, Switzerland; and to the elementary instruction which is universal amongst the working population of Switzerland and Germany. The facilities for acquiring a knowledge of theoretical and applied science are incomparably greater on the Continent than in this country; and that knowledge is based on an advanced state of secondary education.

Hence, a great effort has been made to obtain similar advantages of education for this country, in order that we may retain the position which we now hold. There can be no doubt that scientific training has become a question no longer admitting of delay; and a demand has arisen for Technical Education, by which we are to understand scientific and artistic education, with a view to improvement in industry.

To promote this object, several educational reforms have been suggested; and first of all, that in the universities and grammar schools instruction in science and art should be placed on the same favourable footing as other studies. Only one-third of the boys in the great public schools go to our universities; and therefore, two-thirds pass directly from the schools to enter upon the various pursuits of life. Now there are two methods of education. One gives a youth direct preparation for his future pursuits; the other trains the mind by processes which are not directly adapted for any worldly career, but which are supposed to strengthen the intellectual faculties.

The latter object is pursued in classical education, which is defended upon the ground that, though it does not provide special instruction for the useful purposes of the world, it still furnishes general culture. No one can deny that classical education supplies excellent training in certain directions; but there is a growing conviction that, for the practical purposes of life, the classics have been tried and found wanting; that, while they serve for ornament and for delight, they are not "good for life."

But even with a view to culture, we should not overlook the importance of Science in mental training. Science, properly taught, is one of the best means of educating the highest faculties of the human mind. By proper teaching, however, we must understand, not merely instruction in the facts of science, but discipline in the methods of science. Mere head-knowledge may do a man very little good; it is the habit of mind, the training in method, that determines the character of the man. Hence, the minds of the young should be imbued with scientific principles and trained in scientific methods.

A twofold advantage is asserted by scientific advocates: that as science has now reached so high a stage, it may be used as a means of the best mental cultivation; while, at the same time, it communicates a kind of knowledge which may be made practically useful in every walk of life.

A movement has already been made in some quarters, but sparingly, not to say grudgingly. Some schools have admitted science on about equal terms with dancing, that is to say, they give one or two hours a week to it. Or they may even admit it on equal terms with French; but it is generally made quite subordinate; and while classics are rewarded with high honours, science receives few distinctions. At Harrow the teaching of physical science has been introduced, but has not yet been made part of the regular curriculum; boys are not obliged to learn physical science, though they may get prizes for it. The most difficult point in this part of the subject is where to find suitable masters for the teaching of science. This, no doubt, must be a work of time; but if the demand springs up, the supply will follow.

But beside the demand for a reform in the institutions already existing, there is a general conviction that scientific and technical schools are required in all the great centres of industry; that such schools ought to be established; that we must have "Technical Education." In many districts those who desire to send their own sons or the sons of their better workmen for instruction in science, are unable to carry out their views because no suitable schools exist in their neighbourhood. There are numerous grammar schools in different parts of the country, but many of them were founded in the two centuries which followed the Revival of Classical Learning. Consequently, they are generally under the influence of classical traditions; and a comparatively small proportion of the boys are learning the physical or natural sciences.

The fact is that technical schools cannot be permanently supported unless we diffuse a taste for science and art. If we create the taste, the technical schools will be well filled. We must introduce the elements of science and art into the primary schools, and we shall soon change the secondary education of the working men.

It too often appears that, from the utterly defective education of the people, they do not know what is good for them, and have not the slightest conception of the methods that should be taken to improve their present ignorant and imperfect condition. In some instances so deplorable is the state of elementary education that it is found impossible to give the working classes the instruction which they desire to receive in the sciences connected with their work. They are not able to read with sufficient facility to master the books put before them; they cannot write well enough to take notes of the lectures which they hear; nor are they sufficiently familiar with arithmetic to make the necessary calculations. Hence it results that one of the first difficulties in promoting technical instruction is the want of fundamental training as the basis of scientific knowledge.

The learned will have to revise the method of teaching. There is a well-founded suspicion that the course commonly pursued has been wrong in principle. The teachers proceeded from generalities, constructed very pretty systems, and dealt largely in refinements. Many people now believe, on the contrary, that we ought to begin with individual instances, then lead the pupil to construct a broad outline, and gradually to fill up the picture as his knowledge advances.

Or take another illustration. If a man works his way up the mountain side he meets with many difficulties, but at length, when he reaches the top, he enjoys a fine prospect all around. Now, if that man wishes to guide others up the mountain, it is not sufficient for him to harangue from the top, or to dilate upon the fine prospect which he enjoys. He must come down again to the valley; he must take others by the hand, and lead them by the way which he took himself, or very nearly by the same way.

Until recently elementary treatises on science were written *from the top of the mountain*. The authors, enjoying an expanded prospect, were disposed to take general views; and to discuss principles which, however interesting to themselves, had little or no interest for the pupil. There was a want of sympathy with the learner. For example, the writers on Geography began with the globe, and expounded the elements of Spherical Trigonometry and Astronomy, talking of *meridians*, *parallels*, the *tropics*, the *equator*, and the *ecliptic*. At present the best teachers of geography *to young children* begin with the place where the pupil lives and dwells; thence they proceed to the surrounding districts, to neighbouring countries, and end with the Globe.

Bacon says that "wherever it is possible knowledge should be *insinuated* into the mind of another in the manner in which it was first discovered." If this principle were fairly carried out it would work great changes in our methods of teaching.

Queen's College, Cork

## *MOSS LOCHS*

AS these lochs are seldom visited save by sportsmen of either the rod or the gun, it will be necessary for me to give a short description of them. These lochs are generally situated high up, near the tops of the hills, the hills being wholly or in part covered with heather and moss. They are of small size, varying from about a mile to a hundred yards in length; the water is of a dark porter colour. They look as if an immense hole had been dug in the peat, and the hole then filled with water; the banks, which are wholly or in part composed of peat, rising almost perpendicularly out of the water, and at some places extending downwards for many feet under it; at other places going only to a depth of a foot or two, and then extending for some feet in a nearly horizontal direction, when they again dip abruptly to a considerable depth. These abrupt precipices of peat, as seen under the water, are often formed in curious, fantastic shapes, and look more like rock than soft peat; and when seen by the sunshine—broken by the passing waves– through the dusky water, with the surroundings of bleak, bare hill, total silence, save the plaintive cry of some bird passing overhead, and no life, save the lizard and the snake—the whole presents a scene, the weird effect of which on the imagination is seldom if ever exceeded by anything else in nature.

What strikes the observer of these lochs is, that not only are the banks made of peat, but the sides and bottom are wholly or in part made of the same material; and there seems to be no difference between the peat at the bottom of the loch and that on the banks. It looks exactly like as if the peat had begun to be formed at the bottom of the loch, and had gradually extended upwards till it had risen above the water. Yet it could not have done so, because, although water-lilies and some grasses are seen growing under a depth of a foot or two of water, yet all vegetation ceases at a depth of a very few feet. How then came the sides and bottom of these lochs to be formed of peat? There are no signs of any convulsions of nature after the peat had been formed to account for it. If produced by any upheaving of the earth stopping the exit of the water, the upheaving must have been very violent, because many of these lochs are deep and yet of but small size. How, then, came the peat in the position in which we now find it? An examination of the outlet will at once explain the difficulty. The stream which leaves the loch winds its way through mossy ground, the bottom of its channel being covered with water plants. These water plants, as they grow from year to year, are gradually filling up the channel, and so adding to the depth of the loch. It is now easy to understand how peat is found at such depths in these lochs. We will suppose the loch to begin from marshy ground or from a small loch. The channel of the outlet—being covered with water plants—gradually gets filled up, so increasing the depth of the water in the lake, while vegetable life is busy adding peat to the banks. And thus marshy ground or a shallow loch with shelving beach is converted into a deep moss loch with perpendicular sides. The rising of the channel of the outlet and of the sides does not always take place at the same relative rate. In one loch recently visited the peat bank was about eight feet above the water, whilst in another where there was a vigorous growth of water plants in the outlet, the water was within a few inches of being over its banks. That water plants are capable of producing this result will be doubted by none who have seen them fairly establish themselves in a pond, how soon they over-run, and, if left alone, fill it up.

Moss lochs stand in marked contrast to other lochs. In other lochs the water, as it passes from them, has worn their channels, and is year by year wearing them further, so lowering the water in them; whilst in moss lochs the channels are year by year being filled up, so gradually raising the water in them. It may be objected that the water plants in the outlet would be uprooted by the water from the loch during floods; but such is not the case, because in most cases, when the water leaves the loch, it passes through a nearly level channel, so that it never gets up speed sufficient to damage its bed. And besides, these lochs being situated near the tops of the hills, they drain but a small extent of country. In no case visited had any of the lochs a stream of any size running into it, and the amount of water which passed from them was in every case small.

As there are few rules without exceptions, it is possible that the rule that the outlets from moss lochs are covered with water plants may not hold good in every case; it is quite possible that the outlet from a moss loch might be over a rocky channel. If such should happen to be found, it does not necessarily prove that it was not formed in the way shown. The plants might continue to fill up the outlet till the water was raised to such a height that it found a passage over a new channel at a part of the hill where there was no moss and nothing but bare rock. We would thus have a moss loch grown in the way shown, but which had ceased to grow.

JOHN AITKEN

## *WRITERS ON SCIENCE*

AT the recent dinner of the Royal Literary Fund, Sir Henry Anderson proposed the toast of "Writers on Science." We make the following extracts from the reply by Dr. Richardson from the report of the Society:—

"Who are the writers on science? Are they as well known as other great writers? They are not. They are less fortunate, and, therefore, the more worthy of the exceptional honour you would bestow on them. Excuse me a moment or two while I indicate the peculiarities of the position of the writer on science. He is a man communicating to the word that which is, by comparison, new to the world. The poet can cast back for his models to a time when the Greeks had not so much as the figment of an alphabet. The theologian may go back for his lesson to the earliest manifestations of the life of intellect on the planet. The historian finds subject and matter ready for his hand from the oldest and remotest, as well as the newest, writings and traditions of races and peoples. The story-teller is embarrassed with the richness of the past, and troubled by the greed of his admirers for more of his work. These all, indeed, are but the continuing interpreters of things, events, thoughts, which every man who claims to read claims also to understand. The writer on science has none of these advantages; he is but newly born into an old world of thought, and is not simply telling of new wonders, but is often himself learning at the same time as he is instructing an audience unlearned in his knowledge. Thus he comes slowly into the recognised brotherhood of men of letters ; at the best he speaks to but a small audience, amuses rarely, excites sometimes without intention hopes that are delusive, and requires always, in order that he may be fairly understood, a degree of patience it is vain to expect from the multitude. To these difficulties others are added belonging to the work he accomplishes. The most original writers on science are destroyed constantly by the magnitude and overpowering character of the work they have written, and by the practical results that spring from the work. In other literature the book produced lives as the book, and the learner from it, age after age, must go back to the fountain head to drink and drink ; in science literature the book sinks into the fact it proclaims, and the fact remains the exclusive master of the field. A striking example of this flashes across my mind at the present moment. Every reading man and woman knows that in the reign of Queen Elizabeth the book of Shakespeare's plays had its origin, and nearly everyone who has read the book (and who has not?) remembers the curious saying in it, 'I'll put a girdle round the world in forty minutes.' But how many are there who have read another great book of that same reign, entitled 'De Magnete ;' or are aware that at the time when Shakespeare was writing his now-familiar phrases, the author of the book on the Magnet, the Queen's physician, one William Gilbert, when his daily toils of waiting upon the sick were over, was working with his smith in the laboratory at his furnace, needle, and compass, was writing up for the first time the word 'Electricity,' and was actually forging the beginnings of the very instruments that now, in less than forty seconds, put the girdle round the globe? Again, writers on science are lost sometimes in the blaze of their own success. They raise wonder by what they do, and fall beneath it. All knowledge newly born is miracle, but by-and-by, as the knowledge becomes familiar, the miracle ceases. In this way advances in science become part of our lives, while the men who write them down cease to us. When the Leyden jar was first described, Europe was mentally as well as physically convulsed with the thing ; now a Leyden jar is a common object—we all know it ; but how few know of Mr. Cuneus, who first described this instrument of science? The whole civilised world is cognisant in this day that communication from one part of the world to the other, by telegraph, is almost child's play ; but how many have seen or heard of Mr. Cavallo's original Essay on Electricity as a means of communicating intelligence to places distant from each other? There is nothing more commonplace, in our day, than to know that a living human being can be placed in gentle sleep, and, while in blissful oblivion, can have performed on him what were once the tortures of the surgeon's art ; but how few have heard or seen Sir Humphry Davy's paper announcing to mankind this grand beneficence ! These are some of the difficulties of writers on science ; and yet there is another I must name, be it ever so lightly. I refer to the desperate struggles of the man of science who has nothing but science to carry him on in life. None but such as are placed as I am, practising as physicians in the metropolis of the world, and admitted at the same time, as men of science, into some knowledge of the subject upon which I now speak, can form a conception of the almost hopelessness of the position of the pure scholar of science. On this I say no more. I would awaken but not weary your sympathy . . . . much of the difficulty these writers have had to bear I recognise with admiration, as their truest glory ; and I see that hope for better worldly prospects is near. A profession of science is no doubt organising. The world is at last asking men of science to employ themselves in teaching the world ; and the teachers, bending to the labour, are, in their turn, willing to suspect that they are but as children, or at best youths, in the race after knowledge. This is most hopeful ; and it is hopeful also to find that men who claim to be conservators of a knowledge that was matured when science was unborn, are listening now to our scholars with an attentive ear, and are beginning to accept that the Lord of Nature, whether he reveal himself to the ancient law-giver in the burning bush that was not consumed, or to the modern astronomer in the burning glory of the omnipotent sun, is one and the same Lord. Thus there is hope, I may say certainty, in the future for the literature of science ; for its poetry, its parables, its facts, nay, even for its religion."

## *FEARFUL EARTHQUAKE IN CHINA*

THE American Minister in China, General Lowe, has just forwarded to the Secretary of State at Washington the following account of the fearful earthquake which occurred in the Bathang, in the province of Szchuen, on the 11th of April, which he has had translated from the report of the Chinese Governor General of the province in which it occurred :—"Bathang lies on a very elevated spot beyond the province about 200 miles west of Li-Tang, and about thirty post stations from the district town of Ta-tsien, on the high road to Thibet. About eleven o'clock on the morning of the 11th of April, the earth at Bathang trembled so violently that the government offices, temples, granaries, stone houses, storehouses, and fortifications, with all the common dwellings and the temple of Ting-lin, were at once overthrown and ruined ; the only exception was the hall in the temple grounds, called Ta-Chao, which stood unharmed in its isolation. A few of the troops and people escaped, but most of the inmates were crushed and killed under the falling timber and stone. Flames also suddenly burst out in four places, which strong winds drove about until the heavens were darkened with the smoke, and their roaring was mingled with the lamentations of the distressed people. On the 16th the flames were beaten down, but the rumbling noises were still heard under ground like distant thunder, as the earth rocked and rolled like a ship in a storm. The multiplied miseries of the afflicted inhabitants were increased by a thousand fears, but in about ten days matters began to grow quiet, and the motion of the earth to cease. The grain collector at Bathang says that for several days before the earthquake the water had overflowed the dykes, but after that the earth cracked in many places, and black, fœtid water spurted out in a furious manner. If one poked the earth the spurting instantly followed, just as is the case with the salt wells and fire wells in the eastern part of the province ; and this explains how it happened that fire followed the earthquake in Bathang. As nearly as can be ascertained there were destroyed two large temples, the offices of the collector of grain tax, the local magistrates' offices, the Ting-lin temple, and nearly 700 fathoms of wall around it, and 351 rooms in all inside ; six smaller temples, numbering 221 rooms, besides 1849 rooms and houses of the common people. The number of people killed by the crash, including the soldiers, was 2,298, among whom were the local magistrate and his second in office. The earthquake extended from Bathang eastward to Pang-Chahemuth, westward to Nan-Tun, on the south to Lintsah-shih, and on the north to the salt wells to Atimtoz, a circuit of over 400 miles. It occurred simultaneously over the whole of this region. In some places steep hills split and sunk into deep chasms, in others mounds on level plains became precipitous cliffs, and the roads and highways were rendered impassable by obstructions. The people were beggared and scattered like autumn leaves, and this calamity to the people of Bathang and the vicinity was really one of the most distressing and destructive that has ever occurred in China."

## *ON THE STRUCTURE OF THE EEL'S SKULL*

THE skull of the Eel is much less specialised than that of most other Osseous (*Teleostean*) fishes. I was made aware of this many years since whilst preparing skeletons of the common kind (*Anguilla acutirostris*), and of the conger (*Muræna conger*). Afterwards, when Prof. Huxley's "Croonian Lectures" (Proc. Roy. Soc.) came into my hands, the importance of the aberrant structures of this type of skull was shown to me; and since that time I have been on the watch for further opportunities for dissecting and working out both this type, and also that of the Amphibia, which it serves to illustrate. In a few weeks' time I shall be able to make myself understood with regard to those morphological changes which take place in the vertebrate skull as it passes from a low Ichthyic into the higher Amphibian type. This will be done by the illustration and description of the frog's skull in the forthcoming part of the "Philosophical Transactions," an abstract of which paper has already appeared in these columns. At present the nomenclature of the parts of the cranium and face of the fish is in a state of painful confusion. I shall not, however, trouble the student with confusing references, but continue to use those terms which he will find in my other morphological papers. I may, however, remark that these differ in some instances from those used by Professor Huxley, for instance, his "squamosal" is my "pterotic" (see "Elem. Comp. Anat.," p. 188). This is a bone called "mastoid" by Cuvier, and this term was adopted by Prof. Owen. These anatomists came much nearer the truth than my friend; but the bone only represents *part* of the human "mastoid"—its antero-superior region. Again, the terms for the palato-pterygoid arcade are very confusing; Cuvier's "internal pterygoid," also called ento-pterygoid by Owen and Huxley, does not correspond to the internal pterygoid plate of man and the mammalia generally, but to a third piece, which I call meso-pterygoid, and which occurs in a young pig's and in a young fox's skull in my collection; I have also found it in the palate of all sorts of birds, except the fowls and Struthionidæ. The true representative of the human internal pterygoid is, in fishes, called "transverse" by Cuvier; most correctly the "pterygoid" by Owen; confusingly the "ecto-pterygoid" by Huxley. I drop the frequently misapplied terms, "ecto-" and "ento-pterygoid," altogether, and call the true "transverse bone" of the reptile—never seen in fishes—the "transpalatine." Most of the other terms used by me agree with those used by Prof. Huxley in his "Elements."

There is, however, in the hyoid arch one segment which requires its name,—that given to it by Prof. Owen—to be changed; I refer to that lump of cartilage which becomes segmented off from the lower part of the hyoid cornu by a joint cavity, and which has two ossific centres. This has been called the "basi-hyal;" but it is merely a distal and not a basal bone, the key-stone being the "glosso-hyal," which passes into the basi-branchial bar. I would call it the "hypo-hyal," as it is the manifest "serial homologue" of the "hypo-branchials." All these things I hope soon to make plain in a paper now in hand, on the "Structure and Development of the Salmon's Skull." My materials at hand, from which I have studied the eel's skull, are the adult conger's skull, that of a small *Muræna* (? species), and the heads of large and small common eels. The smallest of these are the gift of Mr. F. Buckland; they measure 2 inches 8 lines in length. The cranium of the eel is long, triangular, and depressed, the nasal region being very pinched and narrow, whilst the occipital is expanded, and sends out over-hanging outgrowths, — backwardly projecting crests, which are continuous in the conger, but distinct spurs in the eel.

These crests in the eel are formed by the super-occipital at the mid-line; then a pair from the epiotics; and below, and external to these a bilobate pair, belonging largely to the pterotics, but also to the ex-occipitals.

The flat top of the skull, up to the exit of the fifth nerve, is square, the top of the cranium then narrows suddenly to half the breadth of the square part.

On each side, there is, in the broad part of the skull, a large overhanging eave, below which is the double recess which forms the glenoid cavities for the hyo-mandibular. If the large parietals which meet at the mid-line were removed, we should see the "great upper fontanelle," bounded behind by the perfected occipital arch, and laterally by the cranial and auditory elements. Indeed, the term cranio-auditory elements would be a correct term for several of these bones, the auditory capsule coalescing very early with the rising crests of the investing mass, and the subsequent ossifications enclosing both the sense-capsule and the membranous cranium. Behind, the expanded occipital region is largely indebted to the "epiotics," and "pterotics," two pairs of which bones are really primarily related to the cartilaginous auditory sac. There is no opisthotic, and the large "pro-otic" is surmounted by a part of the posterior sphenoid, which is to be found in the bird, but not in the reptile or mammal. I allude to the post-frontal, a great outstanding projection from the "ala magna," a crested, fore-turned, supero-lateral element of the primordial skull. In front of the "foramen ovale," the "ali sphenoids" wall-in the skull; they are unusually large for an osseous fish; they rest upon an inverted "saddle" of bone, with a free fore-edge. This is the fish's basi-sphenoid, and corresponds to the pre-pituitary part of the human basi-sphenoid, and to its anterior clinoid region. In high-skulled fishes this bone is Y-shaped, the descent of its long crus showing that the "meso-cephalic flexure" of the embryo is never wholly recovered from in these fishes; and its slender size showing that the connective band which brought the investing mass into union with the "trabeculæ cranii," was a feeble strip of cartilage. Behind the saddled-shaped basi-sphenoid of the eel is the open pituitary space, which, as in birds, is merely closed below by the ossification of sub-mucous fibrous tissue, in the form of the para-sphenoid. The large basi-occipital, which encloses all the retiring notochord that belongs to the skull, helps to form an elegant tri-radiate synchondrosis in the floor of the skull; for all that part of the "investing mass" from which the notochord had retired, is invested, not by a basi-sphenoidal ossification, but by the huge "pro-otics" which meet at the mid-line, behind the open pituitary space. The structures of the skull that have morphological continuity with the vertebral column cease behind the optic nerves, and even the parts surrounding the pituitary body are of a secondary or connective character, bringing the true cranial structures into fusion with parts derived from the first or pre-stomal facial arch, the trabeculæ cranii. Now there comes in a most important condition of the skull of the eel; for the anterior sphenoidal region has no cartilaginous walls whatever; the roof is formed by the narrow frontals (frontal in the conger); the side walls are membranous, and the floor is that sub-mucous bone the para-sphenoid. In young eels, 5 in. long, the trabeculæ may be traced to their union with the "investing mass" in the pre-pituitary region; but there they unite with each other, and in the anterior sphenoidal region, instead of turning upwards to form a skull floor, they grow downwards, investing the convex upper face of the para-sphenoid (see Fig. B). Over the optic region the *pterotics* overlap, in the conger they nearly reach as far as the hinder end of the bony ethmoid; and here the frontal sends out a few post-orbital snags, and sends downwards on each side a thick post-orbital process, which articulates with the ali-sphenoid. At this part the narrow skull bends downwards in a Roman-nosed manner. The solid nasal region in front is of equal length with the long membranous interorbital space; these are separated by the large, thick, ear-shaped unossified pre-frontals, or lateral ethmoids. The median ethmoid is ossified entirely by the thick, bony bar, which commences as a knife-shaped vertical plate, or parostosis; here in the eel as in the Amphibia, the distinction between parostosis and endostosis at times breaks down. The long tooth-bearing vomer splits the parasphenoid with its long style, as far back as the pituitary space; it coalesces with the ethmoid when the eel is five or six inches in length. Where the bony ethmoid and vomer unite there is a groove; along this the olfactory crus runs, protected outside by the grooved, soft, lateral, ethmoidal wing, which arose as an outgrowth of the trabecular bar; the "cornua" of the trabeculæ (Fig. C) persist as filiform prolongations, continuous with the lateral ethmoids behind, and end in blunt points near the fore part of the ethmo-vomerine bony mass. In the conger, but not in the eel, the vomer sends out a wing on each side for the lateral ethmoids to rest upon. The parasphenoid is very deeply split at both ends, both for the vomer and the basi-occipital; it has large wings in the basi-temporal region, which underlie, in a squamose manner, the lower edge of the prootics. These latter bones divide the foramen ovale; behind and below the posterior opening there is a small passage evidently the distinct foramen for the "portio dura." The vomer and parasphenoid are azygous splints applied to the under surface of the coalesced and metamorphosed trabecular bars.

When the membranous cranium dips downwards in front (mesocephalic flexure) then the trabeculæ are not only parallel with the base of the first cerebral vesicle, but also nearly so with their immediate successors, the mandibular bars; whilst thus contiguous they form a *secondary connection*, which, of course, lengthens as the trabeculæ ascend with the cranial sac, and thus enlarge the mouth cavity. This bar is well chondrified in fishes

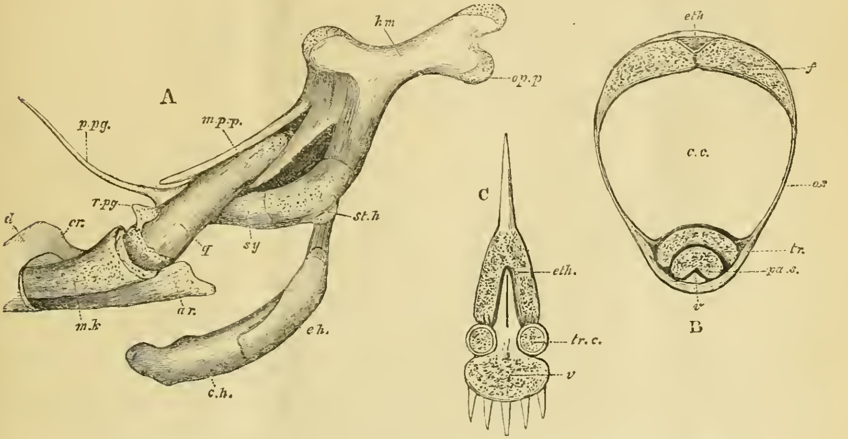

FIG. A.—INNER VIEW OF MANDIBULAR AND HYOID ARCHES OF A YOUNG EEL, 2⅞ inches long: *r.pg.* rudiment of cartilaginous pterygoid; *p.pg.* pterygo-palatine; *q.* quadratum; *ar.* articulare; *d.* dentary; *cr.* coronoid; *mk.* Meckel's cartilage; *hm.* hyo mandibular; *sy.* symplectic; *st.h.* stylo-hyal; *e.h.* epi-hyal; *c.h.* cerato-hyal; *op.p.* opercular process; *mp.p.* metapterygoid process.

FIG. B.—SECTION OF ANTERIOR SPHENOIDAL REGION IN A YOUNG EEL, 5 inches long: *eth.* ethnoid; *f.* frontal; *o.s.* orbito-sphenoidal region: *tr.* trabeculæ: *pa.s.* parasphenoid; *v.* vomer; *c. c.* cranial cavity.

FIG. C.—SECTION THROUGH THE NASAL REGION OF THE SKULL OF A YOUNG EEL, 5 inches long: *eth.* ethnoid; *v.* vomer; *tr. c.* trabecular cornu.

*All the figures are magnified about 25 diameters.*

generally, and in the tailless Amphibia. In the tailed Amphibia it is abortively developed, and no solid hyaline cartilage is found in this part in Sauropsida and Mammals. (See "On Skull of Fowl," Phil. Trans., 1869, pl. 81, figs. 1, 3, 6, 10, and 11, p. 767.)

The eel also has no solid cartilage in this bar, save a slight rudiment behind, as in the "Urodela" (Fig. A), and the three ectostal plates that invest the large cartilaginous bar in most osseous fishes—the palatine, meso-pterygoid, and pterygoid—are represented by a needle-like, solid style of bone, pointed in front, and pedate behind where it attaches itself to the inside of the front edge of the quadrate. In old eels this style becomes a flattened bar, articulating by a squamose suture with the quadrate, and loosely attached to the lateral ethmoid and the maxillary in front. This bone is the counterpart of the single plate in the Lepidosiren's mouth (see Huxley's Elem., Figs. 84 and 85, D, pp. 208, 209); but the pterygo-palatine of that fish is applied to a thick cartilaginous connective that fills in the whole sub-ocular region. As in the Lepidosiren and the Amphibia, tailed and tailless, the eel has only one ossification on the pier of the mandibular arch, and the generalised nature of the fish is shown in the partial coalescence which takes place between this and the succeeding (hyoid) pier. In the Lepidosiren, as in the Chimæra, the coalescence is entire between all but the free segmented rays of the first and second post-stomal arches; in the Urodelæ we have a similar state of things, but in the Anoura coalescence only takes place in the lower half of the pier. In all these it is cartilaginous confluence, but in the eel it is merely the anchylosis of the bony symlectic (Fig. A, *sy.*, *q.*) with the quadrate. Although there is no metapterygoid perched upon the quadrate, yet that element sends upwards a metapterygoid process which runs between and within two large denticulations of the hyo-mandibular. This latter bone (*hm.*) is very massive, and being most strongly united both by synchondrosis and deeply serrated suture to the quadrate, the suspensorium of the eel is exceedingly strong, quite as strong as, and more elastic than, the quadrate of the Sauropsida. It forms an acute angle with the basi-cranial line, as in most other fishes, but in *Muræna helena* (see Huxley, Croon. Lect., p. 34, and Osteol. Catal. Mus. Coll. Surg., vol. i., p. 14), the suspensorium is very frog-like, forming an obtuse angle. The well-developed heads of the hyo-mandibular fit into proper glenoid cavities, the foremost of which is made in the post-frontal and pro-otic, and the hinder pit is in the pterotic. The knob for the opercular is very large in the adult, and in eels five or six inches long the only sign of the separateness of the symplectic is the transverse cartilaginous tract which connects it with the hyo-mandibular; but in my youngest specimen it can be seen separate, with its own ectosteal sheath (Fig. A, *sy.*); it is very short, and the cartilaginous interspace above is very large. From the middle of that synchondrosis there arises a small semi-segmented bud of cartilage, the "stylo-hyal" (*st. h.*); this becomes ligamentous in the adult; in other Teleostei it forms a rather small cylinder, completely segmented off, and it acquires a bony sheath. The rest of the descending hyoid cornu is a thickish arcuate rod of cartilage ossified by two ectosteal sheaths, the "epi"- and "cerato-hyals." In Teleostei generally, the distal end is cut off by a joint cavity, and ossifies from two more ossicles, forming the "hypo-hyal" segment; this structure is not attained in the less specialised eel. The arch is finished by a long and stout glosso-hyal. Even the free bar of the first post-stomal arch—the mandible—has its peculiarities, for, contrary to rule, it has no angular splint—and the "coronoid," so seldom present in Teleostei, and so constant in Sauropsida, is well developed in the eel; it is very small in old individuals of the cod-fish. The dentary alone is dentigerous, and is very large and strong, with a large coronoid process; the "articulare" is short and massive. In the upper part of the face the specialised subcutaneous bones (*parostoses*) are very instructive; several belong to the lateral-line series, but, modified and broken up into two rows in the head, they form tubular mucous bones; these are the nasals and "sub"- and "pre-orbitals." Another facial series, which may run obliquely from the snout to the hinge of the lower jaw, has only two on each side,—the pre-maxillary and maxillary. Here we have, contrary to rule, the short pre-maxillary edentulous and the maxillary bearing teeth. The specialised bones of the back-face and throat are worth mention; the pre-opercular is oblong, twisted, strongly convexo-concave, and burrowed by mucous glands. The opercular fits by a deep cup to the knob on the hyo-mandibular; like the feebler sub-opercular, it is strongly falcate; the latter fits by a sliding joint to the pedate upper end of the wedge-shaped large inter-opercular. The long, thick-based, slender-pointed "branchiostegals" are eleven in number on each side in the common eel; the basal bone of this wondrously specialised series of dermal bones is the so-called "uro-hyal;" it is knife-shaped behind, and in front terminates in a massive head, facetted for the cerato-hyals. I call this bone the "basi-branchiostegal;" for the "uro-hyal" of the bird is the remnant of the basi-branchial bar. The student can easily obtain both the gigantic conger and the larger specimens of the common eel, and, having become familiar with the parts of the skull and face of such an ordinary teleostean as the cod, and of the larger amphibian types, both tailed and tailless, he will then be able to gain a much clearer idea of the fundamental harmony existing between such diverse types, if this intermediate eel-type be once well understood.

The development of the skull in the culminating amphibian, the frog, has yielded me already such satisfactory results that I am somewhat restless to know the early conditions of that of the fish: then whole groups of low vertebrate types will begin to be seen in harmonious relation.

W. K. PARKER

## NOTES

THE following is a list of the Presidents of Sections nominated by the Council of the British Association for the approaching meeting at Edinburgh:—Section A, Prof. P. G. Tait, of Edinburgh; Section B, Dr. Andrews, of Belfast; Section C, Prof. Geikie; Section D, Prof. Allen Thomson; Section E, Alex. Keith Johnston, sen.; Section F, Lord Neaves; Section G, Prof. Fleeming Jenkin. The Evening Discourses will be delivered by Prof. Abel and Mr. E. B. Tylor.

IT is stated that the labours of the Royal Commission on Coal, appointed a few years ago by Sir George Grey, are on the point of completion, and the result is the demonstration of the fact that, assuming a certain annual increase in the rate of consumption, sufficient economically gettable coal exists in Great Britain and Ireland to last from 800 to 1,000 years. We shall be very glad to see such an important fact demonstrated.

WE have to record the death of Mr. George Grote, Vice-Chancellor of the University of London, whose serious illness we mentioned a fortnight since. He died on Sunday last, after a long illness, in his seventy-seventh year. We can ill afford to lose men who have so long and so ably thrown their influence and their abilities into the cause of the higher education of all classes of the community.

WE regret to announce that Mr. Numa Edward Hartog, Senior Wrangler of the University of Cambridge in 1869, died on Monday last of smallpox. Mr. Hartog was still, in common with other Nonconformists, excluded from the substantial reward of his exertions; but in the present Session he gave important evidence before the Lords' Committee on University Tests, and it is due perhaps to the sympathy which his exclusion excited that the Lords proposed a measure which would have admitted him to a Trinity Fellowship. Before, however, he could take advantage of the passing of the University Tests Bill the man who was expected to be the first to reap its fruits had passed away.

AT the recent examination for the newly-established Diploma in State Medicine given by the University of Dublin, the first place was taken by Mr. J. W. Moore, ex-scholar Trinity College, Dublin; the second by Dr. A. W. Foot, Junior Physician to the Meath Hospital and County of Dublin Infirmary; the third by Mr. Yeo, who obtained the Junior Medical Exhibition in 1864, and the Senior Medical Exhibition in 1866; and the fourth by Mr. Todhunter, a gentleman already well known in certain circles for his literary abilities.

THE new museum and library at Clifton College were inaugurated on Saturday last by a *conversazione*. There was a good collection of objects of interest contributed by gentlemen of the neighbourhood; some music, and a speech from the Rev. Principal of the College, interested the large company, and Prof. Church delivered an address on "Colour."

THE new buildings of St. Thomas's Hospital on the southern Thames Embankment, opposite the Houses of Parliament, were opened yesterday by the Queen in person.

THE Victoria Institute concluded its fifth session on Monday. Its members are now 305 in number, seventy having joined since February; the papers for the coming session include two on subjects connected with the vegetable kingdom.

THE managers of the London Institution, in accordance with the recommendation of the annual meeting of proprietors, have resolved to afford opportunities during the ensuing season for the reading and discussion of papers on subjects of special interest in science, literature, commerce, and the arts, provided they receive such offers as will insure a succession of suitable communications. It is believed that this proposed extension of the use of the Lecture Theatre in Finsbury Circus will produce a series of attractive meetings similar in character to those of the Society of

Arts, but representing more directly the business and thought of the City. The managers do not intend to restrict the reading and discussion of papers to the proprietors of the Institution, or to limit the range of subjects otherwise than by the provisions of the charter, which precludes politics and theology.

ON Saturday last, the 17th, the Rugby School Natural History Society made an excursion through Charnwood Forest. Mr. Hambly, the manager of the Mount Sorrel granite works, conducted them over his workshops and quarries; and Mr. Ellis showed them his slate pits at Swithland. They also visited Woodhouse Eaves, the Beacon, the Monastery, and Bardon Hill. The geologists, botanists, and entomologists were alike well content with the results of a very pleasant day's excursion. The party numbered forty-one.

SIR JOHN PAKINGTON, as President of the Institution of Naval Architects, has addressed a letter to the President of the Board of Trade, in which, among other suggestions, he proposes as an additional clause in the "Prevention of Accidents Act" that in future adjusters of compasses shall be duly certified by the Board of Trade, after examination, as properly qualified.

WE are requested to state that the value of the Natural Science scholarship at Magdalen College, Oxford, will be 95*l.*, and not 80*l.* as stated last week, and that the name of the successful competitor for the Johnson Memorial Prize Essay is John G. Gamble, not James S. Gamble.

DR. MURCHISON, F.R.S., has been this week recommended by the Grand Committee for election by the Governors as Physician to St. Thomas's Hospital, Mr. Croft for election as Surgeon, Dr. John Harley and Dr. Frank Payne as Assistant Physicians, and Mr. Francis Mason and Mr. Henry Arnott as Assistant Surgeons.

DR. HOOKER reports that the upper valleys of the Atlas range are very steep and picturesque, and are thickly inhabited by a fine race of people called Shelloos. The first positive indication of ancient ice action met with was a stupendous moraine at about 6,000 feet—a perfectly unmistakeable one, but, curiously enough, with no traces above or below it, no *roches moutonnées*, no striated or grooved surfaces, and no perched blocks, except on the moraine itself. The height of the peaks of the axis is very uniform for a considerable distance, and they have very steep faces; there are no glaciers nor perpetual snow, properly so called; but snow lies all the year in steep gullies of the north face, stretching downwards for probably 5,000 feet from the summit. The vegetation is chiefly Spanish.

THE following works on Science are amongst the publishers' announcements for the next few weeks:—From Messrs. Longman—Dr. Ueberweg's "System of Logic and History of Logical Doctrines," translated by Thos. M. Lindsay; "Cooper's Dictionary of Practical Surgery and Encyclopædia of Surgical Science," new edition by S. A. Lane; in Gleig's School Series: "Animal Physiology," by Dr. E. D. Mapother; "Physical Geography," by W. Hughes. From Mr. Murray—"Rambles among the Alps, 1860—1869," by E. Whymper. From Griffith and Farran—"The Theory and Practice of the Metric System of Weights and Measures," by Prof. Leone Levi, F.S.A.; "A Compendious Grammar and Philological Handbook of the English Language," by J. Stuart Colquhoun, M.A., barrister-at-law. From W. and R. Chambers—"Class Book of Science and Literature; Zoology from do.; Botany from do.; Geology from do."; "Standard Animal Physiology," Part I. for Standard IV.; "Standard Geography," Part I. for Standard IV.; "Standard Physical Geography," for Standards IV., V., VI.; "Mackay's Arithmetical Exercises," for Standard Work, Parts I., II., III., IV.; Part V., embracing Metric System; "Standard Algebra;" "Explicit Euclid," Books I. and II. From S. Low, Son, and Co.—a complete treatise on the "Distillation and Preparation of Alcoholic Liquors," translated from the French of M. Duplais, by Dr. M. McKennie; a treatise on "The Manufacture of Vinegar," by Prof. H. Dussance. From Cassell, Petter, and Galpin—"Selected Obstetrical and Gynæcological Works of Sir J. Y. Simpson," edited by Dr. J. Watt Black; "Model Drawing," by Ellis A. Davidson, being the new volume of Cassell's Technical Manuals, with numerous illustrations and drawing copies; the "Technical History of Commerce," by Dr. Yeats, LL.D.; the "Natural History of Commerce" (second edition), by Dr. Yeats, LL.D.

WE reprint the following sentence from the recently published address of the President of the Tyneside Naturalists' Field Club, commending it to the notice of similar institutions throughout the country now that the season for excursions is commencing:—"We have no law excluding ladies from our club, but yet we have no lady members. Ladies, however, sometimes attend our meetings, and it would, I think, be an advantage to the club (may I hint also that it might be an advantage to the ladies?) if more of them came, and oftener. It is of infinite importance that mothers should be able to impart to their children an intelligent interest in Nature. They cannot do this unless they first possess that interest themselves, and in what way can it be more pleasantly developed and refreshed than by meetings such as ours? It may perhaps be objected that the length and occasionally the rugged character of our walks prove an obstacle to the presence of the weaker sex; but my impression is that this is not the case to any very serious extent, and in many of our excursions ladies have proved themseves quite equal to walks as long and as arduous as are at all desirable for our purposes. I would therefore recommend—not any new rule, which is needless—but simply that we should persuade our lady friends to join the club as members, and not as only casual visitors."

WE have received the prospectus of a proposed American *Archæological Review and Historical Register*, devoted to Archæology, Anthropology, and History, to be devoted to the rapidly increased interest displayed in these subjects in America, and designed not to meet the wants of men of science only, but of all interested in the Origin and Antiquity of Man. Its contents will include original contributions, the reports of learned societies in America and abroad, and a department of "Notes and Queries." The *Review* is intended to be published either monthly or quarterly in New York, and will be edited by Dr. Wills de Hass.

WE learn from the *American Naturalist* that Messrs. J. A. Allen and Richard Bliss, jun., of the Museum of Comparative Zoology at Cambridge, Mass., with Mr. C. W. Bennett, of Holyoke, Mass., started late in April on a six months' collecting trip to the Plains and the Rocky Mountains. The primary object of the expedition is to collect the larger mammals of the West.

THE Ohio Legislature has appropriated 21,000 dols. for continuing the survey of that State, and 18,000 dols. for publication of the results. This survey is under the direction of Prof. Newberry himself; and his corps, which has been employed for some time, will be increased by Prof. J. T. Hodge, Prof. J. H. Stevenson, and others, for the purpose of more speedily finishing the work.

MANY scientific societies have been desirous of taking advantage of the International Exhibition and of the Albert Hall to hold meetings in connection with the Exhibition, and to bestow attention on scientific visitors. The small theatres have, however, been occupied by specimens exhibited, and the Albert Hall is considered too large.

A BRILLIANT meteor of unusual form was seen at Panama on the morning of May 1 at half-past two. It was due south and about 30° above the horizon. It was of the form of a darting flame, parallel to the earth's surface from east to west. The head was of dazzling whiteness, the middle bright yellow, and the tail violet. It ended in a train of brilliant sparks of about 2° in length, and was visible about two minutes. The whole sky was of a rosy colour, and particularly in the east. The same tinge was visible in the evening at half-past seven.

A SCIENTIFIC sanitary question has arisen in India. On the ground of necessity, public offices have been supplied with anti-thermic arrangements; but the economical fit, still strong, has led to a government decree that it cannot afford such provision, and that kuskus windows and their essentials must be provided at the expense of the officials. This will afford an additional pressure on the agitation for transferring the public departments to the English towns, sanitaria, or tea plantations in the hills.

IT is stated that Assurance Companies in India have declined to accept the lives of the officers of the Geological Department there on account of the exposure to which they are subjected.

A UNITED Service Institution for India has been formed, and it is gratifying to observe that it is to be established at Simla in the Himalayas, in a healthy district instead of an unhealthy place.

THE severe earthquake of the 25th of February in Chile has called attention to the views of Mr. Darwin and Prof. Rudolph Falb of Prague. Mr. Darwin was in Chile in the great earthquake of February 20, 1835. It is observed that the recent earthquake began at the same time, 11.30 A.M. Mr. Darwin considered that the space from under which the volcanic matter was erupted in Chile was 720 miles in one line and 400 in another, and that the existence was indicated by a subterranean table of lava of the area of the Black Sea. Prof. Falb maintained that the influence of the moon is the chief cause of earthquakes, and in a letter to NATURE of the 14th of April, 1870, he explained and defended his doctrine, and referred to the earthquakes of Manilla, the volcano of Puraco in Columbia, and convulsions in Peru. His prophecies of a great earthquake in Peru, which occasioned so much alarm, were not realised. The Manilla earthquake, he says, took place two hours and a half after the culmination of the moon. It is affirmed that the late earthquake in Chile had no relation to the culmination of the moon. It is to be noted that the great earthquake in Honolulu in the Hawaian Islands took place on the night of February 19, six days before that of Chile.

AN earthquake was felt at Rawul Pindee and Murree, in the Himalayas, in April.

THE Russian Government are believed to be organising an expedition to New Guinea for the purposes of scientific research and exploration. It is, however, believed in Australia that this is only an indirect method of obtaining a foothold in that country, and it is proposed that the Government of Victoria should send an expedition to New Guinea, in order to obtain by treaty certain portions of territory for purposes of settlement. Should this design be carried into effect, it is to be hoped that every facility will be given to Naturalists to accompany the expedition into this large and comparatively unknown country.

THE *Friend of India* states that from the report on the general state of the weather in the North-West Provinces and Oudh during March, it appears that the direction of the wind, as in the preceding two months, was for nearly the whole month from the north-west in the N.W. portion of the provinces, and west elsewhere. During the first half of the month a tendency to change to the east was occasionally perceptible, and this was especially the case during the time of the barometric depression from the 13th to the 20th. The month as a whole was much drier than usual.

## *MR. BENTHAM'S ANNIVERSARY ADDRESS TO THE LINNEAN SOCIETY*

(*Continued from page* 114)

IN geographical biology Denmark proper is of no great importance except as a connecting link, on the one hand, between the Scandinavian peninsula and Central Europe, and, on the other, as the separating barrier between the Baltic and the North Seas. Low and flat, without any great variety in its physical features, it is unfavourable for the production or maintenance of endemic organisms, and forms an inseparable portion of the region of Central Europe. But the Arctic possessions included in the kingdom, Greenland, Iceland, and the Faroe Islands, are of great interest; and Denmark itself is remarkable for the number of eminent naturalists, zoologists as well as botanists, produced by so small a state. Its reputation in this respect, established by the great names mentioned in my review of Transactions in my Address of 1865, is being well kept up by Bergh, Krabbe, Lütken, Mörch, Reinhardt, Schiödte, Steenstrup, and others in zoology; whilst Lange, Œrsted, and Warming are among the few who now devote themselves more or less to systematic botany. Their general zoological collection, when I last visited it, many years since, was not extensive, although rich in northern animals, and very well arranged under the direction of Steenstrup, and the insects in the Storm Gade Museum were very numerous; whilst at the University was deposited the typical collection of Fabricius. The Herbarium at the Botanic Garden, valuable for the types of Vahl and other early botanists, has been in modern times enriched by the extensive Mexican collection of Liebmann, the Brazilian ones of Lund and others; whilst Œrsted's Central-American and Warming's Brazilian plants are also at Copenhagen, but whether public or private property I know not. The botanical and zoological gardens are of no great importance, but the biological publications are kept up with some spirit, especially the Transactions of the Royal Society of Science, Schiödte's continuation of Kröyer's "Tidsskrift," and the "Videnskabelige Meddelelser" of the Natural History Society; and some of the authors have adopted a practice strongly recommended to those who write in languages not understood by the great mass of modern naturalists, that of giving short *résumés* of their papers in French. On the most important contributions to systematic zoology since those mentioned in my address of 1868, I have received the following memoranda:—Prof. Reinhardt, in publishing in the Transactions of the Royal Danish Academy (1869) nine posthumous plates, executed under the direction of the late Prof. Eschricht, illustrating the structure of various cetacea, has accompanied them with short explanations. Prof. Reinhardt has further published, in the "Videnskabelige Meddelelser" for 1870, a list of the birds inhabiting the Campos district of central Brazil; notes on the distribution, habits, and synonymy are copiously added; and the introductory remarks on the geographical distribution, &c., are very suggestive, and ought to be translated for the benefit of the friends of ornithology in England and elsewhere. The same "Videnskabelige Meddelelser" contains an essay by Dr. Lütken on the limits and classification of ganoid fishes, chiefly from a palæontological point of view, accompanied by a synopsis of the present condition, in systematical and geological respects, of that important branch of palæichthyology. In Mollusca, Dr. Bergh has published, in Kröyer's "Tidsskrift" for 1869, one of his elaborate, anatomical, and systematic monographs of the tribe Phillideæ, with many plates, of which a detailed notice is given in the "Zoological Record," vol. vi. p. 559. In insects, Prof. Schiödte, in the same journal for 1869, has given an elaborate essay containing new facts and views on the morphology and system of the Rhynchota, analysed in the "Zoological Record," vol. vi. p. 475. To Dr. Krabbe we owe the description of 123 species of tapeworms found in birds, an elaborate monograph accompanied by ten plates, and printed in the Transactions of the Royal Danish Society for 1869, with a French *résumé*. (Noticed in "Zoological Record," vol. vi. p. 633.) In Echinoderms, Dr. Lütken's valuable essays on various genera and species of Ophiuridæ, recent and fossil, with a Latin synopsis of Ophiuridæ and Euryalidæ, and a general French *résumé*, forming the third part of his "Additamenta ad Historiam Ophiuridarum," in the Transactions of the Royal Danish Society for 1869, have been analysed in the "Zoological Record," vol. vi. pp. 369, 462, &c. No contribution to systematic botany of much importance has appeared in Denmark since those mentioned in my Address of 1868.

There exists no general Danish Fauna; but I have a rather long list of detached works and essays from which the Danish inhabitants of the different classes of animals may be collected. Of these the most recent are Collin's Batrachia, in Kröyer's "Tidsskrift" for 1870, and Mörch's marine Mollusca, publishing in the "Videnskabelige Meddelelser" for the present year.

With regard to Iceland, the only works mentioned are Steenstrup's terrestrial mammals, or rather mammal, of Iceland, in the "Videnskabelige Meddelelser" for 1867; and Mörch's Mollusca in the same journal for 1868. C. Müller's account of the birds of Iceland and the Faroe islands dates from 1862, and Lütken's of the Echinoderms from 1857, and I find no mention of any special account of the insects of the island; whilst in botany, C. C. Babington has given us, in the eleventh volume of our Linnean journal, an excellent revision of its flora, the phænogamic portion of which may now be considered as having been very fairly investigated; and E. Rostrup, in the fourth volume of the Tidsskrift of the Botanical Society of Copenhagen, has enumerated the plants of the Faroe Islands.

The Scandinavian peninsula is, on several accounts, of great interest to the biologist. It includes a lofty and extensive mountain-tract, with a climate less severe than that of most parts of the northern belt a similar latitudes, and the uniformity of the geological formation is broken by the limestone districts of Scania. It thus forms a great centre of preservation for organic races beween the wide-spread tracts of desolation to the east and the ocean on the west, and has therefore been treated as a centre of creation, whence a Scandinavian flora and fauna has spread in various directions. As the home of Linnæus it may also be considered as classical ground for systematic biology, the pursuit of which is now being carried on with spirit, as evidenced by such names as Holmgren, Kinberg, Liljeborg, Malm, Malmgren, G. O. Sars, Stal, Toreil, and others in zoology; and Agardh, Andersson, Areschoug, Fries, Hartmann, and others in botany. Two of the academies to whose publications Linnæus contributed, those of Upsala and Stockholm, continue to issue their Transactions and Proceedings; and to these are now added the memoirs published by the University of Lund. They lost Linnæus's own collections, and the Zoological Museum at Upsala, when I saw it many years since, was poor, that of Stockholm better, and in excellent order. In the herbaria, Thunberg's and Afzelius's collections are deposited at Upsala, and Swartz's at Stockholm, where the herbarium of the Academy of Sciences has been of late years considerably increased under the care of Dr. Andersson.

The Scandinavian Fauna and Flora have been generally well investigated. The numerous Floras published of late years show considerable attention on the part of the general public. I observe that Hartmann's Handbook is at its tenth edition; Andersson has published 500 woodcut figures of the commoner plants, taken chiefly from Fitch's illustrations of my British Handbook; and my lists contain many papers on Swedish Cryptogams. The relation of the Scandinavian vegetation to that of other countries has also been specially treated of by Zetterstedt, who compared it with that of the Pyrenees, and by Areschoug, Andersson, Ch. Martins, and others, as alluded to in more detail in my Address of 1869. Many works have succeeded each other on the Vertebrate Fauna since the days of Linnæus; amongst which those of Liljeborg as to Vertebrata in general and of Sundeyall as to Birds are still in progress. The Crustacea, Mollusca, and lower animals have been the subjects of numerous papers, the marine and freshwater faunas having been more especially investigated by the late M. Sars and by G. O. Sars; and Th. Thorell, in the Upsala Transactions, has given an elaborate review of the European genera of spiders, evidently a work of great care, preceded by apposite remarks on their generic classification, and a general comparison of the Arachnoid faunæ of Scandinavia and Britain, all in the English language although published in Sweden. This work, however, does not extend to species, beyond naming a type (by which I trust is meant an example, not the type) of each genus; nor is the geographical range of the several genera given. There appears to be no general work on Scandinavian insects

The fauna and flora of Spitzbergen have specially occupied Swedish naturalists. To the accounts of the Vertebrata by Malmgren, and of the Lichens by T. M. Fries, have now been added, in recent parts of the Transactions or Proceedings of the Royal Swedish Academy, the Insects by Holmgren, the Mollusca by Mörch, the Phænogamic Flora by T. M. Fries, and the Algæ by Agardh.

An excellent and elaborate monograph of a small but widely spread genus of Plants, entitled "Prodromus Monographiæ Georum," by N. J. Scheutz, has appeared in the last part of the Transactions of the Academy of Upsala. Several interesting features in the geographical distribution of some of the species are pointed out, amongst which one of the most curious is the almost perfect identity of the *G. coccineum* from the Levant and the *G. chilense* from South Chile, the differences being such only as would scarcely have been set down as more than varieties had both come from the same country. The whole memoir is in the Latin language; the specific diagnoses are rather long, but the observations under each section and species point out the connection with and chief differences from the nearest allies.

The whole of the botanical literature published in or relating to Sweden has been regularly recorded in annual catalogues, inserted by T. O. B. N. Krok in the "Botaniske Notiser" of Stockholm.

The chief interest in the biology of Russia consists in its comparative uniformity over an enormous expanse of territory. Extending over more than 130 degrees from East to West, and above 20 degrees from South to North, without the interposition of any great geological break in mountain,* or ocean, all changes in flora or fauna, in the length and breadth of this vast area are gradual; whilst the mountains which bound it to the south and to the east, and the glacial characters of the northern shores, offer to the Russian naturalist several more or less distinct biological types, such as the Caucasian, the Central Asiatic, the Mantchurian, and the Arctic, all blending into the great Europeo-Asiatic type, and the three first-named, at least apparently, constituting great centres of preservation. By the careful discrimination of the various races which give to each of these types its distinctive character, the study of their mutual relations, of the areas which each one occupies without modification, of the complicated manner in which these several areas are interwoven, of the gradual changes which distance may produce, of the cessation of one race and the substitution of another without apparent physical cause, the Russian, even without travelling out of his own country, can contribute, more than any other observer, valuable materials for the general history of races. In botany I have on former occasions referred to Ledebour's "Flora Rossica" as the most extensive complete flora of a country which we possess, and to the numerous papers by which it has been supplemented. Several of these are still in progress, chiefly in the bulletin of the Society of Naturalists of Moscow, and I have notes of local floras and lists from various minor publications. The last received volume of the Memoirs of the Academy of Petersburgh include the botanical portion of Schmidt's travels in the Amur-land and Sachalin, in which the geographical relations of the flora are very fully treated of; and the first part of a very elaborate "Flora Caucasi" by the late F. J. Ruprecht, which may be more properly designated Commentaries on the Caucasian Plants than a flora in the ordinary sense of the word. It is an enumeration of species, with frequent observations on affinities, and a very detailed exposition of stations in the Caucasus, but without any reference to the distribution beyond that region; above 300 large 4to pages only include the Polypetalæ preceding Leguminosæ, and the lamented death of the author will probably prevent the completion of the work. N. Kaufmann, Professor of Botany at the University of Moscow, an active botanist of great promise, whose death last winter is much deplored by his colleagues, had published a Flora of Moscow in the Russian language, which had met with much success. In the zoology of Russia the most important recent work is Middendorff's "Thierwelt Sibiriens," analysed in the "Zoological Record," vi. p. 1, which, with the previously published descriptive portion and the botany of the journey by Trautvetter, Ruprecht, and others, forms a valuable exposition of the biology of N.E. Siberia, a cold and inhospitable tract of country, where organisms, animal as well as vegetable, are perhaps poorer in species and poorer in individuals than in any other region of equal extent not covered with eternal snows. Middendorff's observations on this poverty of the

* The celebrated chain of the Oural, which separates Asia from Europe is, in the greater part of its length too low, and the ascent too gradual to have much influence on the vegetation. The so-called ridge between Perm and Ekaterinburg is, according to Erman, not 1600 feet above the level of the sea, and rises from land which, for a breadth of above 120 miles, is only 700 feet lower.

fauna of Siberia, its uniformity and conformity to the European fauna, on the meaning to be given to the species, on their variability and on the multiplicity of false ones published, on the complexity of their respective geographical areas, on their extinction and replacement by others, &c., are deserving of the careful study of all naturalists. L. v. Schrenck's Mollusca of the Amur land or Mantchuria (reviewed in the "Zoological Record," iv. p. 504) is equally to be recommended for the manner in which the specific relations, the variability, affinities, and geographical distribution of Mantchurian Mollusca are treated. The publications of the first meeting of the Association of Russian Naturalists include a review of the Crustacea of the Black Sea by V. Czerniavski, an account of the Annulata Chætopoda of the Bay of Sebastopol by N. Bobretzki, and a paper on the zoology of the Lake of Onega and its neighbourhood by K. Kesslar, including a review of the fishes, Crustacea, and Annulata of the Lake of Onega, and of the Mollusca collected in and about the Lakes Onega and Ladoga, and a list of the butterflies of the Government of Olonetz. The historical and scientific memoirs published by the University of Kazan, of which several volumes have recently reached us, include a systematic enumeration and description of the birds of Orenburg (329 species), with detailed notes of their habits, &c., by the late Prof. E. A. Eversmann, edited after his death by M. N. Bogdanoff, forming an 8vo volume of 600 pages in the Russian language.

There is not in Russia at the present moment sufficient encouragement on the part of the public to induce the publication of independent biological works beyond a few popular handbooks; but the Imperial Academy of Petersburg has, on the other hand, been exceedingly liberal in the assistance it affords, and active in its issue of Transactions with excellent illustrations, as well as of its bulletin of proceedings. The volumes recently received include J. F. Brandt's "Symbolæ Sirenologicæ" and researches on the genus *Hyrax* (reviewed in "Zoological Record," v. p. 3, and vi. p. 5), A. Strauch's Synopsis of Viperidæ, with full details of their geographical distribution, E. Metschnikoff's studies on the development of Echinoderms and Nemertines, and N. Miklucho-Maclay's Memoir on Sponges of the N. Pacific and Arctic Oceans, with remarks on their extreme variability inducing the multiplication of false species. In botany, Bunge's Monograph of the Old-World species of *Astragalus* is the result of many years labour and careful investigation. The eight sub-genera and 104 sections into which this extensive genus is divided appear to be very satisfactory; but the species (971) are probably very much too numerous, and we miss that comparison with American forms which, considering the very numerous cases of identity or close affinity, is essential for the due appreciation of the N. Asiatic species. Bunge has also published a monograph of the *Heliotropia* of the Mediterraneo-Oriental region in the Bulletin of the Society of Naturalists of Moscow, which continues its annual volumes. The parts recently received continue several of the botanical enumerations already noticed, together with various smaller entomological papers.

(*To be Continued*)

## GEOLOGY

### On the Supposed Legs of the Trilobite, Asaphus platycephalus*

At the request of Mr. E. Billings, of Montreal, I have recently examined the specimen of *Asaphus platycephalus* belonging to the Canadian Geological Museum, which has been supposed to show remains of legs. Mr. Billing, while he has suspected the organs to be legs so far as to publish on the subject,† has done so with reserve, saying, in his paper, "that the first and all-important point to be decided, is whether or not the forms exhibited on its under side were truly what they appeared to be, locomotive organs." On account of his doubts, the specimen was submitted by him during the past year to the Geological Society of London; and for the same reason, notwithstanding the corroboration there received, he offered to place the specimen in my hands for examination and report.

Besides giving the specimen an examination myself, I have submitted it also to Mr. A. E. Verrill, Prof. of Zoology in Yale College, who is well versed in the Invertebrates, and to Mr. S. I. Smith, assistant in the same department, and excellent in crustaceology and entomology. We have separately and together considered the character of the specimen, and while we have reached the same conclusion, we are to be regarded as independent judges. Our opinion has been submitted to Mr. Billings, and by his request it is here published.

The conclusion to which we have come is that the organs are not legs, but the semi-calcified arches in the membrane of the ventral surface to which the foliaceous appendages or legs were attached. Just such arches exist in the ventral surface of the abdomen of the Macrura, and to them the abdominal appendages are articulated.

This conclusion is sustained by the observation that in one part of the venter three consecutive parallel arches are distinctly connected by the intervening outer membrane of the venter, showing that the arches were plainly *in the membrane*, as only a calcified portion of it, and were not members moving free above it. This being the fact, it seems to set at rest the question as to the legs. We would add, however, that there is good reason for believing the supposed legs to have been such arches in their continuing of nearly uniform width almost or quite to the lateral margin of the animal; and in the additional fact, that although curving forward in their course toward the margin, the successive arches are about equidistant or parallel, a regularity of position not to be looked for in free-moving legs. The curve in these arches, although it implies a forward ventral extension on either side of the leg-bearing segments of the body, does not appear to afford any good reason for doubting the above conclusion. It is probable that the two prominences on each arch nearest the median line of the body, which are rather marked, were points of muscular attachment for the foliaceous appendage it supported.

With the exception of these arches, the under surface of the venter must have been delicately membranous, like that of the abdomen of a lobster or other macruran. Unless the under surface were in the main fleshy, trilobites could not have rolled into a ball.

James D. Dana

* From the American *Journal of Science and Arts*, Vol. I, May, 1871.

† Q. J. Geol. Soc., No. 104, p. 479, 1870, with a plate giving a full-sized view of the under surface of the trilobite, a species that was over four inches in length.

## SCIENTIFIC SERIALS

*Annales de Chemie et de Physique.* The whole of the last part of the "Annales" is occupied by M. Berthelot's *Méthode universelle pour réduire et saturer d'hydrogène les composés organiques*, which is a *résumé* of the elaborate and exhaustive researches on the action of hydriodic acid on organic substances in which he has been engaged for the last three or four years. Most of the results have been already published from time to time in the *Bulletin de la Société Chimique de Paris*, and this classical research is now completed by the publication of the details of the methods of analysis and the thermochemical considerations involved. The author has found that any organic compound can be transformed into a saturated hydro-carbon, having, in general, the same number of atoms of carbon as the original substance, by heating it for a sufficient length of time to a temperature of 275°C., with a large excess of an aqueous solution of hydriodic acid of the specific gravity of 2.0. The proportion of the acid is varied according to the nature of the substance submitted to its action, twenty or thirty parts being sufficient to reduce an alcohol of the fatty series, whilst a member of the aromatic series and such substances as bitumen, wood charcoal, and coal, require, at least, one hundred times their weight; the large excess of acid serving the purpose of dissolving the iodine set free during the reaction, thus preventing its destructive action on the organic compound, and also in allowing the quantity of hydriodic acid necessary for the reduction of the substance, to be withdrawn from the solution without reducing its strength so far that the reaction ceases. One of the most remarkable results exhibited in the application of this method is that of the direct transformation of benzene into the saturated hydrocarbon, hexylene hydride, $C_6 H_6 + 8 H I = C_6 H_{14} + 8 I$, affording, as it does, an instance of a direct passage from the aromatic to the fatty series. When other members of the phenyl series are treated with hydriodic acid, the ultimate product is the same; but there is an intermediate step in the reaction, resulting in the formation of benzene, which, by the continued action of the acid, is transformed into the corresponding saturated hydrocarbon. The fifth and last part of the paper is of great interest from a theoretical point of view, since it comprises the results of the author's experiments on bitumen, wood charcoal, and coal. The former of these substances, under the influence of hydriodic acid, yields hexylene hydride, the saturated hydrocarbon corresponding to benzene, from which it may be inferred that bitumen is a derivative of benzene, produced by condensation and loss of hydrogen. Charcoal and coal, when treated according to M. Berthelot's method, are transformed into a mixture of various saturated hydrocarbons, identical with those found in petroleum oil. In fact *the coal is changed into petroleum oil.*

THE most important paper in the first three numbers of vol. xiii. of the *Atti della Società Italiana di Scienze Naturali* (April and November 1870, and January 1871), is a continuation of Prof. Delpino's article on "Dichogamy in the Vegetable Kingdom." In this paper the author passes in review the various modes in which the impregnation of plants is effected, with especial reference to the provisions for the impregnation of one plant by the fecundating organs of another.—M. A. Curò publishes a note on parthenogenesis among the Lepidoptera.—M. F. Sordelli contributes a note on the anatomy of the genus *Acme*, and on some of the hard parts of *Cœcilianella acicula*, illustrated with a plate; and further an anatomy of *Limax Doriæ*, Bourg., also illustrated, and including a tabular arrangement of the species of the genus *Limax*, for the elucidation of the characters of two new species, which the author describes under the names of *L. punctulatus* and *L. Bettonii*.—The Secretary of the Society, Dr. C. Marinoni, notices some remains of *Ursus spelæus* from the Cave of Adelsberg.—M. G. Bellucci gives an account of some evidences of prehistoric man in the territory of Terni.—M. L. Ricca communicates some observations on dichogamy in plants made by him upon the Alps of Val Camonica in 1870; and also a systematic catalogue of the vascular plants growing spontaneously in the olive-zone of the valleys of Diana, Marina, and Cervo, with indications of the special conditions of growth, times of flowering of each species, and occasional remarks upon their characters.—At p. 130 is the description of a supposed hybrid *Orchis*, *O. coriophoro-laxiflora*.—From M. C. Bellotti we have some observations on the disease of flaccidity, which destroys so many silkworms (*morts-flats*) in France and Italy; and from Dr. Taramelli a memoir, illustrated with an elaborate coloured plate, on the ancient glaciers of the Drave, Save, and Isonzo.

## SOCIETIES AND ACADEMIES

### LONDON

Geological Society, June 7.—Mr. Joseph Prestwich, F.R.S., president, in the chair. Messrs. Henry Collinson and Thomas Milnes Favell were elected Fellows, and Dr. J. J. Kaup, of Darmstadt, was elected a foreign member of the society. The following communications were read:—1. "On the persistence of *Caryophyllia cylindracea* Reuss, a Cretaceous Coral, in the Coral-fauna of the Deep Sea." By Prof. P. Martin Duncan, F.R.S. The author first referred to the synonyms and geological distribution of *Caryophyllia cylindracea*, Reuss, which has hitherto been regarded as peculiar to the White Chalk, and as necessarily an extinct form, inasmuch as it belonged to a group possessing only four cycles of septa in six systems, one of the systems being generally incomplete. The distribution of the *Caryophlliæ* of this group in the Gault and the Upper Chalk, the Miocene, and the Pliocene, was noticed, and also that of the species with the incomplete cycle. The falsity of this generalisation was shown to be proved by the results of deep-sea dredging off the Havannah, under Count Pourtales, and off the Iberian peninsula under Dr. Carpenter and Mr. Gwyn Jeffreys. The former dredged up *Caryophyllia formosa* with four complete cycles, and the latter obtained, from depths between 690 and 1090 fathoms, a group of forms with four complete and incomplete cycles. This group had a Cretaceous facies; one of the forms could not be differentiated from *Caryophyllia cylindracea*, Reuss; and as a species of the genus *Bathycyathus* was found at the same time, this facies was rendered more striking. The representation of the extinct genera *Trochosmilia*, *Parasmilia*, *Synhelia*, *and Diblasus*, by the recent *Amphihelia*, *Paracyathi*, and *Caryophylliæ* was noticed, and it was considered that as the Cretaceous forms throve under the same external conditions, some of them only being persistent, there must be some law which determines the life-duration of species like that which restricts the years of the individual. It was shown that deep-sea conditions must have prevailed within the limits of the diffusion of the ova of coral polyps somewhere on the Atlantic area ever since the Cretaceous period. Mr. Gwyn Jeffreys remembered that at the spot where the coral in question was dredged up the sea-bottom was extremely uneven, varying as much as fifty fathoms within a quarter of a mile. It was also not more than forty miles from land. The species of mollusca dredged up were extremely remarkable, and many were totally different from what he had previously seen. They were, however, living or recent; none of them were Eocene or Miocene, much less Cretaceous, like *Terebratula caput-serpentis*. He quoted from Mr. Davidson other instances of the persistence of forms, especially of the genus *Lingula* from the Silurian formation. The persistence of this species of coral, as well as that of Foraminifera, from the Cretaceous to the present time, was therefore not unique, and other cases of survival from even earlier times might eventually be recognised. Dr. Carpenter, after commenting on the reductions that extended knowledge enabled naturalists to make in the number of presumed species, could not accept the mere identification of species as of the highest importance in connecting the Cretaceous fauna with that of our own day. The identity of genera was, in his opinion, of far more importance. He instanced *Echinothuria* and *Rhizocrinus* as preserving types identically the same as those of a remote period, and as illustrating the continuity of the deep-sea fauna from Cretaceous times. The chemical and organic constitution of the deep-sea bottom of the present day was also singularly analogous to that of the Chalk sea. The low temperature at the bottom of the deep sea, even in equatorial regions, was now becoming universally recognised, and this temperature must have had an important bearing on the animal life at the sea-bottom. Prof. Ramsay thought that there was some misapprehension abroad as to the views held by geologists as to continuity of conditions. They had, however, always insisted on there having been an average amount of sea and land during all time; and the fact of sea having occupied what is now the middle of the Atlantic since Cretaceous time would create no surprise among them. If, however, the bed of the Atlantic were raised, though probably many Cretaceous genera, and even species, might be found, there would on the whole be a very marked difference between these Atlantic beds and those of the Chalk. Mr. Seeley had already, in 1862, put forward views which had now been fully borne out by recent investigation. His conviction was that, from the genera having persisted for so long a time, the genera found in any formation afforded no safe guide as to its age, unless there were evidence of their having since those formations become extinct. Mr. Etheridge maintained that the species in different formations were sufficiently distinct, though the genera might be the same. Recent dredgings had not brought to light any of the characteristic molluscan forms of the Cretaceous time; and it would be of great importance to compare the results of future operations with the old Cretaceous deep-sea fauna. Prof. Rupert Jones, with reference to the supposed sudden extinction of chambered Cephalopods, remarked that Cretaceous forms had already been discovered in Tertiary beds in North America, and also that cold currents could not have destroyed them, seeing that icebergs came down to the latitude of Croydon in the Chalk sea.—2. "Note on an *Ichthyosaurus* (*I. enthekiodon*) from Kimmeridge Bay, Dorset." By J. W. Hulke, F.R.S. In this paper the author described the skeleton of an *Ichthyosaurus* from Kimmeridge Bay, agreeing in the characters of the teeth with the form for which he formerly proposed the establishment of the genus *Enthekiodon*. The specimen includes the skull, a large portion of the vertebral column, numerous ribs, the bones of the breast-girdle, and some limb-bones. The first forty-five vertebral centra have a double costal tubercle. The coracoids have an unusual form, being more elongated in the axial than in the transverse direction, and this elongation is chiefly in advance of the glenoid cavity. The articular end of the scapula is very broad. The paddles are excessively reduced in size, the anterior being larger than the posterior, as evidenced by the comparative size of the proximal bones. The species, which the author proposed to name *I. enthekiodon*, most nearly resembles the Liassic *I. tenuirostris*. The length of the preserved portion of the skeleton is about 10ft., the femur measures only 2in., and the humerus 2·7in.—3. "Note on a Fragment of a Teleosaurian Snout from Kimmeridge Bay, Dorset." By J. W. Hulke, F.R.S. In this paper the author described a fragment of the snout of a Teleosaurian obtained by Mr. J. C. Mansel, F.G.S., from Kimmeridge Bay, and which is believed to furnish the first indication of the occurrence of Telosaurians at Kimmeridge. The specimen consists of about 17in of a long and slender snout, tapering slightly towards the apex, where the præmaxillæ expand suddenly and widely. The nostril is terminal and directed obliquely forwards; the præmaxillæ ascend 2·5in. above the nostril, and terminate in an acute point; and each præmaxilla contains five alveoli. The lateral margins of the snout are slightly crenated by the alveoli of the teeth, of which the three front ones are smaller than the rest; most of the teeth have fallen out, but a few are broken off, leaving the base in the sockets. Mr. Seeley thought it likely that Mr. Hulke would eventually be led to re-establish his genus *Enthekiodon*. He remarked on the peculiar characters presented by the specimen, and referred especially to the coracoids, which were unlike those of *Ichthyosaurus*, but presented a close resemblance to those of *Plesiosaurus*. He considered that there were indications of its having been connected with a cartilaginous sternum. The scapula furnished an important character in its widening, which formed a distinct acromion process. Mr. Seeley remarked that double-headed ribs occur only in animals with a four-chambered heart; and that, considering this and other characters, there was no reason for placing *Ichthyosaurus* lower than among the highest Saurians. He considered that the Teleosaurian snout differed from all known types. Dr. Macdonald believed that what is called the coracoid has nothing to do with the shoulder-girdle, and thought it might be a part of the palate. Mr. Mansel stated, in answer to the President, that the fossils were obtained from about the middle of the Kimmeridge Clay. Mr. Etheridge suggested that it would be desirable to ascertain whether the horizon of the *Ichthyosaurus* described was the same as that of the specimens from Ely. Mr. Gwyn Jeffreys inquired as to the food and habits of the *Ichthyosaurus*. Mr. Hulke, in reply, stated that, from the presence of a stain and of numerous small scales, under the ribs, the food of the *Ichthyosaurus* probably consisted of Squids, and small fishes. He showed that the so-called coracoid was clearly a part of the shoulder-girdle.

Geologists' Association, June 2. — Rev. T. Wiltshire, president, in the chair. A paper on "Flint" was read by Mr. Hawkins Johnson, F.G.S. After stating the reasons which had induced him to pay special attention to the subject of the formation of flint, the author described the characters and mode of occurrence of nodular and tabular flint and chert. The various combinations into which silicon enters were then recapitulated, and a description of sponges introduced a statement of the theory contended for in this paper to account for the formation of chalk flints. This theory is simply that *silicon* replaced the *carbon* of the sarcode of the sponges of the Cretaceous seas. Flints are therefore merely silicified sponges. The empty shells of echinoderms were frequently used by sponges which in many cases outgrew and surrounded the shells, and these sponges afterwards becoming silicified we find the tests of echinoderms either wholly or partly embedded in chalk flints. Prof. Tennant dwelt upon the opinions of Dr. Bowerbank, and pointed out in opposition to the views of that authority that agates could not have derived their origin from sponges, since they were found in volcanic rocks. Mr. Deane, who had been associated with Dr. Mantell in his researches with respect to the origin of flints, stated that, contrary to the general belief that fossils were not found in any flints except those from the Upper Chalk, organisms had been discovered in flints from the Lower or Grey Chalk. Dr. Bedwell, who had paid great attention to this subject for a long time, denied Dr. Bowerbank's assertion that a central layer of chalk is not present in horizontal as it is in vertical tabular flint, and he could not admit the possibility of vertical walls of flint, sometimes of great height, being produced by the silicification of sponges which grew on each side of a fissure in the bed of the chalk sea, as had been contended for by Dr. Bowerbank and Mr. Johnson. Prof. Morris, after complimenting the author on the value of the paper and the knowledge of the subject which he had displayed, referred to the investigations into the orig n of flint by the observers of the last century, and gave a very interesting *résumé* of the principal facts connected with the occurrence of flint in the stratified rocks. The Professor contended for the segregation of the silica of the chalk around nuclei, in opposition to the theory advocated by Mr. Johnson, which was first propounded by Dr. Brown of Edinburgh. The amount of diffused silica in the Upper Chalk is much less than in the Lower Chalk, in which flints are rare. The tests of echinoderms are never silicified, nor are phosphatic animal substances, such as bone. He believed that the sponges of the old seas, from what we know of the sponge-gravel and the Upper Greensand, were chiefly silicious, and not ceratose; and that they were extremely abundant is shown by the fact that in the Haldon Hill Greensand masses of chert occur eight feet thick, which are quite full of the spiculæ of sponges. Mr. Johnson briefly replied, but was scarcely prepared then to combat the observations of Professor Morris. Very fine collections of flints showing peculiarities were exhibited by Messrs. Johnson, Bedwell, Evans, Leighton, Deane, and Meyer.

Mathematical Society, June 8.—Mr. W. Spottiswoode, F R.S., president, in the chair. Messrs. W. Chadwick, M.A., and J Griffiths, M.A., were elected members of the society.—Prof Cayley, V.P., stated results he had arrived at in his investigation of Plücker's models of certain oceanic surfaces. He had been able to identify eight out of the fourteen models in the Society's possession (presented by Dr. Hirst.) — W. Samuel Roberts, M.A, gave an account of his paper "On the Motion of a Plane under certain Conditions."—Prof. Henrici, V.P., exhibited cardboard models of two ellipsoids, of a hyperboloid of one sheet, and of an elliptic paraboloid, also stereograms of the models of surfaces exhibited at former meetings of the society.

Entomological Society, June 5.—Mr. J. W. Dunning, F.L.S., vice-president, in the chair.—The Secretary read a letter from the Rev L. Jenyns, of Bath, with reference to the reported showers of insects or other organisms at Bath, noticed at the last meeting. Mr. Jenyns had examined some of these organisms, and found they were *Infusoria*, probably *Vibrio undula* of Müller, many of them being congregated into spherical masses enveloped in a gelatinous substance. They fell during a heavy shower of rain.—Mr. Butler exhibited specimens of *Lepidoptera*, upon which he and Mr. Meldola had experimented with a view to ascertain the action of dyes. Many species had been subjected to aniline dyes, and all kinds of colours produced. Mr. Butler also found that when the insects were immersed in a solution of soda for the purpose of causing the dyes to be more readily taken, the colouring matter of the scales was completely discharged and collected at the bottom of the solution. Mr. Bicknell had subjected *Gonopteryx rhamni* to the action of cyanide of potassium, acting upon a suggestion made last meeting, and the yellow colour was changed to orange-red.—Mr. W. C. Boyd exhibited an example of *Ramia cratægata*, captured near London, the apical portion of one wing of which was changed to brown.—Mr. Müller exhibited the bell-shaped nest of *Aglena brunnea*, a spider; also galls of an undescribed species of *Phytophus* on *Betula*.—Mr. F. Smith exhibited three rare British species of *Hymenoptera*, captured by Mr. Dale in Dorsetshire, consisting of *Myrmecomorphus rufescens* (*Proctotrupidæ*), *Ichneumon glaucopterus*, and *Osmia pilicornis*.—Mr. Holdsworth, of Shanghai, communicated notes on the method practised by the Chinese in cultivating the silk-producing *Bombyx Pernyi*.—Mr. Butler read "Descriptions of Five New Species of Diurnal *Lepidoptera* from Shanghai."—Mr. Baly communicated "Descriptions of a new genus, and of some recently-discovered species of *Phytophaga*."—Mr. Kirby communicated "Synonymic Notes on *Lepidoptera*."

Statistical Society, June 20.—Mr. Hyde Clarke read a paper "On the Transmissibility of Intellectual Qualities in England." As one kind of test of intellectual exertion, he took the statistics of the writers of books in the Biographia; of 2,000 authors, 750 were born in country districts, and 1,250 in town districts. Examining the towns and the distribution in them, 333 were allotted to London, 73 to Edinburgh, and 53 to Dublin. The largest numbers in the tables beyond these were found in cathedral and collegiate cities. The deductions he drew were that intellectual activity is distributed unequally, but that it is more among the town or more highly educated population than among the rural populations. He pointed out that the larger the concentrated educated population, the larger is the intellectual development, and he referred to the like examples of Greece, Rome, and modern Europe, where the same law is to be traced. The great modern centres of industry in England occupy a low relative position in the list, and are scarcely to be noticed, but they are now beginning to contribute. He affirmed that the literary class was produced from the educated class, and not from the illiterate classes. While no educational effort will produce men of great genius, he inferred that literary attainments are in relation to literary culture or the culture of the educated classes, and that by extending education to other classes of the population, the intellectual capacity of the community will be extended and propagated within certain limits.

MANCHESTER

Literary and Philosophical Society, April 4.—"Notes on drift of the eastern parts of the counties of Chester and Lancaster." By E. W. Binney, F.R.S., F.G.S., president. Having in a previous paper given a short description of the higher drift found in these counties, the author now proceeds to consider the thick surface covering of the general drift, which nearly hides from our view the underlying strata, except where they are exposed in river courses or in canal or railway cuttings. This generally reaches to an elevation of about 700 feet above the sea, and does not alter much in its appearance, whether it is seen at Blackpool, Ormskirk, or Liverpool, or at Burnley, Rochdale, Glossop, or Macclesfield, except being usually more divided as it is found inland, and approaches the sides of the Pennine chain. It consists of beds of till, clay, sand, and gravel. It has been treated on by various authors, a list of whose works are given.

Annual Meeting, April 18.—Mr. E. W. Binney, F.R.S., F.G.S., president, in the chair. The report of the Council was read by one of the secretaries. The Council have the satisfaction to report that the past year has been one of steady progress for the Society. The following gentlemen were elected officers of the Society and members of the Council for the ensuing year:—President: Mr. Edward William Binney, F.R.S., F.G.S. Vice-presidents: Mr. James Prescott Joule, D.C.L., F.R.S., F.C.S., Mr. Edward Schunck, F.R.S., F.C.S., Mr. Robert Angus Smith, F.R.S., F.C.S., Rev. William Gaskell. Secretaries: Mr. Henry Enfield Roscoe, F.R.S., F.C.S., Mr. Joseph Baxendale, F.R.A.S. Treasurer: Mr. Thomas Carrick. Librarian: Mr. Charles Bailey. Other Members of the Council: Mr. Peter Spence, F.C.S., Mr. William Leeson Dickinson, Mr. Henry Wilde, Mr. Robert Dukinfield Darbishire, F.G.S., Prof. Osborne Reynolds, and Mr. William Boyd Dawkins, F.R.S. Dr. Joule, F.R.S., drew attention to the remarkable atmospheric phenomenon which had been seen by several persons in Derbyshire and elsewhere, on the evening of Good Friday, April 7, and stated that he had witnessed a similar appearance near Glasgow on the day before it was observed in this neighbourhood. The perpendicular ray extended upwards from the sun to an altitude of 30°, and was very clearly defined. It was observed from half an hour before, until after the sun had set. The phenomenon was also witnessed, at the same time, by Prof. J. Thomson, who was sailing on the Firth of Clyde.

CAMBRIDGE

Philosophical Society, May 15.—"On Dr. Wiener's model of a cubic surface with twenty-seven real lines," Prof. Cayley, F.R.S.—"On the tides in a rotating globe covered by a Sea of depth constant at all points in the same latitude, attracted by a moon always in the plane of the equator; considered with reference to the tidal retardation of the earth's angular motion about its axis," Mr. Röhrs. "On the motion of imperfect fluid in a hollow sphere, rotating about its centre under the action of impressed external periodic forces, considered with reference to the phenomena of precession and nutation," Mr. Röhrs.

May 29.—"On an illustration of the empirical theory of vision," Mr. Coutts Trotter. "On a table of the logarithms of the first 250 Bernoullis Numbers," Mr. Glaisher.

NEW YORK

Lyceum of Natural History, Oct. 24, 1870.—"The Geological Position of the Remains of Elephant and Mastodon in North America," by Dr. J. S. Newberry. The genera *Elephas* and *Mastodon* existed on the globe during the Miocene Tertiary Epoch and were represented by various species from that time to the advent of man. The question is, when the two species *Elephas primigenius* and *Mastodon giganteus* are first met with in ascending the geological scale. In Europe it is claimed that remains of these species are found in the true Boulder Drift, and in California in the Pliocene Tertiary deposits. Whether either of these statements is strictly true remains to be decided by future investigations. In central and eastern North America the remains of elephant and mastodon are found abundantly in peat bogs and other superficial and recent deposits, also in some strata of unconsolidated material which are considered as belonging to the drift, although there has been much difference of opinion whether these beds form part of the true undisturbed drift, or whether they consist of re-arranged drift-materials or what is called "Modified Drift. The facts now offered seem to prove conclusively that the remains of elephant and mastodon are found in the true and unchanged drift, but only in the more recent of the drift deposits. The presence of these great mammals must therefore be considered as one of the incidents in the history of the drift, but as incidents belonging only to the last chapters in this long and somewhat eventful history. In order that the advent of the elephant and mastodon may be properly placed in the sequence of phenomena embraced in the Drift period, it will be necessary to make a brief review of these phenomena so far as they are known to us. The geological periods immediately antecedent to the Drift are the Cretaceous, which was a period of marked continental submergence, when the ocean covered most of the western half of the continent and reached several hundred feet higher than now over the basis of the eastern highlands; and the Tertiary with its three subdivisions Eocene, Miocene, and Pliocene. The Eocene was a period of continental progressive emergence—land area gradually expanding, climate subtropical. In the Miocene and Pliocene epochs the topography was in a general way what it is now, but in detail the surface was considerably more diversified, especially by the presence of great fresh-water lakes which occupied much of the surface on both sides of the Rocky Mountains. At this time there was probably a land connection between the northern part of North America and Europe on the one hand and Asia on the other. The climates of Alaska and Greenland were then as mild as that of Virginia now; the flora was luxuriant and varied, and was common to Europe, Iceland, Spitzbergen, Greenland, our continent, and North-eastern Asia; palms grew farther north than the Canadian line. The fauna was much richer than now, including elephant, rhinoceros, and many other animals not now living in either of the Americas, and indeed as large a number of the great mammals as are now found in Africa. The superficial boulders and gravels of the Drift are clearly the result of iceberg action. It is proved by the undisturbed condition of the clays below, that they must have been *floated* to their present resting places, just as boulders, sand, and gravel are floated from Greenland to the banks of Newfoundland, and there spread broadcast over the sea bottom. In the Drift deposits above the blue clay, remains of Elephant and Mastodon have been repeatedly found, still more frequently in the Peat-bogs of the present surface, and the much-discussed question has been, whether these mammalian remains were deposited with the upper layers of the Drift or were buried in them by subsequent shifting, as in the valleys of streams. The facts to which attention is now specially directed would seem to decide that question. It has long been known that in many parts of the valley of the Mississippi, wells penetrating twenty, thirty, or more feet, the superficial accumulations of *drifted* materials—clays and sands, with gravels and boulders brought from the far north—encounter sticks, logs, stumps, and sometimes a distinct carbonaceous soil. Combining facts of this character, of which records have been accumulating from year to year, with those brought to light by recent investigations directed specifically to this object, it is proved that over a great area at the West a sheet of buried timber, a vegetable soil, beds of peat covered with sphagnous moss, erect stumps, and in some cases standing trees, form a distinct line of demarcation between the older and newer drift deposits. In or above the horizon of this ancient soil have been found numerous animal remains: *Elephas*, *Mastodon*, *Castoroides* (the great extinct beaver) and some others.

PARIS

Academy of Sciences, June 5.—M. Faye in the chair. M. Delaunay gave some supplementary information relative to the attempts made by the Communists to set fire to the National Observatory. The director of the establishment says that M. Yvon Villarceau was somewhat incorrect in the description of the damage done to the instruments belonging to the geodesic service, of which he is the chief and superintendent. The National Observatory, which was built more than two centuries ago under the reign of Louis XIV., is a very strong building, with thick walls, and the garden itself is at an elevation of 10ft. from the level of the surrounding land. The extent of the garden is about half an acre. The Communist forces had garrisoned it, and it was only when obliged to retreat that they tried to burn it down, which attempt was defeated only by the personal exertions of the staff, their families, and well-disposed persons in the vicinity.

The spherical copper caps of the equatorials were perforated by many holes from Versaillists' rifles, and the equatorials themselves were slightly hurt. But altogether the damage done is nothing in comparison with the harm which was contemplated.—Dr. Guyot sent a paper on Dynamite, and the means of protecting storehouses from spontaneous explosion. Dynamite is known to be a mixture of sand and nitro-glycerine. When it is wrapped in a cartridge, made as usual with paper, the capillary attraction works on the nitro-glycerine, which is slowly separated from the sand, and impregnates the protecting matter. In this new form nitro-glycerine is almost as explosive as in its ordinary liquid state, which may very easily be proved.—M. Elie de Beaumont read a circular noticing that the next session for the British Association will be held this summer at Edinburgh. The learned perpetual secretary expects that many members will try to attend it, so that French science may have a fair representation, which is seldom the case on these occasions.

June 12.—M. Delaunay in the chair. The greater part of the members, who were obliged to escape from Paris, have resumed their seats. M. Leverrier was congratulated on having resumed his professorial duties at the Sorbonne, where he has opened this very morning his regular course of lectures on Mathematical Astronomy, Almost every scientific editor of the Parisian papers has returned also to his seat.—M. Serret presented a memoir on the principle of least action, economy of mechanical work by natural forces acting from certain centres by attraction. Euler and Lagrange had confined their exertions to show that the first differential was always zero. This was not sufficient, as such a differential may belong to a maximum if the second differential becomes negative, which was left to be demonstrated by Euler and Lagrange. The work was very difficult indeed.—M. Becquerel read a very long paper on atmospheric electricity. It was worked by himself as well as by his son, as the first part of a theory which can be reviewed only when completed. M. Becquerel, advocating the opinions started by Pelletier, thinks that the electricity of the upper regions is positive, and he says, moreover, that it comes from the sun, which is a focus of positive force. The electrical connection from the sun to our upper atmosphere is maintained through celestial space, which is not an absolute vacuum, but is filled with gases at a low pressure. The electricity of the earth is negative, and every thunder clap is a discharge between the earth and the upper regions through the air.—M. W. de Fonvielle sent a note reviewing the organisation of the Postal Telegraphic service in England, and showing that the French Government is wrong in maintaining two different administrations. The case of the French Government is very bad, as the two administrations were amalgamated during the war by the Tours delegation, under M. Steenackers, and ultimately separated. M. Buys Ballot, the celebrated director of the Utrecht Meteorological Observatory, asked from the Portuguese Government the establishment of a Meteorological station, or rather system, in the Azores Archipelago. This will result in the issuing of regular reports when the south-western gales are on their way to visit the British Islands and Western Europe. M. Delaunay, who read over the note at full length in the name of M. Buys Ballot, strongly advocated the proposition of his learned colleague. It is greatly to be hoped that the Portuguese Government will yield very shortly to the suggestion.

Academy of Inscriptions and Belles Letters, June 9.—The first sitting for a long period, as almost every member had been a refugee outside Paris, except a few officials. M. Haureau, director of the National Printing Office, explained that nothing was disturbed at this establishment. The Oriental Department is in excellent working order. The manuscripts of several members, which are kept there as well as valuable documents, are safe, owing to the mild rule of M. Debock, a working compositor, who was appointed a delegate by the Commune, and who protected also the National Archives, which are located in an adjoining building.—M. Alfred Maury, who had been left as Director of Archives by the Commune, had much trouble in protecting it against Communist fury, even with an order signed by Debock. M. Maury was praised for the energy exhibited and the courage shown in remaining at his post, running the risk of being taken as a hostage. He was much assisted in his work of protection by the gate-keeper, who severally turned out small parties of incendiaries coming with petroleum to execute their infamous orders. M. Leon Renier said that the stock of Borghesi works printed by the Academy, has perished at the same time as the Louvre Library. But the Borghesi manuscripts are safe. The 7th volume had not been distributed, and it will be necessary to print it again at the expense of the Academy, which had a limited credit for the whole edition. M. Leopold Delisle said that the manuscripts of the National Library, which had been concealed in the Archives, are safe. A few shelves had been slightly attacked by damp, but the real damage amounts to very little. There are seven nominations required in order to fill up the vacancies; death has removed four members, two ordinary members and one foreign associate. The Academy has adopted a proposition of M. Renan to fill up the vacancies gradually. On the 16th the Academy will appoint a commission for reporting upon the respective merits of candidates as foreign associate members. On the 23rd the Academy will examine the titles of the candidates for filling the seats of MM. Villemain and Alexander, whom the Academy lost before the Prussian siege. On the 30th the Academy will appoint a committee for reporting upon the candidates to two honorary memberships; but the nomination for the last two ordinary memberships will be postponed till next winter.

## BOOKS RECEIVED

English.—Scrambles among the Alps, 1860-1869: E. Whymper (Murray).—The Antiseptic System: Dr. A. Sansom (H. Gillman).—Introductory Text-book of Meteorology: Dr. A. Buchan (Blackwood and Sons).—Manual of Modern Geography: Rev. A. Mackay, 2nd edition (Blackwood and Sons).

Foreign.—(Through Williams and Norgate)—Die Grundzüge des graphischen Rechnens u. der graphischen Statik: K. von Ott.—Der Seideospinner des Maulbeerbaumes: F. Haberlandt.

## PAMPHLETS RECEIVED

English.—Chemical Phenomena of the Blast Furnace, Pt. II.: J. Lowthian Bell.—Annual Address by the President of the Royal Geographical Society.—Practical and Experimental Philosophy, Pt. II: R. Willis.—Report of the Winchester College Natural History Society.—Vaccination viewed politically: F. W. Newman.—An Essay on Unsolved Ethical Questions: D. Rowland.—Transactions of the Northumberland and Durham Natural History Society.—On Barometric Differences and Fluctuations: J. K. Laughton.—Thirty-eighth Annual Report of the Royal Cornwall Polytechnic Society.—A Catalogue of Hardy Perennials, &c.: W. Robinson.—British Statesman and Churchman, No. 10.—Will the Earth become a Sun-Spot?: R. Holmes.

American and Colonial.—Australasian Medical Gazette, No. 37.—Catalogue of the Iowa University, 1870-71.—Lectures delivered at the Industrial and Technological Museum, Melbourne, during the Spring Session of 1870.—Population: its Law of Increase: N. Allen.—The Physiological Laws of Human Increase: N. Allen.

Foreign.—Ueber einige Trematoden und Nemathelminther: R. von W. Sakow.—Ofversigt af konigl., V. Akademie, Forhandlingen.—Die Geographische Verbreitung der See-gräser.

## RAMBLES ROUND LONDON

*Saturday Afternoon Rambles Round London. Rural and Geological Sketches.* By Henry Walker. (London: Hodder and Stoughton. 1871.)

THE title of this book is suggestive of one of the movements of modern times, the Saturday Half-holiday, a movement in the right direction, if the recipients of the boon fully appreciate and understand how to use it beneficially. This may be done in various ways, either in the study of the subjects contained in the different museums in the Metropolis devoted to Art, Manufactures, or Natural Science; or in excursions in the vicinity, either for obtaining health or becoming acquainted with the various natural objects met with in the rambles, thus adding to the stock of intellectual and physical enjoyment, enlarging knowledge, and, perhaps, adding some new fact to the already rich stores of local observation. The institution of Field Clubs and Naturalists' Societies is not altogether new in principle, but their steady increase is a marked feature of late years; and while they have largely contributed to stimulate more systematic researches, they have at the same time exercised a social influence in bringing together persons whose tastes and pursuits have generally for their common object the investigation of the varied manifestations of creative intelligence. To those whose love of natural history leads them into the field, this small volume will be found a useful companion and guide, as it gives in a very able and pleasant manner much useful information respecting the more favoured spots easily accessible by the naturalist around London.

We can believe that these "Saturday Half-Holiday Rambles" have been the means of emancipating many young men from the gas-light hours on the Saturday to a good long afternoon of daylight. Many of them who have rural tastes, and even tastes for natural history, have never heard of the Quekett, the Geologists' Association, the South London Microscopical, and other London societies, part of whose programme consists of natural history rambles on the Saturday afternoon. So huge a place is London that there is danger of the amateur naturalist foregoing much that he might profit by, for want of such knowledge. The more we know of London life, the more do we see that this is the kind of work for young men closely engaged in the exhausting pursuits of a great city. Natural history pursuits are just the recreation they need; and the movement inaugurated by the energetic Secretary of the Saturday Half-holiday Committee of the Early Closing Association appears to fill up a gap in the previously existing modes for employing their time.

The Saturday Afternoon Rambles comprise London park and forest trees, Battersea Park, with its subalpine and tropical floras, Kew Gardens, visits to Burnham and Knockholt Beeches, Hampstead Heath and Hornsey, and autumn tours round Godalming. Interesting, however, as is the present landscape scenery of these districts, the author carries us back to the more ancient geography of the London area: the old sea-bed in Middlesex, and the subsequent changes it has undergone, and by which the present physical features have been produced.

Among the many interesting geological features to be noticed in the neighbourhood of London, the Thames valley is one, and is fully described in the work before us. Few of us are aware, except those acquainted with Mr. Prestwich's work, "The Ground beneath Us," that the familiar Thames of to-day has a pre-historic history distinct from its association with man and his fortunes, from which it is too commonly supposed to derive its sole interest and charm Still, the Thames, if we trace it from its source to the sea is replete with considerable interest, especially when we take into consideration the origin and character of the strata over which it flows in its onward course. These rocks reveal to us successive changes in the physical features and distribution of land and water during long past periods in the history of the globe; they tell us of successive oceans, or perhaps to some extent of a continuous ocean, more or less tropical in character, abounding in various forms of life adapted to the then existing conditions, which forms were successively replaced either by evolution or by new creations, coincident with the different inorganic changes which that area has undergone.

Without entering into a description of these changes (which we feel will be fully illustrated in the forthcoming work by Prof. Phillips), we will attempt to trace from the book before us the origin and condition under which the deposits in the Thames valley were accumulated, such as those which may be observed from the neighbourhood of Kew to Erith, and beyond it. The present stream, the parent of commerce and of civilised life, with its valley so rich in interesting landscapes, is but a diminished representative of a pre-historic larger river, by the agency of which, to a considerable extent, the present valley was formed. Even in the vicinity of London we have traces of older sea beds, such as the chalk, the London clay with its subordinate estuarine beds of the Woolwich series, and its overlying marine strata of middle Eocene age represented by the Bagshot sands, capping here and there the summits of the adjacent hills, and these again overlain by deposits of much later age, and indicating considerable change in the climatal conditions of the period, namely, the beds of glacial age which abut upon the northern heights of the valley, as at Highgate and elsewhere. That the present physical features of the Thames valley are of remote antiquity there can be little doubt, and many have been the opinions suggested as to its origin and age. Some have considered it partly of preglacial or glacial age, others as due to the torrential action of vast bodies of water produced by the summer thaws when the winters of England were of an arctic severity, or that the river itself was the agent by which the valley was formed. Suffice it, however, to say that from the corresponding nature of the strata on each side, which shows they were once continuous, for instance between Highgate and Norwood, it is evident, as suggested by Mr. Prestwich, that the valley of the Thames acquired its present dimensions in a period of greater atmospheric waste than the present, and of river erosion of greater intensity. Whether or not its features were partially moulded previous to the glacial period, it is probable that during the emergence of the land from the glacial sea, its present contour was more prominently determined, and it has been subsequently further modified and enlarged by the older river and its tributaries. There is even some reason for believing that its present outflow was not its former one, but that, acording to Mr. S. V. Wood, jun. (whose researches are so well known) the river probably drained southward into the Weald, being barred in by a ridge of lofty land *now* cut through by the Thames river.

The deposits of the ancient river afford memorials of considerable interest, for they tell us that along its forest-clad margins lived numerous mammalia, most of which have become extinct in the British area, although some of the genera are now restricted to the Europeo-Asiatic continent. Thus we find remains of the rhinoceros, elephant, hippopotamus, bear, and lion entombed in the valley deposits, affording a proof that at that period or previously England was joined to the Continent, over which land these animals probably migrated, so that the insular position of England is but of comparatively modern date. A further study of these remains yields to us the important evidence that in this area there were representatives of a northern and southern fauna,—the commingling of which, as the reindeer and musk ox with the hippopotamus and rhinoceros, may have arisen from the Thames area having been on the borders of two distinct zoological provinces. While, however, the majority of the Mammalia belong to extinct species, the Mollusca with which they are associated are, with two or three exceptions, still found in Britain; one shell, however, the *Cyrena fluminalis*, is at present restricted to the Nile; this assemblage in the old brick-earth deposits of the Thames valley indicating a greater tenacity of life in the molluscan than in the mammalian fauna.

## WEINHOLD'S EXPERIMENTAL PHYSICS

*Vorschule der Experimentalphysik.* Von Adolf F. Weinhold, Professor an der Königl. höheren Gewerbschule zu Chemnitz. Erster Theil. (Leipzig, 1871. London: Williams and Norgate. Pp. 208.)

THIS is by far the best school-book of Physics we have ever seen. Its leading characteristic will be understood by many readers from the statement that it is intended to be for Physics what Stöckhardt's well-known "Vorschule der Chemie" is for Chemistry. The author endeavours, as far as possible, to bring the reader into personal contact with physical experiments and phenomena. He does this by describing in detail, not only how to produce the phenomena and make the experiments of which he speaks, but also, in most cases, how to make the necessary apparatus with such materials as are to be got in almost any country-town. The result is that we cannot imagine a boy who possesses, in any degree, what is called a "mechanical turn" reading this book, without wanting to set to work at once to make experiments for himself. One of the main objects of the book is, in fact, to give a definite and useful direction to the "taste for making all sorts of things," which, as the author says, is so common amongst boys. With this intention he has made a careful choice of such experiments as, "by their pleasing nature, are adapted to awaken an interest in physical studies, but has avoided, as far as possible, the introduction of mere playthings, and has altogether excluded everything like conjuring tricks." With regard to the expenditure required for making the experiments described, the author estimates it at about fifty thalers (7*l.* 10*s.*) or a little more, but points out to those who are unwilling or unable to incur the gradual outlay of this sum, how much may be done for far less. A hammer and pair of pliers, "a small vice, a hand-vice, a few files, some sheet brass and wire, a spirit-lamp, a stock of glass tubing, and one or two retort-stands, suffice for a great deal, and should be provided before everything else."

We are glad to think that there are nowadays in this country a considerable and increasing number of schoolmasters who are anxious to introduce Experimental Physics as a regular part of school work, but who are deterred partly by the expense of the apparatus commonly thought necessary, and partly from the want of clear and full instructions as to how it should be used when they have got it. To any such we can do no greater service than to recommend them immediately to obtain Prof. Weinhold's book, and to follow implicitly the directions he gives.

We must not, however, leave it to be supposed that this work is simply a collection of practical instructions for making apparatus and experiments. Although each subject, even in the part now before us (which includes the general properties of bodies, statics, dynamics, hydrostatics, and hydrodynamics) is discussed from the point of view afforded by the particular experiments which it is intended that the reader should make for himself, the general conclusions to which the results of these experiments lead are always clearly and carefully pointed out; and a student who would work patiently through the book would lay a broad and sound foundation for a more special study of Physics, and would certainly know far more of the subject than the majority of those who have gone through in the ordinary way books of much greater pretensions. Above all, he could not fail to acquire one indispensable qualification for further progress, namely, the faculty of thinking about physical phenomena as of things which actually exist, and are just as fit subjects for the exercise of common sense as any of the facts of everyday life. This we consider is in itself no small excellence; for whoever has had any experience in teaching the elementary parts of Physics, must have become aware that very often the chief result of the *à priori* method, adopted in nearly all English books on the subject, is to make students think that the forces and motions of which Natural Philosophers talk are, if not fictions invented on purpose to puzzle them, at least so unlike anything that is ever met with in common experience, that it is useless to try to understand anything about them. In fact we believe that, except for students whose previous training has accustomed them to recognise the special cases that are included under general mathematical expression, the majority of English treatises on the fundamental parts of Physics are rather a hindrance than a help to a clear conception of the ideas they profess to explain. The true method of teaching Physics, at least to beginners, we believe to be the one adopted in this book, whereby the learner is made to acquire an actual personal acquaintance with all the most important facts of the science, through the observations which establish them having been brought within the range of his personal experience.

If this is done at all thoroughly, the modes of expressing the laws of physical phenomena in technical mathematical language may almost be left to suggest themselves when the requisite progress shall have been made in pure mathematics.

## BOOK SHELF

*The Sub-tropical Garden; or Beauty of Form in the Flower-Garden.* By W. Robinson, F.L.S. With Illustrations. (London: Murray, 1871.)

THIS volume is a sequel to the valuable works which Mr. Robinson has already given us—"The Wild Garden," and "Alpine Flowers for English Gardens." The title is a misleading one, and is thus defined by the author:—"Sub-tropical gardening means the culture of plants with large and graceful or remarkable foliage or habit, and the association of them with the usually low-growing and brilliant flowering-plants now so common in our gardens, and which frequently eradicate every trace of beauty of form therein, making the flower-garden a thing of large masses of colour only." It is a pity that Mr. Robinson has assisted to perpetuate so erroneous a designation, which conveys the idea of the culture of tender plants fitted only for our hothouses. The greater part of the volume is occupied with an alphabetical list of plants suitable for the above purpose, with description of the peculiarities of their foliage, mode of cultivation, and propagation, &c. The accompanying cut is intended to suggest the effects to be obtained from young and vigorous specimens of hardy, fine-leaved trees. In all these points Mr. Robinson

AILANTUS AND CANNAS

may be safely followed as a guide, combining great practical knowledge of gardening, an extensive acquaintance with the native habits of plants, and an artist's eye to the beauty of form and combination. The following sentence gives his idea of what gardening should be. "Nature, *in puris naturalibus*, we cannot have in our gardens, but Nature's laws should not be violated; and few human beings have contravened them more than our flower-gardeners during the past twenty years. We should compose them from Nature, as landscape artists do. We may have in our gardens, and without making wildernesses of them either, all the shade, the relief, the grace, the beauty, and nearly all the irregularity of Nature." A. W. B.

*The Meteoric Theory of Saturn's Rings, considered with Reference to the Solar Motion in Space; also a paper on the Meteoric Theory of the Sun.* By Lieut. A. M. Davies, F.R.A.S. (London: Longmans & Co.)

PROF. CLERK MAXWELL, in his remarkable essay "On the Stability of Saturn's Rings," which gained the Adams Prize in 1856, exhaustively examines the various theories of the constitution of these rings, and decides what are the impossible mechanical conditions for their maintenance and what is the possible one. He shows that they cannot be solid or rigid; he disposes of the possibility of their being continuously fluid, and he concludes that "the only system of rings which can exist is one composed of an indefinite number of unconnected particles revolving round the planets with different velocities according to their respective distances." Lieut. Davies appears not to have seen Prof. Maxwell's work, as he ascribes to the perusal of a derived exposition of it the enlistment of his interest in favour of the Satellite theory of the rings. Having espoused this theory, he has sought an explanation of Saturn's possession of a ring system in the supposition that the planet has picked up streams of meteors in its path through space; this path being a spiral resulting from the planet's orbital motion in conjunction with the proper motion of the solar system. The spirals traversed by the four planets beyond Mars are projected in accordance with Lieut. Davies's assumption of the solar motion, in order to show that Saturn is (excepting Jupiter) more favourably circumstanced than other planets for encountering wandering streams of meteors that are drawn towards the sun; while, from consideration of the masses and the distances of the two planets from the sun, it is argued that Saturn is better circumstanced than Jupiter for attaching such streams permanently to his system in the form of rings. The details of Lieut. Davies's work can only interest those who are closely concerned with cosmical hypotheses. We will merely remark that he appears to place too great faith in figures: he gives the hourly rate of the solar motion in space to a mile, and quotes the solar parallax to four places of decimals! The velocity is a very uncertain element of the solar motion, and a small alteration of the rate assumed by Lieut. Davies would greatly modify his conclusions. The book includes a paper on the meteoric theory of the sun, a theory with which the author is blindly enraptured. He claims that it "accounts for every phenomenon hitherto observed on the solar surface." He holds that the "willow leaves" are meteoric flights just falling into the sun; that the spots are spaces upon which no meteors are raining; that the periodicity of spots is due to the action of the planets in pulling "the meteoric matter outwards from the surface of the sun into larger orbits, thus temporarily delaying its precipitation," and that "the form of the spots bespeaks their origin as extraneous to the solar machinery. Were they cyclones in the atmosphere, they would invariably present a rotatory appearance . . . . This must result were the origin of the spots in a plane parallel to the tangential plane at the sun's surface; but would not do so if their origin lay in the normal to that plane, as it does in the meteoric theory. A careful study of Mr. Carrington's valuable series of observations of solar spots is decidedly unfavourable to the conclusion that they have forms of rotation." Lieut. Davies is either innocently or wilfully ignorant of the palpably cyclonic appearance which spots frequently present, and which has been frequently depicted by observers who have studied the characteristic features of individual spots. This study did not concern Mr. Carrington. The devotees of the meteoric theory of the sun's maintenance will not feel that it has been much advanced by Lieut. Davies's over-straining advocacy.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### The Eclipse Photographs

In his letter published in Nature on the 1st of June, and to which Mr. Brothers courteously replies in your issue of the 15th, the writer briefly touched upon four different points bearing on the value of the eclipse photographs. Those points are :—1st, The possibility in a comparatively cloudless sky of a luminosity akin to that represented under the name of the corona on page 370 of the number of Nature issued on March 9, but caused only by moisture in our atmosphere, as illustrated by his instance of what he termed a lunar halo ; 2ndly, The presence of a luminosity on what he apprehends should have been the dark disc of the moon, as represented in the photograph of the American observers at Cadiz ; 3rdly, The indifferent definition of the published photograph ; and 4thly, The evidence as presented by the photograph of the identity of the coronal rifts. Referring to the first of these points, Mr. Brothers "fails altogether to see the connection between the solar corona and a lunar halo." If the term halo, as applied to any appearance pertaining to the moon, is confined to the ring of light so frequently to be observed apparently surrounding the lunar disc, the writer would substitute the word "luminosity" for halo. The appearance he alluded to resembles Mr. Brothers's woodcuts of the corona already mentioned, more than anything else to which he can compare it, and in common phraseology may be described as a patch of light surrounding the apparent position of the moon, extending from it to a distance varying from about one degree to two or two and a-half, and having an irregular or rifted outline. The phenomenon in question was observed by the writer when the atmosphere was in such a condition that no trace of cloud whatever was visible for a distance round the moon of some thirty or forty degrees. He mentions this merely to show that even when no visible condensation of moisture is present, an appearance—attributable to nothing but atmospheric moisture, and analogous to what is termed the solar corona—is not to be regarded as out of the common, and nothing to be wondered at. Touching the second point, Mr. Brothers would seem to be of opinion that a solar corona may be seen even when the dark disc of the moon intervenes between it and the observer's eye ; for he says of the luminosity in question that if caused by our atmosphere it would extend all round and all over that disc. The point at issue here is a very simple optical question, in the discussion of which space would be merely wasted, and in reference to which the writer would simply reiterate the opinion he has already expressed, that the luminous appearance as seen extending on to the disc of the moon in the Cadiz photograph, is (if it were visible outside the camera) attributable to nothing but the influence of the terrestrial, or of a lunar atmosphere. Whilst speaking of the American observer's picture, he would remark in answer to two observations by Mr. Brothers, first, that he is not in "possession of exclusive information" concerning the circumstances of its production ; and secondly, that he does not assume that it was taken under conditions less favourable than those prevailing at Syracuse. He does, however, assume that that photograph either represents only the phenomenon to which the instrument used in its production was directed, or that it represents something in addition to that phenomenon. If its representation is confined to the phenomenon, then upon the grounds already shown, he considers that what is called the coronal light in the Cadiz picture not only may be, but most certainly is, in part at any rate, merely the result of atmospheric moisture. If, however, the American observers were unfortunate enough to represent in their photograph a luminosity not belonging to the eclipse at all, then he considers that what did belong to the eclipse is not distinguishable in their picture from what did not. In short, whether the Cadiz picture does or does not represent only what it should do, the writer is of opinion that any evidence it can afford respecting the identity of the coronal rifts must be other than *satisfactorily* conclusive.

Concerning the third point, namely the "indifferent definition," to which he directed attention, Mr. Brothers admits the validity of his remarks, so far as Syracuse picture No. 5 is concerned ; and this picture, it may be observed, Mr. Brothers would seem to consider the best of his series, inasmuch as it is the only one procurable of the opticians in Manchester, and also is the one selected for an engraved representation in the pages of Nature.

Respecting the last of the four points on which the writer has taken the liberty to remark, viz. the evidence afforded by the photographs of identity in the coronal rifts as seen at Cadiz and Syracuse, he is of opinion that he has already said sufficient to justify his observation that that evidence is not "satisfactorily conclusive." If, however, Mr. Brothers should entertain a different opinion, and the Editor of Nature think the matter worthy of further space, he will make a few other remarks, looking at the subject from an altogether different point of view.

In conclusion, the reader should be reminded that the subject under discussion is not the astronomical question—Is the sun surrounded by a medium which is illuminated by his rays and rendered visible under favourable circumstances to the eye of a terrestrial observer? but, assuming this to be the case—Is the luminosity indicated in the photographs under consideration a representation of that medium or is it not?

The writer does not doubt the existence of such a medium round the body of our great luminary (though, assuming it, ought there not to be some trace of it visible above the western horizon, immediately after sunset in a dry climate?), but he does doubt whether the patch of light depicted in the photographs of the late solar eclipse is in the main other than a phenomenon of terrestrial meteorology.

D. Winstanley

### The Solar Parallax

Mr. Proctor entirely misunderstands me if he thinks that my criticism on his account of the solar parallax had reference to any failure on his part to give prominence to the discussion between Mr. Stone and myself, or to correctly apprehend that discussion. To point out all the imperfections and inaccuracies in his account would take a whole column of Nature, and I have neither the time nor the disposition to make such a display of the accidental errors of a fellow-worker in the astronomical field. But, if Mr. Proctor desires it, I will constitute him judge in his own case in form and manner as follows : I will send him privately the list of specifications on which my criticism was founded. If, in his opinion, this list fails completely to sustain the proposition that his history of recent researches on the solar parallax is "imperfect and inaccurate in a remarkable degree," he is to publish it with any defence he chooses to make. Otherwise he may keep it for his own private use in case he brings out a second edition of his work. The kind spirit in which he has taken my remarks is highly appreciated, and I shall be happy to hear from him privately on the subject.

Simon Newcomb

### Halo in the Zenith

At 20 minutes to 6 P.M. on Saturday 10th inst., I witnessed a natural phenomenon which I understand is very unusual. It was a portion of a halo around the zenith. Take the zenith as centre, and with a radius of 20° describe an arc of 120° parallel to the horizon, and having 60° on each side of due west. This gives the position in the heavens, as nearly as I could determine, using no other means of observation except my eyes. The convex surface was red, concave blue. Other colours were also apparent, and were very distinct towards the centre of the arc of 120°, becoming much diluted at a greater distance. The horns of the arc gradually faded away amid the cirri with which the whole sky was covered, its blue colour being only partially obscured. You could tell at a glance that the zenith was the centre of the halo. The phenomenon only continued five minutes from the time I first saw it, until it disappeared altogether. It has been suggested to me that probably the azimuth of the sun and that of the centre of arc of 120° coincided. I think this is very likely, but I did not note it particularly at the time. The wind was easterly, and the sun shone brightly where I was standing. If any of your numerous correspondents would favour me with an explanation of the above I would be greatly obliged. No other halo or portion of a halo was visible at the time.

### What is Yellow Rain?

The letter of Mr. A. Ernst in Nature, May 25, on a recent case of "yellow rain," possesses considerable interest to all who have paid any attention to early prodigies ; because his determination of the nature of that phenomenon, if true, serves to confirm the statements of others who have observed similar occurrences. The confirmation, however, only extends so far, as proving that, a yellowish substance has been seen on bodies after a fall of rain. I can mention instances where sudden appearances have taken place, and would be called *yellow* rain, without the aid of ordinary rain.

The earliest case I am acquainted with occurs in Pliny,* who says:—

"In like manner it rained iron in Lucania, the year before that in which M. Crassus was slain by the Parthians; and together with him all the Lucani, his soldiers, of whom there were many in his army. That which came down in the rain resembled in some sort sponges; and the aruspices gave warning to take heed of wounds from above."

This records two kinds of showers, viz., iron and sponges, but they were, I believe, one shower, although I have never seen any explanation of this curious passage. An account of a few "preternatural showers," I have lately come across, seems to contain exactly the information I have been seeking to clear up this difficulty. As it is novel, and was written in apparent ignorance of Pliny's record, it has at the present time some value. It says, in attempting to explain the cause of "red snow":—

"This singular phenomenon, which has been observed in the Arctic regions, seems to be owing to the presence of oxide of iron in a state of minute division, and also of a resinous vegetable principle of an orange-red colour, belonging apparently to some lichen, of which too, perhaps, the iron may form one of the immediate principles."†

This explains Pliny to a certain extent; in the common ignorance of both ascribing the redness of the snow to iron rust, or oxide of iron, and the matter that remained after the dissolution appearing of a sponge-like texture, and called a sponge or sponges by Pliny, and a resinous vegetable principle of an orange-red colour by Phillips.

This I think is the most probable meaning, and is, perhaps, the earliest "yellow" shower on record. The colour, as stated by the latter, is nearly correct, as shown by the investigation of MM. De Candolle and Prevost, who discovered, microscopically, that the red snow was due to the presence of small globules of a bright red colour, which were surrounded by a gelatinous membrane, transparent and slightly yellow, and were mixed with fragments of moss and dust. "An examination of the crimson snow found by Captain Ross in the Arctic regions by M. De Candolle proved it to be identical with the Alpine red snow; the globular bodies are of a vegetable nature, and were once thought to belong to the *Uredo*, but M. Bauer disproved this, and named the plant *Protococcus nivalis*. There are cases, however, in which the presence of animalcules gives a reddish tinge to snow."‡

Honeydew is mentioned by Pliny (Bk. XVIII. c. 28), who states that a great many of the ancients affirmed that dew burnt up by the scorching sun is the cause of honeydew on corn.

In the *Chronicum Scotorum* is the earliest direct record of a "shower of honey" I know of.§ It says: "A.D. 714 . . . . it rained a shower of honey upon Othan Bec. . . . ."

When it is known that any sudden appearance, giving a colour to the ground, or prominent places, or on trees, &c., is generally thought to have descended from above, this passage is quite intelligible. The "shower of honey" was nothing more than a "secretion of *aphides*," whose excrement has the privilege of emulating the sugar and honey in sweetness and purity."‖ Some contend that it is due solely to the exudation of the saccharine juices of trees; but, feasible as this may seem, it is not sufficient to account for this phenomenon, which often extends over very large tracts of land. If the exudation is promoted by the aphides, and the dew increased by their own excrement, then this explanation is, I believe, the true one. The former view is not to be discarded without some consideration; for one observer states that, in the course of thirty years he had attended to this subject, he had never met with any honeydew which did not seem to him to be clearly referable to aphides as its origin.¶ This view does not go counter to what I conceive to be the correct one; for exudations do take place, and the quantity of "dew" can be increased by the aphides.

### Black Rain

THE following notice of a shower of black rain, which has been sent to me by my friend Mr. G. J. A. Walker, of Norton Villa, near Worcester, though not so exact in its description as I could have wished, may call attention to the subject, and elicit a more detailed account, if in this ungenial season rain of a similar nature has fallen elsewhere. Mr. Walker's residence is about three miles south-east of Worcester, and he says, that after three or four hours of common rain on Tuesday June 6, it became suddenly dark about seven o'clock, P.M., and shortly after a rain like ink poured down for a quarter of an hour, after which light returned upon the scene. The following morning the sheep at Woodhall (an adjacent farm) appeared as if their fleeces had been dyed black; also the dog and a grey pony that Mr. Walker had out in a field close by appeared as if they had been rolling in soot or in a coal hole. The black matter brought down with the rain was of an adhesive nature, and at Littleworth, within a mile of Norton, where this rain fell into some tubs, it was observed to be as black as ink. This black rain was particularly remarked, as clear ordinary rain had been falling for some hours on the day mentioned, but had ceased an hour previously to the commencement of this black downfall. The actual rain of that evening did not extend to Worcester, but I have a note taken at my residence here at the time, that "the gloom was singular and overpowering all the evening." I regret that, going into Herefordshire the next day, I was not aware of this occurrence till some days after, and none of the black rain or the adhesive matter it brought down had been preserved for microscopical examination. EDWIN LEES

### A New View of Darwinism

I HAVE noticed that NATURE is very catholic in its sympathies, and allows all views which are not palpably absurd to be discussed in its pages, and I therefore venture to ask for some space in which to present a few of the difficulties which have been suggested by Mr. Darwin's theory of Natural Selection, and which have not, so far as I know, been as yet discussed. I have not the taste for the language nor the arguments which were used by a *Times* reviewer, and I have much too great a reverence for one of the most fearless, original, and accurate investigators of modern times, to speak of Mr. Darwin and his theory in the terms used by that very ignorant person. Approaching the subject in this spirit, and knowing how very small a section of biologists are now opposed to Mr. Darwin, I may be very rash, but hardly impertinent, in stating my difficulties.

I cannot dispute the validity and completeness of many of Mr. Darwin's proofs to account for individual cases of variation and isolated changes of form. Within the limits of these proofs it is impossible to deny his position. But when he leaves these individual and often highly artificial cases, and deduces a general law from them, it is quite competent for me to quote examples of a much wider and more general occurrence that tell the other way. In this communication I shall confine myself to Mr. Darwin's theory, and shall not trepass upon the doctrine of evolution, with which it is not to be confounded.

The theory of Natural Selection has been expressively epitomised as "the Persistence of the Stronger," "the Survival of the Stronger." Sexual selection, which Mr. Darwin adduces in his last work as the cause of many ornamental and other appendages whose use in the struggle for existence is not very obvious, is only a by-path of the main conclusion. Unless by the theory of the struggle for existence is meant the purely identical expression that those forms of life survive which are best adapted to survive, I take it that it means in five words the Persistence of the Stronger.

Among the questions which stand at the very threshold of the whole inquiry, and which I have overlooked in Mr. Darwin's books if it is to be found there, is a discussion of the causes which produce sterility and those which favour fertility in races. He no doubt discusses with ingenuity the problem of the sterility of mules and of crosses between different races, but I have nowhere met with the deeper and more important discussion of the general causes that induce or check the increase of races. The facts upon which I rely are very common-place, and are furnished by the smallest plot of garden or the narrowest experience in breeding domestic animals. The gardener who wants his plants to blossom and fruit takes care that they shall avoid a vigorous growth. He knows that this will inevitably make them sterile; that either his trees will only bear distorted flowers, that they will have no seed, or bear no blossoms at all. In order to induce flowers and fruit, the gardener checks the growth and vigour of the plant by pruning its roots or its branches, depriving it of food, &c., and if he have a stubborn pear or peach tree which has long refused to bear fruit, he adopts the hazardous, but often most successful, plan of ringing its bark. The large fleshy melons or oranges have few seeds in them. The shrivelled starvelings that grow on decaying branches are full of seed. And the rule is universally recognised among gardeners as applying to all kinds of cultivated plants, that to make them fruitful it is necessary to check their growth and to weaken them. The law is no less general among plants in a state of nature, where the individuals growing in rich soil, and which are well-conditioned and growing vigorously, have no flowers, while the starved and dying on the sandy sterile soil are scattering seed everywhere.

On turning to the animal kingdom, we find the law no less true. "Fat hens won't lay," is an old fragment of philosophy. The breeder of sheep and pigs and cattle knows very well that if his ewes and sows and cows are not kept lean they will not breed; and as a startling example I am told that to induce Alderney cows, which are bad breeders, to be fertile they are actually bled, and so reduced in condition. Mr. Doubleday, who wrote an admirable work in answer to Malthus, to which I am very much indebted, has adduced overwhelming evidence to show that what is commonly known to be true of plants and animals is especially true of man. He has shown how individuals are affected by generous diet and good living, and also how classes are so affected. For the first time, so far as I know, he showed why population is thin and the increase small in countries where flesh and strong food is the ordinary diet, and large and increasing rapidly where fish or vegetable or other weak food is in use; that everywhere the rich, luxurious, and well-fed classes are rather diminishing in numbers or stationary; while the poor, under-fed, and hard-worked are very fertile. The facts are exceedingly numerous in support of this view, and shall be quoted in your pages if the result is disputed. This was the cause of the decay of the luxurious power of Rome, and of the cities of Mesopotamia. These powers succumbed not to the exceptional vigour of the barbarians, but to the fact that their populations had diminished, and were rapidly being extinguished from internal causes, of which the chief was the growing sterility of their inhabitants.

The same cause operated to extinguish the Tasmanians and other savage tribes which have decayed and died out, when brought into contact with the luxuries of civilisation, notwithstanding every effort having been made to preserve them. In a few cases only have the weak tribes been supplanted by the strong, or weaker individuals by stronger; the decay has been internal, and of remoter origin. It has been luxury and not want; too much vigour and not too little, that has eviscerated and destroyed the race. If this law then be universal both in the vegetable and animal kingdoms, a law too, which does not operate on individuals and in isolated cases only, but universally, it is surely incumbent upon the supporters of the doctrine of Natural Selection, as propounded by Mr. Darwin, to meet and to explain it, for it seems to me to cut very deeply into the foundations of their system. If it be true that, far from the strong surviving the weak, the tendency among the strong, the well fed, and highly favoured, is to decay, become sterile, and die out, while the weak, the under-fed, and the sickly are increasing at a proportionate rate, and that the fight is going on everywhere among the individuals of every race, it seems to me that the theory of Natural Selection, that is, of the persistence of the stronger, is false, as a general law, and true only of very limited and exceptional cases. This paper deals with one difficulty only, others may follow if this is acceptable.

Derby House, Eccles HENRY H. HOWORTH

### Ocean Currents

MR. PROCTOR concludes his letter on Ocean Currents, in NATURE for June 15, with the remark that in theories respecting oceanic circulation "the vast distance separating the Polar from the Equatorial regions must not be overlooked." Will you allow me to point out to him that in the experiment he suggests, that vast distance is entirely overlooked; that, in fact, any such experiment, with whatever difference of detail it may be performed, whether in his cylinder or in Dr. Carpenter's trough, in no way illustrates the natural condition of things, and in no way tends to answer that objection to the "temperature" theory of currents which is founded on the infinitesimal nature of the thermometric gradients. The difference of temperature between Arctic and Equatorial water is about 50° F., or 1° F. in 100 miles; or, reducing it to smaller units suitable for an experiment, is $\frac{1}{500000}$ of a degree in one foot; this, if the experimental trough is five feet long, or if the cylinder is ten feet in diameter, gives an extreme difference of $\frac{1}{100000}$ of a degree of Fahrenheit's scale. Can such a difference be represented in any experiment? I think not; but no experiment which shows a much greater relative difference can be accepted as satisfactory; for it is the infinitesimal nature of the thermometric gradient existing in the ocean that constitutes the physical objection to the temperature theory. There are other objections which I will not allude to now; but it is manifestly no answer to this one objection to show that under certain other circumstances—which bear no resemblance in degree to those of nature—hot water and cold will establish a circulation. I, for one, have, for a good many years, been perfectly well aware that they will; but I doubt if it has ever been shown that a sensible motion will result from a thermometric gradient of $\frac{1}{500000}$ of a degree in a foot.

J. K. LAUGHTON

### Alpine Floras

THE fact mentioned in last week's NATURE of the absence of any Alpine flora on the Atlas Mountains, Morocco, though disappointing, is interesting. It seems to show that, during the glacial period, icebergs did not drift to the Atlas. This, however, must have been from local causes only. Mr. Wallace found a European flora on a mountain in the Eastern Archipelago—I think in Borneo—which, most probably, must have got there during the glacial period. JOSEPH JOHN MURPHY

Old Forge, Dunmurry, Co. Antrim, June 19

### A Suggestion

Is it possible that the following facts may account for the presence of *Elastrus dolosus* in the Azores? At all events, I offer them as suggestive, and for the information of Messrs. Wallace, Godman, Murray, Crotch, &c.

Lawrence Almeida, son of the first Portuguese Viceroy in India, was the first European known to visit the coast of Madagascar in the year 1506. The Portuguese circumnavigated the whole island within two years, and subsequently constantly anchored at it in their voyages to the East Indies. They also established a settlement on a steep rock on the bank of the river Franchere and near the village of Hatore, in the province of Anosi (*i.e.*, at the south-eastern extremity of the island). The valuable timber, as ebony, as well as the rich dye-woods, would be well worth taking to Europe, and thus doubtless afforded a conveyance for living larval or pupal Elaters, without any rare or improbable concurrence of events, to the Portuguese islands in the Atlantic. Many of the extremely beautiful and attractive flowering shrubs and plants would also not improbably be forwarded to Europe by the same route, in which some Élateridæ might find shelter. Is the lapse of 300 years sufficient to account for change of development? S. P. OLIVER

Southsea

## HYDROUS SILICATES INFECTING THE PORES OF FOSSILS

DR. T. STERRY HUNT directed attention some time ago* to a remarkable limestone of Silurian age from Pole Hill, New Brunswick, in which I had found the

* Proceedings of the Natural History Society of Montreal.

cavities of fossil crinoids to be filled with a siliceous substance perfectly injecting their most delicate cellular structure, and which Dr. Hunt, on chemical analysis, found to be a hydrous silicate allied to jollyte. I have since, in examining with the microscope various specimens of limestone in the collection of McGill College, met with a British example of this kind of injection, to which I would wish to direct the attention of your microscopists. It is a specimen of olivaceous, imperfectly crystalline limestone, labelled Llangedoc, Wales. The only distinct fossil which it contains is a small body having the characters of the genus *Verticillopora*. It is filled, however, with crinoidal fragments and fragments of shells, and, when sliced, displays a few very minute univalves, probably of the genus *Murchisonia*, and also portions of a sponge-like organism with square meshes. The pores and cavities of many of these fossils are filled with a greenish or brownish finely crystalline silicate, which must have been introduced when the organic bodies were still recent, and which Dr. Hunt has ascertained to have the following composition :—

| | |
|---|---|
| Silica | 35·32 |
| Alumina | 22·66 |
| Protoxide of Iron | 21·42 |
| Magnesia | 6·98 |
| Potash | 1·49 |
| Soda | 0·67 |
| Water | 11·46 |
| | 100·00 |

So that this mineral is almost identical with jollyte. The fact that it fills the minute pores and cavities of the fossils can be seen in transparent slices, especially under polarised light, and also in decalcified specimens. The filling is not, however, so perfect as in the New Brunswick specimens above alluded to. The best, which I suppose to be Upper Silurian, is worthy of the attention of those who may have access to it, as presenting an interesting example of Silurian fossils preserved in the same way with the Laurentian Eozöon. It affords another palæozoic illustration of a mode of preservation of the structures of fossils, which, though perhaps more prevalent in the Laurentian and Cretaceous than in any intervening periods, is to be met with here and there throughout the geological series, and is of equal interest to the palæontologist and the chemical geologist. J. W. DAWSON

Montreal, June 8

## NEW THEORY OF SUN-SPOTS

A LATE number (1,835) of the *Astronomische Nachrichten* reproduces from the notices of the Royal Saxon Scientific Society a paper on the above subject by Professor Zöllner. The author believes that he is the first who has attempted to account for the periodicity of the spots by agencies confined to the sun itself, while he rejects the notion of planetary influence to which the phenomenon has been commonly attributed. In this, however, he is not quite correct, for in the April numbers of *Cosmos* last year there appeared a transcript of a paper read before the Belgian Academy of Sciences, by M. Bernaerts, who tries to explain the various phenomena of the sun spots without reference to any extra-solar action.

Prof. Zöllner, like M. Bernaerts, accepts the theory of a liquid forming the surface of the sun ; but while the Belgian *savant* considers the spots as perforations in the liquid layer traversed by downpouring currents of gases that had previously risen through the liquid from the gaseous nucleus, Prof. Zöllner believes the spots to be formations of slag or scoriæ caused by a certain local cooling of the liquid surface. Over this glowing liquid is a glowing atmosphere, which contains, in a vaporous state, a portion of the matter belonging to the liquid. The same as on the earth, if this atmosphere is cloudless and calm, radiation and cold are induced ; and where this occurs the slag-like products are formed, and spots become visible. But vaporous condensation is also a consequence of the cold. Clouds, therefore, are developed, the radiation is checked, the liquid surface regains its former heat, and the spots are dissolved and disappear ; so that the very cause that effects their formation also tends to their dissolution. The repetition of the same operations gives the spots the character of "intermittent phenomena ; " but their occurrence, as well as their duration, depends on such a complication of meteorological processes that those phenomena cannot be considered otherwise than as perfectly casual.

The action of a spot on the atmosphere in cooling it, and causing cloudlike condensations that oppose radiation and restore the heat, makes the presence of a great spot unfavourable to the formation of other spots, and Prof. Zöllner arrives at the conclusion that "a sun-spot exerts within a certain area, and according to its size, an influence that prevents or obstructs the formation of other sun-spots." Thus, it appears, he explains the *isolation* of the spots. But they occur also in groups over a wide extent of surface, and he infers that "the same conditions of the solar atmosphere that induce the formation of a spot in any one place, prevail in general over a larger space than that occupied by the spot, so that within the area influenced by those favourable conditions, the simultaneous production of other spots is more likely than elsewhere." The size of the spots depends plainly not on the amount of radiation alone, for the slag like products have cohesive properties like our ice-flakes.

I candidly admit that all this is by no means so very plain to me after reading the theory of the isolation of the spots ; and I would refer the reader to the original for a better understanding of the two theories relating to the isolation and the grouping, than I have been able to attain to. I would also refer to the original for the Professor's views of the oscillations of solar temperature and the periodicity of the spots, which he discusses in several paragraphs.

The appearance of the spots in certain zones on both sides of the equator he explains as the effect of currents in the liquid stratum. He asks us to imagine, in the first place, a motionless, atmosphere-enveloped globe maintained at a constant high temperature ; and, after explaining the results, he tells us to fancy such a globe with a liquid envelope heated at bottom by contact with the surface beneath it, and cooled above by radiation. The lower parts of the liquid have a tendency to rise on account of their lower specific gravity, but their ascent anywhere is impossible unless somewhere else a sinking takes place. With equal conditions everywhere prevailing, no motion in either direction could occur ; but those equal conditions do not exist on the sun, whose axial rotation diminishes the force of gravity at the equator. This therefore favours an ascent of the heated lower portions of the liquid at the equator, and a sinking of the cooler upper parts in the regions of the poles. Two streams are thus induced ; one below flowing toward the equator, and one above in a contrary direction. The former as it progresses gains in temperature by contact with the hot surface of the globe ; while the latter in its sub-aerial route loses heat by radiation. Thus the polar regions of the sun are made cooler than the equatorial, as has, in fact, been shown by Secchi's investigations.

These movements in the enveloping liquid (*flüssigen Umhüllungen*) are the cause of atmospheric disturbances, producing in certain places a lowering of temperature and condensation. The fall in temperature is favoured in two ways—by the mixing of the equatorial and polar streams in high latitudes, and by the ascent of an air-current at the equator. As this air-current cools in rising its vaporous constituents are partly condensed in the form of clouds. Yet these clouds need not at all be of so low a temperature as to appear to us like darkened areas; but, on the contrary, when we consider the high temperature of the sun, we may conceive them to be formed of matter in a glowing state, so that products of condensation such as these could scarcely, if at all, be perceived on the luminous disc of the sun. On the other hand, the author believes that in the cases of the great and still warm planets, Jupiter and Saturn, we see the sun-illumined aqueous clouds that rise in bright belts at the equator. We believe the author's object is to show that, while the visible effects of condensation appear in the atmospheres of Jupiter and Saturn, it is only on the liquid surface that they are exhibited by the sun, and thus its atmosphere remains transparent.

We have, accordingly, in the equatorial zone and in the higher latitudes distinct regions of preponderating atmospheric cloudiness, and between them, like the zones of the trade winds on the earth, lie areas of relative clearness. All this, if I rightly understand the author, is not apparent to the observer, but its effects are seen on the glowing liquid solar surface, where, beneath the unclouded areas, radiation is more induced than in other places, and the formation of sun-spots is the consequence.

To the foregoing causes of atmospheric disturbance must be added the eruptions of hydrogen that are shown by the spectroscope.

On the whole it is the *stillness* and *clearness* of certain parts of the atmosphere that induce the formation of spots; and, as the final result of his arguments, Prof. Zöllner sums up as follows:—

"The sun-spots are slag-like products of a cooling process caused by the radiation of heat from the glowing liquid surface, and they dissolve again in consequence of disturbances of equilibrium in the atmosphere which are brought on by themselves. If these disturbances are not merely local, but of more general extent, then, at the times of such general atmospheric disturbances, the formation of new spots is but little favoured, because the essential conditions of a considerable lowering of temperature are wanting, namely—*stillness* and *clearness* of the atmosphere. When the atmosphere, after the dissolution of the spots, gradually tranquillises, the process begins anew, and it assumes a *periodic* character, while the conditions of the solar surface are to be regarded as constant in the *mean* of lengthened periods. The local distribution of the spots must, according to this theory, depend on the zones of greatest atmospheric clearness, which, as has been shown, are generally coincident with the zones of the greatest development of the spots."

Such, as they appear to me, are Prof. Zöllner's views of the sun's spots; and if, as is quite possible, I have not everywhere succeeded in comprehending him, I freely admit that any misconstruction I have made may be attributable to my own shortcomings rather than to his. At the same time I cannot but regard his style as considerably difficult and diffuse, and not perfect in the logical concentration which is so necessary for the clear enunciation of a theory. In some points his conclusions seem, undoubtedly, to agree with observations—for instance, as regards the vaporous masses that are formed over the spots, and which appear sufficiently attested by their strong absorption lines in the spectrum. In the main, however, I cannot say, so far as I may venture to give an opinion, that he has been more successful than other theorists on the same subject; and among several objections which have occurred to me as affecting his views, I will venture to state the following:—

1. Regarding the establishment of currents in the liquid envelope, Prof. Zöllner affirms that in this way alone could the more heated and specifically lighter portions of the liquid at the bottom make their way to the surface; but this appears to me incorrect when we consider that in freezing water there is an interchange of the upper and lower strata until congelation begins, and this without the intervention of currents.

2. He defines the spots as scoriaceous products floating on the liquid surface. The liquid, however, is moving in a current from the equator poleward, and, if so, I would ask how is it that the spots show no tendency to be carried along with it in that direction? I do not believe that any such general tendency has been observed.

3. He makes no attempt to account for the very striking and suggestive appearances of the penumbra, which led Wilson to regard the spots as openings or depressions in the photosphere. Neither does he try to explain the distinct boundaries of the nucleus, the umbra, the penumbra, the light bridges, nor the deeper shading of the penumbra round its exterior limits.

4. The current cools in its advance poleward, and the polar regions are, as the professor tells us, the coolest parts of the sun. Then if, according to his theory, the spots are the products of cold, why do they not increase in development up to the poles? He assumes, indeed, that the cold induced in the polar regions produces clouds in the atmosphere, which are unfavourable to the production of spots; but they are so only as they check radiation and contribute to heat, and if, notwithstanding this, the polar regions are still found to be the coldest, and if cold is the cause of the spots, there seems a defect in the hypothesis. The professor points to an analogy between the spot zones and the clear zones of the trade winds of the earth. The cases are, however, very different; for our own atmosphere is subject to external influences, namely, the action of the sun, as well as those belonging to the earth itself.

Of course, anything from the eminent pen of Prof. Zöllner must be received with the utmost respect, but I conceive that his theory of the sun-spots, as I have attempted partly to show, presents many difficulties; and I cannot avoid stating my humble belief that, notwithstanding all that has been thought and written on the subject, and in spite of the modern discoveries of some of the constituent elements of the sun, we are but little nearer a true conception of its organisation or economy than the theorists of the days of Hipparchus.

J. BIRMINGHAM

## *PROFESSOR TYNDALL ON THEORIES OF DISEASES*

WE reprint this article from the *British Medical Journal*, since it shows how closely connected are the most abstract inquiries with the most practical questions:—

"The surest basis for Medicine is upon the broad foundations of exact scientific observation; and we shall all welcome such contributions as so able a physicist as Professor Tyndall can make either to our knowledge or to our facilities for testing the foundations of our beliefs. The electric beam, which has in his hands played a large part in many able investigations and demonstrative experiments, was lately brought into play to demonstrate the ubiquity of dust in the atmosphere. To some very charming experiments Mr. Tyndall joined some theories which, if capable of proof, were yet not demonstrated by anything which he said or did. The ubiquity of these air-borne particles was perfectly well known, and their illumination by the electric beam, while it has given a more complete demonstration of their presence than was otherwise obtainable, has not added anything to our knowledge of their chemical or biological relations. His experiments, however, have had the valuable effect of demonstrating the uses of cotton-wool as a filter for them, and the advantage of inspiring him with interest in a subject in which we can but be pleased that one of the most brilliant of investigators and expositors of physical science should be interested — the investigation of the origin of zymotic disease.

"In many respects the address shows a considerable advance over previous discourses by the same lecturer on this subject. The fact that the dirt or dust is in large part inorganic and in large part 'dead,' is now put prominently forward. Prof. Tyndall has, in fact, profited greatly by the lessons of Dr. Gull—we shall not venture to assume that it is by anything which we have had to say by way of comment upon his previous addresses—and does not now assume to tell us anything more about the nature of this dirt than we knew before. He proceeds only to reason upon the subject, deriving his information, however, chiefly from chance communications from various physiologists and medical correspondents. One correspondent tells him that 'blood free from dirt' will take longer to putrefy out of the body, and Von Recklinghausen's experiments are brought in reinforcement of the still more striking results and experiments of Prof. Lister; another informs him that vaccination through a bleb raised by blistering is less likely to produce secondary abscesses than by the ordinary method; and Dr. Budd assures Prof. Tyndall that, 'from the day when he first began to think of these subjects, he has never had a doubt that the specific cause of contagious fevers must be living organisms.' The last is, of course, a very interesting proof of early wisdom, but is not of the nature of a strict demonstration. The circumstance mentioned by Mr. Ellis reminds us that we have, on the other hand, seen it stated in print by one gentleman that he had to abandon vaccination by blistering because it was, in his practice, more productive than any other of suppurative and inflammatory accidents. But all this is really beside the question. The whole course of subcutaneous surgery, the whole range of Prof. Lister's experience, the daily experience of the difference in progress between simple and compound fractures, a thousand facts and observations, and the accepted and proved theories of surgical practice, have long convinced every surgeon that, in proportion as air and that which air bears are excluded from the fluids of open wounds, and from the organic fluids of the body, suppurative and putrefactive processes will be lessened and warded off. So much Prof. Tyndall might, so far as our profession is concerned, have taken for granted; and if he chooses to read, for instance, such papers as those we have published of Adams on subcutaneous osteotomy, he will see how largely this knowledge affects our practice in other directions than those to which he has referred. But, after proving to us what we know, Prof. Tyndall takes a leap, and assumes precisely those conclusions which we are desirous of his aid in testing. All these facts are as much accordant with the doctrines of Liebig and the experiments of Bastian, as with the doctrines of Schwann and the experiments of Pasteur. Granted that air-borne particles are prime agents in initiating putrefactive and fermentative change, is this by a development of pre-existent living germs, a growth of deposited ova, or by a communicated molecular motion of dead organic matter in a state of change? Is it from germs or from fermentative organic particles? We wish we could see that Prof. Tyndall had advanced our knowledge at all concerning this, the central knot of the tangle. It does not help us when he quotes certain known examples of parasitic disease, such as arises from pébrine. Because the itch is the result of the activity of the acarus, it does not follow of course that all skin-diseases are parasitic. Mr. Tyndall declares indeed, that the successful workers and profound thinkers of the medical profession are daily growing more convinced that 'contagious disease generally is of the same parasitic character' as the silk-worm disease. We cannot find on what he bases that very broad statement. Where are the works of the 'most successful workers and profound thinkers' which support that statement? It will be very kind of the lecturer to inform us whom he thus dignifies, and to what growing series of authorities he refers. Certainly not to the researches on cholera of Gull, Baly, or Cunningham and Lewes: these negative the parasitic theory. Salisbury started a parasitic theory for measles, but his observations have been generally discredited, if they were ever accepted. Hallier's observations have certainly not gained in authority by the results of many recent investigations such as those of Burdon Sanderson. We are not aware of a parasitic theory of scarlet fever being held by any one. The theory concerning typhoid fever, which Dr. Budd holds strongly and defends ably on purely logical grounds, is as distinctly controverted by Dr. Murchison.

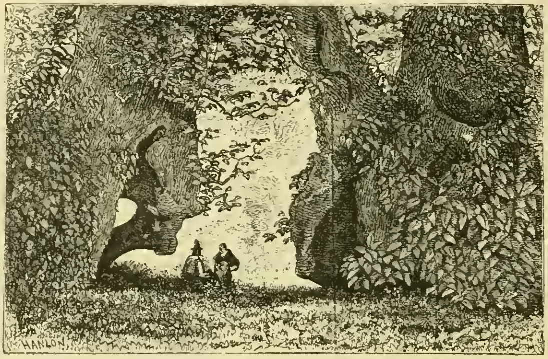
"Prof. Tyndall, however, lays just stress upon one important aspect of the question, which is precisely that which has long fascinated medical observers, and which is of the deepest importance. To it also, however, he adds nothing; and from it he draws, with admirable and unquestioning boldness, precisely the conclusions as to which we have all been debating whether they be the true and only conclusions. Small-pox and scarlatina are, to use the graphic words of Miss Nightingale, in ordinary medical experience, 'dog and cat,' so that one cannot change into the other any more than Tabby can give birth to Fido. When she says that she has seen with her own eyes one or other spring up in a corner of a room from neglected dirt, Miss Nightingale uses, of course, a purely figurative language, and her evidence must be taken *quantum valeat*. But when Mr. Tyndall declares, on the other hand, that zymotic diseases are all of primal inheritance—long descended primeval germs, never changing, never dying out, and ever passing on by lineal descent—he treads also upon ground less secure than he supposes. That this is the ordinary observed mode of extension of contagious diseases no one will dispute. That they have no other many will dispute. When he declares that, for the similarity or identity of effect of like particles acting on like fluids, we have no physical parallel, he obviously leaves out of view the whole series of phenomena of crystallisation from saturated fluids.

"To sum up: The tendency of modern research is certainly not so favourable as Mr. Tyndall believes and expects it to be to the theory of the parasitic origin of contagious disease. We should rather declare it to be unfavourable to that theory. The theory of the permanency and unrelated individuality of zymotic types of disease is not, as he assumes, an undisputed or unquestioned theory. We have to set against it, first, the theory of the correlation of zymotic diseases, which is growing into importance, and likely to attract more attention now than heretofore; second, the observations of statisticians of the complementary character of epidemics of zymotic diseases, and their apparent interchangeability in periods of decline; the theories of the spontaneous origin of zymotic disease by no contemptible observers, and in diseases as distinctly communicable as typhoid; and the observations, experiments, and reasonings of Pouchet and of Bastian, which have not yet been met, and which cannot be disposed of by a few words of philosophic doubt. We appreciate very highly the value of Prof. Tyndall's assistance in solving these questions. We entirely concur in his opinion that, as a physicist, he has a great power of usefulness in this field of investigation; and, if we refer him to the work of Gull, Baly, Cunningham and Lewes, Farr, and Murchison, it is because we are desirous that he should not be content to win easy triumphs with audiences uninstructed in the questions he discusses, or with the partisans of the theory he has adopted, but that he should enter into the heart of the question and face its real difficulties. It would be infinitely satisfactory if we could all arrive at as simple a sole theory of disease as that which Prof. Tyndall accepts entire, symmetrical, and rotund, from the supporters of the germ-theory; but we fear the solution is not yet in hand. It is satisfactory to have enlisted his sympathies, and we shall all be glad of his solid and sincere assistance."

## *THE CHESTNUT TREE OF MOUNT ETNA*

THE traveller in Sicily will recollect the little village of Giarre, about half way between Messina and Catania; and since the opening of the railway between these cities, with a station at no great distance from its principal street. On the sea-side below the town is the shipping port of Riposto, and between Riposto and Giarre lies a fertile plain, rich in olive and vine-yards. Giarre itself has not much to boast of, except perhaps it might do so of the glorious views to be seen from the slight elevation on which it stands. One long principal street, a large plain chapel, a very second-rate inn, and then there is nothing more to be said of the village. It is, however, the nearest town with an inn to the famous giant chestnut tree of Mount Etna, and as such is visited by tourists. This fine old tree grows in the Bosco or woody region close above the town and on the slope of Mount Etna. A narrow, steep road, gradually ascending, leads from Giarre to La Macchia, the broad bed of a river now (in the end of May) rolling down nought but clouds of dust, is passed, and the lava beds formed by the eruptions of 1689 and 1735 are traversed, and at last S. Alfio is reached. This village is about four and a half miles from Giarre, and from it a very fine view of Etna is obtained. The mountain, however, from this side looks low and by no means as imposing as when seen from the sea. A little beyond S. Alfio the road turns to the left still leading upwards; until all of a sudden the giant tree breaks upon the view, the road itself running through its very midst. It stands about 4,000 feet above the sea level, and it requires a good three and a half hours to walk to it from Giarre.

It has been calculated that this tree is about 1,000 years of age. It is a tree, therefore, old enough to have its early history lost in myth; but still it has its story; and this story tells us that long ago a certain Queen of Aragon was passing by this way, when, from the effects of the weather, she and her suite, which consisted of one hundred mounted persons, took shelter under the shadow of its trunk and boughs, and so to this day and from this fact it is known as the Castagno di Cento Cavalli. This story is said to be generally believed, and, at any rate, does not appear to have been much discussed. Not so the tree; and very many opinions may be quoted all more less differing as to its age and size. Some believe, or have believed, that the tree was as large as the story tells us it was, that the interior of the vast trunk has since then decayed away; leaving a number of separate pieces, each large enough to form a big tree, which pieces are covered with bark only on their outer surface. Others assert that there were here several large trees, more or less joined together, and demonstrate on the pieces of these trees still standing the barky layers surrounding the whole of their stems.



THE CHESTNUT TREE OF MOUNT ETNA

Not very long ago there were still four pieces standing, each of them of the dimensions of a very large tree. In the space surrounded by these pieces stood a hut, in which the annual crop of chestnut fruit was stored. One of these trees, or portions of the tree, has since disappeared. The hut has now been removed, and the road, sufficiently wide to allow of a carriage, runs between the remaining pieces and over the ground on which the hut was built. As you approach, one large piece of the tree is to the left-hand side of the road, and two larger pieces are to the right. It is very probable that many of the pieces believed to have belonged to the one original vast stem, were really stems themselves of independent trees, and such would appear to be the case with the large trunk to the left of the present roadway. But there is a strong probability that the two immense pieces to the right of the road were at one time united, and that they form part of the original tree. The annexed woodcut is from a photograph of these pieces. Both of them are deeply hollowed out. The base of the trunk to the right of the woodcut is very much decayed away, and several men could shelter in it; and the portions of the stems seen on looking at the picture are devoid of true bark. If these two portions once formed a single stem, then, indeed, though it might not have thrown a shadow sufficiently large to shade a hundred horsemen, yet it must have been a very giant among all the forest trees. Even now, in its decadence, the three stems are objects of sufficient interest to lead us to ask for them the reader's attention. E. P. W.

## *SCIENCE IN PLAIN ENGLISH*

II.

IN considering the importance of Technical Education with reference to the practical arts, and the claims of Science as an element of culture, we are led to study the methods of teaching.

It has been the custom in English to borrow the technical terms of Science from the so-called "learned languages," particularly Latin and Greek. To such an extent has this been carried that unless a term bears the marks of such a derivation it is hardly recognised by the public as a technical term.

The Germans, on the other hand, in teaching science, employ their own language to a large extent, and impose a definite scientific meaning upon common words. It is a remarkable evidence of the formative power of the German language, that it should have been able to produce an imitation of the systematic chemical nomenclature of the French school so complete that it is used in Germany as familiarly as the original system is in France and England. The fact that the most cultivated nation in the world, the Germans, find that they can teach science in their vernacular, deserves the most careful consideration—it seems to furnish at once an argument and an example.

In discussing this question, it is necessary to examine the capabilities of the English language with reference to the purposes of public instruction, but in the first instance we may glance at the development of scientific language in some of the countries of Europe during the last three hundred years.

When the progress of science rendered it necessary to employ new terms in order to express new ideas, two different methods were adopted by different nations. Let us compare the French and English with the German and Dutch method. When, for instance, the French wanted to express in one word the "knowledge of the stars" or the "study of the stars," they borrowed the Greek word *astronomia*, and called it *astronomie*. In like manner the English said *astronomy* but the Germans expressed the meaning of the term in their own language, calling it *Stern-kunde* or "star-knowledge;" similarly the Dutch said *Starre-kunde*, and they have continued using such words to the present day.

In English, then, it has been the custom to take Latin or Greek compounds ready made, although in many instances we might have translated them if we had chosen to do so. If we look to the literal meaning, the original difference between *sphere*, *globe*, and *ball* is that the first is Greek, the second Latin, and the third Saxon. So the Germans call a *hemi-sphere* a "half-ball," and the *globe* upon which we live the "earth-ball."

Now if, in any language, the compound words are, to a great extent, derived from other tongues, such words will be comparatively unintelligible to those who are not conversant with foreign languages. In such a case, the common people will learn the words rather by practice and association than by any exact knowledge of the original meaning; and to the same degree the learned must enjoy a privilege which the illiterate do not possess. Hence there is, in English, a broad distinction between the speech of the general public and the language of science.

Suppose that a working man, in this country, wishes to study Botany, he cannot read one of the ordinary works on that subject, without having his attention distracted by scores of new words which are either Latin or Greek, or else are derived from those languages. Thus he is often disheartened; or, if he succeeds, it is a long time before he overcomes the check which he experienced at the outset, and many a likely student is thus discouraged at the very threshold of his studies.

But the German writers, when they make books for their people, proceed upon a different plan. For if they give the Latin and Greek terms, it is only in brackets, and by way of parenthesis; while in the body of the work they use plain German words, and keep on employing such terms throughout the whole work. Hence, at the first reading, a German youth may go straight on, without paying attention to the Latin terms, and so make himself master of the facts. Afterwards, at a second or third reading, he may study the learned terms, which are repeated in brackets, from time to time, in order to catch the eye of the reader, and thus imprint themselves upon his memory.

For instance, in describing the parts of a flower, the writer does not begin by talking about a "calyx," but speaks of the *cup* (calyx), and calls the leaves of the cup *cup-leaves* (sepals). Similarly, the "corolla" is the *crown*, and its leaves are *crown-leaves* (petals). Thus, when he wishes to tell the learner that a *crown* (corolla) has several leaves, he does not tell him that the "corolla is polypetalous," but that the "crown is many-leaved," or that the "crown-leaves are many."

There is a danger that some of the terms thus employed may not be quite accurate. But the Germans are willing to risk the chance of misapprehension for the sake of making an impression on the mind of the reader, and gaining his attention. If then, half a loaf is better than no bread, it seems more advisable that an unlettered man who wishes to study science, should go through a book which is intelligible, though not absolutely accurate, rather than attempt to read a treatise which is admirably correct, but so full of hard words, that he is tempted at every line to throw down the book in despair.

We have to consider whether such a method can be carried out in English. There can be no doubt that the public would welcome any proposal for the publication of elementary scientific works written in a simple style. Some steps have already been taken in this direction, and scientific writers appear to be cautiously feeling their way. But the plan has not been carried out systematically or boldly, nor has the language of science been fully examined in reference to popular instruction.

Nor are scientific men entirely convinced that the proposed simplification is practicable, or even desirable. Some of them deny that the English language is equal to the task, because we have lost that power of making compound words which confessedly existed in Old English, and which still exists in German. Others contend that even in German the method is characterised by want of precision, and gives rise to confusion; hence they maintain that it is better to frame the scientific terms in words which are not familiar to the common ear, in order to ensure precision and to guard against error.

But in arguing this question two points may be observed. First—That men of high attainments are less averse to the proposed method than men of inferior ability. Secondly—That all are more disposed to see it tried in some other science than in the one which they themselves profess. The grammarian, or the mathematician would not greatly object to a plan for simplifying Botany; "for that," they say, "is a science of hard names." But the botanist replies, "No, you must not touch Botany; suppose you were to try Mathematics." The argument cuts both ways. It is evident that each acknowledges the value of fixed technical terms in his own science, and yet is not unwilling to see a simplification introduced in other branches of study.

The objections urged against the proposed method are of two kinds:—(1) that the system itself is misleading, and the method inaccurate; (2) that even if the plan be practicable in German it is not possible in English.

We shall, in the next article, review these objections in their order.

WM. RUSHTON

## NOTES

WE are glad to learn that steps are being taken to bring about such a general application from men of science to the Government for further deep-sea explorations as we referred to some little time ago. This is as it should be. We hear also, that, on the invitation of some of the leaders of science there, Mr. Gwyn Jeffreys will proceed to America in the middle of August, to inspect, in company with Prof. Agassiz, the collections obtained in the American dredgings. Such a proceeding will be of the utmost value to science, and no one is more fitted than Mr. Gwyn Jeffreys to perform such an important work.

As we are going to press we hear of the death of M. Claparède, one of the most distinguished naturalists whom Switzerland has produced. We hope in a future number to give an account of his labours, now unfortunately ended at an early age.

THE "Scheme of Education" Committee of the London School Board have sent in their report recommending science teaching in primary schools. We shall take an opportunity of referring to it on a future occasion.

FORTY of the teachers under the Science and Art Department are now in London for the purpose of undergoing practical training in Biology. For the last two or three years chemical courses of a similar nature have been given. These, however, have been suspended this year. It is impossible to over-estimate the good which is being done by the department in this way, and the Government deserves the best thanks, not only of every scientific man, but of every one who cares for the best interests of the country, for what they are doing. There will be similar teaching in Physics next month.

AT a meeting of the Senate of the University of London held on Monday last, Sir Edward Ryan was elected to the office of Vice-Chancellor *pro tem.*, in the place of the late Mr. George Grote.

NOTWITHSTANDING the alleged increased severity of the Matriculation examination at the University of London, and the large proportion who have failed of recent years, the number of candidates presenting themselves at the examination held during the present week is larger than in any previous year, being over six hundred.

THE Ladies' Educational Association has now been definitely connected with University College, London, where all the lectures will in future be held, an arrangement which will doubtless be of great advantage to both students and teachers. The Association has already issued its syllabus for the Michaelmas and Lent Terms of next winter session. The curriculum includes courses for ladies by the professors of Latin, Hebrew, English, French, Italian, German, Philosophy of Mind and Logic, Jurisprudence, Hygiene, History, Constitutional Law and History, Mathematics, Physics, Practical Chemistry, Geology, and Architecture. There will also be classes for Drawing and Painting in connection with the Slade School of Fine Art; and, during the Lent term, Prof. Oliver will deliver a course of ten lectures on the Structure of Plants and General Phenomena of Vegetation, with reference more especially to the general bearing of vegetation upon landscape.

DR. HOOKER and party returned last week from their visit to North Africa. The number of species of plants brought home is estimated at about 1,200, among which it is expected there will be a considerable number entirely new.

A MEETING of the friends and pupils of the late Prof. Goodsir was held in Edinburgh, in June, 1867, under the presidency of Dr. Dunsmure, and it was resolved, "That steps be taken to form a lasting memorial of Prof. Goodsir's distinguished career as an original investigator, and teacher of Anatomy and Physiology, and that the most appropriate manner of commemorating Prof. Goodsir's services, was to establish in the University of Edinburgh a Fellowship in Anatomy and Physiology, to be called the Goodsir Fellowship." A Committee was formed, and subsequently added to, to collect subscriptions, and to decide as to the conditions on which the Fellowship should be awarded. Honorary secretaries were appointed in various parts of the country, and in the Colonies. It was expected that a sufficient fund would have been collected within two years to found the Fellowship. At the present date, however, not more than 620*l.* has been subscribed. The hope of establishing an endowment in the University on the scale of a Fellowship has, therefore, been abandoned, and it is now proposed to institute a Scholarship in Anatomy and Physiology. In order to carry out this project worthily, it is necessary to raise the sum already collected to 1,000*l.*, and renewed efforts are accordingly being now made to provide this amount.

THE Harveian oration on the Progress of Therapeutics was delivered last week in the Royal College of Physicians by Dr. T. K. Chambers, after which the biennial Baly medal for the most distinguished researches in physiological science prosecuted during the past two years, was presented by the president to Dr. Lionel S. Beale.

THE Royal Agricultural Society has decided on appointing a Consulting Botanist, at a salary of 100*l.* per annum, the engagement to be an annual one. It will be the duty of the botanist to examine plants, seeds, &c., for members of the society, and to report the principal work performed from time to time for its members, and to undertake the work at fixed rates, to be arranged before his appointment, and to furnish papers to the Journal on special subjects of botanical interest. The appointment of an Entomologist to the Society has also been in contemplation.

AN International Congress, for the progress of Geographical Science, will be held at Antwerp from the 14th to the 22nd of August. A number of questions in Geography, Meteorology, Navigation, Ethnology, &c., will be submitted for discussion. An exhibition will also be held of objects connected with the purpose of the Congress, maps, plans, instruments used in navigation, &c., and prizes will be awarded for the best object exhibited in each class.

THE excursion of the Geologists' Association to Yeovil and neighbourhood on the 29th of May and three following days was a very successful one. Near Yeovil Junction station the Yellow Micaceous sands, considered by Dr. Wright to be of Upper Liassic Age, were examined, and characteristic fossils obtained. The large collection of Mesozoic fossils collected by the Rev. Edward Bower, at Closworth Rectory, was inspected, as well as that of the Rev. T. C. Maggs, of Yeovil. The next morning, under the guidance of Prof. Buckman, the party ascended the fine escarpment of Babylon Hill, where bands of concretionary sandstone contain fossils essentially Oolite and not Liassic. The characteristic fossils of the well-known "Cephalopod-bed," considered by Prof. Buckman to be at the top instead of at the base of the series, as generally supposed, were obtained at the celebrated Half-way House Quarries, and at a small but very prolific quarry on the Professor's own estate at Bradford Abbas. The following day the far-famed quarries of Ham Hill were visited, and the great bed of Inferior Oolite Freestone, which has supplied material for the churches and other buildings of the district for centuries, was carefully examined. The Middle and Upper Lias were also investigated at South Petherton; and on the fourth day the interesting and picturesque Keuper Cliffs at Seaton were examined, and the coast section followed until the "Landslip" was reached, extending for a distance of about six miles.

THE thirty-seventh Anniversary Meeting of the Statistical Society was held on Thursday, the 22nd of June, Mr. William Newmarch, F.R.S., president, in the chair. The following is the list of president, council, and officers elected to serve for the ensuing twelvemonths, viz.:—President—Dr. William Farr, F.R.S. Council—Dr. T. G. Balfour, F.R.S., R. Dudley Baxter, Samuel Brown, Dr. Hyde Clarke, L. H. Courtney, W. Fowler, M.P., F. Galton, F.R.S., Robert Giffen, Rt. Hon. W. E. Gladstone, M.P., W. A. Guy, M.B., F.R.S., Archibald Hamilton, J. T. Hammick, F. Hendriks, J. Heywood, F.R.S., F. Jourdan, Prof. Leone Levi, Sir Massey Lopes, Bart., M.P., W. G. Lumley, Q.C., J. MacClelland, Dr. F. J. Mouat, W. Newmarch, F.R.S., R. H. I. Palgrave, R. H. Patterson, F. Purdy, W. H. Smith, M.P., T. Sopwith, F.R.S., Col. W. H. Sykes, M.P., F.R.S., Ernest Seyd, W. Tayler, Prof. Jacob Waley. Treasurer—J. T. Hammick. Honorary secretaries—W. G. Lumley, Q.C., F. Purdy, Jacob Waley.

THE Winchester College Natural History Society, founded on March 12, 1870, has just issued its first Report, which includes some useful papers, and botanical, entomological, and palæontological lists of the neighbourhood. It gives promise of good and useful work to be done in future years.

WE have received the thirty-eighth annual report of the Royal Cornwall Polytechnic Society. As might be expected from the locality of the society, the majority of the papers bear on subjects connected with mining and metallurgy; though there are also some meteorological tables, and a useful list of addenda to the fauna of the county. A marked feature of the report is the number of woodcuts illustrative of various adaptations of machinery, &c., connected with the subjects of the papers.

DR. LAUDER LINDSAY has reprinted his essay on the Physiology and Pathology of Mind in the Lower Animals, in which he insists that the mind of the lower animals does not differ in kind from that of man; and that they possess the same affections, virtues, moral sense, and capacity for education, and are liable to the same kinds of mental disorders.

MR. W. ROBINSON, author of "The Wild Garden," "Alpine Flowers for English Gardens," &c., publishes a useful Catalogue of Hardy Perennials, Bulbs, Alpine Plants, Annuals, Biennials, &c., intended as a help to exchanges between cultivators of hardy plants, analogous to those that have long been common among botanists.

WE have received Nos. 203-206 of the "Bücher-Verzeichniss" of Friedländer and Son, of Berlin, comprising the following subjects—"Geology, Mineralogy, and Crystallography," "Botany," "Zoology," and "Mathematics, Physics, Astronomy, and Technology."

MR. PENGELLY has reprinted two papers read before the Devonshire Association for the Advancement of Science, Literature, and Art, "On the rainfall received at the same station by gauges at different heights above the ground," and "On the supposed influence of the moon on the rainfall," in which he thus sums up the conclusions arrived at:—"1. That under unobjectionable conditions, and at the same station, less rain will be received by a gauge high above the ground than by one nearer the surface; 2. That the total defect will increase with increase of height; 3. That the defect will not increase so rapidly as the height." And again:—"The result of my observations then may be briefly summed up thus: At Torquay, the second quarter of the moon, or that which terminates on the day before each full moon, had the least number of wet days, the heaviest average daily rate of rain, and the greatest aggregate rainfall; whilst the third quarter, or that commencing on the day of each full moon, had the greatest number of wet days, the lightest average daily rate of rain, and the second greatest aggregate rainfall. The differences are but slight; but it must be borne in mind that the moon's meteorological influence can be but slight. The results, however, do not accord with any of those mentioned by the authors so largely quoted at the commencement of this paper, yet they are such, and only such, as are calculated to induce any one to pause before giving an opinion for or against the alleged connection of the moon with our rainfall. Perhaps I cannot better conclude than by echoing the words of M. Arago, 'The subject requires to be examined afresh'"

IT is reported that about June 7, an earthquake took place on the south coast of Asia Minor, opposite Rhodes, resulting in the almost total destruction of the small town of Marmaritza.

STRONG earthquakes continue in Peru. There was one in Arequipa on April 11. The movements were from east to west, and the duration forty to fifty seconds. It is worthy of notice that on the same April 11 two slight shocks of earthquake were felt at Rangoon, in Burmah, the direction being from north to south. On the night of the 16th another earthquake was felt.

EARTHQUAKE shocks were felt on May 21st in the vicinity of Rochester and Buffalo, in the state of New York; at Augusta, in Georgia; and at Quebec, Ottawa, and other points in Canada.

THE remote island called Sunday Island, in the Pacific, has been subjected to a terrible volcanic eruption so that the inhabitants have been removed to Norfolk Island, to join the descendants of the *Bounty* Mutineers.

ON February 22 several shocks of earthquake were felt at Puno, in Peru, and on March 4 a slight earthquake of thirty seconds at Arequipa after several rainy days.

ON February 7 two distinct shocks of earthquake were felt in the department of Minititlan, in Mexico, followed by a wave rising one foot.

AMONG the late remarkable disturbances in the Pacific basin are to be numbered those affecting the waters of the ocean around the guano Islands of Guanape on the Peruvian coast, which took place on the 5th of February. During the whole of that day the sea was much agitated, though nothing particular was noted in the tides. On the morning of the 6th there was something strange about the currents, with a westerly wind freshening with dangerous force. The winds and currents ruling along the Peruvian coast are from the S.E., but on the 6th this was not so, for they veered round and came from the W. at six miles an hour (? currents). Then it was noticed that as the day grew on the currents seemed to flow in from all directions, forming numerous whirlpools, while alarm for the shipping was caused by the increasing strength of the west wind. The nights of the 6th and 7th were consequently times of alarm to the masters of the guano ships, which were dashed against each other. The phenomena had a great resemblance to those at Arica and the Chincha Islands on the 15th of August, 1868. On the 9th of February the appearances were calmer, and the wind veered round to S.E.

AT Pichicani, in Peru, an extraordinary meteor appeared on February 12. It was of a red colour, balloon-shaped, with the end or neck pointed to the earth, and exploded as it reached the surface, leaving a dark cloud on the plain, injuring the roofs of several huts, and knocking down a fence of about 500 yards belonging to a farm. Among the fragments of this meteorite were found dead fish of several species, supposed to have been lifted out of the river. Similar phenomena had been observed near Huacochullo and Atucachi.

INDIAN papers report that the tea prospects in Darjeeling this year are so favourable that up to the present time (May) the crop has been from twice to three times what it was at that date last season.

THE report of the Curator of the Natal Botanic Garden for 1870 states that there had been shipped to various public and private gardens 5 Ward's cases, 22 boxes, and 11 parcels, and that there had been received 13 Ward's cases, 9 boxes, and 22 parcels.

IT is reported from Chile that the Planchon Pass across the

Andes, the main line from Chile to Buenos Ayres, has been disturbed for about three miles by the eruption of hillocks.

AN Australian paper states that a live frog had been brought to the office that had been found three or four days before incased in the solid rock, in the drive of the Sultan mine, Barry's Reef, at a depth of 400ft. below the surface. The little animal looked bright-eyed and very lively, and was apparently none the worse for its long term of solitary imprisonment.

## SCIENCE IN AMERICA *

THE forthcoming number of the *American Journal of Science* will contain an extremely interesting announcement in regard to American palæontology, namely, the discovery by Prof. Marsh in the Cretaceous beds of the Rocky Mountain region, of a huge pterodactyl, or flying lizard. This form has long been known as characteristic of the deposits of Europe, and has always attracted much attention from its combination of the characters of the bird and reptile; but until this announcement by Prof. Marsh the family was not supposed to be represented in the New World. The addition therefore of the pterodactyl, to the list of American genera, shows a marked increase in palæontological affluence, and gives additional point to the statements made some time ago, that America, instead of being greatly inferior to the Old World in the variety of its vertebrate fossil remains, now bids fair to greatly exceed it in this respect. The name assigned to this new species is "Pterodactylus Oweni" (in honour of Prof. Richard Owen of London), and it is believed to have had an expanse between the tips of the wings of at least twenty feet.—We regret to learn that during the recent revolution on the Isthmus of Tehuantepec a large number of valuable collections in natural history, made for the Smithsonian Institution by its correspondent in that region, Prof. Sumichrast, were entirely destroyed in the course of the conflicts of the opposing parties.—The annual report of the Smithsonian Institution for 1869 has, after an unusual delay, just made its appearance from the public printing-office, and contains the customary variety of interesting matter, which has made this report so much sought after by persons of scientific tastes in the United States. Preceded by the secretary's usual report of the operations of the Institution for the year, it contains in an appendix numerous articles, partly original, and partly translations from such foreign journals as are not readily accessible to the American student. Among these may be mentioned biographies of Thomas Young, Augustus Bravais, Von Martius, and Marianni; an important original paper by Dr. Sterry Hunt on the chemistry of the earth; and one by Marey on the phenomena of flight in the animal kingdom; an extended paper by General Simpson, upon the march of Coronado in search of the seven cities of Cibola; one by Sir John Lubbock, on the social and religious condition of the lower races of man, &c. The report is in no way inferior in interest to its predecessors. —Salt Lake City has lately been the scene of considerable activity, in connection with the arrival there of several government exploring parties, for the purpose of fitting out for their summer's campaign. Among these may be mentioned Mr. Clarence King, who continues his geological and topographical exploration of the fortieth parallel eastward through Colorado; Major Powell, who renews his examination of the canons of Green River and the Colorado, and who is detained at Salt Lake City in consequence of the late melting of the mountain snows, the low stage of water preventing him from passing through the canons; and a portion of Prof. Hayden's party is also at the same place collecting animals and supplies for a visit to the Yellow Stone region.—By advices from South America we learn that on the 25th of April last Chili was visited by two of the severest earthquakes that have been experienced in the country since 1851. The first shock in Valparaiso was not preceded by any warning sound, and its suddenness and intensity created considerable alarm, the streets of the city being filled in a short time by people who rushed out from their dwellings in a state of indescribable confusion.—Many of our readers are familiar with the names of Mr. Thomas Say, of Philadelphia, and Mr. C. A. Leseur, as having been among the most prominent of our naturalists during the early part of the present century, and as having added many new species to the lists. The labours of Mr. Say were directed largely toward the invertebrata, embracing more particularly the insects, shells, and crustaceans. Many of his explorations were in the vicinity of Beesley's Point, New Jersey, where species were obtained by him that have ever sinc remained almost unknown to science. Several examinations have been more recently made on the New Jersey coast, for the express purpose of recovering these forms; and one of the most successful was prosecuted last spring, under the direction of Prof. Verrill, of Yale College, who, with several companions, spent a week at Somers Point and Beesley's Point. The results of their labours were much greater than they had anticipated, as they not only obtained a large proportion of all the missing forms, but secured quite a number of new species, and detected the occurrence, for the first time, of others previously known as belonging much farther south, among them two echinoderms, of which Cape Hatteras was the limit previously ascertained. Their "catch" for the week summed up about 175 species of marine animals—about 25 of fishes, 50 of crustaceans, 25 of worms, 50 of mollusks, and 15 of radiates and sponges.

## MR. BENTHAM'S ANNIVERSARY ADDRESS TO THE LINNEAN SOCIETY

(*Continued from page* 152)

GERMANY, or rather Central Europe from the Rhine to the Carpathians and from the Baltic to the Alps, is, as to the greater part of it, a continuation of that generally uniform but gradually changing biological region which covers the Russian empire. It is not yet affected by those peculiar western races which either stop short of the Rhine and Rhone or only here and there cross these rivers with a few stragglers; the mountains, however, on its southern border show a biological type different from either of those which limit the Russian portion, indicating in many respects, as I observed in 1869, a closer connection with the Scandinavian and high northern than with the Pyrenean to the west or the Caucasian to the east. The verifying and following up these indications gives a special interest to the study of German races, their variations and affinities. In so far as formal specific distinctions are concerned, all plants and animals, with the exception of a few of those whose minute size enables them long to escape observation, may now be considered as well known in Germany as in France and England; and in Germany especially the investigation of anatomical and physiological characters has of late years contributed much to a more correct appreciation of those distinctions and of the natural relations of organic races. But much remains still for the systematic biologist, and especially the zoologist, to accomplish. Among the very numerous floras of the country, both general and local, there are several which have been worked out with due reference to the vegetation of the immediately surrounding regions, but corresponding complete faunas do not appear to exist. A few in some branches have been commenced; but in these, as in the numerous papers on more or less extended local zoology, as far as I can perceive, animals, and especially insects, seem to be considered only in respect of the forms they assume within the region treated of, frequently with a very close critical study of variations or races of the lowest grades, but neglecting all comparison with the forms a species may assume or be represented by in adjoining or distant countries.

Germany holds a first rank amongst civilised nations in respect of her biological works in most departments; they probably exceed in bulk those of any other country. Her publishi.g scientific academies and other associations, her zoological museums and gardens, her botanical herbaria and university gardens, her zoologists and botanists of world-wide reputation, are far too numerous to be here particularised. She excels all other nations in the patient and persevering elaboration of minute details, although she must yield to the French in respect of clearness and conciseness of methodical exposition. Her speculative tendencies are well known, and the great impulse given to them since the spread of "Darwinismus" appears to have thrown systematic biology still further into the background; the sad events of the last twelvemonth have also temporarily suspended or greatly interfered with the peaceful course of science. Thus the zoological works contained in the lists I have received are almost all dated in 1868 or 1869, and have been already analysed in the reports of Wiegmann's "Archiv" and in the 5th and 6th volumes of the "Zoological Record," and the principal ones relating to exotic zoology will have to be referred to further on. In Systematic Botany also but little of importance has been published within the last ten years beyond the great "Flora Brasiliensis," which, since the death of Dr. v. Martius, has been actively proceeded with under the direction of Dr. Eichler, and to which I shall recur under the head of South America. Rohrbach has published a carefully worked-out conspectus of the difficult genus *Silene*, and, in the "Linnæa," a synopsis of Lychnideæ; and Böckeler, also in the "Linnæa," is describing the Cyperaceæ of the herbarium of Berlin, a work very unsatisfactory, considering the detail in which it is carried out, as it takes no notice whatever of the numerous published species not there represented, nor of any stations or other information relating to those described other than that what are supplied by that herbarium. It is not a monograph, but a collection of detached materials for a monograph.

Switzerland comprises the loftiest and most extensive mountain-range of which the biology has been well investigated—the Alps, which have lent their name to characterise the vegetation and other physical features of mountains generally, when attaining or approaching to the limits of eternal snows. The relations of this Alpine vegetation, both in its general character due to climatological and other physical causes, and in its geographical connection with other floras, has been frequently the subject of valuable essays, several of which I have mentioned on former occasions; and it is most desirable that the results obtained should be verified by or contrasted with those which might be derived from zoological data, and more particularly by the observation of insects and terrestrial mollusca. As a first step it is necessary that the plants and animals of the country should be accurately defined and classed in harmony with those of adjoining regions. This has been done for plants. The Swiss Flora has been well worked up both by German and by French botanists; it is included in Koch's Synopsis and some other German Floras. De Candolle and other writers on the French Flora had to introduce a large portion of the Swiss vegetation, and the compilers of the rather numerous Swiss Floras and handbooks* have generally followed either the one or the other, so that there remains but little difficulty in the identification of Swiss botanical races; but here, as elsewhere, methodical faunas of the country are much in arrear. I have the following notes from M. Humbert of what has been published in this respect during the last three years.

V. Fatio, "Faune des Vertébrés de la Suisse," 8vo, vol. i. Mammifères, 1869 (reported on in "Zoological Record," vi. p 4): the second volume, Reptiles, Batrachia, and Fishes, to appear in the course of the present year, the 3rd and 4th vols. (Birds) to follow. This fauna is the first which has been published on the Vertebrata of Switzerland. Hitherto there have only been partial and incomplete catalogues. The species are carefully described, and there are numerous notes on their distribution and habits, from the author's observations made in all the Swiss collections and in the field. There are also interesting historical details upon certain animals which have more or less completely disappeared from Swiss territory, such as the stag, the roebuck, and the wild boar, as also on the mammifers, whose remains have been found in recent deposits. G. Stierlin and V. de Gautard, "Fauna Coleopterorum Helvetica," in the Nouveaux Mémoires of the Helvetic Society, xxiii. and xxiv., a catalogue with stations and often limits in altitude, supplementing Heer's "Fauna Coleopterorum Helvetica." H. Frey's catalogues of and notes on Swiss Microlepidoptera, in the "Mittheilungen" of the Swiss Entomological Society. P. E. Müller, Note on the Cladocera of the great lakes of Switzerland, from the "Archives" of the Bibliothèque Universelle, xxxvii., April, 1870. In his excellent memoir on the Monoclea of the neighbourhood of Geneva, Jurine had only described the small crustacea of ponds and swamps. He had not investigated the species which inhabit the Lake of Geneva, and he had also neglected some very interesting forms which are only to be met with in large expanses of water, such as *Bythotrephes longimanus* and *Leptodora hyalina*. M. Müller points out the differences there are between the Cladocera of the centre of the lakes and those of the margins. The former, which float freely over the lake, have a peculiar stamp, marking also the marine crustacea of open sea; their bodies have an extreme transparency, and they show a great tendency to the development of long and rigid balancing organs. The latter, on the contrary, are little transparent, have stunted forms, and are without balancing or other elongations which might interfere with their movements amidst solid objects, such as stones and aquatic plants near the shores; most of these littoral species show, moreover, a development of some organ that assists them in moving upon solid bodies. M. Müller finds also a very great connection between the Cladoceral faunas of Switzerland and Scandinavia.

The Association zoologique du Léman, founded upon the model of the Ray Society, has for its object the publication of monographs relating to the basin of the Léman or Lake of Geneva, that is, the region comprised between Martigny and the Perte du Rhone, with the valleys of the affluents received by the Rhone in this portion of its course. It has been carried on as successfully as could have been expected from a scientific undertaking of this nature, reckoning at the present moment nearly 200 members. It has already published papers by A. Brot on the shells of the family of Naiadæ, with nine plates; by F. Chevrier on the Nyssæ (Hymenoptera); by V. Fatio on the Arvicolæ, with six plates; by H. Fourniet on the Dascillidæ (Coleoptera), with four plates; and is now issuing a more important work, the result of long and patient investigation, G. Lunel's "Histoire Naturelle des Poissons du Bassin du Léman," in folio, with twenty plates beautifully executed in chromolithography. Two parts, with eight plates, have already appeared, and the work is in rapid progress. A specimen of the plates, received from M. Humbert, lies on the tables of our library. I have also a rather long list of papers on the zoology of the same district or of the Canton de Vaud, inserted in the Bulletin of the Société Vaudoise of Natural History, and of others on the zoology of other districts, from various other Swiss Transactions, all of which are noticed in our "Zoological Record," vols. v. and vi. To these must be added J. Saratz's "Birds of the Upper Engadin," from the 2nd volume of the Bulletin of the Swiss Ornithological Society, 1870. The valley of the Upper Engadin commences at 1,860 metres above the level of the sea, and ends at 1,650 metres, where commences the Lower Engadin. The list therefore given by M. Saratz includes no point situate below that elevation. He classes the birds of this valley and of the mountains which enclose it into—1, sedentary birds; 2, birds which breed in the Upper Engadin, but do not spend the winter there; and 3, birds purely of passage. He enumerates 144 species, and gives upon every one notes of its station, times of passage, abundance or rarity, &c.

Meyer-Dür has a short note in the "Mittheilungen" of the Swiss Entomological Society (iii. 1870) on certain relations observed between the insect faunas of Central Europe and Buenos Ayres—a question worthy perhaps of some consideration in connection with the above-mentioned coincidence of a Chilian and East-Mediterranean *Geum* and a very few other curious instances of identical or closely representative species of plants in the hot dry districts of the East Mediterranean, the central Australian, and the extratropical South American regions.

Swiss naturalists continue their activity in various branches of biology. E. Claparède's very valuable memoirs on Annelida Chætopoda and on Acarina have been fully reported on in the "Zoological Record," as well as Henri de Saussure's entomological papers, which have been continued in the more recently published volumes of the Memoirs of the Société de Physique of Geneva and of the Swiss Entomological Society. In Botany, since I last noticed De Candolle's "Prodromus," the sixteenth volume has been completed by the appearance of the first part, containing two important monographs—that of Urticaceæ, by Weddell, and of Piperaceæ, by Casimir De Candolle, together with some small families by A. De Candolle and J. Müller. The social disturbances of the last twelvemonth have much delayed the preparation of the seventeenth volume, which is to close this great work; but it is hoped that it will be now shortly proceeded with. Of Boissier's "Flora Orientalis," mentioned in my address of 1868, the second volume is now in the printer's hands. Dr. G. Bernouilli, who had resided some time in Central America, has published, in the

* In the list of publications of the last three years only, sent me by M. A. De Candolle, are the following new Swiss Botanical Handbooks:—J. C. Ducommun, "Taschenbuch für den Schweizerischen Botaniker," 1 vol. 8vo of 1024 pages, with some analytical woodcuts: few details on stations. R. T. Simler, "Botanischer Taschenbegleiter der Alpenclubisten," 1 vol. 12mo, 4 plates: alpine species only. Tissière (late Canon of St. Bernard, now deceased), "Guide du Botaniste au Grand St Bernard" 1 vol. 8vo: a catalogue with detailed localities. J. Rhiner, "Prodrom der Waldstätter Gefässpflanzen," 1 vol. 8vo: a catalogue with details as to localities. Morthier, "Flore analytique de la Suisse," 1 vol 12mo: imitated from an older German "Excursions Flora fur die Schweiz," by A Gremli. A new (3rd edition of L. Fischer's "Flora von Bern" and Fischer-Ooster's "Rubi Bernenses;" the latter work, together with some contributions to the Swiss Flora of A. Gremli, adding 98 pages to the volumes of Batological literature we already possess, without advancing a step either in giving us a clear notion of what is a species of Bramble, or in facilitating our naming those we meet with, unless in the precise localities indicated by the several authors.

Memoirs of the General Helvetic Society (vol. xxiv.) a review of the genus *Theobroma*, after having compared his specimens in the herbaria of Kew, Berlin, and Geneva.

The biological interest of the Mediterranean Region, which includes Southern Europe, the north coast of Africa, and those lands vaguely termed the Levant, is in many respects the opposite of that of the great Russian empire. Extending from the Straits of Gibraltar to the foot of the Caucasus and Lebanon, over 40 to 45 degrees of longitude, by 10 to 12 degrees of latitude, from the southern declivities of the Pyrenees, of the Alps, the Scardus, and the Balkan, to the African shores, it shows, indeed, a certain uniformity of vegetation through the whole of this length and breadth; but it has evidently been the scene of great and frequent successive geological convulsions and disturbances, which, whilst they have wholly or partially destroyed some of the races most numerous in individuals, have at the same time so broken up the surface of the earth as to afford great facilities for the preservation or isolation of others represented by a comparatively small number of individuals. The consequence is that there is probably no portion of the northern hemisphere in the Old World, of equal extent, where the species altogether, and especially the endemic ones, are more numerous, none, I believe, which contains so many *dissevered* species (those which occupy several limited areas far distant from each other), and certainly none where there are so many strictly local races, species or even genera, occupying in few or numerous individuals single stations limited sometimes to less than a mile. In all these respects the Mediterranean region far exceeds, absolutely as well as relatively, the great Russian region, which has three times its length and twice its breadth; it presents, also, perhaps almost as great a contrast to a more southern tract of uniform vegetation extending across the drier portion of Africa and Arabia as far as Scinde. This diversified endemic and local character exemplified in the plants of the Mediterranean region has, as far as I can learn, been observed also in insects.

Of the three great European peninsulas which form the principal portion of the region, the Italian is the narrowest and has the least of individual character in its biology, but it is the most central one, and, including its continental base with the declivity of the Alps, may be taken as a fair type of the region generally; it is also by far the best known. Italy was the first amongst European nations to acquire a name in the pursuit of natural science after emerging from the barbarism of the middle ages; and although she has since been more devoted to art, and has allowed several of the more northern states far to outstrip her in science, she has still, amidst all her vicissitudes, produced a fair share of eminent physiologists as well as systematic zoologists and botanists; and within the last few years the cultivation of biology appears to have received a fresh impulse. It is only to be hoped that it may not be seriously checked by local and political intrigues, which appear to have succeeded, in one instance at least, in conferring an important botanical post on the least competent of the several candidates. Amongst the various publishing academies and associations mentioned in my address of 1865, the Italian Society of Natural Sciences at Milan issues a considerable number of papers on Italian zoology; and a few others in zoology and palæontology are scattered over the publications of the Academies of Turin and Venice and of the Technical Institute of Palermo. From the lists I have received, there appear to have been recent catalogues of Sicilian and Modenese birds by Doderlein in the "Palermo Journal," of Italian Araneida and Modenese fishes by Canestrini in the "Milanese Transactions," and of Italian Diptera, commenced by Rondani in the Bulletin of the Italian Entomological Society. Malacology, so peculiarly important in the study of the physical history of the Mediterranean region, has produced numerous papers, chiefly in the Milanese Transactions, and in Gentiluomo's "Bulletino Malacologica," and "Biblioteca Malacologica" published at Pisa. I also learn that at the time of the decease of the late Prof. Paolo Savi, in the beginning of April, the manuscript of his "Ornitologia Italiana" was complete, and had just been placed in the printer's hands.

In Botany, Parlatore's elaborate "Flora Italiana" has continued to make slow progress. We have received up to the second part of the fourth volume, reaching as far upward as Euphorbiaceæ, having commenced with the lower orders. The old Journal of Botany ceased with the year 1847, as I presumed to have been the case when I mentioned it in 1865, and has since been replaced by a "Nuovo Giornale Botanico Italiano," which continues, with tolerable regularity, issuing four parts in the year, the last received being the second of the third volume. The most valuable of the systematic papers it contains are Beccari's descriptions of some of his Bornean collections. Delpino, well known for his interesting dichogamic observations, as well as for some rather imaginative speculations, has also contributed to systematic botany a monograph of Marcgraviaceæ, but, unfortunately, without sufficient command of materials for the compilation of a useful history of that small but difficult group, and with a useless imposition of new names to forms which he thinks may have been already published, but has not the means of verifying. De Notaris, under the auspices of the municipality of Genoa, has published a synopsis of Italian Bryology, forming a separate octavo volume of considerable bulk.

Of the other two great European peninsulas I have little to say, notwithstanding their great comparative biological importance. The Western or Iberian Peninsula is the main centre of that remarkable Western flora to which I specially alluded in 1869, and which, more perhaps than any other, requires comparison with entomological and other faunas. But Spain is sadly in arrear in her pursuit of science. With great promise in the latter half of the last century, and certainly the country of many eminent naturalists, especially botanists, she has now for so long been subject to chronic pronunciamentos that she leaves the natural riches of her soil to be investigated by foreigners. Willkomm and Lange's "Prodromus Floræ Hispanicæ," which, when I last mentioned it, was in danger of remaining a fragment, has since been continued, and, it is hoped, will shortly be completed by the publication of one more part. I have no notes on any recent zoological papers beyond Steindachner's Reports on his Ichthyological tour in Spain and Portugal, and the Catalogues of the Zoological Museum of Lisbon publishing by the Lisbon Academy of Sciences. The Eastern Peninsula, Turkey, and Greece, with the exception of some slight attempts at Athens, has no endemic biological literature, and, with its present very unsatisfactory social state, affords little attraction to foreign visitors. The Levant, in respect of Botany at least, has has been much more fully investigated; but there, as in Turkey, much yet remains to be done; and pending the issue of Boissier's second volume already mentioned, I know of nothing of any importance in the biology of the East Mediterranean region as having been worked out within the last two or three years. As a hiatus, however, and yet a link between the Indian and the European Floras and Faunas, it will amply repay the study to be bestowed upon it by future naturalists.

(*To be continued*)

## *ASTRONOMY*

### On the Great Sun-spot of June 1843 *

ONE of the largest and most remarkable spots ever seen on the sun's disc appeared in June 1843, and continued visible to the naked eye for seven or eight days. The diameter of this spot was, according to Schwabe, 74,000 miles; so that its area was many times greater than that of the earth's surface. Now, it has been observed during a number of sun-spot cycles that the larger spots are generally found at or near the epoch of the greatest numbers. The year 1843 was, however, a *minimum* epoch of the eleven-year cycle. It would seem, therefore, that the formation of this extraordinary spot was an anomaly, and that its origin ought not to be looked for in the *general cause* of the spots of Schwabe's cycle. As having a possible bearing on the question under consideration, let us refer to a phenomenon observed at the same moment, on the 1st September, 1859, by Mr. Carrington, at Redhill, and Mr. Hodgson, at Highgate. "Mr. Carrington had directed his telescope to the sun, and was engaged in observing his spots, when suddenly two intensely luminous bodies burst into view on its surface. They moved side by side through a space of about thirty-five thousand miles, first increasing in brightness, then fading away. In five minutes they had vanished. . . . It is a remarkable circumstance that the observations at Kew show that on the very day, and at the very hour and minute of this unexpected and curious phenomenon, a moderate but marked magnetic disturbance took place, and a storm, or great disturbance of the magnetic element, occurred four hours after midnight, extending to the southern hemisphere." The opinion has been expressed by more than one astronomer that this phenomenon was produced by the fall of meteoric matter upon the sun's surface. Now the fact may be worthy of

* From the "American Journal of Science and Arts," vol. i., April 1871.

note that the comet of 1843, which had the least perihelion distance of any on record, actually grazed the solar atmosphere about three months before the appearance of the great sun-spot of the same year. The comet's least distance from the sun was about 65,000 miles. Had it approached but little nearer, the resistance of the atmosphere would probably have brought its entire mass to the solar surface. Even at its actual distance it must have produced considerable atmospheric disturbance. But the recent discovery that a number of comets are associated with meteoric matter, travelling in nearly the same orbits, suggests the inquiry whether an enormous meteorite following in the comet's train and having a somewhat less perihelion distance, may not have been precipitated upon the sun, thus producing the great disturbance observed so shortly after the comet's perihelion passage.

DANIEL KIRKWOOD

Bloomington, Indiana

## SCIENTIFIC SERIALS

OF the *Sitzungsberichte der naturwissenschaftlichen Gesellschaft Isis in Dresden* we have received the concluding part of the volume for 1869, containing the proceedings of the Society for the months of October, November, and December. Its contents are as usual of the most varied character, and we shall therefore notice only a few of the more prominent papers. In the section for prehistoric archæology Dr. Mehwald gave an interesting notice of the researches made in Norway by a young student, M. Lerange, and further a general account of ancient mining and mining implements. Under the zoological section we find an abstract by Prof. Günther of the faunistic results of recent deep-sea dredgings, founded of course chiefly upon the reports of MM. Pourtales and Agassiz, and our countrymen Messrs. Thomson, Jeffreys, and Carpenter. Under the head of mathematics, physics, and chemistry, is a paper by M. F. Otto on the calamine deposits in Upper Silesia, which would have better taken its place as a geologico-mineralogical paper. An important botanical paper is the revision by Dr. L. Rabenhorst of the Cryptogamia collected in the East (especially in Persia) by Prof. Haussknecht, in which the author catalogues a considerable number of Fungi and Lichens, and describes several new species and a new genus of the former class. The new genus *Seirosporium* belongs to the Discomycetous family Phacidiacei, and the species *S. ocellatum*, which is figured, lives upon dry stems of *Astragalus deinacanthus* Boiss. The new species described belong to the genera *Synchytrium* (2), *Ustilago* (2), *Uromyces* (1), *Puccinia* (2), *Cyathus* (1), *Montaguea* (1, figured), *Coprinus* (1), *Dothidea* (1), *Melogramma* (1), *and Rhytisma* (1).

THE fourth part of vol. xxii. of the *Zeitschrift der deutschen geologischen Gesellschaft* (1870) contains several very important memoirs. The first of these is upon new and little known Crustacea from Solenhofen by Prof. Kunth, illustrated with two plates, and includes detailed descriptions of the Stomatopod *Sculda pennata* (Münst), and of two new species of the same genus; and among the Isopods of *Urda rostrata* (Münst) forming the type of a new family *Urdaidæ*, *Reckur punctatus* (Münst), also referred to the genus *Urda*, *Naranda anomala* (Münst), and a species of *Æga*.—From M. Lemberg we find a detailed and valuable chemico-geological investigation of some calcareous deposits of the Finnish Island of Kimito, in which the author not only describes the chemical composition and mechanical condition of the rocks under consideration, but discusses at considerable length some interesting points connected with the general theories of rock-formation.—M. E. Kayser commences a series of studies of the Devonian of the district of the Rhine with a disquisition on the deposits of that age in the neighbourhood of Aix la Chapelle.—M. C. Weiss publishes an investigation of the Odontotopterides, in which he discusses the forms to be referred to that group, and comes to the conclusion that the whole may be placed under the genus *Odontopteris*, which he divides into two sections, *Xenopterides* and *Callipterides*, the former including as sub-genera, *Mixoneura*, *Xenopteris*, and *Lescuropteris*; and the latter *Callipteris*, *Anotopteris*, *Callipteridium*. He gives a list of the species referable to each of these sub-genera, with remarks upon their characters and distribution; several of them are described as new and figured, with others, in the three plates with which the memoir is illustrated.—These papers are followed by some mineralogical notices by Prof. Rammelsberg treating of the meteoric stone of Chantonnay, of the sulphide of iron of meteoric irons, the composition of Lievrite, and the Anorthite rock of the Basto.—In the concluding paper of this number M. G. Berendt notices the occurrence of Cretaceous and Tertiary deposits near Grodno on the Niemen.

## SOCIETIES AND ACADEMIES

### LONDON

Royal Society, June 15.—"On the Fossil Mammals of Australia. Part V. Genus *Nototherium* Ow." By Prof. R. Owen, F.R.S. The genus of large extinct Marsupial herbivores which forms the subject of the present paper, was founded on specimens transmitted (in 1842) to the author by the Surveyor-General of Australia, Sir Thomas Mitchell, C.B. They consisted of mutilated fossil mandibles and teeth. Subsequent specimens confirmed the distinction of *Nototherium* from *Diprotodon*, and more especially exemplified a singular and extreme modification of the cranium of the former genus. A detailed description is given of this part from specimens of portions of the skull in the British Museum, and from a cast and photographs of the entire cranium in the Australian Museum, Sydney, New South Wales. The descriptions of the mandible, and of the dentition in both upper and lower jaws, are taken from actual specimens in the British Museum, in the Museum of the Natural History at Worcester, and in the Museum at Adelaide, S. Australia, all of which have been confided to the author for this purpose. The results of comparisons of these fossils of *Nototherium* with the answerable parts in *Diprotodon*, *Macropus*, *Phascolarctos*, and *Phascolomys*, are detailed.

Characters of three species, *Nototherium Mitchelli*, *N. inerme*, and *N. Victoriæ*, are defined chiefly from modifications of the mandible and mandibular molars. A table of the localities where fossil *Nototherium* has been found, with the dates of discovery, and the names of the finders or donors is appended. The paper is illustrated by subjects for nine quarto Plates.

"On the Organisation of the Fossil Plants of the Coal-measures. Part II. *Lepidodendra* and *Sigillariæ*." By Prof. W. C. Williamson, F.R.S. The *Lepidodendron selaginoides* described by Mr. Binney, and still more recently by Mr. Carruthers, is taken as the standard of comparison for numerous other forms. It consists of a central medullary axis composed of a combination of transversely barred vessels with similarly barred cells; the vessels are arranged without any special linear order. This tissue is closely surrounded by a second and narrower ring, also of barred vessels, but of smaller size, and arranged in vertical laminæ which radiate from within outwards. These laminæ are separated by short vertical piles of cells, believed to be medullary rays. In the transverse section the intersected mouths of the vessels form radiating lines, and the whole structure is regarded as an early type of an exogenous cylinder; it is from this cylinder alone that the vascular bundles going to the leaves are given off. This woody zone is surrounded by a very thick cortical layer, which is parenchymatous at its inner part, the cells being without definite order, but externally they become prosenchymatous, and are arranged in radiating lines, which latter tendency is observed to manifest itself whenever the bark cells assume the prosenchymatous type. Outside the bark is an epidermal layer, separated from the rest of the bark by a thin bast-layer of prosenchymna, the cells of which are developed into a tubular and almost vascular form; but the vessels are never barred, being essentially of the fibrous type. Externally to this bast-layer is a more superficial epiderm of parenchyma, supporting the bases of leaves, which consist of similar parenchymatous tissue. Tangential sections of these outer cortical tissues show that the so-called "decorticated" specimens of *Lepidodendra* and of other allied plants are merely examples that have lost their epidermal layer, or had it converted into coal; this layer, strengthened by the bast-tissue of its inner surface, having remained as a hollow cylinder, when all the more internal structures had been destroyed or removed.

From this type the author proceeds upwards through a series of examples in which the *vessels* of the medullar become separated from its central *cellular* portions and retreat towards its periphery, forming an outer cylinder of medullary vessels, which are arranged without order, and enclose a defined cellular axis. At the same time the encircling ligneous zone of radiating vessels becomes yet more developed, both in the number of its vessels and in the diameter of the cylinder relatively to that of the entire stem. As these changes are produced, the medullary rays separating the laminæ of the woody wedges become more definite, some of them assuming a more composite structure, and the entire organisation gradually assuming a more exogenous type. At the same time the cortical portions retain all the essential features of the Lepidodendroid plants. We are thus brought, by the evidence of internal organisation, to the conclusion that the plants which Brongniart has divided into two distinct groups, one of which he has placed amongst the vascular Cryptogams, and the other amongst the Gymnospermous Exogens, constitute one great natural family.

*Stigmaria* is shown to have been much misunderstood, so far as the details of its structure are concerned, especially of late years. In his memoir of *Sigillaria elegans*, published in 1839, M. Brongniart gave a description of it, which, though limited to a small portion of its structure, was, as far as it went, a remarkably correct one. The plant, now well known to be a root of *Sigillaria*, possessed a cellular pith without any trace of a distinct outer zone of medullary vessels, such as is universal amongst the *Lepidodendra*. The pith is immediately surrounded by a thick and well-developed ligneous cylinder, which contains two distinct sets of primary and secondary medullary rays. The primary ones are of large size, and are arranged in regular quincuncial order. They are composed of thick masses of mural cellular tissue. A tangential section of each ray exhibits a lenticular outline, the long axis of which corresponds with that of the stem. These rays pass directly outwards from pith to bark, and separate the larger woody wedges which constitute so distinct a feature in all transverse sections of this zone, and each of which consists of aggregated laminæ of barred vessels, disposed in very regular radiating series. The smaller rays consist of vertical piles of cells, arranged in single rows, and often consisting of but one, two, or three cells in each vertical series. These latter are very numerous and intervening between all the numerous radiating laminæ of vessels that constitute the larger wedges of woody tissue. The vessels going to the rootlets are not given off from the pith, as Gœppert supposed, but from the sides of the woody wedges bounding the *upper* part of the several large lenticular medullary rays; those of the *lower* portion of the ray taking no part in the constitution of the vascular bundles. The vessels of the region in question descend vertically and parallel to each other until they come in contact with the medullary ray, when they are suddenly deflected, in large numbers, in an outward direction, and nearly at right angles to their previous course, to reach the rootlets. But only a small number reach their destination, the great majority of the deflected vessels terminating in the woody zone. A very thick bark surrounds the woody zone. Immediately in contact with the latter it consists of a thin layer of delicate vertically elongated cellular tissue, in which the mural tissues of the outer extremities of the medullary rays become merged. Externally to this structure is a thick parenchyma, which quickly assumes a more or less prosenchymatous form, and becomes arranged in thin radiating laminæ, as it extends outwards. The epidermal layer consists of cellular parenchyma with vertically elongated cells at its inner surface, which feebly represents the bast-layer of the other forms of Lepidodendroid plants. The rootlets consist of an outer layer of parenchyma, derived from the epidermal parenchyma. Within this is a cylindrical space, the tissue of which has always disappeared. In the centre is a bundle of vessels surrounded by a cylinder of very delicate cellular tissue, prolonged either from one of the medullary rays, or from the delicate innermost layer of the bark, because it always accompanies the vessels in their progress outwards through the middle and outer barks.

The facts of which the preceding is a summary lead to the conclusion that all the forms of plants described are but modifications of the Lepidodendroid type. The leaf-scars of the specimens so common in the coal-shales, represent tangential sections of the petioles of leaves when such sections are made close to the epidermal layer. The thin film of coal of which these leaf-scars consist, in specimens found both in sandstone and in shale, does not represent the entire bark as generally thought, and as is implied in the term "decorticated," usually applied to them, but is derived from the epidermal layer. In such specimens, all the more central axial structures, viz., the medulla, the wood, and the thick layer of true bark, have disappeared through decay, having been either destroyed, or in some instances detached and floated out; the bast-layer of the epiderm has arrested the destruction of the entire cylinder, and formed the mould into which inorganic materials have been introduced. On the other hand, the woody cylinder is the part most frequently preserved in *Stigmaria*; doubtless because, being subterranean, it was protected against the atmospheric action which destroyed so much of the stem.

It is evident that all these Lepidodendroid and Sigillarian plants must be included in one common family, and that the separation of the latter from the former as a group of Gymnosperms, and as suggested by M. Brongniart, must be abandoned. The remarkable development of exogenous woody structures in most members of the entire family indicates the necessity of ceasing to apply either to them, or to their living representatives, the term Acrogenous. Hence the author proposes a division of the vascular Cryptogams into an Exogenous group, containing *Lycopodiaceæ*, *Equisetaceæ*, and the fossil *Calamitaceæ*, and an Endogenous group containing the Ferns; the former uniting the Cryptogams with the Exogens through the *Cycadeæ* and other Gymnosperms, and the latter linking them with the Endogens through the *Palmaceæ*.

"Contributions to the History of the Opium Alkaloids. Part II. On the Action of Hydrobromic Acid on Codeia and its derivatives." By C. R. A. Wright, D.Sc. It has been shown in Part I. of this research * that the action of hydrobromic acid on codeia gives rise, without evolution of methyl bromide, first to bromocodide, and secondly to two other new bases termed respectively deoxycodeia and bromotetracodeia, the latter of which, under the influence of hydrochloric acid, exchanges bromine for chlorine, yielding a corresponding chlorinated base, chlorotetracodeia; when, however, the action of hydrobromic acid is prolonged, methyl bromide is evolved in some little quantity. By digesting codeia with three or four times its weight of 48 per cent acid for five or six hours in the water-bath, vapours were evolved which, condensed by the application of a freezing-mixture to a colourless mobile liquid, the boiling-point of which was found to be 10°·5 to 11°·5, and the vapour of which burnt with a yellow-edged flame, exploded violently with oxygen, forming carbonic and hydrobromic acids. It becomes, therefore, of interest to examine in detail the action of hydrobromic acid on each of the three bodies produced from codeia under its influence.

"On the Physiological Action of the foregoing Codeia derivatives." By Michael Foster, M.D. The hydrochlorate of chlorotetracodeia and the hydrobromate of bromotetramorphia, in doses of a decigramme by subcutaneous injection or by the mouth, produced in adult cats in a very few minutes a condition of great excitement, almost amounting to delirium, accompanied by a copious flow of saliva and great dilatation of the pupils. Nicturation and defæcation occurred in some instances, and vomiting was observed on two occasions with the morphia-salt, but was very slight. The excitement was very peculiar, being apparently due partly to increased sensitiveness to noises, and partly to an impulse to rush about.

The same doses of the morphia-salt given to a young kitten produced the same flow of saliva, dilatation of pupils, and excitement (without vomiting); but the stage of excitement, which in adult cats passed gradually off in a few hours, was followed by a condition marked by a want of co-ordination of muscular movements, and presenting the most grotesque resemblance to certain stages of alcoholic intoxication. This stage was followed in turn by sleepiness and stupor, in which the kitten was left at night; in the morning it was found dead.

Two observations have shown that these salts paralyse (in dogs and cats) the inhibitory fibres of the pneumogastric; they also seem to lower the internal tension, but want of material has prevented me from ascertaining how this is brought about.

On rabbits neither salt, even in doses of a decigramme, seems to have any effect, except perhaps a slight excitement. There is no dilatation of the pupils, no flow of saliva, and, if one observation can be trusted, no paralysis of the inhibitory fibres of the pneumogastric.

No marked difference was observable between the two salts, except that the morphia salts seemed rather more potent than the corresponding codeia bodies.

The salts of deoxycodeia and deoxymorphia given by mouth or by subcutaneous injection in doses of a decigramme, produced in adult cats, almost immediately after exhibition, a series of con-

* Proc. Roy. Soc. vol. xix. p. 371

vulsions much more epileptic in character than tetanic. In one case there was a distinct rotatory movement.

In a few minutes these convulsions passed away, leaving the animal exhausted and frightened. Then followed a stage of excitement with dilated pupils and flow of saliva, very similar to the effects of the tetracodeia and tetramorphia salts, but less marked.

Doses of half a decigramme given to adult cats produced the stage of excitement only, without the convulsions.

In no case, with any specimen of product, has vomiting been witnessed.

Trials with rabbits gave only negative results. Like the tetracodeia and tetramorphia products, the deoxycodeia and deoxymorphia salts appear to paralyse the inhibitory fibres of the pneumogastric.

No marked differences could be observed between the hydrochlorates and hydrobromates of deoxycodeia or deoxymorphia.

"On the Calculation of Euler's Constant." By J. W. L. Glaisher, F.R.A.S.

Zoological Society, June 20.—R. Hudson, F.R.S., vice-president, in the chair. The Secretary read a report on the additions made to the Society's Menagerie during the month of May, 1871. Amongst these particular attention was called to a Tamandua Ant-eater (*Tamandua tetradactyla*) from Santa Martha, obtained by purchase, May 29, being the first specimen of the singular Mammal ever exhibited alive in the Society's collection.—Prof. Macdonald, of the University of St. Andrew's, Scotland, exhibited and made remarks on a series of specimens illustrative of the cranial bones of Fishes.—An extract was read from a letter received from Mr. Walter J. Scott, giving notice of a living specimen of the Australian Cassowary which had been lately captured in Queensland by Mr. Haig, and which Mr. Haig was anxious to present to the Society.—Prof. Newton exhibited and made remarks on some supposed eggs of the Sanderling (*Calidris arenaria*), procured by the North German Polar Expedition.—A communication was read from the Rev. O. P. Cambridge, containing notes on the Arachnida collected by Dr. Cuthbert Collingwood during his recent travels in the Chinese seas.—A communication was read from Dr. John Anderson, Curator of the Indian Museum, Calcutta, containing notes on some rare species of Rodents collected by Mr. Forsyth during his recent expedition to Yarkand.—Messrs. Sclater and Salvin read a revised List of the species of Laridæ which have been found to occur within the limits of the Neotropical region. These were stated to be 32 in number, whereof one belonged to the sub-family Rhynchopinæ, 14 to the Sterninæ, 16 to the Larinæ, and one to the Lestridinæ.—A communication was read from Dr. J. E. Gray, F.R.S., containing notes on the Bush-bucks (*Cephalophi*) contained in the collection of the British Museum, together with the descriptions of two new species of the genus from the Gaboon.—A second communication from Dr. J. E. Gray contained some notes on the skull of a roebuck in the British Museum, originally received from the Museum of the Zoological Society of London.—Mr. Sylvanus Hanley communicated the description of a new species of *Monocondylæa* from Sarawak, Borneo, which he proposed to call *M. Walpolei*.—Mr. D. G. Elliot read a review of the genus *Ptiloris*, Sw.—Mr. D. G. Elliot also read a description of a supposed new species of Guinea-fowl from Ugogo, Central Africa, founded on a drawing made by Colonel Grant during the expedition of Messrs. Speke and Grant, which he proposed to name *Numida Granti*.—Mr. R. B. Sharpe read a paper on the Birds of Cameroons, Western Africa, based upon collections recently formed by Mr. A. Crossley in that locality. The Avi-Fauna of the country was shown to be almost identical with that of Gaboon. A species of Thrush was believed to be new to science, and was proposed to be called *Turdus Crossleyi*.—Mr. John Brazier communicated some notes on the localities of *Dolium melanostoma*, *Conus rhododendron*, and other species of land-shells found in Australia and in the adjacent islands of the Australian seas.—Mr. W. Saville Kent read a paper on two new Sponges from North Australia, the principal peculiarity of which consisted of their being arranged round a central stem or axis. These he referred to a new genus proposed to be called *Caulispongia*.—Prof. Flower communicated a paper by Mr. J. B. Perrin on the myology of the limbs of the Kinkajou (*Cercoleptes caudivolvulus*), to which were added some remarks on the myology of the limbs of the *Paradoxurus typus* and *Felis caracal*, and more particularly with reference to the chief points of difference between these animals.

BRISTOL

Observing Astronomical Society.—Observations to May 31, 1871. *The Sun.*—Mr. T. W. Backhouse writes that on March 19 at 21h. 30m. a spot on the sun's S. hemisphere had an umbra 19,000 miles long, but its greatest width was but 3,500 miles. This spot passed the centre of the sun on the 21st. On the 22nd at 3h. there was a curious curve of numerous small spots starting from it. An extensive group which passed N. of the sun's centre on the 23rd contained on the 27th at 5h. the largest spot then on the sun. Its penumbra was 29,000 miles in diameter, and its umbra 14,000 miles long; yet if it existed at all on the 24th at 21h. it must have been quite small. A spot in the sun's S. hemisphere which passed the middle of the sun on April 11, and which was not large on the 6th, on the 7th at 21h. 35m. had a penumbra 63,000 miles long. On the 9th at 21h. 15m. it was about 41,000 miles long, and its chief umbra 13,000 miles in diameter, and mostly of a light shade. On April 20 at 21h. 45h. a spot also in the southern zone had an umbra 25,500 miles long; but its *f* part was very narrow, its *p* part was very irregular. Its *f* part became broader, and on the 24th at 20h. was separated from the *p* part. The umbra had previously shortened, being only about 21,000 miles long on the 23rd; at 21h. on the 23rd it passed the same centre. On the 28th at 3h. 20m. the penumbra was 38,000 miles long. At that time there was another large solar spot also in the S. zone, which had a penumbra 33,000 miles in diameter then; but on May 4 at 5h. 15m. it was 43,000 miles long and 35,000 miles wide, and it is now (May 8) larger still. Its umbra was roundish and much mottled, and on May 4 at 4h. was 17,000 miles long and 14,500 wide. On the 5th at 21h., however, there was a very slender bridge of light across it towards the southern part, and another farther north two-thirds across it. The latter still remains (May 8, 3h. 30m.), and nearly cuts the umbra in two; but the former has disappeared. Mr. Albert P. Holden, of London, reports as follows:—"April 10, 1871. A large spot, surrounded by an extensive penumbra, has recently appeared, which I observed at 2h. this day. The chief spot was rather long and narrow, except at one end, which was considerably wide, and the narrow portion was crossed by three complete (and one partial) bridges. The penumbra was unusually pale, and the umbra of a decided light-brown hue. In the upper part of the broad portion of the umbra was a large nucleus intensely black, and so large and dark as to be visible with a very low power. Almost joining the 'yawning gulf' of the nucleus was a light triangular patch, not quite so light as the penumbra. From the great ease with which the nuclei have been seen on this and other occasions it would seem as if they increased in visibility with the approach of the maxima of the sun-spot period. When they are visible, as on the present occasion, the windward penumbra of the spot in which they occur are always unusually light in colour."—Mr. William F. Denning, of Bristol, observed the sun with his $10\frac{1}{4}$in., and 4in. reflector on May 26, but with the exception of a large scattered group the spots were neither large nor interesting.

*Jupiter.*—Mr. Albert P. Holden says: "On February 20 at 7h. 30m. I observed this planet, and found the usual equatorial belts to present a most remarkable appearance. The whole equator was covered by what appeared to be great masses of clouds stretching across the planet in four parallel, but rather irregular, rows, each row containing about four or five distinct masses of cloud. As I was using a diagonal eyepiece I thought at first the mirror had become covered with moisture, but found the phenomenon to be really on the planet's surface. With a low power the whole equator had a mottled appearance, but higher powers brought out the masses of cloud very distinctly. The clouds coming over prevented my observing whether the rotation of the planet would change the scenery of the disc at all." Edmund Neison, of London, writes with regard to Jupiter: "The only result worth mentioning is the gradual deepening of the tinge of the equatorial belts and the increase in the general orange tinge of the whole disc. In fact, on May 15 it appeared to have changed to a distinct red. This is probably due merely to the low altitude of the planet, and its immersion in the orange mists of sub-sunset."

*Mars.*—Mr. Albert P. Holden, with his 3in. refractor, has obtained some very good views of this planet. He writes: "The Kaiser Sea and Dawes Ocean come out very distinctly. This planet seems to bear magnifying much more readily than other objects, eighty to the inch of aperture giving most excellent views."

PARIS

Academie des Sciences, June 19.—M. Claude Bernard in the chair. M. Claude Bernard read a letter from Mr. Alexander Herschel, noticing the death of his father on behalf of himself and of his eldest brother now in India. The lamented Sir John Herschel was the senior foreign associate member of the Institute. The foreign associate members are only five in number; it is considered the highest honour the Academy can offer to a foreigner. The President noticed also the death of the celebrated General Probert, who was an academician of long standing, and had devoted his whole life to the study of projectiles. His memoirs are numerous in the *Comptes Rendus*, but more numerous at the War Office. He was of opinion that the Prussian steel gun should be adopted by the French artillery, but his Imperial Majesty being a great artillerist, his opinion was totally disregarded. The vacancies to be filled amongst members and associates are now six. They have never been so numerous. There were twelve correspondents to elect before the investment of Paris took place. M. Dumas presented a memoir on the reciprocal action of magnetism and electricity circulating in a vacuum. The memoir was written by M. De La Rive, a foreign associate member of the Academy, and describes experiments tried with an apparatus analogous to the magnificent instruments exhibited by M. De La Rive at the "Champ de Mars" universal exhibition.—M. Elie de Beaumont, the other perpetual secretary, has directed public attention to the extraordinary cold experienced on the 18th May and 3rd June 1871, and asked for observations relating to it. Every information must be directed to him, and will be mentioned in the *Comptes Rendus*. Several other communications are duly acknowledged, and will be printed. Some of them relate to other severe depressions of temperature witnessed late in the season in former years; hoar frost was observed as late as in July 1802, which appears to have been one of the worst years ever known for low temperature in the summer.—M. Grèmand de Lany, the senior member of the Scientific Staff of the Parisian papers, has published an interesting book on the Academy of Sciences during the siege of Paris, giving a fair idea of the amount of work executed by members resident in Paris during that eventful period of its annals. The Academy has to appoint a committee for reporting upon the memoirs sent to compete for the great prize of mathematics proposed by the government. The subject proposed belongs to the theory of elliptical functions. No qualification of nationality is required. The names of the competitors are kept sealed and opened only if successful. MM. Bertrand, Hermite, Serret, Leonville, and Bonner were appointed.—A most interesting discussion took place on a paper relating to the treatment of typhus during the Mexican campaign, showing that typhus is unquestionably contagious, as well as many other diseases of the same kind. The cold and moisture is not so much to be feared as stagnant hospital air, and treatment under canvas even in cold weather is perhaps the best that can be imagined.—M. Campion, the first assistant to M. Payen, presented a memoir on the manner of blasting rocks with dynamite. That paper is a kind of *résumé* of M. Campion's experiments during the first investment of Paris. He was closely engaged in dangerous operations, practised for protecting the town. According to every probability, he will be appointed a member to fill the chair of his professor.—Five or six other papers were read, too long to report.

VIENNA

I. R. Geological Institution, May 2.—Dr. Gümbel, of Munich, gave an account of his investigations of the different forms of Dactylopora, found chiefly in the Triassic limestones of the Alps. Notwithstanding some differences in the structure, he recognised in them a strong resemblance to living and tertiary Dactylopora. Great and constant varieties in the forms led him to distinguish a large number of different species.—Mr. F. Pick, who had visited the Isle of Milo in the month of March, made a report of the numerous earthquakes which had been observed there since the beginning of the year. From the middle of January up to the month of March they continued incessantly, and during the time between the last days of February till the 3rd March more than twenty shocks were felt daily, not seldom two or three in one hour. The St. George volcano on Santorin was seen on March 20 in continuous, but feeble activity.—M. v. Lill discovered the rare Ullmannite (Nickel-Antimon-Pyrites) at a new locality in Carinthia, the Rinkenberg, near Bleiburg, where it is imbedded in slaty schists and crystalline dolomite.—Another mineralogical discovery of interest communicated by T. Niedzwiedski is the occurrence of Trinkerite at Gams, near Hieflau, in Styria. This fossil resin, which contains more than 4 per cent. of sulphur, was first described a few months ago by Dr. Tschermak, of Carpano, in Istria, where it was found in a coal of Eocene age. At Gams it is imbedded in a dark coloured rock, which belongs to the Gasau (Upper Cretaceous) formation.—Prof. E. Suess on the Tertiary land fauna of middle Italy. The study of the rich collections of fossil mammalia in the museums in Pisa and Florence enabled the author to parallelise the different faunæ of the Upper Tertiary beds of middle Italy, which had been distinguished quite correctly by Falconer, Lartet, &c., with those of Austria. The first mammalian fauna of the Vienna Basin, the fauna of Eibiswald, with Amphicyon intermediaries, Hyotherium Sömmeringi, Palæomerix, Crocodilus, Trionyx, &c., is represented in Italy by the fauna of the lignites of Monte Bamboli. The second fauna of the Vienna Basin, the fauna of Eppelsheim with *Mastodon longirostris*, *Hippotherium gracile*, &c., is not yet known in Italy. The fauna of the Arno Valley, on the contrary, which is represented in a marvellous richness in the museum of Florence, seems to be wanting in the Vienna Basin. This third fauna is characterised by *Elephas meridionalis*, *Machairodus*, *Bos etruscus*, *Hippopotamus major*, &c.; traces of it M. Suess thinks he has recognised in some fossils from the caverns of the Karst (Istria). The fourth fauna, with *Elephas primigenius* which is to be found everywhere in our loess, has been discovered also in some localities of Tuscany in the so-called Pauchina, a clay similar to the loess.—M. Schwackhöfer exhibited a series of rocks rich in phosphoric acid, which occur in the Silurian, as well as in the Cretaceous beds of Eastern Gallicia, the discovery of which he hopes will be of great use for agricultural purposes.

## SENSATION AND SCIENCE

THE morbid craving for excitement, which is characteristic of mental indolence, as well as of effete civilisation, has led to the introduction of Sensation (as it is commonly called), not merely into our newspapers and novels, but even into our pulpits. It could not be expected that our popular scientific lectures would long escape the contamination. We have watched with regret its gradual introduction and development, and have often meditated an article on the subject. But now, when a splendid opportunity has come, we feel how unfit we are for the task. None but a Spurgeon can effectively criticise a Spurgeon; nóne but a *Saturday Reviewer* could be expected to tackle with delicacy and yet with vigour the gifted author of the "Girl of the Period." So we must content ourselves with the spectacle of the Rev. Prof. Haughton as criticised by himself. We have not been able to attend his recent lectures at the Royal Institution, but we have it on excellent authority that they were racy (*i.e.* sensational) in the extreme. Happily we find in the *British Medical Journal* what is described as an authorised version of them. A few extracts from this will enable us to dispense with a great deal of comment. We shall first take the Science, and then permit the Sensation to speak for itself.

Prof. Haughton's subject is *The Principle of Least Action in Nature;* and we are told that he believes he has succeeded in discovering in this the true principle on which the Science of Animal Mechanics must be founded, and has been enabled to sketch out the broad outlines of its foundation.

Maupertuis's Principle of Least Action is indeed "well known to mathematicians," but is by no means easy of explanation to the ordinary reader. We can, therefore, sympathise with the lecturer in his repeated failures to make it intelligible. But we cannot admit any justification of the constant use of the same words, sometimes in one sense, sometimes in a totally different one. To a mathematician (Prof. Haughton speaks as at once mathematician, anatomist, medical man, natural philosopher, "expert" at shot-drill, the crank, and the treadmill, clergyman, &c., &c., and even as potential farmer and landlord-shooter!) we should have thought that, when once $x$, $y$, $z$, or whatever else, is introduced, it has and continues to have a definite meaning, until *in a new problem* it comes to be applied to something possibly quite different. How then can we account for such sentences as the following?—

"The great problem—the problem of doing a given amount of work *with a minimum of effort.*"

"Nature aims at producing a given quantity of work *with the least quantity of material.*"

"I could show that these [tendons of the legs and arms of animals] are constructed *with a wonderful economy of force* of the same kind as that with which the bee constructs its cell"

"By what force, or by what intelligence, do the limbs of animals describe their proper path? Who places the socket of each joint in the exact position (which can be calculated with unerring certainty by mathematics) which enables the muscle to perform its allotted task *with the least amount of trouble to itself?*"

"The Principle of Least Action is that the arrangement and mutual position of all muscular fibres, bones, and joints must be such as to produce the required effect *with the minimum amount of muscular tissue.*"

"Before proceeding to apply *this principle of least action or least trouble* to nature," &c.

In all these extracts the italics are ours. If the reader but glance them over, he will not require to read the lectures to see what a very Proteus is this so-called principle. There is no knowing where to have it. It is a minimum, an economy, a least quantity, and what not; sometimes of effort, sometimes of material, then of trouble, and anon of muscular tissue, or of force of the same kind as that with which the bee constructs its cell! But the most curious feature about it is that in none of its metamorphoses does it in the slightest degree resemble the least action of Maupertuis, with which it would seem throughout to be held as identical.

Even in his remarks on this perfectly definite mathematical question, Prof. Haughton commits a grave error, for he says:—

"If I take the points A and B in the planet's path, S representing the sun, I only require to know those points A and B, and the sun S, to calculate for you, from the Principle of Least Action—which I can do to the millionth part of an inch at each point of this orbit—the path that the planet must describe, on the supposition that it is a lazy, intelligent animal, trying to swim round the sun in such a manner as to give the least trouble to itself."

It seems to us that all that the principle of least action can tell us, is that, supposing the sun's attraction to vary inversely as the square of the distance, the planet will describe *some conic section or other*, whose focus is S, and which passes through A and B. Which it will be of the innumerable conics satisfying these conditions, ellipse, parabola, or hyperbola (or possibly circle) there is nothing to indicate, within quadrillions of miles—yet we are told it can be done to the millionth of an inch!! As to what a "lazy, intelligent animal" (of course, not acted on by gravity) would do in "trying to swim [in what?] round the sun," we unfortunately possess no information. But this is merely another proof that we are dealing with Sensation where we looked for Science.

Here we have caught our instructor in a palpable and inexcusable blunder, and we could easily point out many others of a similar kind in his remarks on light, &c. It is not so easy to do so, or rather to make the general reader aware that we have done so, when he leaves strictly mathematical applications, and plunges headlong into a wild sea of speculation *without previous careful definition of his terms.* These terms are, in fact, as he employs them, so elastic, that it is only by contrasting (as we did above) portions of his lectures with other portions in which the same words acquire other and different meanings, or in which different words are employed for the same meaning, that we see how excessively loose and slipshod is the whole affair. Another little group of quotations will admirably illustrate this:—

"The law of *least action* is attended to in every department of nature *down to the most minute details.* . . . . *Not even one grain of material is ever used,* when less would suffice for the purpose."

This is, no doubt, admirable, and would suit the most frantic of the mischief-making teleologists. But, alas ! like the Editor of the *Little Pedlington Observer,* "What in one line we state we retract in another." For there follows—

"We can demonstrate by mathematics that in the use of every such muscle [triangular, &c.] *there is a necessary loss of force.* . . . I have always maintained that beauty of form . . . was one of the pre-existing conditions in the mind of the Contriver of the universe, as well as economy of force."

As intermediate to these two quotations, and in itself amusing from its *bonhommie* and condescension, we may take the following :—

"Nature, according to my principle, is entitled to employ these two forms of muscles whenever she pleases."

The reader may take our word that these are but single gems, selected from among many similar and often richer ones, mainly on the Principle of Least Trouble (in copying out for press).

As to really scientific matters, occasionally referred to in these lectures, we need merely mention that the author is ignorant of, or ignores, Dr. Pettigrew's extraordinary researches on wings and other adaptations for progression ; researches which ought to be thoroughly mastered by any one who attempts to write on the subject of animal mechanics ; and that, in his remarks on the strength of the uterine muscles, he seems to have entirely forgotten to notice how thoroughly least action theories (at least as applied by him) have been upset in a late number of the *Dublin Quarterly Journal of Medical Science.*

We promised Science first and Sensation afterwards. In attempting to collect the Science we have got hold of little but Sensation : so we need give only one extract more. Would it have been considered possible (till the 23rd of last May) that a Dublin professor, an M.D., a D.C.L., an F.R S., and a clergyman of the (till lately) Established Church, should, even in jest, speak as follows in the Royal Institution in London ?—

". . . . A brilliant idea came across my mind . . . . What in the world is to hinder me from taking a farm in Westmeath, deliberately and wilfully refusing to pay my rents, and in due time shooting my landlord, and, instead of using him as a New Zealand tenant would, dissecting him at my leisure ?"

We have only to add that the *British Medical Journal,* in publishing the above, conspicuously prints the remark :—

"In reproducing the *ipsissima verba* of the lecturer, and giving them a permanent place in scientific literature, an enduring service will be rendered to Science."

Which means, we hope, that all men, scientific or otherwise, will, once for all, take warning from this terrible example. If such be the result, Prof. Haughton will, indeed, not have lectured in vain. But if the *British Medical Journal* intends its remarks to signify approval, we can say of it and of Prof. Haughton, in the language of Cervantes—

No rebuznaron en valde
El uno y el otro Alcalde.

## BASTIAN ON THE ORIGIN OF LIFE

*The Modes of Origin of Lowest Organisms : including a Discussion of the Experiments of M. Pasteur, and a Reply to some Statements by Professors Huxley and Tyndall.* By H. Charlton Bastian, M.A., M.D., F.R.S., &c. (Macmillan and Co., 1871.)

IT may be as well to state at the outset that the present volume is not Dr. Bastian's long-promised work on "The Beginnings of Life ;" and it would have been better had some title been devised to prevent the confusion that will inevitably be caused by its appearance at this juncture. We have here, however, a condensed sketch of the whole controversy on Spontaneous Generation, and a statement of some very important researches conducted by the author since the discussion which followed Prof. Huxley's Presidential Address at Liverpool last September. It will be remembered that the objections to Dr. Bastian's experiments and to the results he deduced from them were twofold. It was said that we have no proof that these minute organisms (*Bacteria,* &c.), or their germs cannot resist the heat to which they were subjected. It was also said that no proof was given that the supposed organisms found by Dr. Bastian in these boiled and hermetically sealed liquids were alive. The motions exhibited might be "Brownian" motions, and the experimenter probably found nothing in his vessels but what he put into them. The answer to these objections is now given. The test of vitality is said to be, not movement, which is admitted to be uncertain, but the *power of reproduction.* It is found that if a portion of liquid containing *Bacteria* is divided into two parts, one of which is boiled, and a drop from each of these portions is mounted as a microscopic object, under a covering glass surrounded by quickly-drying cement, the unboiled specimen exhibits a marked increase from day to day in the quantity of imprisoned *Bacteria,* while the boiled specimen continues unchanged during the same time. Making use of this test of vitality, it was next ascertained what degree of heat was fatal to these low organisms. By using a lower and lower temperature, it was found that exposure to 140° F. for ten minutes destroyed *Bacteria,* while after exposure to 131° F. for the same time they rapidly multiplied. Somewhat higher organisms—*Vibrios, Amœbæ, Monads, Vorticellæ,* &c., were, however, killed by exposure to 131° F. for five minutes. It was subsequently ascertained that a four hours' exposure to a temperature of even 127° F. destroyed *Bacteria* and *Torulæ.* It is argued that, as in all these experiments the solutions used swarmed with *Bacteria,* &c., in various stages of increase, their hypothetical "germs" cannot be supposed to have been entirely absent ; and that we may therefore conclude that the "germ" has no greater power of resisting heat than the animal itself.

Dr. Bastian also criticises many of the experiments of Pasteur, and the arguments founded on them. He maintains that the corpuscles found by the latter to exist in the atmosphere, and which "resemble" spores of fungi, have never been proved to be such ; and even if they were so proved, it would not account for the constant occurrence of *Bacteria* and other low organisms, whose "germs" are quite unknown, and which there seems no reason to believe could retain their vitality in a dry state in the atmosphere. The fact that vessels with bent necks or with plugs of cotton-wool do not produce organisms, while other vessels not so protected produce them in abundance, is shown, by numerous experiments, not to be universal. The evidence now adduced is held to prove that a variety of conditions hitherto not attended to affect the result, such as temperature, the strength of the solution, and especially the presence of particles of organic matter, other than "germs," derived from the atmosphere. A summary is given of sixty-five comparative experiments, which are believed to show, among other things, that the non-production of *Bacteria*, &c., in infusions and other suitable liquids, is so common an occurrence that the negative experiments of Pasteur and others have no weight as compared with the positive results obtained by a considerable number of observers, to whom the author refers, as well as by himself.

Some of these comparative experiments are very suggestive. Hay infusion, for instance, exposed to air, produced abundance of *Bacteria* in forty-eight hours, and these had increased considerably in sixty-eight hours. A similar infusion, sealed up after the fluid had become cold, behaved in a similar manner. The same in a flask with neck two feet long and having eight acute flexures, remained unchanged for twelve days. A similar infusion, hermetically sealed during ebullition, on the other hand, showed turbidity in forty-eight hours, which subsequently increased, and *Bacteria*, *Vibriones*, *Leptothrix*, and *Torulæ* were found in abundance. Here, then, whatever inference may be drawn from the first three experiments is entirely negatived by the fourth. Other experiments show that ammonia-tartrate solution sealed *in vacuo* at a temperature of 90° F. produced in eighty-four hours abundance of *Bacteria;* while the same solution, if boiled at 212° F. and exposed to the air in flasks covered with paper caps, remained quite clear for nine days; yet as soon as it was inoculated with living *Bacteria*, they increased rapidly and produced turbidity. These, and a number of other equally suggestive experiments, indicate that the conditions favourable to the *origin* and to the *increase* of these low forms are not always identical. Both are very complex, and we cannot avoid the conclusion that the advocates of the universal germ theory have been somewhat hasty in founding their doctrine upon insufficient data, for the most part of a negative character.

We have here, undoubtedly, an important addition to the experimental evidence by which alone the question can be decided, and we are glad to observe the unprejudiced and philosophical spirit with which Dr. Bastian discusses this most interesting and important problem.

A. R. WALLACE

## THE WORKSHOP

*The Workshop.* Edited by Prof. W. Baumer, J. Schnorr, and others. (London: J. Hagger, 67, Paternoster Row.)

EVERY year of our national progress strengthens the national appreciation of the wisdom expressed in those words of the late Prince Consort, when he told the manufacturers of Birmingham that "the introduction of Science and Art as the *conscious* regulators of productive industry is destined to play a great and important part in the future development of this nation, and the world in general." I take the liberty of italicising the word "conscious," remembering well the emphasis with which it was spoken, and being strongly impressed with the vast importance of this qualification.

Science of some sort, and art of some sort, have always regulated the operations of productive industry. The club of the savage is not uncommonly carved with much art, and shaped and poised with sound practical knowledge of the whereabouts of the weapon at which will be concentrated the whole force of the blow when it swings through the curve which the stroke of the arm will give it. The savage artisan is, however, utterly unconscious of the dynamical principles upon which the centre of oscillation or percussion is determined, and upon which his own skill depends. He follows a blind instinct but one degree higher than that which impels the bee to construct its honey-comb upon sound statical principles. The more civilised workman who merely proceeds according to the "rule of thumb" and the traditions of his trade, is in a similar intellectual condition to that of the bee and the savage. In his daily occupation his specially human faculties are scarcely exercised. The constructive instinct which he possesses in common with the beaver or the wasp is sufficient to guide his muscles in doing such work in such a manner. To talk of the "dignity of labour" when labour is thus conducted is merely to indulge in senseless and vicious phrase-mongering.

The whole life and being of the artisan becomes changed immediately his daily work is *consciously* regulated by science and art. It then becomes an elevating instead of a brutalising occupation; the "dignity of labour" is removed from the sphere of platform verbiage to that of practical fact, and the workshop becomes a school of intellectual and moral culture.

We must always remember that the character of a man is formed by the daily, hourly, and continuous habits of his life, that no quantity or excellence of mere Sunday sermons, or occasional evening meetings, can overpower these. The philanthropist who would practically influencce the character of the workman must operate upon him in and through the workshop; and it appears to me that there are no conceivable means so effectual for this purpose as the converting his bread-winning work from a mere mechanical brutal drudgery into a moral and intellectual exercise. To understand thoroughly the scientific principles involved in all the operations of any common handicraft is to know a great deal more than our greatest philosophers are yet acquainted with, and therefore the field of the consciously scientific artisan is wide enough for the intellectual effort of a life time. If, in addition to the physical science of his trade, he is conscious of his own social relations and functions, if he knows the part which he is playing in the great machinery of society, the motive to his industry will not be that of a merely sordid grubbing for wages, but the sense of duty and the chivalry of reciprocal beneficence will be introduced, and will perpetually operate as necessary results of this scientific consciousness of his own social functions.

If soldiers and sailors can be taught to glorify their work, and rise to heroism in their efforts to do their duty and serve their country, why should not the spinner, the weaver, the tailor, the agriculturist, the miller, and the baker do the same? Surely it is as noble and as glorious and as serviceable to one's country, to be engaged in clothing the naked and feeding the hungry, as in shooting and drowning our fellow creatures?

I have referred above only to the artisan, but have chosen him and the workshop merely for the sake of typical illustration; the remarks apply equally to all who are engaged in useful industry, to the distributor as well as to the producer, to the capitalist and organiser of labour as well as to the labourer himself. The grocer, for example, who should understand and take intelligent interest in the natural history of the products that cross his counter, and the social machinery that brought them there from all the corners of the earth, would be a very different being from the mere parcel-tying and change-counting machine that usually weighs our tea and coffee.

I have thus dwelt upon some of the grounds for giving special emphasis to the word "conscious," believing that the advocates of Technical Education are too apt to regard the subject from a merely technical point of view. It is of the utmost importance that we should be convinced of the perfect harmony which naturally and necessarily exists between moral and material welfare, when the best and soundest means of obtaining either one or the other are followed, especially as there does exist in the minds of a certain class, both of workers and dreamers, a foolish prejudice and misconception, leading them to regard the advocates of Technical Education as a set of cold-blooded materialists, who look upon the workman as a mere productive engine which they seek to improve only in order to get more out of him. My opportunities of learning the opinions and feelings of the better class of self-improving workmen have been rather extensive, and I have met with this idea more frequently than one might suppose were possible. Certain flashy and trashy hollow-headed writers, who are constantly babbling about "the materialistic tendencies of the age" have encouraged these ideas, and as the arts of smart writing and showy oratory are so very easily acquired, this class of sentimentalists is very numerous.

The work above-named, which has suggested these remarks, is published in shilling parts, each containing a large number of well-selected and well-executed illustrations of art workmanship, a supplementary sheet of detailed working drawings, and essays on art-industry and miscellaneous technological subjects. Most of the illustrations are representative of continental art, and the character of the whole work is essentially German, including the typography, and some clerical errors in the English. As the chief use of such a work is to supply the English manufacturer with ideas that may help to emancipate him from slavish adherence to mere trade customs and models, this feature is advantageous, provided it does not foster the too common fallacy of believing that our continental neighbours have a monopoly of artistic taste—a fallacy which is sometimes carried to the length of an extravagant prejudice.

I have little doubt that if an equal amount of industry and taste were exerted in selecting models from the English fittings, English furniture, and English ornaments of English mansions, another and retaliatory "Workshop" of equal intrinsic merit, and equally suggestive to the continental workman, might be compiled.

There are several designs for German porcelain stoves, which are especially worthy of the attention of the English manufacturer. Their value is not confined to their artistic merits; the introduction to this country of such stoves would add much to the comfort and economy of English households, by taking the place of our barbarous open fire-places which give 90 per cent. of their heat to the clouds, and with the residue roast us on one side while the other is exposed to the cold blasts that converge from all sides towards the chimney, round which we are compelled to huddle whenever we have any really cold weather, such as that of last winter. The contrast between the genial, well-diffused warmth of the sitting-rooms of a well-ordered North German household and those of English houses of a corresponding class is anything but favourable to "the Englishman's fireside;" and as reason has so little power against prejudice, it may be well to call in art to the aid of science, in order to try whether the elegant designs of some of the German fire-places may have some effect upon those who reply to all demonstrations of the inefficiency and wastefulness of the English fireplace, that they must have an open fire "to look at," or on account of its "cheerful appearance."

A work of this kind, that a man may purchase or borrow from a library, and thus deliberately study at home, has a special value over and above that of Art Museums and International Exhibitions, though of course in these he has the great advantage of seeing the objects themselves.

The great fault of the work is the want of direct connection between the letter-press and the engravings. There are essays on various branches of art-manufacture, and illustrations of these; but the illustrations are distributed at random throughout the work, which, although published in separate parts, has no part complete in itself. A re-arrangement and proper classification of the materials of this book would greatly increase its value. The publishers may possibly suppose that by devoting certain shilling parts to knockers, hinges, gates, railings, and other ironmongery illustrations, another part to jewellery, another to mantelpieces, others to cabinet-work, &c., they would be holding out an inducement to their customers to buy only isolated numbers, while by the present arrangement, which sprinkles each man's special requirements throughout the work, they compel their subscribers to take the whole series. Whatever be the motive or origin of this arrangement, or want of arrangement, the commercial result must be to prevent many practical men from purchasing it at all, who would be glad to possess those parts relating to their own trades. As a mere picture-book, the confused miscellaneous arrangement may be the most popular, it gives great variety to the contents of each number; but in reference to higher usefulness this is a serious drawback to the merits of an otherwise valuable work. W. MATTIEU WILLIAMS

## *LETTERS TO THE EDITOR*

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### A New View of Darwinism

I AM much obliged to Mr. Howorth for his courteous expressions towards me in the letter in your last number. If he will be so good as to look at p. 111 and p. 148, vol. ii. of my "Variation of Animals and Plants under Domestication," he will find a good many facts and a discussion on the fertility and sterility of organisms from increased food and other causes. He will see my reasons for disagreeing with Mr. Doubleday, whose work I carefully read many years ago.

CHARLES DARWIN

Down, Beckenham, Kent, July 1

---

THE very ingenious manner in which Mr. Howorth first misrepresents Darwinism, and then uses an argument which is not even founded on his own misrepresentation, but on a quite distinct fallacy, may puzzle some of your readers. I therefore ask space for a few lines of criticism.

Mr. Howorth first "takes it" that the struggle for existence "means, in five words, the persistence of the stronger." This is a pure misrepresentation. Darwin says nothing of the kind. "Strength" is only one out of the many and varied powers and faculties that lead to success in the battle for life. Minute size, obscure colours, swiftness, armour, cunning, prolificness, nauseousness, or bad odour, have any one of them as much right to be put forward as the cause of "persistence." The error is so gross that it seems wonderful that any reader of Darwin could have made it, or, having made it, could put it forward deliberately as a fair foundation for a criticism. He says, moreover, that the theory of Natural Selection "has been expressively epitomised" as "the persistence of the stronger," "the survival of the stronger." By whom? I should like to know. I never saw the terms so applied in print by any Darwinian. The most curious and even ludicrous thing, however, is that, having thus laid down his premisses, Mr. Howorth makes no more use of them, but runs off to something quite different, namely, that *fatness* is prejudicial to fertility. "Fat hens won't lay," "overgrown melons have few seeds," "overfed men have small families,"—these are the *facts* by which he seeks to prove that the *strongest* will not survive and leave offspring! But what does nature tell us? That the strongest and most vigorous plants *do* produce the most flowers and seed, not the weak and sickly. That the strongest and most healthy and best fed wild animals *do* propagate more rapidly than the starved and sickly. That the strong and thoroughly well-fed backwoodsmen of America increase more rapidly than any half-starved race of Indians upon earth. No *fact*, therefore, has been adduced to show that even "the persistence of the stronger" is not true; although, if this had been done, it would not touch Natural Selection, which is the "survival of the fittest."

ALFRED R. WALLACE

---

## Our Natural History Museum

IN a few days the country will be called upon to vote 30,000*l*. or 40,000*l*. towards the erection of the new Natural History Museum at Kensington. 7,000*l*. were voted last year for the purpose of drawing up estimates and preparing the site, and our present one at Bloomsbury has become such a crying evil that we can scarcely anticipate a refusal of the grant.

So liberal a sum being offered at the shrine of Science, the community at large will necessarily expect great things of her, and first among all a radical redress of all existing grievances. Yet, if rumour whispers true, the prospects of the future are scarcely so brilliant or pregnant with promises of better things to come as they should be. Plans have been drawn up and decided upon, and the chiefs of the present Natural History Departments have been subsequently consulted as to the amount of space required for the several collections under their charge.

This is itself a faulty commencement, for the building should be constructed for the requirements of the collections, and not the collections cut to the size of the building, and, as might have been anticipated, such policy already threatens to prove productive of disappointment and dissatisfaction. Some departments will profit by the change, while others, including the one mostly needing an elargement of its borders, will absolutely have less than the present amount of space awarded it. We refer to the zoological one, whose present overcrowded and semi-arranged condition is a disgrace to the nation. And yet, on the completion of the present plans, this cramming process is threatened to be still further carried out, though it is to be hoped the voice of opposition and common sense will save us yet from so unfortunate a catastrophe. We hear again that no consideration whatever has been devoted to the subject of a library for the new building, nor a single foot of space allotted to the purpose of constructing one. Such a blunder as this surpasses the first one. The scientific volumes in the present library are in constant requisition by the officers of the various departments to assist them in the determination and arrangement of the specimens. Many of these again are unique or only replaceable at a great cost, and the inconvenience and loss of advantages that will arise to the official staff on being separated from the collection of works they now have access to, cannot be over-estimated. If the Natural History collections must be removed, an edifice suitable for their thorough utilisation, and replete with every convenience for prosecuting scientific research, including efficient laboratories, should be erected.

But to commence at the root of the evil. No progress can be expected under present auspices, or so long as the chief administration of the establishment, and the appointment and promotion of all officers, is vested in the hands of some fifty or sixty trustees, out of whom not more than two can be said to take a direct interest in the promotion of Natural Science. Nor, again, so long as such little discrimination is exercised in the distribution of these officers. Curiosity has prompted inquiries which have elicited anything but satisfying discoveries. We find men with talents for one branch of natural history stationed in departments where their particular talents cannot be utilised; recent zoologists in the geological department, palæontologists in the recent botanical one, and men peculiarly gifted for literary pursuits and without the slightest taste for scientific research, in the former. Taking next the department of Recent Zoology, the inadequacy of the present staff and the ill-proportioned attention that is devoted to particular sections, to the entire neglect of the remaining ones, are painfully apparent. In the Vertebrate division, though abundant room for improvement, there is not so much cause for censure; but on descending to the lower and far more bulky one of the Invertebrates, what do we find? Of a staff of five, two are conchologists, and the remaining three entomologists, while the Crustacea, Arachnida, and the whole of the old group of the Radiates, including the Echinodermata, Molluscoida, Cœlenterata, and Protozoa, are left to shift for themselves, and make way for the necessities of the others. Have we no men in England capable of superintending the arrangement of these neglected classes? or is it that the present remuneration for scientific work, for all but those highest in authority—so slender as to necessitate their utilising every leisure hour in eking out other means of subsistence, and taxing their brains, to the detriment of the amount of work discharged in official hours—deters them from coming forward? At any rate, the evil should be attended to, and the present glaring incongruities abolished. Whether new buildings are erected at Kensington, or the existing ones enlarged, it is absolutely incumbent that the administration shall be thoroughly reorganised. A permanent committee of some dozen eminently scientific men should supply the place of the present host of uninterested trustees, and the staff of officers should be distributed in accordance with the plan adopted in the Paris and various Continental Museums. Each zoological section should have its superintendent, with a number of assistants varying according to its requirements, while one governing mind should assume the responsibility and direct the machinery of the whole; and until such reformation is accomplished, there is no hope of any practical improvements. We do not see why the two large wings of the present establishment, now occupied as residences by the superior officers, should not be converted into exhibition rooms; space enough being reserved for one official residence on either side; and if necessary, additional suitable ones might be rented in the immediate neighbourhood, and the collections thus saved the unavoidable wear and tear of removal, and at the same time preserved in their present convenient position of access to the general public. But the exodus has been decided upon, and the question itself is of secondary importance compared with that of administration. On a future occasion I would direct attention to a few other points.

BATHYBIUS

## Steam Lifeboats

THE *Globe* of Friday last contained a report of the proceedings of the Committee of the Steam Lifeship Fund, from which it would appear that the subject of the construction of a steam lifeship is seriously contemplated. As one who has for several years given great attention to this most desirable object, perhaps you will allow me to give the results of my labours.

It has already appeared to me that the object to be attained was not the construction of a lifeship, but rather the fitting of lifeboats with steam machinery, thereby improving their efficiency and diminishing the risk of life, as a boat so constructed could be worked, and that more efficiently, by at most three men, instead of the large number now required to man them. The only means of propulsion which can be applied is, in my opinion, the hydraulic propeller, as, the turbine being enclosed, all risk of fouling pieces of wreck, weed, &c., is thereby avoided. To attempt to use a lifeboat fitted with a screw or paddle would only be courting danger and disaster. Such being the case, the boat designed by me consists of three tubes, the outer ones being circular, and the centre one in which the propeller works being semicircular, and placed underneath the platform grating connecting the two circular tubes. The three tubes would be turned up and unite at the ends, and would somewhat resemble a whaleboat. The peculiar advantage of the hydraulic propeller when applied in this manner is, that the boat could be turned round on its own centre, and sent ahead or astern by the man in charge by simply turning a handle, without issuing an order to any one, an advantage which I need hardly say is of the very greatest moment under such circumstances as those in which lifeboats are usually employed.

The system of towing lifeboats by means of steam tugs to some point as near as possible to the site of the wreck, is one attended with danger, and the lifeboat, when cast off, is deprived of its means of propulsion at the very time when engine power would be most effective in enabling it to contend with the broken water round a wreck. I remember a case at Bombay, when a lifeboat proceeding to a wreck was towed right under, and the Chinese crew swept out of the boat and nearly all drowned.

Tubular lifeboats, I need hardly say, are no novelty, and the addition of a centre tube to carry the propeller and the steam engine and boiler will certainly not diminish their efficiency.

### The Internal Stucture of the Earth

ARCHDEACON PRATT'S letter in NATURE for June 22 calls for some remarks on my part. He communicates a few marginal notes written by Mr. Hopkins on a copy of the second part of my "Researches in Terrestrial Physics," which appeared in the "Philosophical Transactions," and seems seriously to regard these curt expressions as judicial utterances beyond which there can be no appeal.

In the first place, I am accused of incorrectly stating the nature of Mr. Hopkins's hypothesis as to the non-existence of friction between the fluid nucleus and solid shell of the earth. The words quoted from my paper as incorrect immediately follow a symbolical expression presented by Mr. Hopkins as the final result of his analysis, and my remark distinctly refers to this mathematical expression, and to nothing else. Remembering that the whole of Mr. Hopkins's mathematical investigations on the internal structure of the earth culminated in the deduction of this very expression, it is well to examine what are the words he uses in the course of his investigations which refer to the existence of friction between the shell and nucleus.

In his first memoir, "Philosophical Transactions," 1839, he says, "and since there will be no friction with the assumed perfect fluidity of the interior matter," p. 386. In his second memoir, I do not recollect that anything about friction is mentioned; but in his third, which summarises the whole of his preceding labours, after presenting the formula already alluded to, he states that it was established on the supposition of "the transition being immediate from the entire solidity of the shell to the *perfect* fluidity of the mass." He afterwards gives reasons for believing that a stratum of imperfect fluid probably exists between the shell and the perfect fluid, and he further uses the words, "Consequently *the assumption made in our investigations of the absence of all tangential action between the shell and fluid* will not be accurately true," p. 43. As my remark refers to these investigations and their immediate result, it is unnecessary to say to whom the charge of inaccuracy may justly apply. In affirming the existence of friction between the shell and nucleus to such an extent as to cause both to rotate as one solid mass, friction between the particles of the fluid is clearly implied; for if no such friction existed, the film of liquid touching the shell and moving with it might slip over the remainder of the nucleus. I have, therefore, been all along at issue with Mr. Hopkins on this point, when I concluded that the rotation of the shell and nucleus must take place as if the whole were solid. Mr. Hopkins declares this conclusion to be "a mechanical impossibility." It is this "impossibility" which has been reaffirmed by M. Delaunay in stronger terms than those I used. It has been shown to be not merely possible, but rigorously true, in a particular case, by an experiment of M. Champagneur, which I have myself recently verified, and it has been further so clearly illustrated in these pages by two correspondents A. J. M. and A. H. Green (May 18, p. 45) as to require no further observation. The coincidence of the axes of instantaneous rotation of the shell and nucleus necessarily follows if the whole moves as a solid mass; and to charge me with implying the coincidence in one of my formulæ is equivalent to charging me with being strictly consistent On this point Mr. Hopkins is of course at issue with M. Delaunay as well as with myself. The next important question referred to on which I totally differ from Mr. Hopkins is that of the form of the inner surface of the shell. If the shell has been gradually formed by solidification from a fluid mass, it is evident that the rate of progressive solidification at the interior of the shell must depend on the rate of refrigeration of the surface of the nucleus. This takes place, and has probably taken place for ages, at an almost insensible rate of slowness, and therefore also the successive additions of matter to the shell's inner surface. Between the perfectly solidified and comparatively rigid part of the shell and the fluid nucleus, the matter on the point of becoming solidified is probably in a pasty or imperfectly fluid state (as Mr. Hopkins has admitted), and it is this matter which is subjected to a moulding action by the changes of shape of the nucleus, as I pointed out in the publication already alluded to. This pasty matter becoming slowly impressed with the shape of the nucleus, and freely yielding to the impression as it passes to the solid state, the more rigid part of the shell, precisely as the outer case of a mould, is saved from strain, and cannot undergo a corresponding change of figure. In the discussion which followed the reading of my communication to the French Academy of Sciences on March 6, it appears from the *Comptes Rendus* that M. Elie de Beaumont made some remarks which illustrate and support this view of the process of formation of the shell. The conclusion to which I was thus led, that the inner surface of the shell could not be less elliptical than its outer surface, was reaffirmed soon after the publication of my researches by an eminent mathematician, the late Baron Plana, of Turin. All this Mr. Hopkins considers as quite inadmissible, and very reasonably, too, in the opinion of Archdeacon Pratt, and all the results deduced therefrom are judicially pronounced to be "valueless." But my conclusion as to the interior ellipticity of the shell is only a necessary deduction flowing from the fundamental principles from which my inquiries start, a principle upon which I am as much at issue with Mr. Hopkins as upon anything referred to in his marginal notes. As this is the really vital divergence between us, a few words of explanation are desirable

The hypothesis of the entirely fluid state of the earth anterior to its present state forms the groundwork of mathematical inquiries as to the earth's figure. The problem, as hitherto treated, always involved an additional hypothesis either openly or tacitly implied, namely, that the distribution of the particles composing the earth underwent no change by the earth's transition from a completely fluid condition to its present state. While Mr. Hopkins tacitly assumed this second hypothesis throughout his investigations, I have reason to believe that it was for the first time rejected in my paper on the "Figure and Primitive Formation of the Earth," which forms the first of my "Researches in Terrestrial Physics." By this step we are at liberty to investigate, with the aid of mechanical and physical laws and the known properties of the earth's materials, the probable arrangement and laws of density of the interior strata of the shell and nucleus. In attempting to do so, I was led to conclusions as to the earth's internal structure widely differing from those of Mr. Hopkins. I have great difficulty in believing that the crude comments on my researches communicated to Archdeacon Pratt, could have been intended to meet the public eye. Long before Mr. Hopkins sent these remarks to Archdeacon Pratt, he wrote to me promising to comment publicly upon my conclusions; and since then an opportunity occurred for pointing out in his presence at a meeting of the British Association what I conceived to be the inconclusive character of his results. Mr. Hopkins promised to reply, but neither this nor his former promise was ever realised. He avoided public discussion, whil as it now appears he *privately* depreciated results incompatible with his own. To Archdeacon Pratt I am grateful for producing evidence of the kind of weapon which I had long suspected to have been employed by my distinguished adversary. HENRY HENNESSY

Dublin, July 1

### Oceanic Circulation

MR. LAUGHTON treats an experiment which was only intended to be illustrative as if it had been advanced as probative, and tests it by a doctrine of "thermometric gradients" which does not correspond to the facts of the case. A uniform reduction of the temperature of ocean-water from the Equator to the Pole would doubtless give a "thermometric gradient" of infinitesimal minuteness. But the water of the circumpolar area, on which what Sir John Herschel truly designated the intense action of polar cold is exerted, brings with it so much of equatorial heat that a very decided increase of its specific gravity must be produced by the cooling process to which it is subjected within the polar area. This increase will be adequate, as I have attempted to show, to produce a continuous downward movement of the whole mass of water subjected to the cooling process; and such a movement, however slow, will make itself perceptible in a continuous outflow of the chilled dense water along the deepest floors of the great oceanic basins, and in a continuous indraught of warmer surface water into the polar area. The proof that such is the case seems to me to be afforded by the fact that temperatures not much above 32° seem to be uniformly met with at depths exceeding 2,000 fathoms, even under the equator; a fact of which Mr. Laughton and those who think with him have not, so far as I am aware, offered any account. That there is nothing in depth, *per se*, which produces this depression is shown by the absence of it in the Mediterranean.

It would be difficult, if not impossible, to carry out a probative experiment that should represent the actual conditions of the case. Taking the distance from the pole to the equator at 6,250 miles, and the average depth to which the chilled water would descend at 2½ miles, we should require a trough having a proportion of 2,500 to 1 between its length and its depth, or (in round numbers) a length of half a mile to a depth of a foot. Let it be supposed that cold were continuously applied by a powerful freezing mixture to the surface of the water occupying one extremity of the trough as far as one-tenth of its length, and that heat were applied to the surface of the water occupying the opposite extremity to a corresponding extent, the intervening water being neither heated nor cooled artificially, would, or would not, a continuous circulation from the one end of the trough to the other come to be established? To me it seems that what Sir John Herschel calls the "common sense of the matter" teaches that the continuous descending movement given to the water at the polar end of the trough must in time propagate itself to the equatorial, provided only that the conducting power of the sides and floor of the trough were sufficiently bad to prevent the chilled stratum which falls to the bottom at one end from losing its cold before it reaches the other.

When such masters of Thermotics as Pouillet and Herschel consider that the doctrine of a general oceanic circulation sustained by differences of temperature is conformable to the facts at present known, I would suggest whether it would not be wise if those who are interested in the subject, instead of attempting to controvert their views on theoretical considerations, were to use their endeavours to collect additional data for practically testing them. By the kindness of the Hydrographer to the Admiralty I hope, in the course of the present season, to obtain some further information of a reliable kind; and I am doing my utmost to urge upon our Government a systematic inquiry into what the Secretary of the Scottish Meteorological Society has truly designated (in a recent letter to me) as "the most important problem in Terrestrial Physics."

July 3 WILLIAM B. CARPENTER

I SHOULD need Mr. Laugbton's hint if I had ever supposed that the cause of the vertical circulation of the ocean could be determined by such an experiment as I suggested. The experiment was specially intended to throw light on the easterly and westerly oceanic movements. For this purpose it is only necessary that the rate of rotation of the shallow cylinder should be duly adjusted to the observed rate of the vertical motions. But even in this respect the experiment would afford but an illustration, not a demonstration.

The subject of oceanic circulation is altogether too wide and too difficult for discussion in letters. Every point touched on by Mr. Laughton requires many columns for its full discussion. I just note that the infinitesimal nature of the thermometric gradients scarcely seems a sounder objection to the temperature theory of oceanic circulation than to the temperature theory of atmospheric circulation. In one case, as in the other, we must integrate the effects of the solar light on tropical and subtropical regions. RICHARD A. PROCTOR

### Day Auroras

LAST evening, about eight o'clock, being in the grounds belonging to the Radcliffe Observatory, I was exceedingly surprised at seeing what I *have no doubt* of being true auroral streamers, forming a little to the east of the south meridian, reaching an altitude of about 25°, and after travelling some distance in a westerly direction, vanishing. This lasted at least ten minutes, when the sky, which had been overcast nearly all day again became so. I pointed the streamers out to several people who were near me, some of whom watched them with me, as a proof of what I had before doubted, namely, that auroras are visible by daylight. JOHN LUCAS,
Assistant at Radcliffe Observatory

Radcliffe Observatory, Oxford, June 28

### The Solar Parallax

I REGRET that I have misinterpreted the severity of Prof. Newcomb's remarks respecting my chapter on the Solar Parallax. The fact is, that so far back as February 1 I was warned by an eminent astronomer that Prof. Newcomb had vowed here last November that he would annihilate all who upheld the finality or correctness of Mr. Stone's researches.

Prof. Newcomb must be sensible that his offer to supply information as to the history of inquiries into the solar parallax during the last few years is a very generous one; and that it will be immensely to my advantage to profit by his exceptional familiarity with the subject. I thank him very earnestly. I have an especial distaste for inquiries into the historical parts of scientific subjects, and shall rejoice to be saved the labour of looking up authorities, &c., in this particular matter. If I find my account requires alteration, I shall admit the fact without a particle of hesitation. It is indeed most desirable (though not, perhaps, for students of science, for whom I specially write, and who need trouble themselves little on the matter) that to each worker in the subject of the solar parallax his due proportion of credit should be assigned; and as in this case not only I, but Sir John Herschel, as well as the Council of the Astronomical Society, would seem to have done Prof. Newcomb less than justice, the sooner recantation is made the better.

Prof. Newcomb refers to "the kind spirit in which I have taken his remarks;" meaning rather, perhaps, the appreciative way in which I have spoken of his labours. His critique, regarded as a whole, was not, I take it, kindly meant; and though I by no means feel annihilated by it, I should be speaking untruly if I seemed to admit its justice. If I failed to note how I viewed his comments, it was only because I found a pleasanter subject to speak about in those important researches whereby he bas advanced astronomy. RICHARD A. PROCTOR

P.S.—I take this opportunity of noting that the remark in my former letter respecting the work of Mr. De La Rue and F. Secchi in 1860 must not be understood as implying that the account in F. Secchi's book *Le Soleil* is incorrect. On the contrary, I have no doubt it is strictly accurate. I was fortunate in securing a copy of *Le Soleil* before Paris was beleaguered, and derived considerable assistance from its perusal.

### Lee Shelter

PERHAPS it is worth noting that a lee shelter is almost as effectual as a screen to the windward. The fact may be quite well known and understood; but I did not become aware of it till I was on Bognor Pier, when a strong gale was blowing directly on the broadside. There are seats backed and covered overhead and on the sides, alternately, on the one or other side of the pier, and on this occasion all the seats to the windward were occupied, so that, wanting a rest, I had to put up with one

of those directly facing the gale. I naturally expected to have it strong in my face; but, on the contrary, I found I had almost as perfect a shelter from the wind as if I had been on the other side.
C. M. INGLEBY

Malvern Wells, July 3

## AFFINITIES OF THE SPONGES

MR. H. J. CARTER is devoting much attention at the present moment to the study of the Protozoa. In March last he published in the *Annals* and *Magazine* of *Natural History* the results of his investigations on Coccoliths and Coccospheres, stating his opinion that these minute bodies are of vegetable and not animal organisation, as hitherto supposed. Should his supposition prove correct, it will materially modify the theory of the mode of support of animal life at great depths, advocated by many recent deep-sea explorers. In the pages of the same journal for this month (July), Mr. Carter lays before us the results of his more recent researches into the ultimate structure of the marine calcareous sponges, and which entirely harmonise with those already arrived at by Prof. James Clark, of Boston, U.S. The sum total of these are that the Spongiadæ, as a group, are most closely allied to the Flagellate Infusioria; the animal portions of the genera *Leuconia*, *Grantia*, and *Clathrina* among the calcareous sponge-forms, and *Spongilla*, *Isodictya*, *Hymeniacidon*, and *Cliona* among the silicious representatives examined by Mr. Carter, being found by him to consist, for the most part, of aggregations of the same peculiar funnel-bearing ciliated cells characteristic of the new Flagellate Infusorial genera *Codosiga*, *Salpingœca*, *Bicosœca*, &c., introduced by Prof. Clark. The only point at issue between these two explorers in the same field is, whether each separate cell possesses a distinct mouth, or is capable of engulphing food, after the manner of an ordinary Rhizopod, through any portion of its body. Mr. Carter here adopts the latter view.

The most important result of Mr. Carter's investigations is, however, the additional evidence he brings forward in refutation of Ernst Haeckel's no longer tenable hypothesis, that the sponges are most closely allied to, and should even be collated in the same primary group as, the Cœlenterata. Prof. Haeckel's opinions have already been strongly opposed by myself (See *Ann.* and *Mag. Nat. Hist.* for March and September 1870); and Mr. Carter's recent investigations practically deprive Prof. Haeckel and those supporting his views of their last foot-hold. The Calcispongiæ is the group on which Ernst Haeckel and his collaborateur Mickluco-Maclay have more particularly concentrated their attention; it is the especial one, again, they have made choice of, as demonstrating in their opinion, more closely than any, the relationship they would seek to establish. Prof. Clark and Mr. Carter, however, prove beyond doubt their bond of union with the Flagellate Infusoria, the addition of a general investing sarcode layer and a spicular or horny supporting skeleton being, indeed, the only clearly defined characters that separates them from the group.

In seeking to establish other affinities, Mr. Carter is scarcely so happy. In his opinion, the Spongiadæ are more closely allied to the compound Tunicata than to the Cœlenterata, but he allows himself to be led further away here by analogous or general external resemblances than even Prof. Haeckel. To effect his purpose, he proposes that the branchial openings in the gelatinous mass of *Botryllus* "are analogous if not homologous" with the pores of the Spongiadæ, while the common cloacal cavity and fæcal orifice are respectively analogous to the excretory canal system and vent. Fascinating as these external resemblances may appear at first sight, we must penetrate a little beneath them, and before Mr. Carter can hope to substantiate the affinities he would establish, he must demonstrate to what extent the individual zooids of the Ascidian colony can be correlated with the single or aggregated ciliated cells of the sponges. In the former we have highly-organised animals, possessing a well-developed neural, hæmal, digestive, and respiratory system, while in the latter, simple uniciliated cells and undifferentiated sarcode are the only materials to be dealt with. Mr. Carter, again, would institute comparisons between the tough, gelatinous, or albuminous mass in which the Ascidian zooids are embedded, and that sarcode layer more or less generally diffused throughout all sponge structures; but in the first we have formed matter, like bone, horn, or shell, no longer possessing vital properties, while in the sarcode of the sponge we have living substance constantly altering its conditions of relationship, secreting the supporting skeleton, and contributing to the general welfare of the sponge community. Mr. Carter's inference in support of his proposition, drawn from the presence of calcareous bodies resembling spiculæ being met with in certain compound Ascidia, is but of little importance, considering that comparisons on the same grounds might be made between the sponges and the Nudibranchiate Mollusca; these latter likewise frequently secreting calcareous spiculæ in the substance of their integument.

The hiatus between the Spongiadæ and the Tunicata is far too wide to admit of such an institution of homological comparisons; the group of the Cœlenterata is evidently the nearest related to the former, but even here there are at present too many important links wanting to justify our uniting the two in one sub-kingdom, as proposed by Haeckel. *Inter se*, the sponges constitute a very natural division of the Protozoa, intimately related on the one hand through their special ciliated cells to the Flagellate Infusoria, and by the remaining sarcode layer, or skeletal secreting portion, to the simpler Rhizopoda.

In the paper here alluded to, Mr. Carter describes, under the name of *Trychogypsia*, a new calcareous sponge form differing from all others with which he is acquainted in possessing linear fusiform and no triradiate or quadriradiate spicules. The genus *Aphroceras*, described by Dr. Gray in 1858 (see Proc. Zoo. Soc., pp. 113, 114), is recognised by the same characters.

W. SAVILLE KENT

## ON RECENT MOA REMAINS IN NEW ZEALAND

IN January 1864 a remarkably perfect specimen of *Dinornis robustus*, Owen, found on the Manuherekia Plains in the interior of the Province of Otago, was transmitted to the museum at York, and formed the subject of a memoir by Prof. Owen in the Transactions of the Zoological Society for 1869. These remains were considered unique on account of the well-preserved condition of some parts of the skeleton, portions of the ligaments, skin, and feathers being still attached to some of the bones, whereas Moa bones in the condition in which they are usually found are partially fossilised, or have at least undergone a sufficient change to deprive them not only of all ligamentous appendages, but to some extent of their proper proportion of organic matter. The discovery in the following year of the unique specimen (now in the museum) of a Moa's egg containing the bones of an embryo chick and attached membranes—within twenty miles of the same locality—was recorded by me in 1867 (Proc. Zool. Soc. p. 991.) I have now to announce the acquisition of another interesting specimen from the same district, being the cervical vertebræ of a Moa, apparently of the largest size, upon the posterior aspect of which the skin, partly covered with feathers, is still attached by the shrivelled muscles and ligaments.

I saw the specimen in question in the possession of Dr. Thomson, of Clyde, who obtained it from a gold miner. It was discovered in a cave formed by an overhanging mass of mica schist, but the particulars of the locality have not yet been accurately ascertained, or whether any other parts of the bird are still to be found. Dr. Thomson has kindly undertaken to prosecute a further search, and to forward the specimen already obtained to the museum for examination.

These interesting discoveries render it probable that the inland district of Otago, at a time when its grassy plains and rolling hills were covered with a dense scrubby vegetation or a light forest growth, was where the giant wingless birds of New Zealand lingered to latest times. It is impossible to convey an idea of the profusion of bones which, only a few years ago, were found in this district, scattered on the surface on the ground or buried in the alluvial soil in the neighbourhood of streams and rivers. At the present time this area of country is particularly arid as composed with the prevalent character of New Zealand. It is perfectly treeless; nothing but the smallest-sized shrubs being found within a distance of sixty or seventy miles. The surface features comprise round-backed ranges of hills of schistose rock with swamps on the top, deeply cut by ravines that open out on basin-shaped plains formed of alluvial deposits that have been everywhere moulded into beautifully regular terraces to an altitude of 1,700 feet above the sea level. That the mountain-slopes were at one time covered with forest, the stumps and prostrate trunks of large pine trees, and the mounds and pits on the surface of the ground which mark old forest land, abundantly testify, although it is probable that the intervening plains have never supported more than a dense thicket of shrubs or were partly occupied by swamps. The greatest number of moa bones were found where rivers debouch on the plains, and that at a comparatively late period these plains were the hunting grounds of the Aborigines can be proved most incontestably. Under some overhanging rocks in the neighbourhood of the Clutha river, at a place named by the first explorers Moa Flat, from the abundance of bones which lay strewn on the surface, rude stone flakes of a kind of stone not occurring in that district were found associated with heaps of Moa bones. Forty miles further in the interior, and at the same place where the Moa's neck was recently obtained, Captain Fraser discovered in 1864 what he described to me as a manufactory for such flakes and knives of chert as could be used as rough cutting instruments in a cave formed by overhanging rocks, sheltered only from S.W. storms, as if an accumulation by a storm-stayed party of natives. With these were also associated Moa bones and other remains. Again, on the top of the Carrick Mountains, which are in the same district, but at an altitude of 5,000 feet above the sea, the same gentleman discovered a gully, in which were enormous heaps of bones, and along with them native implements of stone, among which was a well-finished cleaver of blue slate, and also a coarsely-made horn-stone cleaver, the latter of a material that must have been brought from a very great distance.

Still clearer evidence that in very recent times the natives travelled through the interior, probably following the Moas as a means of subsistence, like natives in other countries where large game abounds, was obtained in 1865-6 by Messrs. J. and W. Murison. At the Maniototo Plains, bones of several species of Dinornis, Aptornis, Apteryx, large Rails, Stringops, and other birds, are exceedingly abundant in the alluvium of a particular stream, so much so that they are turned up by the plough with facility. Attention was arrested by the occurrence on the high-ground terrace which bounds the valley of this stream, of circular heaps composed of flakes and chips of chert, of a description that occurs only in large blocks along the base of the mountains at about a mile distant. This chert is a very peculiar rock, being a "cement" or "water quartz," or sand and gravel converted into a hard quartzite by infiltration of silicious matter. The resemblance of the flakes to those they had seen described as found in the ancient Kitchen-Middens, and a desire to account for the great profusion of Moa bones on a lower terrace-shelf nearer the margin of the stream, led the Messrs. Murison to explore the ground carefully, and by excavating in likely spots, they found a series of circular pits partly lined with stones, and containing, intermixed with charcoal, abundance of Moa bones and egg-shells, together with bones of the dog, the egg-shells being in such quantities that they consider that hundreds of eggs must have been cooked in each hole. Along with these were stone implements of various kinds, and of several other varieties of rock besides the chert which lies on the surface. The form and contents of these cooking-ovens correspond exactly with those described by Mantell in 1847 as occurring on the sea-coast, and among the stone implements which Mantell found in them, he remembers some to have been of the same chert, which occurs *in situ* at this locality fifty miles in the interior. The greater part of these chert specimens found on the coast are with the rest of the collection in the British Museum. There are other circumstances which incidentally support the view that while the Moas still existed in great numbers, the country was open and regularly traversed by the natives engaged in hunting. Near the old Maori ovens on the coast Mantell discovered a very curious dish made of steatite, a mineral occurring in New Zealand only on the west coast, rudely carved on the back in Maori fashion, measuring twelve by eight inches, and very shallow. The natives at the time recognised this dish by tradition, and said there should be two of them. It is very remarkable that since then the fellow dish has been discovered by some gold diggers in the Manuherikia Plain, and was in use on a hotel counter at the Dunstan township as a match-box, till lately, when it was sent to England, and, as I am informed, placed in a public museum in Liverpool.

The manner in which the Maoris use their cooking ovens suggests to me an explanation of the mode in which these flakes of chert came to be found in such profusion, while only a few of them show any signs of having been trimmed in order to fit them for implements. The native method of cooking is to heat the hardest stones they can find in the fire, and then placing the food to be cooked on top, to cover the whole with leaves and earth, and through an opening pour in water, which coming in contact with the hot stones, causes the formation of steam by which the food is cooked. If masses of the white chert be heated and quenched with water in the manner described, the result is the formation of flakes of every variety of shape with sharp cutting edges. It is natural to suppose that when one of these flakes was found of shape convenient for a particular purpose, such as a knife, cleaver, or spear-head, it was trimmed and dressed in the manner of a gun-flint, when the edge became defective, rather than thrown away, and favourite forms might be preserved and carried even as far as the coast. This suggested explanation of how a race advanced probably far beyond the period of such rude-looking implements might yet find it convenient to manufacture and use these, is supported by the circumstances that along with the trimmed chert flakes the Messrs. Murison found finished adzes of aphanite and even jade, which shows that the hunting natives had the same implements as those which are so common among the natives at the present day, though their use is now superseded by iron.

In the ovens on the coast, besides flakes and rough knives of chert and flint, are found flake-knives of obsidian, a rock which only occurs in the volcanic district of the North Island, and also adzes and stone axes of every degree of finish and variety of material. Although there is no positive evidence in the latter case that more highly finished implements were in use by a people contemporaneous with the Moa, whose remains, collected by human agency, are so abundant in the same place, nevertheless the fact of a similar association occurring far in the interior affords strong presumptive evidence on this point, as the finely-finished implements must have been carried inland and to the same spots where the Moa remains occur, to be used at native feasts, of which these bones are the only other existing evidences.

So far I have been dealing with evidence gathered in the South Island of New Zealand of the recent co-existence of Man and the Moa, but in the North Island there is no lack of similar proofs. During the summer of 1866, H.E. Sir George Grey, K.C.B., made a fine collection at Waingongoro on the west coast of this island, being the same locality from which Mantell gathered the magnificent series of bones which he forwarded to Europe in 1847. At this place, along with the bones of the Moa and other extinct birds, were found those of dogs, seals, and many species of birds that are common at the present day, such as the albatross, penguin, nestor, and porphyris, and notably the notornis, a gigantic rail, which till a comparatively recent date, was supposed, like the Moa, to be extinct, and of which as yet only two living examples have been obtained. Associated with these remains Sir George Grey obtained artificially formed stone flakes of a very peculiar kind, being chips from rolled boulders of hard crystalline sandstone, produced by a single blow, probably when the stone was heated and quenched in water. The stones from which these chips were obtained had evidently been used, in the first instance, for cooking, as the ancient *Umus*, or cooking-ovens, are chiefly formed of them; and, indeed, in the sandy tracts on the west coast, where stones are rare, the identical stones that in former days were used for cooking Moas are still in use by the natives of the district for cooking pigs and shell-fish. Here again we find that the same necessity and circumstance which suggested the use of the chert flakes in the South, gave origin to a similar adaptation of the chips from the sandstone boulders. It is of some interest to find that native tradition points to the sandy flat at Waingongora, called Te Rangatapu, as the spot where the first Maori immigrants to the district originally settled; and there appears to be nothing in the abundant traces which they have left of these great feasts, which we must refer to that period, that would indicate any difference in their domestic habits from those of the Maoris now existing, and who, no doubt, are their direct descendants.

What has been advanced affords strong presumptive evidence that the Moas, although belonging probably to a race that was expiring from natural causes, was finally exterminated through human agency; and on this subject Mr. Murison has suggested how infallibly the wholesale consumption of the eggs, which were evidently highly prized as an article of food, must have led to their rapid extinction, without its being necessary that the birds themselves should have been actually destroyed. That wide-spreading fires contributed, in some instances, to the destruction of these wingless birds, is rendered probable from the occurrence of little heaps of bones, in spots where flocks of them would be overtaken when fleeing before the destroying element. At the south-west extremity of a triangular plain, by the side of the Wakatipu Lake, in 1862, I counted thirty-seven of such distinct skeleton-heaps, where the steep rocky slope of the mountain, covered with fallen blocks and tangled shrubs, meets the lake, and would, therefore, stop the progress of the fugitives in that direction. From what we know of habits of birds akin to the Moas, we may fairly infer that they did not frequent heavily-timbered country, but roamed over coppice-covered plains and mountain slopes. This view is supported by the comparative rarity of Moa remains in forests, the few exceptions being easily accounted for.

The whole of the eastern district of the South Island of New Zealand back to the Southern Alps was completely surveyed and mapped as early as 1862, and had been thoroughly explored at least ten years before that date, without any of these gigantic birds being met with; but there is a large area of rugged mountainous country, especially in the south-west district of Otago, which even to the present time is only imperfectly known. The mountain sides in this region are clothed with open forest, in which Kiwis, Kakapos, and other expiring forms of apterous birds are still to be found in comparative abundance, but where we could scarcely expect to meet with the larger species. Nevertheless, owing to the lofty tabular configuration of this district, the mountains afford very extensive areas above the forest limit—which are covered with Alpine shrubs and grasses—where it is not impossible that a remnant of this giant race may have remained to very recent times. The exploration, however, to which the country has been subjected during the last few years, by parties of diggers prospecting for gold, forbids any reasonable hope that any still exist. I may here mention that on one of the flat-topped mountains near Jackson's Bay, visited in January 1863, I observed, at an altitude of 4,000 feet, numerous well-beaten tracks about sixteen inches wide intersecting the dense scrub in all directions, and which, owing to the height of the scrub (two to four feet) could only been formed in the first instance by the frequent passage of a much larger bird than either the Kiwi or Kakapo, which, judging from the droppings, were the only birds that now resorted to them. On the sides of the tracks, especially near the upper confines of the forest, are shallow excavations, 2ft. to 3ft. in diameter, that have much the appearance of having been scraped for nests. No pigs or any other introduced animals having penetrated to this part of the country, it appears manifest that these were the tracks of some large indigenous animal, but from the nature of the vegetation it is probable that such tracks may have been for a very long period in disuse, except by the smaller ground birds, without becoming obliterated.

The above facts and arguments in support of the view that the Moa survived to very recent times, are similar to those advanced at an early period after the settlement of the colony, by Walter Mantell, who had the advantage of direct information on the subject from a generation of natives that has now passed away. As the first explorer of the artificial Moa beds, his opinion is entitled to great weight. Similar conclusions were also drawn by Butler, who is personally familiar with the facts derived from the North Islands, in an article which appeared in the *Zoologist* for 1864. The fresh discovery therefore of well-preserved remains of the Moa only tends to confirm and establish these views; and it would have been unnecessary to enlarge on the subject by the publication of the foregoing notes, which for the most part were written several years ago, but for the entirely opposite conclusions advanced by Dr. Haast in a recent address, which, from the large amount of interesting and novel matter it contains, will doubtless have a wide circulation.

JAMES HECTOR

## *ON THE GASEOUS AND LIQUID STATES OF MATTER*

A DISCOURSE was delivered on Friday evening, June 2, at the Royal Institution in Albemarle Street, by Dr. Andrews on the "Gaseous and Liquid States of Matter," from which we make the following extracts:—"The liquid state of matter forms a link between the solid and gaseous states. This link is, however, often suppressed, and the solid passes directly into the gaseous or vaporous form. In the intense cold of an arctic winter, hard ice will gradually change into transparent vapour without previously assuming the form of water. Carbonic acid snow passes rapidly into gas when exposed to the air, and can with difficulty be liquefied in open tubes. Its boiling point, as Faraday has shown, presents the apparent anomaly of being lower in the thermometric scale than its melting point, a statement less paradoxical than it may at first appear, if we remember that water can exist as vapour at temperatures far lower than those at which it can exist as liquid. Whether the transition be directly from solid to gaseous, or from solid to liquid and from liquid to gaseous, a marked change of physical properties occurs at each step or break, and heat is absorbed, as was proved long ago by Black, without producing elevation of temperature. Many solids and liquids will for this reason maintain a low temperature, even when surrounded by a white hot atmosphere, and the remarkable experiment of solidifying water and even mercury on a red hot plate, finds thus an easy explanation. The term spheroidal state, when applied to water floating on a cushion of vapour over a red hot plate, is, however, apt to mislead. The water is not here in any peculiar state. It is simply water evaporating rapidly at a few degrees below its boiling point, and all its properties, even those of capillarity, are the properties of ordinary water at 96°·5C. The interesting phenomena exhibited under these conditions are due to other causes, and not to any new or peculiar state of the liquid itself. The fine researches of Dalton upon vapours, and the memorable discovery by Faraday of the liquefaction of gases by pressure alone, finished the work which Black had begun. Our knowledge of the conditions under which matter passes abruptly from the gaseous to the liquid and from the liquid to the solid state may now be regarded as almost complete.

"In 1822 Cagniard de la Tour made some remarkable experiments, which still bear his name, and which may be regarded as the starting point of the investigations which form the chief subject of this address. Cagniard de la Tour's first experiments were made in a small Papin's digester constructed from the thick end of a gun barrel, into which he introduced a little alcohol and also a small quartz ball, and firmly closed the whole. On heating the gun barrel with its contents over an open fire, and observing from time to time the sound produced by the ball when the apparatus was shaken, he inferred that after a certain temperature was attained the liquid had disappeared. He afterwards succeeded in repeating the experiment in glass tubes, and arrived at the following results. An hermetically sealed glass tube, containing sufficient alcohol to occupy two-fifths of its capacity, was gradually heated, when the liquid was seen to dilate, and its mobility at the same time to become gradually greater. After attaining to nearly twice its original volume, the liquid completely disappeared, and was converted into a vapour so transparent that the tube appeared to be quite empty. On allowing the tube to cool, a very thick cloud was formed, after which the liquid reappeared in its former state.

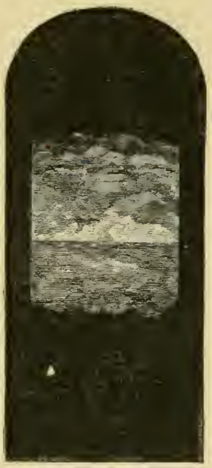

FIG. 1—Cloud below critical point

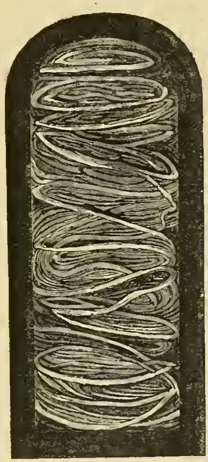

FIG. 2—Striæ above critical point

"It is singular that in this otherwise accurate description Cagniard de la Tour should have overlooked the most remarkable phenomenon of all—the moving or flickering striæ which fill the tube, when, after heating it above the *critical point*, the temperature is quickly lowered. This phenomenon was first observed by the lecturer in 1863, when experimenting with carbonic acid, and may be admirably seen by heating such liquids as ether or sulphurous acid in hermetically sealed tubes, of which when cold they occupy about one-third of the capacity. The appearances exhibited by the ascending and descending sheets of matter of unequal density are most remarkable, but it is difficult to give an adequate description of them in words or even to delineate them.

"These striæ arise from the great changes of density which slight variations of temperature or pressure produce when liquids are heated in a confined space above the critical point already referred to; but they are not formed if the temperature and pressure are kept steady. When seen they are always a proof that the matter in the tube is homogeneous, and that we have not liquid and gas in presence of one another. They are, in short, an extraordinary development of the movements observed in ordinary liquids and gases when heated from below. The fact that at a temperature 0°·2 above its critical point carbonic acid diminishes to one-half its volume from an increase of only $\frac{1}{87}$ of the entire pressure is sufficient to account for the marked characters they exhibit.

"If the temperature is allowed to fall a little below the critical point, the formation of cloud shows that we have now heterogeneous matter in the tube, minute drops of liquid in presence of a gas. From the midst of this cloud (as shown in Fig. 1) a faint surface of demarcation appears, constituting the boundary between liquid and gas, but at first wholly devoid of curvature. We must, however, take care not to suppose that a cloud necessarily precedes the formation of true liquid. If the pressure be sufficiently great, no cloud of any kind will form."

After describing the results obtained by the lecturer with carbonic acid under varied conditions of temperature and pressure, of which a full account has already appeared in NATURE,* Dr. Andrews remarked that it would be erroneous to say that between liquid and gas there exists one intermediate state of matter, but that it is correct to say that between ordinary liquid and ordinary gas there is an infinite number of intermediate conditions of matter, establishing perfect continuity between the two states. Under great pressures the passage from the liquid to the gaseous state is effected on the application of heat without any break or breach of continuity. A solid model, constructed by Prof. J. Thomson, from the data furnished by the experiments of the lecturer, exhibited very clearly the different paths which connect the liquid and gaseous states, showing the ordinary passage by break from the liquid, as well as the continuous passages above the critical point.

After referring to the experiments of Frankland on the change produced by pressure in the spectrum of hydrogen, and to those of the same able chemist and Lockyer on the spectrum of the spark in compressed gases, Dr. Andrews described the remarkable change from a translucent to an opaque body, which occurs when bromine is heated above the critical point; and then drew attention to the general fact that when the critical point is reached, the density of the liquid and gas become identical.

In order to establish the continuity of the solid and liquid states, it would be necessary in like manner, by the combined action of heat and pressure, to obtain the solid and liquid of the same density and of like physical properties. To accomplish this result would probably require pressures far beyond any which can be reached in transparent tubes, but future experiment may show that the solid and liquid can be made to approach to the required conditions.

* See NATURE, vol. ii. p. 278.

---

## *ON AN ADDITIONAL TRUE RIB IN THE HUMAN SUBJECT*

THE almost absolute rule that there are seven true ribs in the human subject has, like every other rule, its exceptions. Occasionally instances are met with in which there are eight sternal ribs on one or both sides. But Nature does not effect her evolutions by *per saltum* transitions between extreme points, but steadily makes progress by degrees almost imperceptible to human intelligence. So in the matter of rib transition, there are various grades met with between the presence of a complete eighth sternal rib on the one hand, and its absence on the other. In the sternum of a female subject recently dissected at the Royal College of Surgeons, the right seventh and eighth rib cartilages blended together about a quarter of an inch distant from the mesosternum. On the left side the eighth rib cartilage was arrested about an inch and a half from the mesosternum. The latter was free at its sternal end. In another subject—a moderately muscular male—the eighth rib cartilage on the right side extended within an inch of the mesosternum, its extremity being free. On the left it was aborted at the distance of two and a half inches from the mesosternum. In the latter subject the sternum was exceedingly large; all the rib cartilages, especially the seventh on the left side, were well developed, and the xiphisternum was very much elongated, spatulate, and curved in an anterior direction. Occasionally specimens are met with in which the sixth rib cartilage is implanted upon the distal extremity of the mesosternum (rather than upon its distal lateral aspect), lying in front of the xiphisternum, and separated from its fellow of the opposite side by a small interval. In the receding angle formed by their divergence, the seventh sternal ribs are placed, lying directly upon the xiphisternum, and articulating with it, barely attaining an attachment to the mesosternum. This closely simulates the arrangement met with when the eighth sternal rib is present.

In another adult male skeleton, I found a complete specimen of an eighth sternal rib, but only on the right side. It articulated with the xiphisternum, and not with the mesosternum. On the left side the seventh sternal rib cartilage was larger than the corresponding one on the right side, and articulated with both the mesosternum and xiphisternum.*

On examining the skeletons (human) in the Hunterian Museum, I noticed another instance of an eighth sternal rib in an adult male African negro, occurring on the right side only. It was in every respect similar to the preceding. This is the only instance out of the fifteen skeletons (human) contained in the museum which deviated from the average standard number of seven true ribs. It is just possible that it may be more frequently present and remain undetected. In maceration the cartilages are very frequently removed, and articulators prepare artificial ones in their place corresponding to the average seven.

On examining the higher quadrumana, &c., I noticed that this additional true rib was present only in one young chimpanzee, but not in the gorillas and orangs. It was present in the gibbon and silvery gibbon, the pig-tailed monkey, *Macacus Rhesus*, Galeopithecus, and Indri. The aye-aye, the slender lemur, and the squirrel monkey, have each nine true ribs. The grand galago, the awantilo, the slender loris, the douroucouli, and the potto, have each ten true ribs. Prof. Flower very kindly called my attention to a paper on the axial skeleton of the Primates by Mr. St. George Mivart,† in which these rib variations are described as follows:—"In the highest forms of the Primates, the number of true ribs is seven, but in Hylobates there are sometimes eight pairs. In Semnopithecus and Colobus there are generally seven, but sometimes eight pairs of true ribs. In the Cynopithecinæ the normal number is eight. In the Cebidæ there are generally seven or eight pairs, but in Ateles sometimes nine. In Hapale there are sometimes as few as six, sometimes as many as eight; seven or eight in Galago, Lemur, and Indris; nine in Cheiromys. The highest number, as might be expected, is found in the Nycticebinæ, there being as many as ten pairs of true ribs in Perodicticus and Loris."

Professor Flower remarks ‡ that "in the higher Simiina the ribs do not differ very notably from those of man, except in number; but in the lower forms, and especially in the Lemurina, they more resemble those of the Carnivora."

In the Carnivora the number of nine sternal ribs is fairly constant. There are some exceptions, however, *e.g.* the Esquimaux dog—the Arctic wolf and Proteles have only eight true ribs. The common badger (*Meles taxus*) has ten true ribs—the tenth rib being implanted on the apex of the xiphisternum. The ninth rib in all these animals is more or less intimately associated with the xiphisternum, but rarely forming so decided an articulation with it as in the badger.

In a dog's sternum lately in my possession, the xiphisternum had the ninth rib articulated directly with it.

* This does not obviate the rule laid down by Prof. Flower in his recent admirable book on the Osteology of the Mammalia, that the xiphisternum never carries any true ribs. This is the average rule. But variations are frequent, although they cannot be considered in a text-book on average, and not irregular, Osteology.

† Proceedings of the Zoological Society of London June 27, 1865.

‡ Osteology of the Mammalia, p. 89.

The former (xiphisternum) was bifid through its whole length.

The scientific value of this additional sternal rib—in a Darwinian sense—is simply great. It evinces in a clear and forcible manner a latent disposition in the human subject, either to revert to an original and lower condition, or to retain traces of that previous condition. We have already seen that some of the lowest forms of Primates have ten true ribs, others have nine, some eight, and others again seven, as in the human subject. But it is interesting, indeed, to find that the conflict between the major number ten and the minor seven takes place in the lower Primates. As we pass up to the higher Primates, there seems to be a decided tendency towards fixity at the number of seven true ribs. But yet a few solitary examples—besides the human subject—illustrate the lower type, as in the chimpanzee already mentioned. The number of ribs in the lower forms of monkeys seems to be a repetition of that in the Carnivora, and subject to the same fluctuations between seven and ten true ribs. Although the few specimens which I have examined of the higher Primates show a decided tendency towards fixity at the number of seven, yet I believe that in a very large number of skeletons of each of the higher species, various transitional grades would be met with closely according with those in the human subject. It is somewhat remarkable that each of the variations of the eighth rib in the human subject which I have described should all be on the right side.

From the preceding facts it may be decidedly inferred that the tenth, ninth, and eighth true ribs are gradually lost in the transition from the lower to the higher Primates, except in a few isolated examples. The recurrence of the eighth true rib in the human subject cannot be looked upon as an accident, any more than the presence of a distinct peroneus quartus, and a moderately large extensor primi internodii hallucis coming from the tibialis anticus, exactly as in the chimpanzee, in the same individual whose sternum, with an almost complete eighth rib, has been described.

J. BESWICK-PERRIN

## *NOTES*

THE men of the North do not seem disposed to let grass grow under their feet in respect to their proposed College of Physical Science, at Newcastle-upon-Tyne. Of the 35,000*l*. required, in addition to to the Durham University endowment, to carry out their plans, upwards of 23,600*l*. has been already subscribed. Three of the professorial chairs have now been filled, viz.:—Experimental Physics: A. S. Herschel, M.A. Chemistry: A. Freire-Marreco, M.A. Geology: David Page, LL.D., F.R.S.E. No decision has yet been made public in respect to the professorship of Mathematics. This appointment, together with the chair of Experimental Physics, is in the hands of the Dean and Chapter of Durham. These selections will give general satisfaction, and are sufficient assurance of the desire of the Committee to obtain the services of the men within reach, without reference to local influence or predilections. Indeed it seems to us just possible that the claims of one eminent local geologist may have suffered somewhat through the fear of a charge of partiality. Few family names stand higher in the scientific world than that of Herschel, and its present representative is well known as a teacher of experimental philosophy. M. Freire-Marreco has long served the University of Durham as its reader in chemistry and the Newcastle College of Medicine as its lecturer. Apart from his acquirements as a chemist and his ability as a teacher, there is perhaps no one who is so thoroughly versed in the chemical technology of the industries of the North of England. Dr. Page's elementary works on geology are widely appreciated, and if one may judge of his capacity as a lecturer by his power of interesting a general audience, he is eminently fitted to instruct the rising generation of mining engineers. We learn that the opening of the College is fixed for October 7, and shall watch with pleasure the progress of the undertaking, bidding it heartily "God speed."

AT a meeting of the Council of University College, London, held on Saturday last, a scheme for the establishment of a Sharpey Physiological Scholarship in the College was adopted. It is expected that the annual value of the Scholarship will be about 100*l*.

SIR DOMINIC CORRIGAN, Bart., M.D., M.P., has been appointed Vice-Chancellor of the Queen's University in Ireland, in the room of the late Sir Maziere Brady, Bart.

ONLY one gentleman has this year obtained the degree of D.Sc. of the University of London, Mr. W. A. Tilden, in Chemistry.

M. H. SAINTE-CLAIR-DEVILLE, one of the most learned and popular members of the Institute, was a candidate at the recent French election on the moderate Republican ticket. M. Broca, the celebrated anthropologist, who will soon be a member of the Institute, was also a candidate on the same ticket, as was also M. Wolowsky, a member of the Académie des Sciences Morales et Politiques. We learn that M. Wolowski has been returned at the head of the poll, and that MM. Scheurer-Restner and Laboulaye have also been elected for Paris. The Institute is fast becoming, not actually a political body, but a body more closely connected with politics than it was formerly. For some time past a *résumé* of the sittings of the Academy has been inserted regularly in the *Journal Officiel*, which is becoming every day more scientific in its character. The National Society of Men of Letters recently held its ordinary meeting, when it was proposed to erase from its list of members MM. Victor Hugo, Pyat, and Rochefort, who are being prosecuted for their deeds during the Commune. But the meeting rejected the motion.

THE *Revue des Cours Scientifiques* commences with July 1 a new series, with the new title *La Revue Scientifique*, under the old editorship of MM. Yung and Alglave. The first number of the new series contains a sketch of the labours of the late M. Claparède, translations of Profs. Huxley and Tyndall's addresses at the Liverpool meeting of the British Association, and some fresh notes by Prof. Van Beneden on Commensalism in the Animal Kingdom.

THE weekly journal, *L'Institut*, has just entered on the fortieth year of its existence.

HERR RÜMKER has communicated to the *Astronomische Nachrichten* the following ephemeris of a new comet discovered by Temple on the 14th ult.:

$0^h$ BERLIN MEAN TIME.

| | R. A. | N. Decl. |
|---|---|---|
| | h m | ° ′ |

| ,, 8 | 33·0 | 41 |
| ,, 10 | 29·0 | 46 |
| ,, 12 | 25·0 | 52 |
| ,, 14 | 21·1 | 58 56 |
| ,, 16 | 17·2 | 59 1 |
| ,, 18 | 9 13·3 | 59 5 |

AT the Anniversary Meeting of the Meteorological Society, held June 21, C. W. Walker, Esq., F.R.S., F.R.A.S., the president, in the chair, the following officers were elected:—President: Dr. John W. Tripe. Vice-Presidents: N. Beardmore, C. O. F. Cator, G. J. Symons, C. V. Walker, F.R.S. Treasurer: H. Perigal. Trustees: Sir Antonio Brady, S. W. Silver. Secretaries: Chas. Brooke, F.R.S., Jas. Glaisher, F.R.S. Foreign Secretary: Lieut.-Col. Alexander Strange, F.R.S.

Council: Arthur Brewin, Geo. Dines, F. W. Doggett, H. S. Eaton, Fred. Gaster, Rev. C. H. Griffith, Dr. R. J. Mann, W. W. Saunders, F.R.S., R. H. Scott, F.R.S., Thos. Sopwith, F.R.S., S. C. Whitbread, F.R.S., E. O. W. Whitehouse.

THE annual distribution of prizes at Owens College, Manchester, was held on June 23, when the chairman, Mr. A. Neild, stated that the report of the Principal exhibits a very satisfactory amount of work done during the session, and a considerable increase in the number of students. The quality of the work has also not in any degree fallen off. The session was opened by a lecture from Dr. Balfour Stewart, on his appointment to the chair of Natural Philosophy; but his work was interrupted soon afterwards by a terrible accident which occurred to him at Harrow. He was glad, however, to be enabled to say that Prof. Stewart had so far recovered that he would be able to resume work at the commencement of the next session. A great deal had been done of late in the North of England in the way of increasing the teaching of Natural Science. He thought that so far as the means at their disposal enabled them, the managers of Owens College had made the institution a great school of Natural Science. At the same time, he hoped they should never fall into the opposite error of neglecting classical study and all that belonged to it. There is every reason to anticipate that Owens College will enter on its new premises in the course of session 1872-73. In addition to the prizes in the various classes, the following scholarships, &c., were then awarded:—Shuttleworth Scholarship (Political Economy), value 50*l.* per annum, tenable for two years: James Parkinson; Dalton Chemical Scholarship, value 50*l.* per annum, tenable for two years: William Robert Jekyll; Dalton Senior Mathematical Scholarship, value 25*l.* per annum, tenable for one year: John Henry Poynting; Dalton Junior Mathematical Scholarship, value 25*l.* per annum, tenable for one year: Arthur Walton Fuller; Ashbury Scholarship (Engineering), value 25*l.* per annum, tenable for two years: Edgar S. Cobbold; Dalton Natural History Prize, value 15*l.*: Charles Henry Wade; Engineering Essay Prize, Books of the value of 5*l.*: John Alfred Griffiths.

THE *Glasgow Star* says that the trustees of Anderson's University have been informed by their president—Mr. Young, of Kelly—that a gentleman had of his own accord made an offer of 2,000*l.* towards founding a chair of Applied Physics. Among other things, the trustees agreed to record their hearty approval of the scheme for establishing a College of Technology in Glasgow.

THE conditions necessary to the completion of the Brown Trust by the University of London have now been fulfilled. The University has been placed in possession of an excellent site, and abundant funds are forthcoming to carry out the objects of the Trust by founding an institution for the reception and treatment of sick and diseased domestic animals, which will afford invaluable opportunities for the advance of our knowledge of their diseases and their relation to those of man—a subject, says the *British Medical Journal*, of scientific and national importance.

DR T. BUCHANAN WHITE, President of the Perthshire Society of Natural Science, and editor of the *Scottish Naturalist*, publishes a first contribution towards a knowledge of the animals inhabiting Perthshire, in the form of a list of the Lepidoptera of the county.

THE last number of Petermann's "Mittheilungen" contains an admirable map of the Diamond Fields of Natal and the Orange River.

THE York School Natural History Society has issued its thirty-seventh Annual Report, from which we are glad to learn that the members show no lack of interest in the various branches of Natural Science. The collections exhibited at the close of last year were as follows: in Botany, three, varying from 257 to 96 species; of Lepidoptera, five, ranging from 105 to 72 species; of Coleoptera, six, containing from 212 to 64 species, and one illustrative of Insects generally. Three Natural History diaries were exhibited, and three recording astronomical observations, the latter especially being the result of much care and labour, and the observatory has been very diligently used. We trust that the society will long continue to exercise its useful influence, and that the members will profit in after life by the opportunities which have been afforded them.

THE Eastbourne Natural History Society, although only established in 1867, has already done a useful work in compiling for a new "Guide" to the neighbourhood a provisional list of the Fauna and Flora of the district. The space at their disposal being necessarily limited, it was impossible to give more than an enumeration of the animals and plants of the neighbourhood: but the attempt is worthy of note as a step in the right direction. The mammalia and reptilia are arranged according to Bell, the birds and fishes after Yarrell; for marine mollusca "Forbes' Handbook," and for land and freshwater species "Jeffreys' British Conchology," are followed; while the butterflies and moths follow respectively Morris and Newman. The flowering plants and ferns are arranged according to the "London Catalogue;" the mosses and algæ after Wilson and Gray; there is also a list of fungi. The secretary of the society, the Rev. A. K. Cherrill, will be glad to receive any additional information. A valuable museum, chiefly geological, has been bequeathed to the town, and is to be placed under the care of the society, so soon as a suitable building can be provided for its accommodation.

AT a meeting of the Royal Bavarian Academy of Sciences, on the 28th of March, Baron Liebig spoke thus of the future relations between Germany and France:—"The Academy seizes this moment to declare openly that there exists no national hatred between the German and Latin races. The peculiar character of the Germans, their knowledge of languages, their acquaintance with foreign people, the past and present state of their civilisation, all tend to make them just toward other peoples, even at the risk of often becoming unjust toward their own; and thus it is that we recognise how much we owe to the great philosophers, mathematicians, and naturalists of France, who have been in so many departments our masters and our models. I went forty-eight years ago to Paris to study chemistry; a fortuitous circumstance drew upon me the attention of Alexander Von Humboldt, and a single word of recommendation from him caused M. Gay-Lussac, one of the greatest chemists and physicists of his time, to make to me, a young man of twenty, the proposal to continue and finish with his co-operation an analysis which I had commenced; he introduced me as a pupil into his laboratory; my career was fixed after that. Never shall I forget the kindness with which Arago and Thenard received the German student; and how many compatriots, physicians and others, could I not name who, like myself, gratefully remember the efficacious assistance afforded to them by French men of science in finishing their studies. An ardent sympathy for all that is noble and grand, as well as a disinterested hospitality, form some of the most noble traits of the French character."

THE *British Medical Journal* states that a person named G. M. Raufer puffs and sells for three shillings, under the name of "lemonade for strengthening the memory," a fluid mixture of about 30 grammes, containing 15 parts of phosphoric acid, 15 of glycerine, and 70 of water. This is sold in Vienna.

IT is stated in the *British Medical Journal* that the Emperor of All the Russias has intimated to the University of Helsingfors, through the Senate of Finland, his willingness to permit women to attend the medical lectures at that University, in furtherance of the expressed wishes of His Majesty's Finnish subjects.

AT the last Calcutta University Convocation the novelty was the presence of eight native Brahme ladies.

GOLD is reported in New Caledonia, near the Scot River.

SUCH is the ease with which scientific intelligence is now propagated that the experiments of Dr. Fayrer, in India, on snake-bites, have attracted attention in the *Panama Herald*. It is there stated that an efficacious native Indian remedy for snake-bites has long been employed in many parts of the interior, and more successfully than ammonia, codron, cuaco, and other substances. The composition referred to is made by adding to a bottle of alcohol, as strong as can be got, and of at least 35°, the contents of the gall-bladders of every poisonous snake that can be got at. The dose is a thimble-full internally and the like externally.

THE *Mechanics' Magazine* for June 9 and 16 contains a full and interesting report of the recent *conversazione* of the Institution of Civil Engineers.

## *FIRST REPORT OF THE SCHEME OF EDUCATION COMMITTEE OF THE LONDON SCHOOL BOARD*

THE questions referred to us appear to fall under two chief divisions :—(1) The nature of the schools which it is desirable that the School Board should provide ; and (2) the methods of instruction which should be adopted in such schools ; and we shall therefore group our recommendations under these two heads.

Before proceeding to state these recommendations, it is important to observe that they need not be considered to apply, unreservedly, to those already existing schools which may now, or hereafter, be taken over by the Board.

The nature of the schools to be provided by the School Board will, as a general rule, be determined by the conditions under which grants of public money are made to schools by the Education Department.

Under the new code grants are made to public elementary schools of two kinds—those in which the instruction is given in the daytime, and those in which it is given in the evening. Under the regulations of the Science and Art Department, payments are made to teachers of science and art classes upon the results of examinations passed by the scholars. It will be desirable, in the first place, to deal with the two kinds of schools, viz., public elementary day schools, and public elementary evening schools, which it is the immediate duty of the Board to provide ; and, subsequently, to consider the classes of the Science and Art Department, in relation to these schools.

### I. PUBLIC ELEMENTARY DAY SCHOOLS

Public elementary day schools are conveniently classified into infant schools, for children below seven years of age ; junior schools, for children seven and ten years of age ; and senior schools, for older children.

Some of the recommendations we have to make are general, or hold good for all three classes of schools, while others apply only to one or two of them.

#### *General Recommendations*

*a.* MIXED OR SEPARATE SCHOOLS.—By mixed schools, we understand schools in which male and female children are taught in the same classes ; by separate schools, those in which boys and girls are taught in separate rooms.

It is universally agreed that infant schools may be mixed, not only without detriment, but with positive advantage to the children.

We therefore recommend that infant schools be mixed.

With respect to junior schools, so much depends upon the previous training of the children, and upon local circumstances, that we do not think it advisable to lay down any general rule regarding them.

On the other hand, while evidence has been brought before us tending to show that, under certain conditions, senior schools may be mixed, we are decidedly of opinion, and we recommend, that the senior schools provided by the School Board of London should be separate.

*b.* LARGE OR SMALL SCHOOLS.—A Board school should contain, under one management, an infant school or schools, a junior school, a senior boys' school, and a senior girls' school.

Large junior and senior schools of 500 children and upwards, can be worked with much greater economy and efficiency than small schools ; and we have no hesitation in recommending that large schools be established wherever it is practicable to do so. But we are of opinion that the number of children in average attendance in any infant school, or infant department of a school, under one principal teacher, should not exceed 250 to 300.

*c.* THE PROPORTION OF TEACHERS TO SCHOLARS.—Efficient and economical teaching, other things being alike, depends upon two conditions : the first, the regularity of the attendance of the scholars ; the second, the due proportion of the teaching power to the number of the scholars.

We are of opinion that the minimum number of teachers for a junior or senior school of 500 children should be 16—namely, 1 principal teacher, 4 assistant certificated teachers, and 11 pupil teachers ; and that the teaching staff should be increased by 1 assistant certificated teacher and 3 pupil teachers for every additional 120 children.

*d.* THE EMPLOYMENT OF FEMALE TEACHERS.—In infant and girls' schools, as a general rule, we recommend the employment of female teachers only ; and we are of opinion that, in many cases, women may advantageously take charge of mixed junior schools. We do not think it advisable that female teachers should be employed in senior boys' schools.

*e.* HOURS OF INSTRUCTION.—We recommend that the period during which the children are under actual instruction in school should be five hours daily for five days in the week.

We recommend that arrangements should be made by which, during the time of religious teaching, any children withdrawn from such teaching shall receive separate instruction in secular subjects.

*f.* CORPORAL PUNISHMENT.—While we consider that the frequent use of corporal punishment is a mark of incompetency on the part of the teacher, we by no means deny the necessity of the occasional and exceptional employment of such punishment. But we recommend that every occurrence of corporal punishment be formally recorded in a book kept for the purpose ; that the pupil teachers be absolutely prohibited from inflicting such punishment ; and that the head teacher be held directly responsible for every punishment of the kind.

*g.* MUSIC AND DRILL.—On the 1st of February, 1871, the Board resolved—"That it is highly desirable that means should be provided for physical training, exercise, and drill, in public elementary schools established under the authority of this Board :" and on the 22nd of March the Board passed another resolution—"That the art and practice of singing be taught, as far as may be possible, in the Board schools, as a branch of elementary education."

The new code of the Education Department encourages drill, by providing that attendance at drill, under a competent instructor, "for not more than two hours a week and twenty weeks in the year," may be counted as school attendance ; and although it does not make the teaching of vocal music compulsory, it inflicts a fine at the rate of one shilling per scholar in average attendance upon all schools in which vocal music is not taught.

We recommend that music and drill be taught in every school during the period devoted to actual instruction.

*h.* MORAL AND RELIGIOUS INSTRUCTION.—On the 8th March, 1871, the Board resolved—That in the schools provided by the Board, the Bible shall be read, and there shall be given such explanations and such instruction therefrom in the principles of morality and religion, as are suited to the capacities of children ; provided always—

1. That in such explanations and instruction the provisions of the Act, in Sections VII. and XIV., be strictly observed, both in letter and spirit, and that no attempts be made in any such schools to attach children to any particular denomination.

2. That in regard of any particular school, the Board shall consider and determine upon any application by managers, parents, or ratepayers of the district, who may show special cause for exception of the school from the operation of this resolution, in whole or in part.

We recommend, therefore, that provision should be made for giving effect to this resolution.

#### 2. *Particular Recommendations*

INFANT SCHOOLS.—We cannot too strongly insist upon the importance of schools for children under seven years of age. In a properly conducted infant school, children are not only withdrawn from evil and corrupting influences, and disciplined in habits of order, attention and cleanliness, but they receive such an amount of positive instruction as greatly facilitates their progress in the more advanced schools. There appears to be no doubt that by regular attendance in an infant school, provided with efficient teachers, a large proportion of ordinary children of six or seven years of age may be enabled to pass in the first standard of the new code.

The inducements which lead parents to keep older children from school are almost wholly absent in the cases of those under seven years of age, who are able to earn little or nothing, and are of no use in the house. And the fact that the younger children are taken care of in an infant school will often remove one of the chief difficulties in the way of securing the regular attendance of the elder girls of a family at the junior and senior schools.

The subjects in which we recommend that instruction should be given in infant schools are :—

*a.* Morality and religion.

*b.* Reading, writing, and arithmetic.

*c.* Object lessons of a simple character, with some such exercise of the hands and eyes as is given in the "Kinder-Garten" system.

In addition, the general recommendations respecting music and drill apply to infant schools, in which singing and physical exercises, adapted to the tender years of the children, are of paramount importance.

JUNIOR AND SENIOR SCHOOLS.—We recommend that certain kinds of instruction shall form an essential part of the teaching of every elementary school; while others may or may not be added to them, at the discretion of the managers of individual schools, or by the special direction of the Board.

A. ESSENTIAL SUBJECTS.

*a.* Morality and religion.

*b.* Reading, writing, and arithmetic: English grammar in senior schools; with mensuration in senior boys' schools.

*c.* Systematised object lessons, embracing in the six school years a course of elementary instruction in physical science, and serving as an introduction to the science examinations which are conducted by the Science and Art Department.

*d.* The History of Britain.

*e.* Elementary geography.

*f.* Elementary social economy.

*g.* Elementary drawing, leading up to the examinations in mechanical drawing, and to the art teaching of the Science and Art Department.

*h.* In girls' schools, plain needlework and cutting out.

B. DISCRETIONARY SUBJECTS, which may be taught to advanced scholars.

*a.* Algebra and geometry.

*b.* Latin or a modern language.

II.—PUBLIC ELEMENTARY EVENING SCHOOLS

Evening Schools are of great importance, partly as a means of providing elementary education for those who, for various reasons, fail to obtain sufficient instruction in elementary day schools; and, partly, because it is easy to connect with such schools special classes in which a higher kind of instruction than that contemplated by the Sixth Standard can be given to the more intelligent and older scholars. In this manner the advantages of further instruction may be secured by those scholars who are unable or unwilling to go into secondary schools, but who are both able and willing to pay for instruction of a more advanced kind than that given in primary schools.

We recommend that the course of instruction in these evening schools shall be of the same general character as that already recommended for the junior and senior elementary day schools. Elementary evening schools should, in all cases, be *separate*, and the General Recommendation (*a*) respecting moral and religious instruction applies to them. In all other respects we recommend that the managers should be left free to adapt the instruction given in the schools to local requirements.

According to the New Code, the scholars in evening schools must be not under 12, nor above 18, years of age, and no attendance is reckoned unless the scholar has been under instruction in secular subjects for one hour and a half.

III.—SCIENCE AND ART CLASSES

Numerous classes for instruction in Science and Art are already in existence; their current expenses, and the remuneration of teachers, being defrayed, in part, by the grants paid upon the result of the annual examinations, and, in part, by pupils' fees.

These classes are usually held in the evening, and are frequently connected with evening schools.

The Science and Art Department comes into relation with these classes, and with the examination of the scholars taught in them, through the agency of Committees who voluntarily charge themselves with the responsibility of seeing that the regulations of the Department are carried out. The establishment of Science and Art Classes in connection with Public Elementary Evening Schools, therefore, would not involve the Board either in trouble or expense.

We recommend that the formation of such classes be encouraged and facilitated.

The Elementary Education Act does not confer upon a School Board the power of providing secondary schools, and it is silent as to the mode by which a connection may be established between the elementary and the secondary schools of the country. But it is of such importance to the efficiency of popular education that means should be provided by which scholars of more than average merit shall be enabled to pass from elementary into secondary schools that we feel it our duty to offer some suggestions upon the subject

The practical difficulty in the way of the passage of boys and girls from an elementary into a secondary school, is the cost of their maintenance; and the best way of meeting that difficulty appears to be to establish exhibitions equivalent to the earnings of boys and girls of from 13 to 16 years of age, tenable for the period during which they remain under instruction in the secondary schools. The funds out of which such exhibitions may be created already exist, and the machinery for distributing them has been provided by the Legislature in the Endowed Schools Act.

The Endowed Schools Commissioners have fully recognised the claims of scholars in public elementary schools to share the advantages of the endowed schools. We recommend, therefore, that the Board enter into official communication with the Endowed Schools Commissioners, and agree with them upon some scheme by which the children in public elementary schools shall be enabled to obtain their rightful share of the benefits of those endowments with which the Commissioners are empowered to deal.

T. H. HUXLEY (*Chairman*).

JOHN G. CROMWELL—

Except that, looking to the three concluding clauses of the Report and to the sixth recommendation founded thereon, I feel unable to join in recommending that "Latin or a modern language may be taught to advanced scholars" in schools provided by the Board.

J. ALLANSON PICTON—

Except the application of General Recommendation (*h*) to public elementary evening schools.

SANDON—

Except that I object to the teaching of Latin or a modern language in primary public elementary schools; and that I also object to pronouncing any opinion in this Report upon the appropriation of existing endowments to the public elementary schools of London, as I do not consider that it is competent to a committee appointed by the School Board "to consider and report upon the scheme of education to be adopted in the public elementary schools" to consider, or make recommendations upon, this important subject.

## *MR. BENTHAM'S ANNIVERSARY ADDRESS TO THE LINNEAN SOCIETY*

(*Concluded from page* 172)

FRANCE, without any special endemic character, unites within her limits portions of several biological regions, thus requiring from her naturalists the study of all the European Floras and

Faunas in order rightly to understand her own. The greater part of her surface constitutes the western extremity of that great Russo-European tract I have above commented upon, its flora, and probably also its fauna, here blending with the West European type, which spreads more or less over it from the Iberian peninsula. To the south-east she has an end of the Swiss Alps, connected to a certain degree with the Pyrenees to the south-west by the chain of the Cevennes, but at an elevation too low, and which has probably always been too low, for the interchange of the truly alpine forms of those two lofty ranges. South of the Cevennes she includes a portion of the great Mediterranean region; and the marine productions of her coasts are those of three different aquatic regions—the North Sea, the Atlantic, and the Mediterranean. The few endemic or local races she may possess appear to be on those southern declivities which bound the Mediterranean region; and if the volcanic elevations of Central France have a special interest, it is more from the absence of many species common at similar altitudes in the mountains to the east or to the south-west, than from the presence of peculiar races not of the lowest grades, with the exception, perhaps, of a very few species now rare, and which may prove to be the lingering remains of expiring races.

With so many natural advantages, French science, represented during the last two centuries by as great, if not a greater, number of eminent men than any other country, has long felt the necessity of a thorough investigation of the biological productions of her territory. The French Floras, both general and local, are now numerous, and some of them excellent. The geographical distribution of plants in France has also been the subject of various essays as well as separate works. It is only to be regretted that in the Floras themselves the instructive practice of indicating under each species its extra-Gallican distribution has not yet been adopted. In Zoology no general fauna has been attempted, since De Blainville's, which was never completed, and none is believed to be even in contemplation; but I have a long list of partial Faunas and Memoirs on the animals of various classes of several French departments; and Rey and Mulsant are publishing, in the Transactions of two Lyons Societies, detailed monographs of all French Coleoptera.

The progress of French naturalists in Biology in general up to 1867 has been fully detailed as to Zoology by Milne-Edwards, in his "Rapport sur les Progrès de la Zoologie en France;" and as to Systematic Botany by Ad. Brongniart in his "Rapport sur les Progrès de la Botanique Phytographique." The recent progress as to both branches, as well as in regard to other natural sciences, has also been reviewed by M. Emile Blanchard in his annual addresses to the meetings of the delegates of French scientific societies, held every April at the Sorbonne from 1865 to 1870. The Société Botanique de France had also up to that time been active, and the publication of its proceedings brought down nearly to the latest meetings. I am compelled, however, for want of time, to defer some details I had contemplated relating to the recent labours of French biologists; but I cannot refrain from inserting the following note on a work mentioned only, but not analysed, in the last volume of the "Zoological Record," obligingly communicated to me with other memoranda by Prof. Deshayes, whilst slowly recovering from a severe illness contracted during the German siege:—

"In Mollusca we have also to regret that we have no complete work embracing the whole of this important branch of the animal kingdom. It is true that we make use of numerous works published in England, amongst which several are excellent, such as those of Forbes and Hanley, Gwyn Jeffreys, &c. Nevertheless I have to point out to you an excellent work published in 1869 by M. Petit de la Saussaye. The author, a very able and scientific conchologist, is unfortunately just dead. He has had the advantage of preparing a general catalogue of Testaceous Mollusca of the European Seas, possessing in his own collection nearly the whole of the species inserted, and of having received direct from the authors named specimens of the species foreign to the French coasts. This work is divided into two parts. The first is devoted to the methodical and synonymical catalogue of the species amounting to 1,150. In the second part, these species are distributed geographically into seven zones, starting from the most northern and ending with the hot regions of the Mediterranean. These zones are thus distinguished:—1, the Polar zone; 2, the Boreal zone; 3, the British zone; 4, the Celtic zone; 5, the Lusitanian zone; 6, the Mediterranean zone; and 7, the Algerian zone. Some years since it would have been impossible for M. Petit to have established the fifth zone, for that nothing, literally nothing, was known of the malacological fauna of Spain. Its seas were until 1867 less known than those of New Holland or California. It was only in that year that Hidalgo published a well drawn up synonymic catalogue in Crosse and Fischer's "Journal de Conchyliologie."

The British Isles have less even than France of an endemic character in respect of biology. They form, as it were, an outlying portion of regions already mentioned, the greater part, as in the case of France, belonging to the extreme end of the great Russo-European tract. Like France, also, they partake, although in a reduced degree, of that Western type which extends upwards from the Iberian Peninsula. They are, however, completely severed from the Mediterranean as from the Alpine regions; their mountain vegetation, and, as far as I can learn, their mountain zoology, is Scandinavian; and if it shows any connection with southern ranges, it is rather with the Pyrenees than with the Alps. The chief distinctive character of Britain is derived from her insular position, which acts as a check upon the passive immigration of races, and is one cause of the comparative poverty of her Fauna and Flora; the isolation, on the other hand, may not be ancient enough or complete enough for the production and preservation of endemic forms. As far as we know, there is not in phænogamic botany, nor in any of the orders of animals in which the question has been sufficiently considered, a single endemic British race of a grade high enough to be qualified as a species in the Linnæan sense. How far that may be the case with the lower cryptogams cannot at present be determined; there is still much difficulty in establishing species upon natural affinities, and in some Lichens and Fungi, for instance, much confusion between phases of individual life and real genera and species remains to be cleared up. The study of our neighbours' Faunas and Floras is therefore necessary to make us fully acquainted with the animals and plants we have, and useful in showing us what we have not, but should have had, were it not for causes which require investigation; such, for instance, as plants like *Salvia pratensis*, a common European species to be met with in abundance the moment we cross the Channel, but either absent from or confined to single localities in England.

There is no country, however, in which the native Flora and Fauna has been so long and so steadily the subject of close investigation as our own, nor where it continues to be worked out in detail by so numerous a staff of observers. To the Floras we possess, a valuable addition has been made within the last twelvemonth in J. D Hooker's "Student's Flora of the British Isles;" the best we have for the purposes of the teacher, and in which the careful notation of the general distribution of each species is a great improvement on our older standard classbooks. H. C. Watson's recently completed "Compendium of the Cybele Britannica" treats of the geographical relations of our plants with that accuracy of detail which characterises all his works. In Zoology, although we may not have compact synoptical Faunas corresponding with our Floras in all branches of the animal kingdom, the series of works on British Vertebrata published by Van Voorst are a better and more complete account of our indigenous races than any Continental State can boast of; and I observe with much pleasure that in the new edition announced of the "British Birds," Mr. Newton proposes specially to follow out the determination of their geographical range, upon which Mr. Yarrell had bestowed so much pains. With regard to our Mollusca, we have been very fortunate. Forbes and Hanley's costly work, published by the Ray Society, has been followed by Gwyn Jeffreys's "British Conchology," the great merits of which as a Malacological Fauna of Britain have been fully acknowledged abroad as well as at home. The present geographical as well as the fossil range of the species is specially attended to, and the only thing missed is perhaps a general synoptical view of the characters of the classes, families, and genera into which the species are distributed. The Ray Society series comprises also several most valuable works on the lower orders of British animals; but the entomological fauna of our country, especially in relation to the insects of the adjoining Continent, notwithstanding the numerous able naturalists who devote themselves to its study, appears to be somewhat in arrear. In answer to my query as to works where our Insects are compared with those of other countries, I received from our Secretary, Mr. Stainton, the following reply:—"The questions you have put to me with reference to our entomological literature are very important; they, however, painfully call my attention to the necessarily unsatisfactory nature of my replies. Wollaston's 'Coleoptera Hesperidum'* is the only separate

* Referred to in my Address of 1869.

work to which I can direct your attention as giving the fauna of a particular district, with the geographical range of such of the species as are likewise found elsewhere. R. M'Lachlan, who in 1865 had published (Trans. Ent. Soc. ser. 3, v.) a Monograph of the British Caddis-flies, gave in 1868 (Trans. Ent. Soc. for 1868) a Monograph of the British Neuroptera Planipenna, but little is there said of the European range of our species. In 1867 (Entom. Monthly Mag. iii.) Mr. M'Lachlan, who is one of our most philosophical writers, gave a Monograph of the British Psocidæ, and he there says with reference even to their distribution in our own country, 'As a rule, I have not mentioned special localities; these insects have been so little collected that an enumeration here of known or recorded localities would probably appear ridiculous in a few years.' The Rev. T. A. Marshall has given (Entom. Monthly Mag. i. to iii.) an essay towards a knowledge of the British Homoptera, in which occasionally allusion is made to the European distribution of our British species.

"The position of the Insect-fauna of Britain may be thus stated: the late J. F. Stephens commenced in 1827 a systematic descriptive work of all the orders of British Insects as 'Illustrations of British Entomology;' it ceased to appear after 1835, until a supplementary volume came out in 1846. The Lepidoptera, Coleoptera, Orthoptera, Neuroptera were wholly, the Hymenoptera partly, done, the Hemiptera and Diptera altogether left out. In 1839 Mr. Stephens published, in a more compendious form, a 'Manual of British Beetles.' In 1849 an attempt was made to supply the gaps in the British Entomology left by Stephens, and a scheme of a series of volumes called 'Insecta Britannica' was elaborated, in which Mr. F. Walker was to undertake the Diptera, Mr. W. S. Dallas the Hemiptera, and great progress having been made in our knowledge of the smaller moths since 1835, I undertook to write a volume on the Tineina. This scheme was so far carried out, that three volumes on the British Diptera by Mr. F. Walker (assisted by the late A. H. Haliday) appeared in 1851, 1852, and 1856, and my volume on the British Tineina in 1854. In 1859 another great group of the smaller moths was described by S. J. Wilkinson in a volume entitled 'The British Tortrices.' The British Hemiptera, not having been done by Mr. Dallas, were undertaken by Messrs. Douglas and Scott for the Ray Society; and in 1865 a 4to volume was issued, containing the Hemiptera, Heteroptera, leaving the Homoptera for a second volume, still in progress. Even in this elaborate work little or nothing is said of the geographical distribution out of Britain of our British species. The same will apply to the late J. F. Dawson's 'Geodephaga Britannica,' published in 1854; to Westwood's "Butterflies of Great Britain,' published in 1855; and to E. Newman's 'Illustrated Natural History of British Moths,' published in 1869.

"I believe I do not at all exaggerate if I say that for many years Entomology was pursued in this country with an insularity and a narrow-mindedness of which a botanist can scarcely form a conception. The system of only collecting British Insects was pursued to such an extent, that it was almost a crime to have a non-British insect in one's possession; if accidentally placed in one's cabinet it might depreciate the value of the entire collection, for Mr. Samuel Stevens can assure you that the value of the specimens depends very much upon their being indubitably and unmistakeably British. A specimen caught in Kent which would fetch 2*l*. would not be worth 2*s*. if caught in Normandy. I satirised this practice several years since in the 'Entomologists' Weekly Intelligence' (vol. v. and 1858, articles 'Jeddo' and 'Insularity'), but it is yet far from extinct"

Perfectly concurring in Mr. Stainton's observations in the last paragraph, I would however add that there are purposes for which a local or geological collection distinct from the general one may be of great use, and such a collection would be much impaired by the introduction of stray foreign specimens. In a local museum, a separate room devoted exclusively to the productions of the locality is very instructive with reference to the history of that locality, and I have seen several such spoiled by the admission of exotic specimens, giving the visitor false impressions, which it takes time to remove. But it is never from such an exclusive collection that the fauna or flora of the district can be satisfactorily worked out, or that any branch of Zoology or Botany can be successfully taught.

Mr. Stainton adds, "It has been suggested to me that those who have critically studied the distinctions between closely allied species have rarely the time to work out in addition their geographical range, and that those who might work up the latter subject might fail in their good intentions for want of a proper knowledge of species." Upon this I would observe that, in the due appreciation of a species of its limits and connections, its geographical range and the various forms it assumes in different parts of its area are an essential element; and it appears to me that the neglect of this and other general characters is one reason why many able naturalists, who have devoted their lives to the critical distinction of races of the lowest grades unduly raised to the rank of species, have really contributed so little to any science but that of sorting and naming collections. On the other hand, the study of geographical range without a proper knowledge of species is little more than pure speculation. Division of labour carried too far tends to narrow the mind, and rather to delay than advance the healthy progress of science.

Mr. Stainton informs me that "there has just appeared a monograph of the Ephemeridæ, by the Rev. A. E Eaton (Trans. Entom. Soc. 1871), treating of those insects throughout the globe; and when any species are noticed which occur in this country, their entire geographical range is noticed. It is altogether a valuable paper, on account of the thoroughness with which it seems to be done."

Since I last noticed our biological publications two valuable and beautifully illustrated but costly Ornithological works, Sclater and Salvin's "Exotic Ornithology," and Sharpe's "Monograph of the Alcedinidæ," have been completed, and various Memoirs by Flower, Mivart, Parker, and others, have considerably advanced our knowledge of the comparative anatomy of various groups of Mammalia. In our own country also, as well as on the Continent, the biology of various distant lands has continued to be worked out in Memoirs or independent publications, which I had contemplated noticing in succession; but time obliges me now to stop, and defer to a future occasion the compilation of the notes I had collected on North American, Australian, and other Monographs, Faunas, and Floras.

## *SCIENTIFIC SERIALS*

THE *Geological Magazine* for June (No. 84) commences with some notes on Crinoids by Mr. John Rofe, relating rather to the zoological than to the geological aspects of that class of animals. Mr. Rofe describes some experiments made on recent Crinoids by treating them with solution of potash or muriatic acid, from which he arrives at the conclusion that their hard parts are invested by a membrane giving them a certain degree of flexibility, a general position which few naturalists will be inclined to dispute. But the details of structure described by Mr. Rofe will be found of much interest. In his concluding remarks he endeavours to show an approximation between the Crinoids and the Tunicata, which, to say the least of it, is very doubtful.—Mr. S. Allport publishes a note on the microscopic structure and composition of a rock from the "Wolf Rock" off the Land's End, which he identifies with phonolite, and justly protests against the system which gives different names to rocks identical in mineral composition because they happen to be of different geological ages.—Mr. D. Mackintosh describes the drifts of the west and south borders of the Lake district, with especial reference to their great granitic dispersions which he believes have taken place; and Messrs. C. and A. Bell discuss the divisions of the English Crags as indicated by their invertebrate fauna. They propose as the result of their investigations, to divide the Crag into Upper, Middle, and Lower; the Upper including the Norwich, and the upper part of the so-called Red Crag; the Middle, the remainder of the Red Crag; and the Lower, the Coralline Crag. The last paper consists of a comparison of the metamorphic rocks of Scotland and Galway, by Mr. G. H. Kinahan. The first and last of these papers are illustrated with plates.

The second part of Tome xliii. of the *Bulletin de la Société Impériales des Naturalistes de Moscou*, completing the first half volume for 1870, is the last portion of this publication that has yet reached this country. It contains the continuation of M. Ferd. von Herder's notice of the monopetalous plants collected by G. Radde and others (*Plantæ Raddeanæ Monopetalæ*) in Eastern Siberia, the Amurland, Kamtschatka, and Russian America, and includes references to numerous species of Compositæ.—M. N. Erschoff communicates a note upon the Lepidoptera of Western Siberia, containing a list of species from the town of Omsk. — A Russian paper on the Oligochætal Annelid, *Pelorycles inquilina*, by M. H. Zingera, will probably attract few English readers.—M. E. Regel publishes a portion of a second supplement to the enumeration of the plants collected by Sewerzow in 1857 in Central Asia. It includes the Ranunculaceæ, Berberideæ, Nymphæaceæ, Papaveraceæ, Fumariaceæ, and Cruciferæ. Several new species are described.—Another botanical paper is an abridged French translation of part of the Introduction to a Flora of Moscow, by M. N. Kauffmann, the translation being made by Mr. G. O. Clerc. The Flora, which is a Catalogue of the vascular plants of the Government of Moscow, will appear in future numbers.—We find in this number two entomological papers, both on Coleoptera, and one of them of great importance, namely, a Monograph of the Graphipteridæ by the Baron Chaudoir. The other paper is a continuation, by M. Victor Motschoulsky, of his apparently interminable enumeration of the new species of Coleoptera collected by him in his journeys. It includes descriptions of species of Melasomata, and is illustrated with two plates.—M. G. Schweizer describes an easy method of approximately finding the meridian line; and M. A. Trautschold gives a short notice of some cretaceous fossils from Ssaratof and Ssimbirsk.

*Palæontographica.—Beiträge zur Naturgeschichte der Vorwelt.* Herausgegeben von Dr. W. Dunker und Dr. K. A. Zittel. Band xx. Lief 1., 1871. In this part of the well-known and most valuable "Palæontographica," Prof. Geinitz commences a monograph of the fossils of the Lower Quader and Lower Pläner beds in the Saxon Elbe valley, which he regards as forming the lowest part of a great Quader-formation, including the Senonian, Turonian, and Cenomanian stages of the French geologists. His Lower Quader is equivalent to the Upper Greensand of English geologists. It is well known that sponges are among the most abundant and striking fossils of our Upper Greensand, and the corresponding beds in the valley of the Elbe seem to be equally rich in remains of this lowest class of animals. With the exception of a summary of the geology of the district, the whole of the present part of Prof. Geinitz's work is occupied by descriptions of sponges, the species of which are beautifully figured in the accompanying plates. Laying the reproaches of Oscar Schmidt to heart, Prof. Geinitz endeavours to arrange his fossil forms in accordance with the system of that author, although, as he justly remarks, it is impossible in the study of fossil sponges to have recourse to those minute characters derived from the spiculæ, which form the basis of recent attempts to classify the recent forms. He notices in all twenty-eight species, of which six appear to be new.

## SOCIETIES AND ACADEMIES

### London

Royal Society, June 15, "On a Law in Chemical Dynamics." By John Hall Gladstone, F.R.S., and Alfred Tribe.

It is well known that one metal has the power of decomposing the salts of certain other metals, and that the chemical change will proceed until the more powerful metal has entirely taken the place of the other. The authors have investigated what takes place during the process.

The experiments were generally performed as follows:—72 cubic centimetres of an aqueous solution of the salt of known strength, and at 12° Centigrade, were placed in a tall glass; a perfectly clean plate of metal of 3,230 square millimetres was weighed and placed vertically in this solution without reaching either to the top or bottom; the action was allowed to proceed quietly for ten minutes, when the plate was removed, and the deposited metal was washed off. The loss of weight gave the amount of metal dissolved, and represented the chemical action.

The most complete series of results was with copper and nitrate of silver.

In the earlier terms of this series, *twice the percentage of silver-salt gives three times the chemical action.* The close agreement of the observed numbers with those calculated on this supposition continues as far as the 9th term. The law then breaks down, and after about 7 per cent. the increased action is almost in direct ratio with the increased strength.

The position of the plate in the solution was found to make no difference to this 2–3 law.

Similar series of experiments were made with zinc and chloride of copper, zinc and sulphate of copper, zinc and nitrate of lead, iron and sulphate of copper, and other combinations; and in every instance where the solution was weak and the action simple, the law of three times the chemical change for twice the strength was found to hold good.

It was proved that the breaking down of the law at about 3·5 per cent. of salt in solution was irrespective of the quantity of the liquid, or of the time for which the plate was exposed. With 72 cub. centims. of a 1·41 per cent. solution of nitrate of silver, the rate of action remained sensibly the same for as long as twenty-five minutes, notwithstanding the constant deposition of silver. This apparently paradoxical result is due to fresh relays of the original solution being brought up to the plate by the currents produced, and that period of time elapsing before any of the products of decomposition are brought back again in their circuit.

When it was perceived that within easily ascertainable limits the chemical action is the same for similar consecutive periods of time, experiments were made in far weaker solutions. It was only necessary to lengthen the time of exposure. It was thus found that the law of three times the chemical action for twice the strength of solution holds good through at least eleven terms of the powers of 2; in fact, from a solution that could dissolve one gramme of copper during the hour, to a solution that dissolved only 0·000001 gramme, a million times less.

The manner in which the silver is deposited on a copper plate was examined, and the currents produced were studied. At first a light blue current is perceived flowing upwards from the surface of the plate, presently a deep blue current pours downwards, and these two currents in opposite directions continue to form simultaneously. A similar phenomenon was observed in every case where a metallic salt attacked a plate of another metal. The downward current was found to be a solution of almost pure nitrate of copper, containing about three times as much $NO_3$ as the original silver solution, while the upward current was a diluted solution of the mixed nitrates. Moreover, the heavy current took its rise in the entangled mass of crystals right against the plate, while the light current flowed from the tops of the crystalline branches. It was evident that when the fresh silver was deposited on these branches, and the fresh copper taken up from the plate, there was not merely a transference of the nitric element from one combination to another, but an actual molecular movement of it towards the copper plate, producing an accumulation of nitrate of copper there, and a corresponding loss of salt in the liquid that is drawn within the influence of the branching crystals. Hence the opposite currents.

The amount of action in a circuit of two metals and a saline solution must have as one of its regulating conditions the conducting-power of that solution. It appeared by experiment that a strong solution of nitrate of silver offers less resistance than a weak one; and it was also found, on adding nitrate of potassium to the nitrate of silver, that its power of attacking the copper plate was increased; that the augmentation of the foreign salt increased the action still further; and that the 2-3 law holds good between two solutions in which both the silver and potassium salt are doubled, though it does not hold good if the quantity of foreign salt be kept constant. Similar results were obtained with mixed nitrates of silver and copper.

While these later experiments offer an explanation of the fact that a solution of double the strength produces more than double the chemical action, they do not explain why it should produce exactly three times the effect, or why the ratio should be the same in all substitutions of this nature hitherto applied. The simplicity and wide range of the 2-3 law seems to indicate that it is a very primary one in chemical dynamics.

"On Cyclides and Sphero-Quartics." By John Casey, LL.D.

Royal Institution of Great Britain, July 3.—Sir Henry Holland, Bart., M.D., F.R.S., president, in the chair. William Amhurst Tyssen Amhurst and Lawrence Trent Cave were elected members.

Royal Geographical Society, June 26.—Major-General Sir Henry C. Rawlinson, K.C.B., president, in the chair. The following new fellows were elected: Thomas Brassey, M.P.; T. B. Baker, C.B.; D. Chinery (Consul-General for Liberia); Commander C. D. Inglis, R.N.; William Charles Jackson; G. W. Kennion; Alfred Morrison, William G. Margetts, Colonel R. Maclagen, R.E.; Captain G. S. Nares, R.N.; and James Rickards. A letter was read from Sir Roderick Murchison, giving Dr. Kirk's views of Dr. Livingstone's position, as communicated in a recent letter from Zanzibar, dated the 30th April last. It appeared that no one at Zanzibar had been to Manime, the place where Livingstone was last heard of; but Dr. Kirk had ascertained that it was about a month's journey (200 or 300 miles) west of Lake Tanganyika, and was a thriving ivory-mart. Dr. Kirk expressed his hopes that, if Livingstone should have settled the problem of the outflow of Tanganyika, he would be satisfied, and leave all the rest of the work to future travellers, seeing that he has been out upwards of five years, and must sorely want rest. Abundant supplies were awaiting the great traveller's orders at Ujiji, on the shores of the lake.—Letters were read from Dr. J. D. Hooker to Sir Roderick Murchison, giving a description of his recent ascent of the Atlas Mountains, at two points south-west of the city of Marocco. On the first attempt, Dr. Hooker's party ascended to 12,000 feet; and on the second to the summit of a peak, further westward, 11,500 feet high. Storms of snow and hail were encountered near the crests; but the snow seemed to lie more compactly, and to a lower level (7,000 feet) further east. Constant humid and cold winds from the north are the cause of the low temperature, in consequence of which northern species of plants are found on the Atlas, to the exclusion of southern types.—A paper was read by Captain A. F. P. Harcourt on the districts of Kooloo, Lahoul, and Spiti, in Northern India; and a second one, by Major Sladen, on an exploration between the Irrawady and south-western China. Sir Donald MacLeod (late governor of the Punjaub), Sir Arthur Phayre, General Fytche (Commissioner of British Burmah), Colonel H. Yule, Mr. T. T. Cooper, Sir John Bowring, and others took part in the discussion, which followed the reading of the two papers.—The President announced that the Council had renewed, for the year 1872, the offer of geological prize medals to the chief public schools; and that the special subject for the year, both in the physical and the political divisions, would be South America. A proposition from the president for a vote of thanks to the Chancellor and Senate of the London University, for the use of their great hall, met with unanimous approval. The president stated that, although the ordinary meetings of the session had terminated, it was likely that a special sitting would be held to receive the Emperor of Brazil, an honorary member of the Society, should his Majesty accept, on his arrival, the invitation the Council had forwarded.

Anthropological Institute, June 19.—Sir John Lubbock, Bart., president, in the chair. Mr. G. Latimer was elected a local secretary for Puerto Rico and Logan; Dr. D. H. Russell was elected a local secretary for Bonny, west coast of Africa.—Prof. Busk exhibited two human jaws of remarkable thickness found in the superficial deposit of a cave near Sarawak, Borneo.—Mr. Josiah Harris exhibited from Macabi Island, off the coast of Peru, wood carvings, pottery, and cotton rags. The rags extended many hundred yards at an average thickness of five feet, and below a deposit of several feet of guano. The wood and pottery were discovered at a depth in the guano of from fifteen to forty-five feet.—Mr. G. M. Atkinson communicated some interesting facts connected with the discovery of a kitchen-midden in Cork harbour.—Mr. H. W. Flower exhibited a large jade implement from New Zealand.—A paper by Mr. A McDonald was then read, "On the Mode of Preserving the Dead among the Natives of Queensland."—Dr. Sinclair Holden contributed a paper "On Forms of Ancient Interments in Antrim;" and Mr. Hodden M. Westropp read a paper "On Analogies and Coincidences among Unconnected Nations."

DUBLIN

Royal Irish Academy, April 24.—The Rev. J. H. Jellett, president, in the chair. Mr. R. C. Tichbourne read a report on the molecular dissociation by heat of compounds in solution. The Rev. Dr. W. Reeves read a paper on the Irish tract by Onegus the Culdee, on the mothers of the saints of Ireland.

PARIS

Académie Française.—This is the most ancient of the French Academies, its special object being the publication of a Dictionary of the French language, which is thus officially protected against innovations. No word is considered classical without being duly registered in the Dictionary of the French Academy. Several editions have appeared successively, each of them containing many alterations. The next edition will soon be published, and is just now in active preparation. On June 29 the French Academy elected its Perpetual Secretary. All the votes were taken by M. Patin, a member of the Institute for the last twenty-eight years, and Professor of Greek Literature at the Sorbonne. The principal work of M. Patin is a study of the Greek tragedians, which is highly esteemed in France and abroad. The late Perpetual Secretary was the celebrated M. Villemain, a great friend of M. Guizot, and a former Minister of State in Louis Philippe's time. The election of M. Patin, although undisputed, was an event in the academical world, and many members left their residences, and even foreign lands, to vote for him. Amongst these learned travellers we must notice Father Gratry, of London, and the Marquis de Noailles, French Ambassador in London. MM. Guizot, Octave Feuillet, Nisard, &c., were present.

Académie des Inscriptions et Belles Lettres.—This Academy has also been engaged in filling the vacancies death had created in its ranks. M. Villemain was an ordinary member of this Academy. A scrutiny took place on the 30th ult., for the election of his successor. M. Charles Thurot was nominated by twenty-three votes against very few given to four other candidates. The Academy had also to vote for a successor to M. Alexandre, an inspector of the Academy, who was known merely by the publication of a Greek dictionary, which is the most useful in grammar schools. The succession to this office was more vigorously contested. M. de Rozière was elected only after a scrutiny, since a candidate must receive the actual majority of votes. A correspondent was also appointed. The successful candidate was M. Amari, an Italian learned antiquary of universal celebrity. All these nominations will be submitted to M. Thiers for approval, but it is a mere formality, and the assent of the Executive has never been refused for more than thirty years. M. Thiers himself is a member of the Institute, belonging to the Académie Française.

Academie des Sciences Morales.—The last sitting was occupied by a discussion raised by M. Egger on the degree of perception and intelligence in children. The question is to ascertain if infants are inferior or superior to ordinary animals in their mental condition. The reasoning of the learned member was grounded more on theoretical grounds than on actual observation of facts. None of the arguments offered were supposed to be conclusive, and the problem is left open for future investigations.

## BOOKS RECEIVED

ENGLISH.—Travels in Central America: Mrs. M. F. Squier (Trübner and Co.).—A Practical Treatise on the Manufacture of Soap: Dr. C. Morfit (Trübner and Co.).—Overland through Asia: T. W. Knox (Trübner and Co.)—Notes on the Food of Plants: C. C. Grundy (Simpkin and Marshall).—Transactions of the Woolhope Naturalists' Field Club for 1870.

## THE NEXT TOTAL SOLAR ECLIPSE

IT is infinitely to the credit of English men of science that they are at the present moment busily engaged in making arrangements for observations of the Total Solar Eclipse in December next, and it is extremely fortunate for the advance of Science that this rare phenomenon—rare, that is, so far as the chance of observing it with moderate facility goes—occurs again just as the knowledge gleaned by the recent expeditions is being garnered to serve as a starting point for future inquiry.

When we state that the eclipse will be visible as a total one in India, Ceylon, and Australia, it may at first be imagined that in this case the facilities are not so very great. This would be quite true if it were necessary to garrison all these stations with observers from England; but, as it happens, the Governments both of India and Victoria have under their orders government astronomers —Mr. Pogson at Madras, and Mr. Ellery at Melbourne; and all that is necessary is to forward to those stations instructions, so that the observers there may glean all the experience gained in the last eclipse, and instruments such as are required to advance our present knowledge. And here we may remark that our knowledge in solar matters has recently advanced so rapidly, that astronomers have, as it were, to use new weapons in each attack, as artillery gives place to small arms, and small arms to the bayonet, in less scientific warfare.

That India and Australia will thus be provided with everything that may be necessary will be evident when we state that the Astronomer Royal is superintending the adaptation of instruments already in his possession for use in the former country, while the President of the Royal Society has already communicated with the authorities in Australia, offering to aid in every way in the proposed observations—an offer which we doubt not will be accepted, and in both cases we may hope for results of the highest importance, if the local observers set to work with a will. As to the entire sympathy of both governments there can be no question, India was magnificently helpful to Janssen in 1868, and Australia has her spurs to win; and there are good men in plenty, in both places, in whom the Governments may place their fullest confidence.

There remains, then, Ceylon. Both the Royal and Royal Astronomical Societies have determined, if the Government will help, to send out a small party of observers from England to garrison this mid-station, which modern helps to travel have placed at our doors, and who knows that at one station or other Americans and Frenchmen may not be found to join in the good work? The new railway has made an American Expedition extremely easy.

And now let us enter a little more into particulars.

The central line of the eclipse will first meet the earth's surface in the Arabian Sea, and entering on the western coast of India, will pass right across one of the most important parts of Hindustan, in a S.E. by E. direction. In this part of the peninsula the sun will be about 20° above the horizon when totally obscured. The duration of totality will be two minutes and a quarter, and the breadth of the shadow about seventy miles. On leaving the eastern coast of the Madras Presidency, the central line will cross Palk's Straits, passing about ten miles S.W. of the island Jaffnapatam, and over the northern part of Ceylon, where the small towns of Moeletivoe and Kokelay will lie near the central line; and also the well-known naval station of Trincomalee, which will be about fifteen miles S.W. of the line. Continuing its course over the Bay of Bengal, the shadow will cross the S.E. point of Sumatra, and will touch the south-western coast of Java, where Batavia, the capital, will lie nearly sixty miles N.E. of the central line; and two other smaller towns, Chidamar and Nagara, will also be very near the middle of the shadow path. In the Admiralty Gulf, on the N.W. coast of Australia, the eclipsed sun will be only ten degrees past the meridian, and not far from the zenith; in consequence of which the totality will last $4^m\ 18^s$, or only four seconds less than the time of greatest duration. Lastly, passing through the most barren and uninhabited portion of Australia, crossing the Gulf of Carpentaria and the York Peninsula, the shadow will ultimately leave the earth's surface in the Pacific Ocean.

At present not too much is known about the chances of weather at any place; but what is known seems to point to a fair chance of success in both India and Ceylon, as the eclipse occurs during the N.E. monsoon; but, in any case, the experiences of the last Expedition show that for such a momentary phenomenon these chances need scarcely be taken too seriously into consideration, seeing that where the finest weather was predicted a terrible pall of cloud covered the sky.

Next as to the work which the present state of our knowledge shows to be most desirable. This has been pointed out by Mr. Lockyer, in a communication to the Royal Society, and here we may in the main quote from his paper. Mr. Lockyer states:—

"In my opinion the fundamental points of attack are:

"α. Spectroscopic observations made with such an instrument as the one I took out to Sicily, *equatorially mounted*, and with reference spectra.

"β. Photographic observations made with such an instrument as the one I took out to Sicily, namely, a camera with large aperture and small focal length *equatorially mounted*. . . . .

"Perhaps I may clear the ground by stating what, in my opinion is comparatively UNIMPORTANT, so far as the crucial points are concerned, though to be tolerated if the crucial points are strongly taken up.

"α. Photographing prominences.

"β. Sketching anything but the *changes* in the corona.

"γ. Polariscopic observations.

"δ Observing Baily's Beads.

There should be one instrument, and Mr. Pogson could probably provide this in India, to determine the position of prominences before and after totality. *During totality they should not be observed at all except incidentally.*

"At each place (*i.e.*, India, Ceylon, Australia) the spectroscopes should be employed for half an hour (to be on the safe side) before totality, in scrutinising the crescent at its narrowest place and the chromosphere outside the following limb of the moon.

"At each place, as before defined, there should be a spectroscope with a finder, and equatorial motion (or some equivalent arrangement) directed to the sun's centre, to record any changes which take place in the spectrum from, say, half an hour before to half an hour after totality, and during totality, *bien entendu*. The relative darkness or brightness of the lines should be recorded every ten seconds.

"This spectroscope should have moderate dispersion, large object-glasses for collimator and telescope, and with focal length such that two or three degrees round the sun should be taken in (*i.e.*, 1° or $1\frac{1}{2}$° from the sun's centre), and a large field. . . .

"To come to the details of the expedition to Ceylon; I am of opinion that it need not exceed the following numbers, as my Sicilian experience has taught me that we may depend upon much valuable help from the officers at the place of observation:—

> "1 Telescope-Spectroscopic observer; 2 assistants.
>
> "1 Photographer; 2 assistants. This duty perhaps may be entrusted to skilled Sappers.
>
> "1 Spectroscopic observer; 1 assistant, or 8 in all.

"Among general observations, I would point out as being of extreme importance:

> "*a*. Rays before, during, and after totality—their length, direction, and colour.
>
> "*β*. Colours of the various layers of chromosphere, and of clouds and landscape. The *order* of these colours is of great importance.
>
> "*γ*. Dark rays or *rifts*; whether they change, and whether they extend to the dark moon, or stop short above the denser layers of the chromosphere.
>
> "*δ*. The colours of the corona between bright or dark rays.
>
> "*ε*. All changes in corona.
>
> "*ζ*. Comparative brightness of rays and chromosphere and outer corona. . . . . .

"In the above letter the nomenclature employed is the one I suggested in a recent lecture at the Royal Institution, namely:

> "*Corona*, embracing the whole compound phenomenon outside the prominences (including rays and streamers), part of which is undoubtedly non-solar.
>
> "*Chromosphere*, embracing the whole of the solar portion of corona, and all bright line regions outside the photosphere."

It is scarcely necessary to point out th[illegible] above deals with possibilities, rather than wi[illegible]bilities. We are convinced that a much larger party would do good work in Ceylon, but our scientific leaders are right in asking what our Government cannot refuse; and, moreover, we may hope that the magnificent stations in India on the Neilgherries, at considerable elevations, will be strongly garrisoned, as they can well be by the eminent observers now in India.

We trust that these efforts to procure fresh observations will meet with the largest measure of success, for certainly the question of the Sun's Corona is the scientific question of the day. Once settle what is the real nature of the sun's surroundings, and the path of work is open for the more distant stars. So long as our knowledge of the sun is clouded by contending hypotheses, we cannot hope for real progress.

For our part we do not doubt that the Government will act as admirably as they did last year in the same branch of research when the requirements of Science are properly laid before them; and if the elements are equally kind, we may hope for a large increase of our knowledge.

## TYNDALL'S "HOURS OF EXERCISE IN THE ALPS"

*Hours of Exercise in the Alps.* By John Tyndall, LL.D., F.R.S. (London: Longmans.)

THIS volume is a collection of short articles which have already seen the light in various publications, and are here thrown together, as the author says, "partly to preserve to myself the memory of strong and joyous hours, and partly for the pleasure of those who find exhilaration in descriptions associated with mountain life." Accordingly we find in it accounts of exciting scrambles, such as the Lawinenthor and the Old Weissthor, the first ascent of the Weisshorn, and the various assaults upon the Matterhorn, crowned at last with success. Of sadder interest are the story of the death of Benner, the professor's faithful guide, upon the Haut de Cry, contributed by one of the survivors; notices of the accidents on the Col de Géant and on the Matterhorn; and, hardly less in interest though with happier ending, the rescue of a porter from the jaws of a crevasse on the great Aletsch Glacier, and the author's own hairbreadth escape on the Piz Morteratsch. All these are described with his usual graphic power and intense appreciation of natural scenery; sometimes in the philosophic vein, when a glass of whisky gives "a flash of energy," and even a ham sandwich can only be regarded as a conditioned form of potential muscular force; or sometimes in the more jubilant mood, when we are shown the grave professor "delighting to roll himself in a bubbling pool in some mountain stream, and afterwards dance himself dry in the sunshine."

Together with these sunny memories of alps and cascades, snow-fields and glaciers, there are some chapters of a more distinct scientific import, to which, as most germane to the pages of NATURE, we shall confine our notice. The first of these—the twentieth in the volume—is on Alpine Sculpture. The professor, we need hardly say, is a strong "Erosionist," attributing the valleys to the sculpturing influences of water, frost, and ice, as opposed to those who regard them as the result of fissures in the earth's crust produced by strains during its upheaval. His summary of the evidence for "sculpture *v.* fracture" strikes us as particularly good, and, as it happens, we can bear testimony from personal experience to the accuracy of the facts cited. He shows that by a simple geometric calculation, the width of the fissures produced by the upheaval of a hundred miles of the earth's crust to a maximum height of four miles would bear a very small ratio to the width of the existing valleys; therefore that the most which can be claimed for fissures is that they have guided the action of meteoric forces, have, as it were, drawn the rough sketch on the stone which has directed the picks of Nature's quarrymen, and guided the chisels of her sculptors. He points out that in the most fissure-like of gorges, such as those of the Via Mala or Pfäffers, characteristic water-marks are visible from top to bottom. His description of the latter may be taken as a summary of the evidence in these and many other cases which he has quoted. "Here the traveller passes along the side of the chasm, midway between top and bottom. Whichever way he looks, backwards or forwards, upwards or downwards, towards the sky or towards the river, he meets everywhere the irresistible and impressive evidence that this wonderful fissure has been sawn through the mountain by the waters of the Tamina." The only points in Prof. Tyndall's description to which we a little demur are when he speaks of the traveller "passing along the chasm midway between top and bottom," the fact being that the well-known gallery is only a few yards above the Tamina; and where he quotes the gorge as an illustration of water-action upon *limestone* rock. It is true that the strata here are not crystalline, and they may be occasionally calcareous, but we should hardly venture to apply the name of limestone to the hard black shales or slates out of which the gorge itself is cut. Professor Tyndall also omits to call attention to the close connection between the direction of the principal joints and the form of the gorge. This is especially noteworthy at Pfäffers, where the chasm is not vertical, but inclined to the horizon at an angle of some 70°, the water having followed, as is its wont, the direction of least resistance, viz., one of the sets of joint planes. The gorges of the Pantenbrücke, the Aar above Im-Hof, with many others, might be quoted as instances of the same. We think, indeed, that in arguing against those who ascribe alpine sculpture mainly to fracture, the professor does not quite do justice to the influence which fissures, faults, and joints (which last may, in many cases, be connected with the others) exercise in directing the meteoric agents. These have not, indeed, fashioned the mountains, but they have obliged the sculpturing forces to work in certain directions, have been like the rails or the points which cause a locomotive to follow a particular course instead of wasting its power in wandering over the fields.

Further on in the chapter, Prof. Tyndall refers to his own favourite theory of glacier sculpture, with regard to which he expresses himself more guardedly than in the paper originally published in the *Philosophical Magazine* (vol. xxiv. p. 169). Still we cannot say that we are convinced by his arguments even in their modified form. No one, of course, would deny that a glacier can deepen its bed; the question is simply one of degree. With regard to this our space will allow us to do little more than express dissent, and indicate one or two points where, while not disputing Prof. Tyndall's facts, we cannot accept his inferences.

The silt which is brought down by a glacier stream cannot, we think, be taken as a measure of the abrasion exercised by the glacier; surely the greater part is derived from the stones crushed between the ice and rock; it is the grist from the glacier mill, rather than the detritus of the nether stone. We fail also to see how, unless under exceptional circumstances, a glacier can "do more than abrade." Granted that "rocks are not homogeneous, they are intersected by joints and places of weakness which divide them into virtually detached masses," we doubt if it follows that "a glacier is undoubtedly competent to root such masses bodily away." A heavy body sliding over such masses and in close contact with them, would, we think, be more likely to keep them in their place, and certainly rocks from which glaciers have retreated do not exhibit evidence of this kind of erosive action. We confess, therefore, to still regarding the effects of glaciers as comparatively superficial, and classing the ice ploughs of past ages as among the efforts of scientific imagination.

A considerable portion of the latter part of the volume is devoted to a *résumé* of the "viscous" and "regelation" theories of glacier motion; a controversy which can hardly yet be regarded as concluded, seeing that the experiments of Mr. Mathews and Mr. Froude, to which Prof. Tyndall briefly alludes, appear likely to have a very important bearing upon the question of whether or not ice under any circumstances is a flexible or plastic substance to an appreciable extent.

Among the very miscellaneous scraps with which the volume terminates, is an account of the voyage to Algeria to observe the Eclipse. This, so far as its main purpose went, was a dismal failure, but remarks are introduced on the colour of the sea and sky, a subject already treated by the author in his "Glaciers of the Alps." During the voyage home a number of bottles of sea-water were secured from various stations, which were afterwards examined in London by passing through them a beam of electric light—the purity or impurity of the water is then shown by the less or greater amount of light which it scatters. Briefly, the result was that the dark blue water was very pure, the cobalt-blue rather less so, while the green tints denoted the presence of much suspended matter, and the yellowish green was very thick. A remarkable instance of this variety of colour which, if our memory serve us, he has not quoted, is in the Lakes of Thun and Brienz; the waters of the latter, which receives the silty streams of the Aar and the Lutschine, are distinctly green, while those of the former, into which no important glacier torrent directly enters, are of a beautiful blue.

In fine, though there is little new about the book, many of Prof. Tyndall's admirers will be glad to possess in a convenient form so many thoroughly characteristic papers, displaying at once his thoughtful mind and intense love of nature, as well as his great command over nervous and picturesque English.

T. G. BONNEY

## OUR BOOK SHELF

*The N[illegible]tural History of Plants.* By H. Baillon. Translated by Marcus M. Hartog. Vol. I. (London: L. R[illegible] and Co. 1871.)

HAVING noticed, on its publication, the first volume of Prof. Baillon's "Histoire des Plantes" (see NATURE, vol. i, p. 52) we need scarcely do more than call attention to the English edition which now lies before us. The translation, we may say at the outset, appears to us to be well done; the meaning of the original is, as far as we have observed, carefully preserved; and a better knowledge of his subject is shown by the translator than is always the case in English renderings of foreign scientific works. The co-ordination of the natural orders followed in the work is, as was mentioned in our notice of the original, novel; whether it will stand is a question on which we ought not, perhaps, to express an opinion until the plan is more fully developed. We could have wished that the author had given in this first volume some general sketch of his new system, with a defence of its peculiarities. So competent an authority as Prof. Baillon cannot have departed from the ordinary arrangement without cogent reasons, which we should have liked to have known. It is always a great advantage to English systematists to know the views of their fellow-workers on the Continent. We miss also the great assistance that is afforded to the systematist by a tabulated clavis of the genera belonging to each natural order. The amount of information contained in the volume as to the various relationships of the natural orders described in it, the morphology of their genera, the distribution of the different types, and the economic products obtained from the species, is immense. It possesses, however, the defect so common in foreign scientific works, of the absence of any table of contents or index to the subjects treated of. Had the publishers of the English edition supplemented the index of genera and subgenera with one referring to the various topics discussed, they would have rendered the English edition a practically more useful contribution to botanical literature

CALYCANTHUS FLORIDUS: Floriferous shoot.

than the French original. The illustrations are profuse, and of that excellence which we look for in vain in works originally published in this country. We append one of the well-known "Allspice Tree," the *Calycanthus floridus*. The small order Calycanthaceæ, including only the American *Calycanthus* and the Japanese *Chimonanthus*, is one the true position of which has been much disputed by systematists. Baillon makes it a "series" of Monimiaceæ, with which he also unites the Australian Atherospermeæ, bringing this order forward from its usual position among the Incompletæ to close alliance with Magnoliaceæ and Anonaceæ. A. W. B.

## *LETTERS TO THE EDITOR*

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### A New View of Darwinism

I HAVE only just seen the two letters in answer to one from me on Darwinism which you were good enough to insert in NATURE, and to which I ask the favour of being allowed to reply. I have to thank Mr. Darwin for his references and for the tone of his letter, which is in such marked contrast to the angry dogmatism of Mr. Wallace.

Mr. Wallace commences by ridiculing the phrase the Persistence of the Stronger. The phrase was not mine, it has been used by a better man than I, namely, by Prof. Jowett, and it has the advantage of not involving an identical expression, which the Survival of the Fittest does. "That those forms of life survive which are best adapted or best fitted to survive," is not a very profound discovery; it might have suggested itself even to a child, and if Mr. Wallace means nothing more than this when he speaks of the theory of Natural Selection, he cannot claim to have added much to the world's philosophical opinions.

He then complains that I have only touched one of the many facts relied upon by Darwinians; I refer him to my letter, in which I distinctly say that it contained only one of my objections, and that I have many more which will follow if the Editor have patience with the discussion. The reply to Mr. Wallace will confine me, however, in this letter to the ground covered by the former one. Having disposed of the formal and personal matters, I now approach the matters of fact about which we are at issue.

Here, I am sorry to say, I am met in a very different spirit by Mr. Wallace to that in which Mr. Darwin meets objections. Dogmatism, bold and unwavering, was the privilege of the philosophy of the Schools, but in the 19th century it is puerile. Mr. Wallace states boldly, without any authorities, merely as an imperial *ipse dixit*, that the most vigorous plants and animals are the most fertile. I had, at least, the decency to quote the book of Mr. Doubleday, containing a magazine of facts and examples in support of my view, and which tells exactly the other way.

This view has not been correctly stated by Mr. Wallace. The position I maintain is this, that, as a general law, those individuals which are underfed and lead precarious lives, are more fertile than those whose advantages make them vigorous and healthy. The ringing of the bark and the pruning of the roots of barren fruit trees and the starving of domestic animals to make them fruitful were examples to this end.

Mr. Wallace quotes only one example in his own support, and I will accept it as a crucial test of my position, which he will acknowledge to be fair; the case of the Red Indian and the Backwoodsman. The Red Indian lives entirely on flesh, the Backwoodsman almost entirely on vegetable food. Like meat livers in every part of the world, in Mexico, on the River Plate, in Siberia, in Turkestan, and in some parts of Russia, the Red Indian is not a fertile creature. The Backwoodsman, like vegetable feeders everywhere who are not luxurious, in India, China, Poland, and the Russian provinces bordering on it, Ireland, &c., is comparatively fertile, but only comparatively. It is a mistake to suppose that the Backwoodsman is specially fertile, and in a few years he becomes, as the inhabitants of Kentucky and Tennessee have been long known to be, diminishing in numbers, the population of the States being kept up by immigration.

Mr. Chadwick, in his "Sanitary State of the Labouring Classes," observes that where mortality is the greatest there is much the greatest fecundity; thus, in Manchester, where the deaths are one to twenty-eight, the births are one to twenty-six, while in Rutlandshire, where deaths are but one to fifty-two, births are one to thirty-three, showing that a state of debility of the population induces fertility. This only supports the common dicta of doctors that consumptive patients are generally very fertile. The pastoral tribes of Eastern Russia which have recently taken to agriculture, such as the Tchuvashes, &c., have begun to increase most rapidly. The Hottentots at the Cape, who were formerly a numerous race living very hard lives, are almost extinct now that they are carefully tended and well fed. The Yeniseians, the Yukahiri, and other Siberian tribes, have disappeared like smoke before the advance of Russian culture; they have suffered little if at all from the Russian arms.

Let me quote a curious example in answer to Mr. Wallace from the very race to which he has referred. Captain Musters, in describing his recent journey through Patagonia at the Anthropological Institute, told us that it was the custom for the Patagonian women to be bled at certain times referred to, as they believed *it made them fertile*. Among the Patagonians, therefore, we meet with empirical witnesses, unsophisticated by our philosophy, to the truth of the position I maintain. But those who live in large cities need not travel to Patagonia. The classes among us who teem with children are not the well-to-do and the comfortable, but the poor and half-fed Irish that crowd the lowest parts of our towns. I am not contrasting now the fat with the lean, but the comfortable classes with those who lead precarious lives—the vigorous in health with the sickly, the half-fed, and the weak. It will be asked, why rely so much upon man? The answer is that I quite agree with Mr. Darwin that man is subject to the same natural laws as the animals, and further I believe that since we have studied man more closely and under a greater variety of conditions, facts derived from our experience of man are of greater value than those deduced from our examination of the other animals.

But let us turn to these latter for a space; and here I tread with much greater diffidence, for I am aware of the vast experience and fund of illustration possessed by Mr. Darwin, and I have to say that I am unconvinced by the arguments he has adduced. With the transparent frankness of all his writings, Mr. Darwin, in one of the references to which he has commended me, has collected a very large number of examples that tell very strongly against him, and which I again commend to Mr. Wallace. I refer to the 18th chapter of Mr. Darwin's book on the "Variation of Plants and Animals under Domestication," and especially to that portion beginning on page 149. In speaking of animals, he says:—"The most remarkable cases, however, are afforded by animals kept in their native country, which, though perfectly tamed, quite healthy, and allowed some freedom, are absolutely incapable of breeding Rengger, who in Paraguay particularly attended to this subject, specifies six quadrupeds in this condition, and he mentions two or three others which most rarely breed. Mr. Bates, in his admirable work on the Amazons, strongly insists on similar cases, and he remarks that the fact of thoroughly tamed wild animals and birds not breeding when kept by the Indians, cannot be wholly accounted for by their negligence or indifference, for the turkey is valued by them, and the fowl has been adopted by the remotest tribes. In almost every part of the world, for instance, in the interior of Africa, and in several of the Polynesian islands, the natives are extremely fond of taming the indigenous quadrupeds and birds, but they rarely or never succeed in getting them to breed," and so on, through sixty pages of closely-packed examples. And what is Mr. Darwin's commentary on these facts? I again quote page 158:—"We feel at first naturally inclined to attribute the result to loss of health, or at least to loss of vigour, but this view can hardly be admitted when we reflect how healthy, long-lived, and vigorous many animals are under captivity, such as parrots and hawks when used for hawking, chetahs when used for hunting, and elephants. The reproductive organs themselves are not diseased, and the diseases from which animals in menageries usually perish are not those which in any way affect their fertility. No domestic animal is more subject to disease than the sheep, yet it is remarkably fertile." Mr. Darwin, with equal clearness and conclusiveness, decides that this sterility cannot be due to a failure of sexual instincts, change of climate or of food, or want of food or exercise; and he concludes that certain changes of habits and of life affect in an *inexplicable manner* the powers of reproduction. But what is true of man it is reasonable to suppose is true of all these instances—namely, that it is a more luxurious habit, a more vigorous health, a less precarious existence, induced by the care and attention of domesticators, that have caused the sterility; that these animals are too well off, and not that they are ill off in any way; and this theory explains the whole most conclusively. On the other hand, and in opposition to this vast and uniform collection of examples, Mr. Darwin adduces a few instances which tell the other way, but they are very few in number, and seem to me explicable on other grounds. Ferrets, it is notorious, are always kept in a state of extreme depletion and as thin as possible. Domestic poultry are fed almost entirely on poor vegetable food, while their wild and semi-wild relatives feed much more on worms, insects, and on animal diet generally. In regard to sheep, it is notorious that very weak ewes generally bear twins, that Somersets and Dorsets are more fertile than Southdowns and Leicesters. We have, I may add, no facts to guide us in regard to wild dogs, and few in regard to wild cats; but we do know that in tame ones the half-fed lantern-ribbed curs are more prolific than their sleek relations. In regard to domestic fowls, and especially pigeons, we must remember that their condition is materially altered by the disuse or only very partial and irregular use of their powers of flight, this must reduce their circulation and vigour very considerably, and make them *pro tanto* so much weaker. But these instances, upon which Mr. Darwin relies to answer Doubleday and others, are very partial indeed. In his own pages, as I have already said, they form a very small element compared with the overwhelming cases he quotes on the other side. So much so, indeed, that these cases may be taken as exceptions which prove the rule that domestication and improved conditions of life induce sterility in animals.

It savours of scholastic philosophy to speak of Nature as exercising any influence on the regeneration of races, and yet there may be sound philosophy in the old notion that when an individual or a class is in danger of being extinguished from want, Nature puts forward a special effort to preserve it. The sickly mother, the half-starved plant, is more likely to breed than the healthy and the vigorous. If we remove the peasant's family to the drawing room, it will cease to be composed of ten and twelve children. If we remove our daisies and cowslips to the greenhouse, their flowers grow double, and they ripen no seeds. The vine that has felt the frost is the one to pay the rent. Wherever we turn, in fact, we meet with examples of the universal law; and this law seems to be at issue with an important portion of Mr. Darwin's theory, namely, that in the struggle for existence, the vigorous, the hearty, and the well-to-do, elbow the weak and decrepid until they elbow them out of existence, and supplant them. If I have said anything above which can be construed into an impertinence, I unconditionally withdraw it. The only excuse for soreness, is an impatience at what seems to the writer to be indefensible dogmatism. The days will not be ripe for scientific dogmatism until the Infallibility of Positive Philosophers has been generally accepted, and it does not do to forestal that millennium.

H. Howorth

---

Mr. Wallace has effectually set aside Mr. Howorth's new views on Darwinism, and it now only remains to point out that the latter gentleman, in his instances, puts the cart before the horse. Hens that are fat and don't lay are fat because they don't lay. When the sexual powers, either in plants or animals, are defective from accident or design, the overgrowth always takes place, and this among animals is chiefly by the increase of adipose tissue.

## Recent Neologisms

I have been long accustomed to register the first appearance of new words and phrases. Of course the vast majority of these take no root, perishing where they fall. Here is a sample of the latest issue: *Survival*, introduced, I think, by Darwin; *indiscipline* and *impolicy*, which were brought in by the Franco-Prussian War, and also the vulgarism *to telegram*. The greatest atrocities in this line are committed by "physicists," if the shade of Faraday will pardon me the use of that word; and far away the worst coinage I ever encountered is due to Mr. Alfred R. Wallace. As it is "meet and right and our bounden duty" to stigmatise such intruders, and if possible prevent their adoption, I take the liberty of making my feeble protest against Mr. Wallace's "prolificness," which he introduces to our notice in his letter on Mr. Howorth (Nature, July 6, 1871, p. 181). In this case the hideousness of the coinage is some guarantee against its reception.

## Affinities of the Sponges

I have just read with much interest the paper in Nature by Mr. W. Saville Kent, criticising my friend Carter's article in the "Annals of Natural History" for this month, in which I fully concur. How Mr. Carter can have fallen into such an error, for such I must call it, I cannot imagine, as comparing a group of animals in Botryllus to those sponge cells, even in so highly a developed form as Grantia. For, taking this as the highest known form of sponge animal, it is at most only a monociliated sac, as shown both by Prof. Clark and by Mr. Carter. Now, it is well known to all investigators, and Mr. Carter has shown it himself, that the animals of Botryllus have distinct oral and fæcal apertures, whereas the sponge cell, so far as has yet been seen, has only an oral aperture. Again, the Ascidian Botryllus is shown to be far higher in the scale when we come to compare its internal organisation, and not merely to confine ourselves to the sac-like tunic. The discharge of the fæcal matter into a common cloacal canal is to me not a sufficient reason for comparing these groups of animals to the sponge animals in *Grantia*.

But what I wish to draw attention to more particularly is this, that in the hurry and bustle of our investigators of the present day, all old associations are mostly, if not entirely, forgotten. I can scarcely think that they are ignored, but are forgotten. Thus, Prof. Grant was, I believe, the first to determine the character and the full importance of the seed-like body in *Halichondria* by placing watch-glasses in the vessel in which living specimens of the above sponge was placed; the bodies were thus discharged from the fæcal canal of the parent sponge, and attached themselves to the watch-glasses, and he then carefully watched their development. Mr. Carter, being a pupil of Dr. Grant, no doubt followed his teacher's plan of investigation, which has led to the brilliant results of this gentleman's investigations of the fresh-water species in the tanks at Bombay. The clear and lucid manner of investigation detailed by Prof. Grant in the *Edinburgh New Philosophical Journal* (1826-27) might be held as a pattern for investigators, but he appears to be almost entirely lost sight of.

Again, as regards the animals of *Grantia compressa*, Prof. Reay Greene certainly preceded both Prof. Clark and Mr. Carter in his investigations, and has figured these monociliated animals in his handbook, published in 1859, p. 31, fig. 6. The figures are on the same scale as those given by Mr. Carter, and indeed some of the groups figured are so much like those given by Mr. Carter in the "Annals," pl. 1, sqr. 13, *a*, *g*, *h*, that it would be difficult to separate them, and the same may be said of Fig. 41 of Prof. Clark's in "Ann. Nat. Hist" pl. 6, 1868. The only difference being the want of the funnel-shaped mouth, which seems to have escaped the observation of Prof. Greene, probably owing to want of definition in the instrument used in the investigation. Now there is an amount of credit due to the first demonstrator of these animals, which, so far as I have seen, does not appear to have been accorded to him; and I therefore take the liberty of directing attention to this fact. I do not know Prof. Greene, and therefore do not take up this matter on personal grounds, but only in fairness due from one scientific man to another, and I hope my friend Carter will take this in the spirit it is intended. EDWARD PARFITT

Exeter, July 8

## Cramming for Examinations

I ENCLOSE one or two *bonâ fide* extracts from "Middle Class" examination papers which have during the past few weeks come under my notice officially.

I do not wish thereby to reflect so much on the candidates as upon the mode of teaching in Middle Class schools, which produces such results.

As might be expected, where evidence of "cramming" from a text-book and want of practical knowledge are equally manifest, some of the answers in the papers from which these are selected are pretty good—but what can be the real value of knowledge of this sort?

The questions are sufficiently indicated by the answers.

CANDIDATE A.

Chlorine may be taken from decayed vegetable matter and animal matter, also manure. . . . It is used for killing insects, it is compounded with lime, and is very good when compounded with lime for the manuring of fields. Lime is chiefly formed from Chlorine.

CANDIDATE B.

Chlorine is prepared by mixing $Ca\,Cl_2$ with $H_2O$

$$Ca\,Cl_2 + H_2O = CaO + H_2 + Cl_2$$

Chlorine is a colourless invisible gas. Has no odour nor taste. . . . Hydrochloric acid is prepared as follows—

$$Ca\,Cl_2 + H_2O = CaO + 2\,H\,Cl$$

CANDIDATE C.

Carbon is an elementary substance, it is one of the constituents of the atmosphere, it is found in lime and pits among the coal. When the lime is soaked with water the carbon escapes out and the lime moulds away.

AN EXAMINER

## Great Heat in Iceland during the present Summer

MR. R. M. SMITH has received a note from Dr. Hjaltelin, Corresponding Member of the Scottish Meteorological Society at Reykjavik, dated June 30, of which the following is an extract:—

"We have now the most excellent season you can imagine in these latitudes, the average temperature for this month (June) being as high as 59°, which is 12° higher than the mean temperature of the past four Junes. I was yesterday near the Hengil Mountain, just at that place where we pitched our tent last time you were here, and the heat was quite unsupportable in the valleys. The wind has been continually blowing from the south-west. Some Englishmen setting out for the Geyser will have something to tell of the extraordinary heat we have at present."

ALEXANDER BUCHAN

## The Late Thunderstorm

AN ash tree in the garden attached to the farmhouse of Wester Cringate, near Fintry, struck by lightning on the 20th of June, presents a singular appearance.

About 20ft. from the ground a large branch has been torn from the trunk. The bark has been neatly peeled off for a few feet above and below the place from which the branch shot out. The wood has been first struck a little above the branch, and shows a clean cut, such as might have been made by a sharp-edged tool, as if a chisel three inches broad had been driven into the wood for about four inches. The branch itself has been torn, not cut, and a stripe of the trunk about two feet long below the branch has also been torn out.

For the next four or five feet the tree has suffered no damage of any kind, but after that space the trunk bears six parallel downward scars, varying in length from two to five feet. The scars do not all begin or end at the same height, although each might be cut in some point by a horizontal plane passing through the tree. They spread over about half the circumference of the trunk, and can all, or nearly all, be seen from one standpoint. The most striking circumstance, however, is the almost perfect parallelism of the scars, which are not vertical, but a little twisted round the trunk like the rifling of an Armstrong gun, the rifling in this case being on the outside of the barrel. Six chisels of about half an inch in breadth seem to have ploughed into the wood, tearing off at the same time rather broader stripes of the bark. Towards their lower ends the three right-hand scars cease to be quite parallel, and tend to converge; but all three die out before the convergence takes place, and the tree for the next two feet or so is unscathed. Five feet from the ground (at about the point at which the three scars would converge, if produced) a single rut cutting deeply into the wood commences, which continues down to the soil.

The garden wall (which is a "dry-stone dyke," *i.e.* of loose uncemented stones) passes some three feet behind the tree, on the side directly opposite to that on which the markings above described occur. Outside of this garden the lightning has ploughed two pretty deep parallel ruts through the grassy soil some four feet apart, and stretching from the foot of the wall to the edge of a ditch, a distance of three feet. These ruts are the last observable traces of the passage of the lightning, and were probably made by the currents which engraved the three left-hand scars on the tree. Of course it is impossible to decide whether the currents passed through the open wall, or down the outside of it.

Three sheep on the neighbouring farm of Spittalhill were killed in the same thunderstorm. Their carcases were found lying in a line and were very much swollen, but bore no external marks of injury. A small patch of wool had been stripped from the flank of one of them, but probably this had no connection with the cause of death. R. L. JACK

Geological Survey, Fintry by Glasgow, July 5

## Saturn's Rings

As you have favoured my work on "Saturn's Rings and the Sun" with criticism, I feel sure that as that criticism is adverse to my views, you will in fairness allow me to reply to it.

I will do so in detail. Your reviewer commences very much under the impression that Prof. Clerk Maxwell having investigated the "Stability of Saturn's Rings," no one else is to venture into any discussion touching on their nature or origin. In fact he issues a *caveat*—Prof. Clerk Maxwell has concluded the subject! Next he asserts that I have not seen the Professor's work, because I ascribe to the perusal of Mr. Proctor's "Saturn and its System," the enlistment of my "interest in favour of the Satellite Theory." This is surely beyond his province, as I am free to choose my own point of starting. Mr. Proctor's work interested me, and so did Mr. Clerk Maxwell's, but the former elicited my work, the latter did not.

He next accuses me of placing too great faith in figures, and shows surprise at my giving the hourly rate of the solar motion to a mile, and the solar parallax to four places of decimals. The solar motion is that given by the Herschels, and the solar parallax by several observers. He is hard to please. But my reviewer has unfortunately missed the point of my arguments. The actual velocity of this solar motion is perfectly immaterial; indeed, had he followed the reasoning, he would have seen how pointless are his objections.

As regards my arguments in favour of the meteoric theory of the sun, the reviewer is equally inaccurate. As to my being blindly enraptured with that theory, as he is pleased to state, I only reply that very clever men have held it, as he is perhaps aware; and certainly none of the modern theories, cumbrous vagaries of the brain, can compare with it. I have never said that the meteoric theory is the real explanation, but I doubt if we shall ever arrive at a more truthful representation of the solar phenomena.

Lastly, he culminates by saying I am "either innocently or wilfully ignorant of the palpably cyclonic appearance which spots frequently present." All I can say in answer to this is that, having observed sun-spots myself for many years, probably as often as the reviewer, I have *never* observed one single appearance of a cyclonic nature. As I possess Mr. Carrington's valuable work, I have again referred to it, and find it in agreement with the assertion in my book and my own observation. I must apologise for my lengthy letter. A. M. DAVIES

2, Gloucester Terrace, Sandgate, July 4

## On an Error in Regnault's Calculation of the Heat Converted into Work in the Steam Engine

IN Watts's "Dictionary of Chemistry" (vol. iii. p. 125), in the article on Heat by Prof. G. C. Foster, it appears to me that an important error has crept into the discussion of the above calculation.

The nature of the calculation is as follows:—A unit weight of saturated steam at the temperature of 152°C. contains 653 units of heat. Suppose we allow the steam to expand and to do work until the temperature falls to 503°C. the steam then contains 621 units or 32 units less than before, hence starting with water at 0°C., we give it 653 units of heat, and of this 32 only are converted into work, giving us the fraction $\frac{32}{653}$ as the amount of heat converted into work; but the real work produced by an engine is more than twice this. This difference in theory and practice is accounted for by the fact that saturated steam, in expanding and doing work, is partly condensed, hence the body with which we have to deal at the lower temperature is not all steam, but partly condensed water, therefore, does not contain so much heat as was allowed it.

This explanation is so intelligible as to be at first sight sufficient to account for the whole difference; there is, however, another cause, quite as important, and which is this; every time steam passes from the boiler to the cylinder it does work before it is cut off, and allowed to expand; this work is not done at the expense of the steam that passes into the cylinder, but of the whole mass of steam in the cylinder and boiler, which expands and is thereby cooled. The mass of water and steam in the boiler is, however, so large compared to that which passes into the cylinder, that a thermometer could scarcely detect the cooling effect upon it, and before the next stroke this loss of temperature is made up by the fire. Though thus inappreciable, it is nevertheless very important, and in most engines would amount to one-third the work done; in fact all the work done by the steam before it is cut off and allowed to expand is entirely neglected in this calculation, and a source of error introduced.

To correct it there should be added to the heat in the steam at the initial temperature, as many units of heat as the work done before the steam is cut off, would, if converted into heat, raise the amount of water which passes at every stroke in the form of steam into the cylinder. A. W. BICKERTON

Hartley Institution, Southampton, June 26

## *THE CAUSES OF THE COLOURS OF THE SEA* *

PROF. TYNDALL, in his article in the *Fortnightly Review* for the 1st of March, attributes the greenness of the sea to the matter which it holds in solution. Perhaps the following may corroborate his theory. About the Andaman Islands, where the sea is of the deepest blue, there are most startling and sharply-defined changes of colour, from bright blue to green, where a bed of coral exists. This coral is white out of the water, what its colour when growing may be I know not, but the change I mention appears to corroborate the remarks in the article in question, which are appended below, about the green hues observed upon the plate, the screw blades, and the white bellies of the porpoises. One looks down from a hill into a bay of the brightest blue; you see it broken up here and there like a child's puzzle map by irregular patches of as bright green, often crossing several acres as sharply defined as it is possible to imagine, and indicating the existence of coral beds or reefs just below.

Bellary, Madras Presidency W. M'MASTER

* Communicated by Prof. Tyndall.

[We give the passages referred to from Prof. Tyndall's lecture.—ED.]

"Let us clear our way by a few experiments towards an explanation of the dark hue of the deep ocean.* Colour, you know, resides in white light, appearing generally when any constituent of the white light is withdrawn. Here is a liquid which colours a beam sent through it purple, and this colour is immediately accounted for by the action of the solution on a spectrum. It cuts out the yellow and green, and allows red and blue to pass through. The blending of these two colours produces the purple. Does the liquid allow absolutely free passage to the red and blue? No. It enfeebles the whole spectrum, but attacks with special energy the yellow and green colours. By increasing the thickness of the stratum traversed by the beam, we cut off the whole of the spectrum. Through the deeper layer, which I now place in the path of the beam, no colour can pass. Here, again, is a blue liquid. Why is it blue? Its action on the spectrum answers the question. It first extinguishes the red; then as the thickness augments it attacks the orange, yellow, and green in succession; the blue alone finally remains, but everything might be extinguished by a sufficient depth of the liquid.

"And now we are prepared for a concentrated but tolerably complete statement of the action of sea water upon light, to which it owes its blackness. Here is our spectrum. This embraces three classes of rays—the thermal, the visual, and the chemical. These divisions overlap each other; the thermal rays are in part visual, the visual rays in part chemical, and *vice versâ*. The vast body of thermal rays is here beyond the red and invisible. They are attacked with exceeding energy by water. They are absorbed close to the surface of the sea, and are the great agents in evaporation. At the same time the whole spectrum suffers enfeeblement; water attacks all its rays, but with different degrees of energy. Of the visual rays the red are attacked first, and first extinguished. While the red is extinguished, the remaining colours are enfeebled. As the solar beam plunges deeper into the sea, orange follows red, yellow follows orange, green follows yellow, and the various shades of blue, where the water is deep enough, follow green. Absolute extinction of the solar beam would be the consequence if the water were deep and uniform, and contained no suspended matter. Such water would be as black as ink. A reflected glimmer of ordinary light would reach us from its surface, as it would from the surface of actual ink; but no light, hence no colour, would reach us from the body of the water. In very clear and very deep sea water this condition is approximately fulfilled, and hence the extraordinary darkness of such water. The indigo, to which I have already referred, is, I believe, to be ascribed in part to the suspended matter, which is never absent, even in the purest natural water, and in part to the slight reflection of the light from the limiting surfaces of strata of different densities. A modicum of light is thus thrown back to the eye, before the depth necessary to absolute extinction has been attained. An effect precisely similar occurs under the moraines of the Swiss glaciers. The ice here is exceptionally compact, and owing to the absence of the internal scattering common in bubbled ice, the light plunges into the mass, is extinguished, and the perfectly clear ice presents an appearance of pitchy blackness.

"The green colour of the sea when it contains matter in a state of mechanical suspension has now to be accounted for; and here, again, let us fall back upon the sure basis of experiment. This white plate was once a complete dinner-plate, very thick and strong. It is, you see, surrounded securely by cord, and to it a lead weight is fastened. Forty or fifty yards of strong hempen line were attached to the plate. With it in his hand, my assistant, Thorogood, occupied a boat fastened as usual to the davits of

* A note written to me the 22nd of October, by my friend Canon Kingsley, contains the following reference to this point:—"I have never seen the Lake of Geneva, but I thought of the brilliant, dazzling dark blue of the mid Atlantic under the sunlight, and its black blue under-cloud, both so solid that one might leap off the sponson on to it without fear; this was to me the most wonderful thing which I saw on my voyage to and from the West Indies."—J. T.

the *Urgent*, while I occupied a second boat nearer to the stern of the ship. He cast the plate as a mariner heaves the lead, and by the time it had reached me, it had sunk a considerable depth in the water. In all cases the hue of this plate was green, not, of course, a pure green, but a mixture of green and blue; and when the sea was of the darkest indigo, the green was the most vivid and pronounced. I could notice the gradual deepening of the colour as the plate sank, but at its greatest depth in indigo water the colour was still a blue green.

"Other observations confirmed this one. The *Urgent* is a screw steamer, and right over the blades of the screw there was an orifice called the screw-well, through which you could look from the poop down upon the screw. The surface glimmer which so pesters the eye was here in a great measure removed. Midway down a plank crossed the screw-well from side to side, and on this I used to place myself to observe the action of the screw underneath. The eye was rendered sensitive by the moderation of the light; and still further to remove all disturbing causes, Lieutenant Walton had the great kindness to have a sail and tarpaulin thrown over the mouth of the well. Underneath this I perched myself, and watched the screw. In an indigo sea the play of colours was indescribably beautiful, and the contrast between the water which had the screw-blades for a background, and that which had the bottom of the ocean as a background, was extraordinary. The one was of the most brilliant green, the other of the most lustrous ultramarine. The surface of the water above the screw-blade was always ruffled. Liquid lenses were thus formed, by which the coloured light was withdrawn from some places and concentrated upon others. The screw-blades in this case replaced the plate in the former case, and there were other instances of a similar kind. The hue from an indigo sea was always green at a certain depth below the surface. The white bellies of the porpoises showed the same hue, varying in intensity as the creatures swung to and fro between the surface and the deeper water. In a rough sea the light which had penetrated the summit of a wave sometimes reached the eye. A beautiful green cap was thus placed upon the wave when the ship was in indigo water.

"But how is this colour to be connected with the suspended particles? Take the dinner-plate which showed so brilliant a green when thrown into indigo water. Suppose it to diminish in size until it reached an almost microscopic magnitude. It would still behave substantially as the larger plate, sending to the eye its modicum of green light. If the plate, instead of being a large coherent mass, were ground to a powder sufficiently fine, and in this condition diffused through the clear sea water, it would send green to the eye. In fact, the suspended particles which the home examination revealed in green sea water act in all essential particulars like the plate, or like the screw-blades, or like the foam, or like the bellies of the porpoises. When too gross, or in too great quantity, the suspended particles thicken the sea itself visibly. But when sufficiently small, but not too small, and when sufficiently diffused, they do not sensibly interfere with the limpid greenness of the sea itself. They then require the stronger and more delicate test of the concentrated luminous beam to reveal their presence."

---

## THE TEMPERATURE OF THE SUN

PROF. NEWCOMB, in reviewing P. A. Secchi's work on the Sun, shows that if the temperature reached 10,000,000° Cent., as asserted by the author of "Le Soleil," the earth would speedily be reduced to vapour. In answer to this objection Père Secchi urges, "that a body may have a very high temperature and yet radiate but very little;" contending that "a thermometer dipped inside the solar envelope in contact with the photosphere," would indicate the temperature mentioned. He adds, "This high temperature, besides, is really a virtual temperature, as it is the amount of radiation received from all the transparent strata of the solar envelope, and this body at the outer shell must certainly be at a lower temperature." What information is intended to be conveyed by the statement that 10,000,000° Cent. "is really a virtual temperature," on the ground that it is the "amount of radiation received from all the transparent strata" outside of the photosphere, I will not attempt to explain; but I propose to show that a thermometer dipped inside the solar envelope in contact with the photosphere, cannot possibly indicate the enormous temperature of 10,000,000° Cent. assumed by Père Secchi. The assertion that "a body may have a very high temperature and yet radiate but very little," were it correct with reference to the photosphere, does not affect the question. It is of no consequence whether the sun's photosphere belongs to the class of active or sluggish incandescent radiators imagined by the distinguished savan; the temperature of the radiant surface, not its capacity to radiate more or less copiously, is the problem to be solved. Accordingly the following statement is intended to show that the temperature of the sun's photosphere at the point where the author of "Le Soleil" supposes his thermometer to be applied, cannot much exceed 4,000,000° Fahr. Observations conducted in lat. 40° 42′, with an actinometer (a drawing of which has been published in *Engineering*) have enabled me to ascertain, with desirable accuracy, the intensity of solar radiation for each degree of the sun's zenith distance from 17° to 75°. The atmospheric depth at the first mentioned zenith distance being only 0·046 greater than the vertical atmospheric depth, I have demonstrated, by prolonging the curve constructed agreeable to the observations referred to, that the intensity of solar radiation on the ecliptic is 67·20° Fahr. at the time when the earth passes the aphelion. The accompanying table, the result of two years of observations, shows the atmospheric depth and the intensity of solar radiation for each degree from the vertical to 75° zenith distance. The ratio of diminution of intensity of the radiant heat during the passage of the rays through the atmosphere being accurately defined by this table, it has been easy to calculate that the amount of retardation of the radiant heat on the ecliptic is 0·207 or 17·64° Fahr. Adding this loss of energy to the amount of observed radiant heat, it will be found that the intensity of solar radiation at the boundary of our atmosphere when the earth passes the aphelion corresponds with a thermometric interval of 17·64 + 67·20 = 84·84° on the Fahrenheit scale. Now, the aphelion distance of the earth is 218·1 times greater than the radius of the sun's photosphere; hence, basing our calculations on the established truth that the intensities are inversely as the areas over which the rays are dispersed, we prove that the temperature of the photosphere is $218{\cdot}1^2 \times 84{\cdot}84° = 4{,}035{,}584°$ Fahr. And if we then add the amount of loss of intensity attending the passage of the rays through the solar envelope, we establish, with absolute certainty, the temperature to which a thermometer will be subjected if "dipped inside the solar envelope in contact with the photosphere."

With reference to the retardation of the rays in passing through the solar envelope, we possess practical data of such a nature that the solution of the problem is by no means mere hypothesis. We know that the density of atmospheric air would be reduced to $\frac{1}{8000}$ of the ordinary density if subjected to a temperature of 4,000,000° Fahr.; hence, if we assume that the solar envelope consists chiefly of hydrogen, it may be shown, due allowance being made for the superior attraction of the sun's mass, that the density of the terrestrial atmosphere at equal depth from the boundary is fully 2,000 times greater than that of the solar envelope. Accordingly, as the sun's rays lose only 17·6° in passing vertically through our cold atmosphere, it may be demonstrated that the loss of energy during the passage of the rays through a transparent solar envelope 80,000 miles in depth from the photosphere, cannot exceed 0·01 or 40,000° Fahr. Let us be careful not to confound this diminution of energy with the reduction of temperature consequent on the dispersion of the rays as they recede from the photosphere during their course through the solar envelope. The reduction of temperature attending dispersion, obviously does not involve any diminution of mechanical energy. It would be waste of time to enter on any further demonstration in refutation of the extravagant assumption that a thermometer in contact with the photosphere would indicate some 12,000,000° Fahr. higher temperature than that which we have established on the basis of the known distance and radius of the sun's photosphere, and the ascertained radiant intensity at the boundary of the earth's atmosphere. Nor need we point out the inconsistency of the doctrine that the sun's photosphere possesses less radiant power than incandescent terrestrial substances, such, for instance, as iron and carburetted hydrogen. But the advocates of high solar temperature may urge, that the law, agreeable to which the temperature of 4,000,000° Fahr. has been determined, is mere *theory*, which, although true for distances of a few feet, may be wholly erroneous when the radiator is millions of miles away.

It has been one of the principal objects of my researches connected with solar heat, during the last three years, to endeavour to determine this question. Accordingly, the difference of intensity of solar radiation at midsummer and midwinter has been particularly observed. Fortunately, the eccentricity of the earth's orbit is sufficient to produce a marked difference of intensity at different seasons; but, on the other hand, the varying depths of the atmosphere resulting from the varying inclination of the earth's axis, apart from the varying distance between the sun and the earth, present serious obstacles. My observations as before mentioned have been conducted in lat. 40° 42′, hence 17° 12′ from the ecliptic at the summer solstice, and 64° 12′ at the winter solstice. Accordingly, the depth of atmosphere has varied during the investigations in the ratio of 1·04 to 2·25; thus rendering comparisons between the actual intensities very difficult. A series of observations made at different hours and seasons has ultimately enabled me to construct the curve before referred to, defining the maximum intensity of the sun's radiant heat for all latitudes at the time when the earth passes the aphelion; likewise defining the retardation of solar intensity for all zenith distances not exceeding 75°. Evidently an accurate knowledge of the solar intensity corresponding with given zenith distances removes the obstacles attending the varrying inclination of the axis of the earth. The variation of intensity consequent on the eccentricity of the earth's orbit has also been accurately determined for each day in the year. The detail not being immediately connected with the subject under consideration, it will suffice to state that actinometer observations conducted under very favourable circumstances, January 7, 1871, proved the sun's radiant heat to be 57·25° Fahr., the zenith distance being 63° 15′. Referring to the table, it will be seen that for equal zenith distance—63° 15′—the temperature produced by solar radiation is only 51·77° when the earth passes the aphelion. An *increase* of solar intensity of 57·25 − 51·77 = 5·48°, when the earth is in perihelion, has therefore been established. This important fact enables us to test on a grand scale the correctness of our assumption that the intensity of solar radiation diminishes in the inverse ratio of the area over which the rays are dispersed.

The aphelion distance of the earth being 218·1 times greater than the radius of the sun's photosphere, while the perihelion distance is 210·9 times that radius, the temperatures produced by solar radiation at the boundary of the earth's atmosphere at midsummer and at midwinter, will be inversely as $218·1^2 : 210·9^2$. Consequently, as the ascertained maximum temperature at the former period is 84·84° Fahr., the temperature produced by solar radiation at the latter period will be $\frac{218·1^2 \times 84·84°}{210·9^2} =$ 90·72° Fahr. Let us ascertain if this theoretical temperature correspond with actual fact. Our table shows that the diminution of solar intensity attending the passage of the rays through the atmosphere, when the zenith distance is 63° 15′, amounts to 15·43° in addition to the diminution of 17·64° on the ecliptic, together 33·07°. Adding this to the temperature 57·25°, observed January 7, 1871, we establish the fact that the temperature at the boundary of the atmosphere is 90·32° Fahr. Agreeable to the foregoing theoretical determination, the temperature ought to be 90·72°, difference = 0·4° Fahr. This discrepancy is accounted for by the fact that the sky, although unusually clear, was not quite free from cirrus haze on the day of observation, as proved by the indication of the solar calorimeter, an instrument by which the presence of any obstruction in the atmosphere is ascertained with absolute certainty. In addition to the proof thus furnished in support of the theory on which our calculations are based, that the temperature at the surface of the sun's photosphere does not much exceed 4,000,000° Fahr., other tests have been adopted with nearly identical results, an account of which, together with necessary delineations, has been published in *Engineering*. These tests prove that, unless the photosphere of the sun possesses relatively less radiating power than incandescent cast iron, or metallic substances coated with lampblack, and maintained at ordinary boiling heat, the temperature indicated by a thermometer "dipped inside the solar envelope in contact with the photosphere" will not exceed 4,100,000 deg. Fahrenheit.

*Table showing the depth of atmosphere, and intensity of solar radiation, for each degree of zenith distance, when the earth passes the aphelion.*

J. Ericsson

## GREYTOWN AND ADJACENT COUNTRY

GREYTOWN is important as the only port possessed by Nicaragua on its Atlantic coast, and is situated in 11° N. lat. and 84° W. long. The place itself is insignificant enough, as a glance at the accompanying view of the interior of the harbour will show; at the same time it is of strategical importance in many ways, and its history is not uninteresting. The climate is humid, and along the low coast-lands a tropical heat prevails. The heat is never oppressive while the trade winds blow, but during calms it is sultry and overpowering. The prevailing type of disease appears to be a low form of intermittent fever, which is not to be wondered at, considering that Greytown is built upon a swamp. June, July, and August are considered the unhealthy months, and January, February, and March the healthiest, the thermometer seldom exceeds 82° Fahr., or falls below 71° Fahr. in the shade.

SEASONS *

| RAINY | DRY |
|---|---|
| June | January |
| July | February |
| ⅔ August | March |
| ½ October | April |
| November | May |
| December | ⅓ August |
| | ½ October |
| The rain descends in a perfect deluge, accompanied by thunder and lightning. | Sometimes not a drop of rain falls, but generally it is showery, even in the so-called dry season at Greytown. |

In the interior, where the forest vegetation has been cleared away in the neighbourhood of the islands and lakes, the seasons are more marked, and the dry season is really dry, not a drop falling. At times Greytown is visited by terrible gales or hurricanes styled "Northers," at such times the trade wind is gradually killed, and a

GREYTOWN HARBOUR

calm precedes the coming storm, the barometer falls rapidly, and the clouds bank up in the horizon. After these warnings the norther commences without further prelude, and in an incredibly short time the sea is churned up into great and violent waves, whilst the surf on the bar is terrific. A norther will sometimes last for three whole days.

The whole civilised population of the Nicaraguan and neighbouring republics is collected on the Pacific side of Central America; the Caribbean coasts being almost entirely uninhabited, with the exception of a few independent tribes of Indians along the banks of the large rivers like the Indian and Rama. The principal tribes are the Valiente, Rama Cookwra, Woolwa Tonga, and Poya tribes, all interesting from an ethnological point of view, especially as they are fast disappearing. There is generally a small camp of some of these tribes on the sandy spit (Punta d'Arenas) at the entrance to Greytown harbour, who catch and sell turtle, &c. Accounts of these Mosquito tribes will be found in the Journal of the Royal Geographical Society, 1862, p. 242, &c., by Mr. Bell, and in the last volume of Memoirs of the Anthropological Society, by Mr. Collinson. This region, *i.e.* the valley and lowlands of the San Juan and the lakes of Nicaragua and Managua, is more particularly interesting to naturalists and geologists, as forming the border land between two of the great primary distributional provinces for the terrestrial vertebrata in the present world recognised by Prof. Huxley, viz., the boundary line betwixt *Austro-Columbia* and *Arctogæa*. For it was in this direction apparently, that, during the Miocene epoch, these two great land divisions were separated by that great equinoctial ocean whose currents rolled from eastward beyond and over the present sites of the Sahara deserts and the plains of Hindostan.

As the line of the American Cordilleras was upheaved, the continents more nearly approached each other, an archipelago of detached volcanic summits probably first indicating the future isthmus; whilst the bounds of the ocean were narrowed, and previous to the actual junction but a narrow channel or strait was left. It is supposed that the last indication of this strait is yet observable in the line of the San Juan and the waters drained by it. This theory has received substantial support from the ob-

* See Capt. Pim's "Gate of the Pacific," p. 71.

servations of Mr. Osbert Salvin, the well-known ornithologist, who, from long studying the peculiarities of the Central American bird-fauna, has come to the conclusion that an oceanic separation is plainly indicated as having formerly existed between Costa Rica and the country north of the Nicaraguan lakes. This upheaval has by no means ceased, and the lakes of Managua and Nicaragua, up to which the Spanish galleons proceeded, *viâ* the San Juan, are now 156 and 128 feet respectively above the mean level of the two oceans. So that now with difficulty stern-wheel light-draught steamers, drawing but eighteen inches of water, make their way between the rapids, their cargo having to be shifted across these impediments. A rise of six feet in the waters of the lakes enables bongos to pass the rapids in the wet season.

Every year apparently adds to the difficulties of the navigation, which Mr. Collinson attributes to the continual rise of the Pacific coast. Indeed, it is not improbable, if a careful series of observations were established, that after a lapse of years the rate of rise might be ascertained, which, if compared with seismological observations in the same district, would prove of the utmost value and interest.

It has been before noticed that Greytown is the only settlement of any size on the Caribbean coast, owing to its position at the mouth of the San Juan river, which is the only one which offers facilities for transit across the isthmus; and consequently a portion of the Californian traffic has for some years passed in this channel, an enterprising American company having monopolised the "transit-route." Owing, however, to the rapid silting-up of the embouchure of the San Juan at Greytown, this town would infallibly have lost all its importance, had it not been that the rapid development of marine telegraphy has given rise to a great demand for india-rubber, a valuable kind of which is collected from trees which are numerous in the dense forests of the Central American isthmus, especially on the Atlantic coast.

Greytown is the principal port for the export of india-rubber on the coast. It is collected by parties of Indians, Caribs, or half-caste Creoles, seldom by Europeans, to whom the dealers, who are also storekeepers, advance the necessary outfit of food, clothing, and apparatus for collecting rubber, on condition of receiving the whole of the rubber collected at a certain rate. The rubber hunters are termed *Uleros* (*Ule* being the Creole term for rubber). A party of Uleros, after a final debauch at Greytown, having expended all their remaining cash, generally make a start in a canoe for one of the rivers or streams which abound on the coast, and having fixed on a convenient spot for a camp, commence operations. The experienced rubber hunter marks out all the trees in the neighbourhood. The rubber tree is the *Castilloa elastica*, which grows to a great size, being on an average about four feet in diameter, and from twenty to thirty feet to the first spring of the branches. From all the trees in the almost impenetrable jungle hang numerous trailing parasites, lianes, &c., from these, and especially the tough vines, are made rude ladders, which are suspended close to the trunks of the trees selected, which are now slashed by machetes in diagonal cuts from right to left, so as to meet in the middle in central channels, which lead into iron gutters driven in below, and these again into the wooden pails. The pails are soon full of the white milk, and are emptied into larger tin pans. The milk is next pressed through a sieve, and subsequently coagulated by a judicious application of the juice of a Bejuca (an *Apocyna* ?) vine. The coagulated mass is then pressed by hand, and finally rolled out on a board with a wooden roller. The rubber has now assumed the form of a large pancake, nearly two feet in diameter and about a quarter of an inch thick, on account of which they are termed *tortillas* by the Uleros; these cakes are hung over the side poles and framework which supports the *rancho*, which is erected in the woods, and allowed to dry for about a fortnight, when they are ready to be packed for delivery to the dealer.

In the meantime others of the party go in pursuit of game, such as tapirs or *dantes*, or mountain cows, as they are termed, of which there are several species; or they harpoon the manatee,* which they dexterously follow in their canoes, as it cannot remain under water long. The point of the harpoon used by the Indians is moveable, and, attached to a line and floating reel, it becomes detached from the shaft when the siren is struck. The wild boar or javali (domestic pig run wild?) and the *waree*, or peccary, which are shot in June and July, and the deer, which are shot in December, afford good pork and venison. The waters of all the numerous rivers and lakes are characterised by an astounding number of distinct ichthyological faunæ. The Indians are good fishermen, and will shoot fish in the water by bow and arrow, or cut them down with a machete; the best fish are perhaps the *guapote*, *mojarra*, and *savallo*. By way of feathered game the curassows and guans (*Crax alector*, *C. fasciolata* and several Penelopes) of different species are of good size and flavour, whilst iguanas and land turtle eggs serve to vary the bill of fare of the Ulero gourmet.

The picnic life of the Ulero is not all *couleur de rose*. At night the jaguars and pumas (*Felis onca*, *F. melas* and *F. concolor*) will prowl in the neighbourhood of the *rancho*. These beasts are sometimes brought to bay with dogs by the Carib mahogany cutters in the fork of a low tree, and then speared; the spear in this instance is always provided with a stout cross bar, to prevent the transfixed animal from reaching his assailant.

Besides this the alligators abound in the water, which renders bathing slightly precarious; but as a general rule these brutes are cowardly enough when not hungry. On one occasion one of the party (with whom the author was in these woods) having shot a dante, which sank to the bottom of the River Rama, an Indian dived after it to attach a rope to the carcass: while the alligators, attracted by the smell of blood, surrounded the canoe in a circle of some score yards in diameter, but none of them ventured an attack on the bold diver. Both Caribs and Indians have a profound contempt for the alligator in these rivers. On shore, again, the snakes are numerous, such as the *tboba*, *vipora de sangre*, a long black snake, *Coryphodon constrictor*, the lovely coral, and barber pole snakes, and, worst of all, the small tamagusa or "tommy goff." The Caribs assert the valuable propereies of a vine—a species of Aristolochia—which they declare will allay the effects of a snake bite.

The greatest drawbacks, however, to the enjoyment of Ulero life in Mosquitia and Costa Rica are the swarms of garrapatas or ticks (*Ixodes*), which persecute remorselessly the hunter or woodsman. The *chigoe* or jigger is also another annoyance. By-the-bye, it is said, I do not know on what grounds, that this last-mentioned pest is only to be found where domestic swine are kept. I only know that I have suffered from one in the woods many miles from any domesticated swine. Do they appear therefore where there are wild hog or peccary? There is also a digusting bot fly and swarms of mosquitoes near the water.

The Formicidæ are likewise numerous and formidable; a gigantic black ant which especially pervaded the eboe (*Dipterix oleifera*) trees is justly dreaded, and we always avoided slinging our hammocks from these trees if pos-

* The genus Manatus appears to be the most ubiquitous of the sub order Sirenia, and various species are to be found not only on the rivers inland lakes, and coasts of Tropical America, but along the entire opposite coast of Africa, where the habitat of the *Manatus senegalensis* extends round the Cape, and as far north on the Mozambique coast as the river Zambesi; besides which its presence is recorded in the Lake Shirwa by Dr. Kirk. A species, *M. Vogelii*, also occurs in the upper Niger, and, according to Barth, in Lake Tsad, whilst Heuglin notices one species in the Tana Sea in Abysinia. So it is not improbable that the Manatus may occasionally meet its East Indian congener the *Halicore Dugong*.

sible. Stout Indians will howl and writhe with agony from the effect of their bites. A minute red fire ant also infests the acacia trees, and is barely more endurable. The howling of the black monkeys also is not conducive to sleep when they choose some neighbouring branches for their "serenade." The above slight sketch may serve to give some insight into the pleasures of a country life in the vicinity of Greytown, pleasures, however, of which the Nicaraguan citizens seldom avail themselves.

There have already appeared in NATURE some accounts of peculiar nocturnal vibrations observable in iron vessels off Greytown, which I will not allude to further.

The drawing which accompanies this notice was taken from the pier of the Transit Company's wharf; the town itself is barely visible from this point, and lies beyond the few buildings shown. The remains of one of the flat-bottomed streamers which ascend the river is shown lying by the shore. Canon Kingsley appears to have been disappointed at only twice catching a glimpse of the black fin of a shark during his recent visit to the West Indies; let me recommend the bar of Greytown Harbour and its vicinity as an exceptionally favourable locality for studying these monsters in their native element.

S. P. OLIVER

## *THE DATE OF THE INTERMENT IN THE AURIGNAC CAVE*

IT is a remarkable fact in the history of Archæology that the palæolithic age of the human interments in the cave of Aurignac has been universally accepted without any criticism of the evidence. It has passed into the condition of an article of scientific faith, partly through the eminence of M. Lartet, the describer of the cave, and partly through the high authority of Sir Charles Lyell, who followed his views in the "Antiquity of Man." The ready faith with which it has been received stands in marked contrast to the scepticism which refused to allow the value of the discovery of flint implements in the caves of England and Belgium for more than a quarter of a century, and up to within some three years of M. Lartet's investigations in Aurignac. The importance of examining the data on which M. Lartet's theory is based can hardly be over-estimated in the present state of the science of man. If the human interments really be of the same relative date as the extinct Mammalia found in the cave, and M. Lartet's interpretation of the circumstances be true, then, to quote Sir Charles Lyell, "we have at last succeeded in tracing back the sacred rites of burial, and, more interesting still, a belief in the future state," to the palæolithic age, and we have a powerful argument against the progressive development of religious ideas. This point did not escape Mr. Wallace in his speech at the Exeter meeting of the British Association. If, on the other hand, the interments be not proved to be palæolithic, the sooner an element of error is eliminated from a most difficult problem, the nearer shall we be to its solution. I shall first of all take the facts as they are now universally interpreted; and then I shall check them by the independent evidence of the late Rev. S. W. King, who finally explored the cave.

M. Lartet's account falls naturally into two parts: first that which the original discoverer of the case told him, and secondly that in which he describes the results of his own discoveries. I shall begin with the first. In the year 1852 a labourer named Bonnemaison, employed in mending the roads, put his hand into a rabbit-hole and drew out a human bone, and, having his curiosity excited, he dug down, until, as his story goes, he came to a great slab of rock. Having removed this, he discovered on the other side of it a cavity 7 or 8 feet in height, 10 in width, and 7 in depth, almost full of human bones, which Dr. Amiel, the Mayor of Aurignac, believed to represent at least 17 individuals of all ages. All these human remains were collected, and finally committed to the parish cemetery, where they rest at the present time undisturbed by the sacrilegious hands of archæologists, the discoverer and the sexton being alike ignorant of their last resting-place. Fortunately, however, Bonnemaison, in digging his way into the grotto, had met with the remains of extinct animals and works of art, and these were preserved until, in 1860, M. Lartet heard of the discovery, and resolved to examine the cave for himself. It must be remarked that before his advent the interior had been ransacked, and the original stratification to a great extent disturbed, a circumstance which obviously does away with any argument based on the association of remains in the cave.

M. Lartet's exploration resulted in the discovery that a stratum containing the bones of cave-bear, lion, rhinoceros, and hyæna, along with undisputable works of art of the palæolithic type—like those of the Dordogne—passed from a plateau on the outside into the cave. On the outside he met with ashes and burnt and split bones, which implied that it had been used by the palæolithic hunters as a feasting place; within he detected no traces of charcoal, and no traces of hyænas, which were abundant outside. Inside he met with a few human bones, which were in the same mineral state as those of the extinct Mammalia. That, however, identity of mineral state is any clue to age is disproved by the varying condition of bones of the same geological age in every bone cave with which I am acquainted. As an example I might quote the re-remains of cave-lion in the Taunton Museum. Such is the summary of the facts which M. Lartet discovered. He has, of his personal knowledge, only proved that Aurignac was occupied by a hunter tribe during the palæolithic age.

Is he further justified in assuming that it was used as a sepulchre at that remote period? Bonnemaison's recollections may be estimated at the proper value by the significant fact that, in the short space of eight years intervening between the discovery and the exploration, he had forgotten where the skeletons had been buried. And even if his account be true in the minutest detail, it does not afford a shred of evidence in favour of the cave having been a place of sepulture in palæolothic times, but merely that it had been so used at some time or other. If we turn to the diagram constructed by M. Lartet to illustrate his views (An. des Sc. Nat. Zool. iv. ser. t. xv., pl. 10), and made for the most part from Bonnemaison's recollection, or to the amended diagram given by Sir C. Lyell (Antiquity, fig. 25), we shall see that the skeletons are depicted above the strata containing the palæolithic implements and the quaternary mammals, and therefore, according to the laws of geological evidence, they must have been buried after the subjacent deposit was accumulated. The previous disturbance of the cave earth altogether does away with the value of the conclusion that the few human bones found by M. Lartet are of the same age as the extinct mammalia in the same deposit. The absence of charcoal inside was quite as likely to be due to the obvious fact that a fire kindled inside would fill the grotto with smoke, while outside the palæolithic savages could feast in comparative comfort, as to the view that the ashes are those of funereal feasts in honour of the dead within, held after the slab had been placed at the entrance. The absence of the remains of hyænas from the interior is also negative evidence disproved by subsequent examination.

The researches of the Rev. S. W. King in 1865, hitherto unpublished, complete the case against the current view of the palæolithic character of the interments, insomuch as they show that M. Lartet did not complete the examination which he began; and that he consequently wrote without being in posesssion of all the facts. The entrance was blocked up, according to Bonnemaison, by a slab of stone which, if the measurements of the entrance be correct, must have been at least 9 feet long and 7 feet high, placed, according to M. Lartet, to keep the hyænas from the corpses of the dead. It need hardly be remarked that the access of these bone-eating animals to the cave would be altogether incompatible with the preservation of the human skeletons, had they been buried at the time. The enormous slab was never seen by M. Lartet, and it is very hard to understand how it could have been removed by one workman cutting a trench after a few hours' work. And it certainly did not keep out the hyænas. In the collection made by the Rev. S. W. King from the interior, there are two hyæna's teeth, and nearly all the antlers and bones bear the traces of the gnawing of those animals. The cave, moreover, has *two* entrances instead of one, as M. Lartet supposed, when his paper in the Annales was published. There are also in the collection above quoted —now presented by Mrs. King to the Christy Museum— two metacarpals of sheep or goat—animals which, as yet, have not been proved to have been living in Europe during the quaternary period, and which, probably, were introduced by neolithic races of men, as well as a fragment of pottery of precisely the same kind as that in the superficial deposit in Kent's Hole.

In a word, the evidence in favour of the interment in Aurignac being of a later date than the occupation seems to me to be overwhelming, and it does not afford the slightest ground for any hypothesis as to the belief of palæolithic men in the supernatural. On that point, up to the present time, modern discovery is silent, and negative testimony is valueless. W. BOYD DAWKINS

## *DAYLIGHT AURORAS*

WE have published several letters lately on this subject, in some of which doubts are suggested as to the reality of the phenomenon. The following extracts from a paper which we have received from Mr. Glaisher, will put the matter to rest :—

*The Aurora of Feburary 12, appearing in Daylight.*

"The accounts of auroræ appearing by daylight are very few indeed, yet the following reports made by two of the observers in the magnetic department of the Royal Observatory, Greenwich, who called my attention to the appearance of the sky and to the fixity of the arch, as well as to the apparent avoidance by the clouds of the clear space, together with the disturbed state of the magnetic elements at the time, seem to decide that the appearances were really due to an aurora appearing by daylight.

"Mr. Wright says that at about noon the clouds in the north began to break, and soon after an almost perfect arch of clear sky, with its apex in the magnetic meridian, was visible. This space of clear sky kept its shape more or less perfect for more than an hour—a remarkable fact, as the clouds in the remaining portion of the sky were being driven rapidly across by a strong N.E. wind. The clouds immediately above the top of the arch seemed to be charged with electricity, the edges assuming the ragged appearance common to thunder-clouds. At times these clouds were slightly tinged with a reddish colour. About $0^h 45^m$ P.M., a very remarkable cloud of a reddish-brown colour passed slowly across the clear space from E. to W., being apparently much nearer to the observer than the ordinary clouds. Apart from the ordinary motion of the clouds from N.E. to S.W., caused by the wind, there seemed to be an apparent vibratory motion from E. to W.

"Mr. Marriott says :—'About noon the clouds in the north began to break, and shortly after, there was a perfectly clear space of blue sky in the form of an arch, the apex of the arch being in the magnetic meridian. At the circumference of the arch were very fine cumulus clouds, the edges of which were tinged with a reddish colour; and along the whole of the north horizon there stretched a bank of cumulus clouds to the altitude of 10° or 15°. At about $0^h 20^m$, just below the apex of the arch, I observed something like steam shooting up and moving from east to west ; this, I imagine, is what streamers would be like in the daytime. At $0^h 45^m$ a small cloud of a brick-red colour traversed the clear space ; a few other clouds which passed over at the same time were not tinged. The arch was very well defined for about an hour or an hour and a half; and although the wind was blowing a gale from the north-east, and the clouds passing rapidly over the other portions of the sky, this space was not encroached upon by clouds. The altitude of the arch was about 50°, and the point at which the supposed streamers first appeared was about 7° below the apex. I also observed auroral light at night.

"On the 11th day and till $6^h 35^m$ P.M. the movements of the several magnets were those of the ordinary diurnal changes, and at this time the western declination was 19° 55′. At $6^h 40^m$ a sudden disturbance began ; the declination decreased 19′ by $7^h 19^m$, then increased to 19° 56′ by $8^h$; at $8^h 12^m$ it was 19° 47′, increased to 20° 4′ by $8^h 29^m$, was 19° 45′ at $9^h 11^m$, was 20° 6′ by $9^h 58^m$ P.M., then there were several small movements of 3′ or 4′ both to the east and to the west ; at $11^h 30^m$ the declination was 19° 58′, and by midnight had increased to 20° 12′.

"The magnet still continued to move through small arcs, but gradually decreasing to $4^h 10^m$ A.M. on the 12th. to 19° 47′ ; then there were frequent changes of position, but such that the declination generally increased, and was 20° 3′ at $8^h 45^m$ A.M. ; by $10^h 40^m$ it decreased to 19° 55′.

"There were frequent movements of the magnets between this time and till after noon. On the 12th day, at $0^h 30^m$ P.M., the declination was 20° 12′, at $0^h 45^m$ it was 20° 3′ ; this movement of the magnet towards the east is remarkable as having taken place immediately before the passage of the reddish-coloured cloud from east to west across the clear space of sky, and attained its maximum at about the time of the passage of the cloud. The movement of this cloud was not that of all other clouds, viz. from N.E. to S.W., and it would seem to be of auroral origin. . . . .

"Authentic instances of auroral displays by daylight are very few.

"The first instance I can find is recorded at p. 189, vol. ii. of the 'Transactions of the Royal Irish Academy,' from which the following extract is made :—

"'An account of an Aurora Borealis seen in full Sunshine. By the Rev. Henry Ussher, D.D., F.R.S., and M.R.I.A.

"'On Saturday night, May 24, 1788, there was a very bright aurora borealis, the coruscating rays of which united, as usual, in the pole of the dipping-needle. The next morning, about 11, finding the stars flutter much, I examined the state of the sky, and saw whitish rays ascending from every part of the horizon, all tending to the pole of the dipping-needle, where at their union they formed a small thin and white canopy, similar to the luminous one exhibited by an aurora in the night. These rays coruscated or shivered from the horizon to their point of union.'

"The only other account is extracted from the 5th vol. of the 'Transactions of the Royal Society of Edinburgh,' and is as follows :—

"'An account of an Aurora Borealis observed in daylight at Aberfoyle, in Perthshire, on the 10th of February, 1799. By Patrick Graham, D.D., minister of Aberfoyle.

"'On the 10th of February, 1799, about half an hour past 3 o'clock P.M., the sun being then a full hour above the horizon, and shining with an obscure lustre through a leaden-coloured atmosphere, I observed,' says Dr. Graham, 'the rare phenomenon of an aurora borealis by daylight. The weather for several days before had been intensely cold, and during the two preceding days much snow had fallen. On this day a thaw had come on, and the temperature of the air was mild. The general aspect of the sky was serene. Some dark clouds hung on the horizon between S.W. and W. I was intensely observing a large halo about the sun, of about 20° in semi-diameter. It exhibited the prismatic colours, though obscurely, except in one quarter, where it coincided with the skirt of a dark cloud on the horizon, almost directly west. In that portion of the halo the colours of the iris were very distinctly exhibited.

"'Whilst I was attending to this appearance, the whole visible hemisphere of the heavens became covered with a light palish vapour, as I at first imagined it to be. It was disposed in longitudinal streaks, extending from the west, by the zenith, and all along the sky towards the east. On examining this appearance more narrowly, I found it to be a true aurora borealis, with all the characters which distinguish that meteor when seen by night, excepting that it was now entirely pale and colourless. The stream of electric matter issued very peceptibly from the cloud in the west, on the skirts of which the halo exhibited the prismatic colours; thence diffusing themselves, the rays converged towards the zenith, and diverged again towards every quarter of the horizon; and the coruscations were equally instantaneous, and as distinctly perceptible as they are by night.

"'This appearance continued for more than twenty minutes, when it gradually vanished, giving place to thin scattered vapours, which, towards sunset, began to overspread the sky. Through the ensuing night, I could not discern the smallest trace of these meteors in the sky.'"

## *NOTES*

OUR readers will learn from another column that an appeal is about to be made to Government to aid another Eclipse Expedition, this time a very small one. Seeing that another so favourable opportunity will not occur for some time, it is to be hoped that the Government will respond to the call, and deserve as hearty thanks from all lovers of scientific progress as it earned for its efforts last year.

THE American Association for the Advancement of Science will be opened at Indianopolis, Indiana, on August 17. The president for this meeting is Prof. Asa Gray.

IT is with great regret that we have to record the death of Mr. Alexander Keith Johnston, LL.D., to whose eminent services in the promotion of meteorological and physico-geographical science we had occasion to refer but a few weeks since on the occasion of the medal awarded him by the Royal Geographical Society. Dr. Johnston was president-elect of the geographical section of the British Association at its approaching meeting at Edinburgh. He died on Sunday last, at Ben Rhydding, in Yorkshire.

THE Natural History Society of Montreal, with the aid of the Government of Canada, is sending an expedition to dredge in the deeper parts of the Gulf of St. Lawrence. The Hon. Mr. Mitchell, Minister of Marine and Fisheries, has taken much interest in the matter, and has placed the government schooner *La Canadienne* at the disposal of the party. The gentlemen selected are Mr. Whiteaves, F.G.S., secretary of the Society, and Mr. G. F. Kennedy, B.A. Principal Dawson, the president of the Society, sends the latter gentleman on behalf of the museum of M'Gill University. It is hoped that the deepest parts of the gulf will be searched, and that much interesting information will be obtained, bearing both on zoological and geological questions, and also on the prosecution of the fisheries.

MR. W. S. ALDIS, of Trinity College, Cambridge, Senior Wrangler in 1861, has been appointed Professor of Mathematics at the College of Physical Science at Newcastle-on-Tyne.

WE are enabled to state that the scheme proposed for the institution of the Sharpey Scholarship at University College, London, has been adopted by the Council. Its principal features are that the scholarship may be held for three or a greater number of years, and that the holder of it shall act as an assistant to the Professor of Practical Physiology, having opportunities afforded to him of pursuing original investigations, and having the right to use the laboratory and its apparatus for that purpose.

THE Brown Institution which has just been founded by the University of London, will comprise, in addition to a hospital for the treatment of animals, a laboratory for the study of pathology on the model of the Pathological Institutes of Germany, which have been already described in these columns. In this laboratory those who desire to learn the methods of exact research, or, after having learnt them, to carry out pathological or therapeutical investigations of their own, will have the opportunity of doing so under the guidance of the new Brown Professor, Dr. Burdon Sanderson. As we before announced, Dr. E. Klein, of Vienna, is expected to have the direction of the microscopical work of the laboratory, for which his numerous researches show him to be so pre-eminently fitted.

WE have to record the death of Mr. George Tate, of Alnwick, Hon. Secretary of the Berwickshire Naturalists' Club, which took place on June 7, at the age of 66. His treatises on the archæology of his native borough and county entitle him to take rank among the best of local historians; and his articles on Archæology and Geology, published in the "Transactions of the Berwickshire Naturalists' Club," show powers of observation and clear habits of thought of no ordinary kind.

A REPORT on the progress and condition of the Royal Gardens at Kew during the year 1870 has just been issued by the director, Dr. J. D. Hooker. The number of visitors was not quite so large in 1870 as in 1869. The improvements in the laying out of the grounds of the Botanic Gardens, which have been in progress for the last five years, are now nearly brought to a close. The pleasure grounds have suffered severely from the long and severe drought of last summer, acting on the excessively poor natural soil; very large numbers of trees have perished, especially the older elms, ashes, beeches, and sycamores. These are being replaced, and preparations have been made for the formation of the new Pinetum, which will be immediately commenced. Notwithstanding the rage for planting Conifers which has prevailed in England for many years, and which has almost supplanted the growth of hardy deciduous trees, no complete public, arranged, and named collection of hardy conifers exists in this country. The interchange of living plants and seeds with foreign and colonial botanic gardens has been vigorously prosecuted, especial attention having been paid to the promotion of the growth of the cinchona, and the introduction of the ipecacuanha into our Indian possessions. The museums, herbarium, and library have been enriched by numerous purchases and donations.

AT a recent meeting of the Scientific Committee of the Horticultural Society, Mr. Andrew Murray read a paper on the blight of plants, in which he combated the ordinary theory that the lower forms of vegetable organisms, which constitute ordinary blight, are developed from germs existing in the plant or floating in the air. The extraordinary rapidity of their propagation, frequently after a few hours' east wind, when no trace of them has been visible for many months, the prodigious numbers in which they appear, and the great variety of species developed sometimes on the same plant, and other considerations, have led him to the conclusion that these lowly organised fungi are evolved out of previously-existing organic materials, without the intervention of a germ, by the process erroneously called spontaneous generation.

A VERY interesting collection of paintings is now on view at the Langham Hotel, Portland Place, being delineations of Arctic scenery, by Mr. William Bradford, of New York. In company with Dr. J. D. Hayes, Mr. Bradford spent four months of the summer of 1869 in an expedition to the coasts of Labrador, Greenland, Melville Bay, &c., for the express purpose of studying the pictorial effects of Arctic scenery. A very large number of photographs were taken, as well as many sketches, from which the finished paintings were afterwards completed. The collection is, therefore, unique of its kind. Among the most striking of the paintings is one representing sunset among the icebergs.

THE Geologists' Association organised excursions of its members to Ilford on the 17th of June, and to Riddlesdown on the 1st of July. In the former the chief objects of attraction were the famous mammaliferous brick-pits of Ilford, to which Mr. Henry Woodward acted as cicerone. Mr. Woodward and Mr. Searles V. Wood consider the Ilford beds to be older than those at Grays. The distribution of the fossils is remarkably different; *Elephas primigenius*, for instance, being the common species at Ilford, and *E. antiquus* at Grays. The party were afterwards kindly invited by Sir Antonio Brady to inspect his magnificent collection of mammalian remains. The excursion to Riddlesdown gave a good opportunity for examining the sections of the Upper Chalk, and the sequence of the formations of the Cretaceous system. This was the last excursion of the season.

THE "Working Men's Club and Institute Union" has just issued a paper recommending the establishment of classes at each institution for the study of one or more of such branches of Natural History as Botany, Geology, and Entomology, according to the circumstances of the several localities. It is proposed that these classes shall on Saturday afternoons sally forth into the fields and woods for the collection of specimens illustrating the particular subjects of their studies. With the view of encouraging such pursuits, a member of the Council of the Union offers two prizes of three and two guineas respectively to the best collection made during the present season by members of workmen's clubs. It is hoped that this suggestion may lead to the formation of museums of natural history at the clubs—the contents being collected and arranged by the members. The adoption of such pursuits in leisure hours will not only be productive of much mutual enjoyment to the working people of this country, but afford a powerful argument for the more general adoption of the Saturday half-holiday by employers.

THE Leicester Literary and Philosophical Society has recently revived its old custom of instituting geological excursions to some of the many objects of interest in the county. One of these took place last month under the guidance of the veteran geologist, Mr. J. Plant, and was an eminently successful one.

THE Liverpool Naturalists' Field Club has issued its Report of Proceedings for the Session 1870-71. The address of the president, the Rev. H. H. Higgins, refers chiefly to the interesting palæontological discoveries made during the last two years in the neighbourhood of Liverpool, and is illustrated by a plate of fossils from the Ravenhead Collection in the Free Public Museum. An epitome is given of the results of each of the summer excursions and of the papers read at the evening meetings, including one on the microscopic structure of the plants of the Coal Measures, by Prof. Williamson. A unique feature of this Society is that at each Field Meeting five prizes are competed for, for the best flowers gathered or collected during the excursion. We are glad to see the Report published at so low a price as one shilling, or to members, sixpence, and commend this laudable practice to the notice of other similar societies.

THE following schools have been invited by the Royal Geographical Society to take part in the competition for prize medals for the ensuing year:—English Schools: St. Peter's College, Radley, Abingdon; King Edward's School, Birmingham; Brighton College; Cathedral Grammar School, Chester; Cheltenham College; Clifton College; Dulwich College; Eton College; Haileybury College; Harrow; Hurstpierpoint; Liverpool College; Liverpool Institute. London: Charter House; Christ's Hospital; City of London School; King's College School; St. Paul's; University College School; Westminster School; Royal Naval School, New Cross. Manchester School; Marlborough College; University School, Nottingham; Repton; Rossall; Rugby; King's School, Sherborne; Shoreham; Shrewsbury; Stonyhurst College, Blackburn; Uppingham School; Wellington College; Winchester School. Scotch Schools: Aberdeen Grammar School; Edinburgh Academy; Edinburgh High School; Glasgow High School. Irish Schools: Royal Academical Institute, Belfast; Dungannon Royal School; Ennis College; Portora Royal School, Enniskillen; Foyle College, Londonderry; Rathfarnham, St. Columba's College.

THE part of the "Proceedings of the Geologists' Association" just published contains an interesting article by Mr. H. Woodward "On Volcanoes," and reports of the excursions made during 1870.

THE last number of Petermann's "Mittheilungen" contains an admirable physical map of the region covered by Hayward's journey from Leh to Kaschgar in 1868-69.

UNDER the title "The Geographical Distribution of Sea-grasses," Dr. P. Ascherson gives an account in Petermann's "Mittheilungen," of the distribution of the phænogamous plants native to sea-water. Of these he enumerates twenty-two, belonging to eight genera, and two natural orders. The area of each species is generally very limited, its distribution being dependent on the present condition of the sea in which it is found. Those which grow in temperate regions are frequently represented by closely allied species in tropical seas. Although the Isthmus of Suez is of comparatively modern geological date, the nine species of the Red Sea are entirely distinct from the four species of the Mediterranean, and, with one exception, belong to different genera. A map accompanies the paper.

WE have on our table the *Astronomical Register* for June, and have much pleasure in calling the attention of astronomers to this magazine, which is rapidly improving in usefulness.

THE December number of the *Canadian Entomologist* concludes the second volume. It is intended to be increased on the commencement of the third volume, without any corresponding increase of subscription, to twenty pages each number, and will remain under the editorship of the Rev. C. J. S. Bethune.

THE volume of lectures delivered at the Industrial and Technological Museum, Melbourne, during the spring session of 1870, shows great activity in scientific matters in Victoria. Among the subjects discussed are the Circulation of the Blood, the Conservation of Energy, the Application of Phytology to the Industrial Purposes of Life, Chemistry applied to Manufactures and Agriculture, the Preservation of Food, the common Uses of Astronomy, and On Methods of Diffusing Technological Knowledge.

WE have before us the number for May of the "Journal of the Franklin Institute," containing several valuable articles. We may notice in particular the continuation of a series on "Iron Manufactures in Great Britain," by Mr. R. H. Thurston, and "A Method of Fixing, Photographing, and Exhibiting the Magnetic Spectra," by Dr. A. M. Mayer.

WE have received the first volume of an important continental flora, "Flora der preussischen Rheinlande," by Dr. P. H. Wirtgen, including as far as the end of Thalamifloræ. Descriptions of each species are given, with physiological and morphological annotations, and a copious list of localities of the less abundant species. Independently of its scientific value, the book will be very useful to the numerous summer visitors to that district.

A NEW port has been opened in Southern Chile in the Department of Constitucion. It is called Curanipe, and it appears that already the population is 1,186, and the tonnage in and out 7,867 in 1870.

ON May 11 two distinct shocks of earthquake were felt at Peshawur, in India.

ON May 22 an earthquake was felt at Landour, Meerut, Agra, and Nynee Tal. At the latter place it was severe.

AN earthquake was felt at Hayti on May 30.

ON June 16 a severe storm assailed Constantinople. During its height three waterspouts swept across different parts of the Bosphorus in great volume and with unusual fury. By one of them a caique was destroyed. The lightning struck the lightning-conductor on the great Gulata Tower in Pera, and also the wire at the Observatory connecting it with the arsenal at Tophaneh. On the other side of the Bosphorus, at Scutari, a house was struck.

A REPORT has been published in the Hong Kong press of March 25 by Captain Frost, of the Noord Brabant. He says he sighted Tinakoro, or Volcano Island, one of the Santa Cruz group, in lat. 10, 23 S., 155 long. E., and lay becalmed there five days. The island is a cone of perfect symmetry, resting on a base of three miles in circumference, and, except about the base, destitute of vegetation. The volcano, estimated to be about 2,500 feet high, was in constant activity, presenting the appearance of a great flame vent. Captain Frost denies the description of Captain Wilson, of the *Duff*, that there are several low islands there, at least on its south and west quarters, about seventeen miles off.

A REPORT has been sent in by the Governor of the Province of Leon in Ecuador as to the condition of the volcanic region of Cotopaxi in his province. He states that the principal mountains which stand forth in the great circle formed by the two branches of the Andes are Cotopaxi, Quillindana, Puchalagua, and the Calpon. Of these Cotopaxi alone is known as a volcano, which after many years of inaction became active in June 1851. These eruptions continued and became gradually weaker until 1867, when they ceased. In 1868 subterranean noises were again heard, and a slender column of smoke appeared. In May 1868 there were some earthquakes, which ruined Palate and Pelileo. In July 1869 noises were again heard and an awful flood took place, but without earthquakes and subterranean noises. Abundant fountains of water burst forth, hundreds of immense rocks were rent and thrown down, and the rivers were flooded. The Governor, who was at the time in the Cordillera, considers that the landslides were not owing to the action of water, but rather to a pressure upward from below, as if from accumulated gases seeking an exit. The most curious effect reported by him is a variation in the climate. Many plants, such as the sura, flowered, which had not done so before. After this premature ripening the surales all closed up again, and have not revived. After this event it was noticed the sugar cane could be cut in twenty-four months instead of thirty. At present Cotopaxi is inactive, but its condition is looked upon with dread.

FROM the *Australasian* of April 22, we learn that Mr. Russell, the Government astronomer at Sydney, has visited Deniliquin and picked up there something which astonished him, in the shape of the greater portion of a meteoric stone which fell some years ago at Barratta, thirty-five miles below Deniliquin. The stone (Mr. Russell secured about one half of it, weighing about 150lb.) was originally about 300lb. in weight, but has been broken, and parts of it given away as curiosities. Mr Russell made provision for despatching the stone to the Sydney Museum.

## SCIENTIFIC INTELLIGENCE FROM AMERICA *

AT a recent meeting of the New York Lyceum of Natural History, Professor D. S. Martin described the remarkable deposit of magnetic iron at Cornwall, Pennsylvania, and exhibited the group of minerals found in connection with the iron. The ore is a soft, often pulverulent magnetite, associated with copper, and often pyrites. It is found in three hills which owe their relief to the erosion of their surroundings, and are composed mainly of iron ore embraced between walls of trap, the whole mass lying at the junction of the Triassic red sandstone and older metamorphic series. The yield of the Cornwall mines is 160,000 tons per annum. Prof. Martin exhibited beautiful specimens of allophane, brochantite, and other minerals collected at Cornwall. —Prof. Newberry, at the same meeting, exhibited a series of lignites from the Far West, with ultimate analyses of each. He said these modern coals were the only mineral fuels found west of Omaha. The Los Brances (Sonora) coal is Triassic anthracite. Most of the New Mexico and Arizona coals are Cretaceous, the beds sometimes thirty feet in thickness. The Placer Mountain coal is a Cretaceous anthracite. The coal of Colorado is both Cretaceous and Tertiary; the coal of Mount Diabolo, California, is Cretaceous; and that of Vancouver Island, Coose Bay coal, is Tertiary. Alaska furnishes some of the best Western coal—a Tertiary lignite. A Cretaceous anthracite found in Queen Charlotte's Island is nearly as good as that of Pennsylvania. All these anthracites are caused by volcanic action baking lignites. The calorific power of the Western coals is generally greatly impaired by the large percentage (ten to twenty per cent. each) of oxygen and water they contain. The average Western lignite has about half the heating power of our best coals. The gas and coke made of some of them, however, are excellent furnace fuels, though they are generally worthless.—Prof. Davidson, of the United States Coast Survey, has lately devised an apparatus for recording the temperature at different depths by means of an electro thermal pile. He proposes to register the depth by breaking the circuit of an electric current passing through two insulated wires in the sounding line at about every one hundred fathoms by means of the wheel-work of the Massey or similar apparatus. In the changes of temperature an electro-thermal pile eighteen inches long, insulated, surrounded by a non-conductor except at one end, is used in combination with a Thompson's reflecting galvanometer, not liable to derangement on shipboard. At every one hundred fathoms, when the chronograph registers the depth, the observer notices the readings of the galvanometer, which readings are reduced to Fahrenheit degrees. —One of the most original and important contributions to the zoology of the day is that constituting the third number of the Bulletin of the Museum of Comparative Zoology at Cambridge, treating upon the mammals and winter birds of East Florida. The author, Mr. J. A. Allen, an assistant of Prof. Agassiz, is well known for the thoroughness of his research into the vertebrata of America, and the critical attention paid by him to the proper limitation of species, both in their relationships to each other, and in their geographical distribution. In the present work he gives a summary of the views to which he has been led within a few years past by his studies of the immense collection in the Cambridge Museum, and makes numerous important generalisations. Among these he corroborates the conclusion previously announced by others, of the diminution in size of the American birds in proportion as their birthplace is more southern, and also that there is a similar difference existing between the animals of the higher and lower altitudes. He also finds that with the more southern locality of summer abode there are corresponding differences in colour and proportion, as well as in habits, notes, and song, the vivacity of the bird decreasing as its size increases. The principal difference in colour with the more southern localities consists in the darker tints and the reduced extent of any white markings, with other features that our space will not permit us to give at the present time. The entire work is one eminently worthy of careful study, and is destined to exercise a very important influence upon the methods of zoological research. — Late advices from Prof. Hayden's expedition announced that he was to leave Ogden, Utah, on June 9 for Virginia City and Fort Ellis, in Montana, a distance of about 430 miles, with the special object of proceeding from the last-mentioned place to the exploration of the Yellow Stone Lake and its immediate vicinity. It

* Contributed by the Scientific Editor of *Harper's Weekly*.

is an interesting fact that the head waters of tributaries of the Columbia, the Colorado, the Missouri, and the Yellow Stone rivers rise within a short distance of each other in this mysterious region; which, in addition, is characterised by the extraordinary development of hot springs, spouting geysers, mud volcanoes, extensive beds of sulphur, gypsum, the silicates, &c. The party, as at present organised, embraces thirty-two persons, including specialists in all branches of science, and accompanied by several artists, who take advantage of Dr. Hayden's protection to visit the interesting region referred to. The party carries materials for a boat, which is to be launched on the Yellow Stone Lake, and used in a thorough hydrographical and topographical survey of it. As the expedition will probably remain in that vicinity during the summer, we may hope for a complete solution of all the remaining questions in regard to its physical features and natural history. A competent photographer with the expedition expects to make instantaneous views of the spouting geysers, so as to enable those who cannot visit the locality to have a correct idea of their character. A company of cavalry will escort the expedition into the Yellow Stone Lake region, although no trouble from the Indians is anticipated. In the course of the journey from Ogden to Fort Ellis it is proposed to make an accurate map of a belt fifty miles wide, so as to furnish a basis for reference in subsequent explorations.—In the monthly report of the Department of Agriculture for March and April of the present year, we find a valuable paper upon the cultivation of the Cinchona in Jamaica, by Dr. C. C. Parry, the botanist of the Department, who accompanied the San Domingo Investigating Committee, and in returning spent some time in Jamaica. As the general result of his inquiries in regard to the cultivation of this plant, and the possibility of introducing it into any portion of the United States, he states, first, that the peculiar conditions of soil and climate suitable for the growth of the best varieties of cinchona plants cannot be found within the present limits of the United States, where no suitable elevations possessing an equable, moist, cool climate, free from frost, can be met with; second, that the island of San Domingo, located within the tropics, and traversed by extensive mountain ranges attaining elevations of over 6000 feet above the sea, presents a larger scope of country especially adapted to the growth of cinchonas than any other insular region in the western hemisphere; third, that the existence of successful cinchona plantations in Jamaica within two days' sail from San Domingo, would afford the material for stocking new plantations in the latter island at the least possible expense of time and labour.—In a recent communication to the Academy of Natural Sciences of Philadelphia, by Prof. Leidy, attention was invited to certain teeth of fossil mammals, forwarded to him for examination by Prof. Whitney. One of these was a fragment belonging to the *Mastodon americanus*, obtained from a depth of eighty feet beneath the basaltic lava of Table Mountain, Tuolumne County, California, where it was found associated with the remains of human art. There was also a molar of a large fossil horse, found sixteen feet below the surface on Gordon Gulch. Two other teeth, somewhat similar in character, were determined as belonging to the species of *Protohippus*. In other specimens Dr. Leidy found evidences of the existence of a gigantic animal of the camel tribe, allied to the llama.

## *CORRESPONDENCE OF NORTHERN AND SOUTHERN AURORÆ*

I TAKE the liberty of sending you a paper containing corresponding observations of Aurora Borealis and Australis, with the request to insert them in your valuable journal.

*Corresponding Observations of Aurora Polaris, made in the Northern and Southern Hemispheres.*

In the years 1859-65 I kept up a correspondence with the active director of the Flagstaff Observatory at Melbourne, (Australia), Mr. George Neumayer, in order to make observations concerning the contemporaneous appearance of aurora polaris in the northern and southern hemispheres.*

* See Results of the magnetical, nautical, and meteorological observations made at the Flagstaff Observatory, Melbourne, and at various stations in the colony of Victoria, Melbourne, 1860. His, "Wochenschrift für Astronomie und Meteorologie," 1859, 1860, 1861, 1863, 1865.

Some years since, when Dr. Neumayer returned to his native country, this correspondence was interrupted. But the numerous appearances of aurora borealis which occurred last year, induced me to recommence this correspondence with the present director of the same establishment, Mr. C. Moerlin. Sending him a list of all the appearances of aurora borealis and magnetical disturbances in the year 1870 known to me, I begged him to favour me with the corresponding observations viewed by him. I subjoin the answer of Mr. Moerlin.

I received your letter of December 2, 1870, and in reply shall be most happy to comply with your request, of informing you periodically of the occurrence of the aurora australis, and of magnetic disturbances observed here.

To this end I have made out a list, which is enclosed, of auroræ observed since January 1, 1870, containing the dates and times (Melbourne mean time) of their occurrence, from which it appears that at most of the dates you mention in your letter, as having observed the aurora borealis, the aurora australis has been observed here. The greatest magnetic disturbances occurred on April 5 and October 25; on the latter day the disturbances continued during two days; the minimum of easterly declination occurred about 5 A.M. on the 26th, and the maximum about 6 A.M. on the same day, the range being 51′ of arc, with corresponding disturbances in the other two elements. Unfortunately the sky was completely overcast during the night, with a slight break only at midnight, when the display was very beautiful, but visible only for a few minutes; but during the evening of the 25th an intense, but ever varying, luminosity only of the whole southern sky was the sole indication of aurora.

I would remark that at all the dates on which auroræ were observed, magnetic disturbances invariably took place of a greater or less extent; but disturbances occurred also at other times, of the very same nature as took place generally during aurora displays, on which, however, no auroræ were observed. These dates I give you enclosed also, separately, as these may be of interest to you in connection with the possible occurrences of the aurora borealis on one or the other of those dates.

I shall continue from this date to send you periodical notice of the occurrence of the aurora australis and magnetic disturbances at Melbourne, and shall be happy to furnish any information respecting physical phenomena, which you may desire, and I may be able to give. C. MOERLIN

Melbourne Observatory, Feb. 7

Date and time of occurrence of the Aurora Australis observed at Melbourne during the period from January 1, 1870, to February 21, 1871, during which, at the same time, great disturbances in the magnetic elements generally took place.

LAT. 37° 49′ 53·5″ S. LONG. $9^h\ 39^m\ 54{\cdot}8^s$ E.

1870, January 8.—During the evening the aurora was seen at Adelaide, South Australia, as reported by Mr. Food, Superintendent of Electric Telegraph.

February 1.—A fine display between 8 and 10 P.M.; shortly after nine some magnificent streamers.

April 5.—Became visible shortly after $7^h$ P.M., and lasted all through the evening and night. The display at times was most brilliant, particularly at $10^h\ 30^m$ P.M., and again at $12^h\ 30^m$. Slight disturbances in the magnetic elements occurred during the afternoon, which increased shortly before $7^h$ P.M. At $10^h\ 45^m$ P.M. a rapid decrease of easterly declination and increase of horizontal force took place, which lasted until a few minutes before $11^h$ P.M., when both elements as rapidly returned to their former state. Comparatively slight disturbances until $12^h\ 30^m$, when a similar movement to the above mentioned took place, but to a smaller extent. The minimum of easterly declination took place a few minutes before $11^h$ P.M., and the maximum at 10 minutes before $6^h$ A.M. on the 6th, and the range of the disturbance amounted to about 54′ of arc, while the range in the horizontal force was 0·06273 of the absolute (English) unit, = 0·02892 Continental unit.

May 20.—Faint display, most distinct at $10^h\ 30^m$ P.M.

August 22.—At $6^h\ 40^m$ P.M. some fine streamers visible, but not for long.

September 21.—Visible from about $6^h$ to $8^h$ P.M., but not very brilliant; 24, visible from shortly before $9^h$ P.M.; the finest display took place $11^h$ P.M.; 25, traces visible during evening in S.S.E.; 30, traces visible during evening, S.E.

October 21.—Visible during the evening, at $10^h\ 30^m$ P.M., some fine streamers 30° and 40° high; 25, visible at times during the evening, though completely overcast, as a luminous sheet, extending from S.W. to S.E.; 26, shortly after midnight a beautiful display, though cloudy.

November 9.—Visible shortly after midnight until early morning, again during the whole evening; fine red streamers visible through bright moonlight; 15, auroral light visible during the evening, but no streamers; 17, visible at $9^h\ 30^m$ P.M., for a short time; 18, visible all through the evening; 19, visible all through the evening; at $9^h\ 20^m$ P.M. very fine streamers; 20, visible from $11^h$ P.M.; at 10 minutes past midnight, a fine display, with streamers extending from S.E. to S.W. At $4^h$ A.M. on the 21st the whole extent of the southern sky, from the horizon upwards, was illuminated by a reddish light, terminating in something resembling a corona, but no streamers at all were visible; a thunderstorm occurred towards daylight, and the whole appearance vanished instantaneously at $4^h\ 40^m$ A.M, when a terrific thunderclap occurred; 23, visible between $11^h$ P.M. and midnight; 24, traces visible all through the evening; 25, traces visible all through the evening; 29, visible from $8^h\ 30^m$ to $10^h$ P.M., but not brilliant.

December 10—Faint streamers visible all through the evening; 16, visible all through the evening, at $10^h$ P.M. very fine streamers, and at intervals, up to $2^h$ A.M. on the 17th, a very fine display; 17, visible during the evening, some fine streamers at $9^h$ P.M.

1871, January 3.—Visible during the evening; 13, visible after $11^h$ P.M, no streamers, but strong reddish light in S.S.W.; 15, at midnight, faintly visible; 20, visible during evening, but only faint; 21, visible during evening, but only faint.

February 12, visible for a short time at $9^h$ P.M.

List of dates when great disturbances in the magnetic elements took place, of the same nature as during auroral displays, but when no auroras were visible, or at least observed:

1870: January 3, 4; February 10, 11; March 20, 21; April 22, 23, 28; May 16; June 13, 14, 16, 17; July 5, 28; August 3, 7, 19, 20, 21, 23; September 4, 5, 6, 7, 8, 16, 18, 26, 27; October 1, 15, 24; November 10, 22, 27; December 5, 6, 7, 9, 11, 15, 22, 23, 25, 27. 1871: January 5, 6, 10, 27, 28, 30; February 4, 5, 9, 13, 14, 15.

We add to the above-mentioned auroræ australes and magnetical disturbances observed in Melbourne the following ones observed in our own hemisphere:

1870, January.—To the aurora on January 8, at Melbourne, corresponds the aurora borealis on 8th at Oxford, Liverpool, Cockermouth, and North Shields. To the magnetic disturbances on January 3 and 4 correspond the disturbances observed on the same days at Rome; on January 3 auroræ boreales were observed in Piedmont and in France; also in England at Guernsey, Worthing, Royston, Norwich, Boston, Eccles, and Culloden. Aurora borealis visible on the 4th in England at Wisbech.

February.—To the aurora australis visible on February 1, from 8 to $10^h$, at Melbourne, correspond the aurora borealis seen at many places of the Europe on the same day, at Münster, Munich, Ruhrort, Nevtomysl, Peckeloh, Lennep, at Upsala ($5^h\ 50^m$ to $13^h$), also at Cœslin, Petersburg, Königsberg, Paris, London, Calais, Cracow, Stockholm, and in England at Eastbourne, Royston, Little Wratting, Norwich, Wisbech, Boston, North Shields, and Culloden. To the magnetic disturbances on 11th at Melbourne correspond the aurora borealis observed on the same day at Upsala, and in England at Taunton, Wilton, Streatley, Cardington, York, Hawsker, North Shields.

March.—To the magnetic disturbances at Melbourne on the 21st correspond the magnetic disturbances at Rome on the 22nd and the aurora borealis in England at Little Wratting, Stonyhurst, and York.

April.—To the aurora australis on April 5, at Melbourne, correspond the aurora australis observed at many places of Europe on the same day, at Münster, Peckeloh, Lennep, Bonn, Linzig, Dülken, Brunswick, Niederorschel, Stettin, Kurnik, Munich, Feldkirch, Wolgast, Berlin, France and Italy, Paris, Austria, Athens, at Upsala, Petersburg, Riga, Pulbus, and Stockholm. To the magnetic disturbance on April 23 correspond the magnetic disturbances at Rome, and the aurora borealis at Papenburg on the same day.

May.—To the aurora australis on the 20th at Melbourne corresponds the very fine aurora borealis at Münster, which also was seen on the same day at Mannheim, Paris, and London, and the great magnetic disturbances visible in Rome and Munich.

June.—To the magnetic disturbances in Melbourne on the 13, 14, 16, 17 correspond the magnetic disturbances at Rome on the same days. (Bulletino Meteorologico dell' Osservatorio del Collegio Romano, No. 7, vol x.)

July.—To the magnetic disturbances on July 8 and 28 at Melbourne correspond the disturbances at Rome on the same days.

August.—To the aurora australis on the 22nd at Melbourne corresponds the aurora borealis on the 21st at Volpeglino near Tortona in Italy. To the magnetic disturbances in Melbourne on the 3, 7, 19, 20, 21, 23 correspond the contemporary disturbances of the magnetic instruments at Rome. With the magnetic disturbances on the 7th the aurora borealis at Upsala coincides. With the disturbance on the 19th the aurora borealis at Münster and at Carthaus near Dülmen. With the disturbances on the 20th the aurora borealis at Münster, Groeningen, Peckeloh, Oesel, Leipzig, and Upsala. To the magnetic disturbance on the 23rd corresponds the aurora borealis at Glasgow.

September.—To the aurora on the 25th in Melbourne corresponds the aurora borealis at Carthaus, Danzig, Peckeloh, Weisenheim, also at Arnsburg, Oesel in Schleswig, Lichtenberg, Hamburg, Upsala. To the aurora australis on the 26th at Melbourne corresponds the aurora borealis at Lichtenberg, Weisenheim, Upsala, Glasgow. To the aurora on the 30th at Melbourne corresponds the aurora borealis on the same day at Upsala and Lichtenberg. To the aurora australis on the 21st at Melbourne correspond the contemporary aurora borealis at Upsala, Schleswig, Arnsburg, Lichtenberg, Hamburg, Norburg, Alsen, and the magnetic disturbance at Rome. To the aurora on the 24th at Melbourne corresponds the contemporary aurora borealis at Carthaus near Dülmen, Niederorschel, Groeningen, Danzig, Wolgast, Peckeloh, Weisenheim, Norburg, Alsen, Eger, Prague, Oderberg by the Inn, Kremsmünster, Moncalieri, Vienna, Stockholm, Hawkhurst, London. On the same day great disturbances of the magnetic instruments were observed at Rome and at Kremsmünster.

October.—To the aurora australis on the 21st at Melbourne corresponds the aurora borealis on the same day in England, and on the former day in Westphalia and England. To the aurora australis on the 25th at Melbourne corresponds the brilliant aurora borealis which was seen at many places in Germany, England, Russia, Sweden, Italy,* Greece, and Turkey on the same day. To the aurora on the 26th at Melbourne corresponds the aurora borealis on the same day in Hamburg, Lichtenberg, Keitum, Athens, and in England. To the magnetic disturbances on the 1st at Melbourne corresponds the aurora borealis at Peckeloh, Upsala, and in England, and the magnetic disturbances on the same day. To the magnetic disturbances on the 15th at Melbourne correspond the contemporary mag-

* Bulletino Meteorologico dell' Osservatorio del Collegio Carlo Alberto in Moncalieri.

netic disturbances in Rome, and the aurora borealis at Upsala. To the magnetic disturbance on the 24th at Melbourne correspond the great magnetic disturbances at Rome, and the very fine auroræ boreales on the same day in Germany, Russia, England, Turkey, Greece, and Sicily.

November.—The aurora australis of November 9 at Melbourne, lasting from midnight till the morning twilight, corresponds to an hour to the aurora borealis which was seen at clear full moon on the evening of the 8th in Schleswig, and to the magnetic disturbances at Rome on the 8th and 9th. To the auroræ australes on the 15th, 17th, and 18th at Melbourne correspond the auroræ boreales on the 14th, 17th, and 18th in England. To the great aurora australis on the 19th at Melbourne corresponds the contemporary aurora borealis at Münster, Niederorschel, Peckeloh, Schleswig, also at Upsala and in England. To the aurora on the 23rd in Melbourne corresponds the aurora borealis in England of the 22nd and 23rd. To the aurora australis of the 24th corresponds the aurora borealis at Upsala of the 24th and in England. The magnetic disturbances at Rome on the 19th, 20th, 23rd 24th, 25th, and 29th coincide with the aurora australis, on the same days, and the magnetic disturbances at Rome on the 10th, 22nd, and 27th, with the disturbances at Melbourne on the same days.* Besides the aurora borealis on the 22nd in England, and on the 27th in Brünn coincide with the contemporary magnetic disturbances at Melbourne.

December.—To the aurora australis on the 6th and 17th at Melbourne corresponds the aurora borealis at Peckeloh, Keitum, and in England. To the aurora on the 17th at Melbourne corresponds the contemporary aurora borealis at Münster, Schleswig, Breslau, Keitum, and in England. The magnetic disturbance on the 22nd at Melbourne coincides with the aurora borealis on the 22nd in Schleswig.

January 1871.—To the aurora australis on the 3rd and 13th at Melbourne correspond the magnetic disturbances at Rome on the same day, and to the aurora australis of the 13th corresponds the aurora borealis on the same day at Münster, Breslau, Cologne, Schleswig. To the aurora on the 15th at Melbourne corresponds the aurora borealis at Breslau and Schleswig on the 15th. To the aurora on the 20th at Melbourne corresponds the aurora borealis on the 19th at Thurso.

February.—To the aurora australis on the 12th at Melbourne corresponds the aurora borealis on the 12th at Münster and Niederorschel, Peckeloh, Wolgart, Moncalieri, Coeslin, Breslau, the pharos of the Weser, on the west coast of England, Eger, Datschitz, Florence, Rome, Volpeglino, and the aurora borealis on the 13th at 3 A.M. at Rome. The magnetic disturbances on the 4th at Melbourne correspond to the magnetic disturbances at Rome on the same day. To the magnetic disturbances on the 5th at Melbourne corresponds the aurora borealis at Breslau. To the magnetic disturbances on the 9th at Melbourne corresponds the aurora borealis at Cleve and Thurso.

EDWARD HEIS

Münster, Westphalia, June 30

## *SOCIETIES AND ACADEMIES*

### LONDON

Entomological Society, July 3.—A. R. Wallace, president, in the chair. Prof. Westwood exhibited the minute-book of proceedings of an Entomological Society existing in London in 1780, but which appeared to have been dissolved after about a year. The members seemed to have consisted of Messrs. Drury, Honey, Swift, Francillon, Jones, and Bentley; the meetings being held weekly.—Mr. S. Stevens exhibited a collection of Coleoptera recently made in Ireland, the most interesting species being *Chlænius holosericeus* from near Killaloe. Mr. Champion exhibited an example of *Emus hirtus* recently captured by him in the New Forest; also rare British Hemiptera. Mr. Blackmore exhibited a collection of insects of all orders from Tangiers; locusts were extremely destructive there, and on the shore the pedestrian is often up to his ankles in the dead and dying accumulations of these insects.—Mr. Dunning read a letter from the Rev. Mr. Wayne, of Much Wenlock, calling attention to the damage done to his strawberries in consequence of a Myriopod effecting an entrance into the interior of the ripe fruit; also complaining that his young carrots were destroyed by a dipterous larva, probably that of *Psila rosæ*, which bored into the root.—Mr. Druce exhibited a collection of rare Diurnal Lepidoptera, including species of *Papilio*, *Euryades*, *Heliconia*, *Eresia*, *Catagramma*, *Agrias*. *Paphia*, &c.—Mr. Stainton exhibited an example of *Botys fuscalis* captured by the Rev. R. P. Murray in the Isle of Man, to the head of which a portion of the puparium still adhered; the insect was flying briskly when taken, notwithstanding that it must have been nearly blind. Mr. Albert Müller exhibited a leaf from a vine growing at Basle showing the damage done by *Phytoptus vitis*.—Mr. Riley, State Entomologist for Missouri, exhibited a collection of American insects with their transformations.—Prof. Westwood read a paper on new species of exotic *Papilionidæ*. Mr. S. S. Saunders read a monograph of the Strepsiptera, describing twenty-one species; he considered the group as undoubtedly pertaining to the Coleoptera, in the vicinity of *Rhipiphorus*. Mr. C. O. Waterhouse read a memoir on some species of *Cantharis*. The Baron de Selys Longchamps communicated a statistical sketch of the *Odonata*; the number of species of dragon flies now known he estimated at 1,344.

Society of Biblical Archæology, July 4.—Samuel Birch, LL.D., F.S.A., in the chair. The Rev. F. K. Cheyne, M.A., was duly elected a member of the society. The Rev. B. T. Lowne, M.R.C.S., read a paper "On the Flora of Palestine." He considered that it comprised eight distinct elements, four of the dominant existing floras of Southern Europe, Russian Asia, North Africa, and that of Arabia and North Western India. Each of these floras was stated to occupy a distinct region of the country. Interspersed with these are found numerous examples of plants belonging to palæarctic Europe, constituting its fifth element. The Arctic flora of Hermon and Lebanon constitutes the sixth. Mr. Lowne thought further that the cedars of the Lebanon, and the papyrus of the Jordan lakes were the remnants of two ancient and almost extinct floras belonging to two distinct geological periods.—James Collins read a paper "On the Gums, Perfumes, and Resins mentioned in the Bible," particularly pointing out the fact that few of them were indigenous to Palestine, and that many have been wrongly named by the Greek and later botanists. In the course of his observations Mr. Collins detailed the characteristic differences between the true and false Balm of Gilead, ladanum, sandal wood, &c., and the greater or less efficacy of their medicinal properties. Mr. Lowne and Mr. Collins brought for exhibition a large number of mounted specimens, and a complete collection of gums, perfumes, &c., to illustrate their respective papers.

### PARIS

Académie des Sciences, June 28.—M. Claude Bernard in the chair. M. Robin presented a new edition of his great work on the Microscope.—M. Elie de Beaumont presented a most valuable book by M. Rivat, who died recently, and who was one of the chief engineers in the mining service, containing a new method of extracting silver from sulphuric ores, with the assistance of super-heated steam. The quantity of steam required was originally very great, and is now reduced to $\frac{1}{50}$th of what it was when the first experiments were tried. This process of quantitative analysis is largely used in the Laboratory of the Ecole des Mines, at Paris.—Father Secchi sent a memoir on a supposed relation between protuberances, sun-spots, and "faculæ," as discovered by him.—M. Struve and others sent a letter on behalf of the German astronomers, who will meet at Vienna, and asking for the presence of French astronomers. Some instruments destroyed by the Communists were intended for that meeting.—M. Delaunay has circulated amongst the members a small notice relating to an intended meteorological atlas of France, and presented the volume of meteorological observations made at the National Observatory, which he calls the "Observatory of Paris." M. Charles Sainte-Claire Deville rose immediately in order to present the French Academy with the observations made at the observatory of Montsouris. The two observatories are at a distance of something less than a mile, and a deadly feud appears to exist between them.—M. Ch. Sainte-Claire Deville then read a paper relating to the part taken by him in the projecting of the meteorological atlas of France in 1847.—M. de Falen and Fisher described bathymetrical observations and researches executed on the coasts of France, in 1847, in depths varying up to 250 fathoms. The submarine fauna has no peculiarity worth mentioning. M. Gustave Tissandier, one of the postal aeronauts, presented a *résumé* of the results obtained by the sixty-four postal aeronautical expeditions during the siege of Paris. He merely gives however the number of letters and pigeons sent, but not the number of pigeons returned to Paris, and of letters duly posted in the post-offices of the French postal service delegated in the provinces.

July 3.—M. Claude Bernard in the chair.—M. Delaunay read a letter from M. Marie Davy, in answer to M. Ch. Sainte-Claire Deville's communication on the Physical Atlas of France. The learned astronomer, supporting M. Marie Davy, admits that the idea of constructing a physical atlas belongs to M. Ch. Sainte Claire Deville, who originated it in 1847; but he contends that in 1868 he tried to start it, since nothing had been done during twenty-one years. M. Delaunay contends moreover that it is a duty for the National Observatory to undertake such a publication. It is to be hoped that M. Delaunay's exertions will not interfere with M. Sainte-Claire Deville's own publications, and at all events, that we shall have at least an atlas worthy of the French reputation in meteorological matters. But the safer way for both contending parties should be to agree in a common work. Such a resolution would diminish the expenses to the Republic, and enlarge the chances of common success. M. Sainte-Claire Deville's brother, the chemist, was not returned a member for Paris, although he received more than 50,000 votes.—M. Delaunay presented for M. Latterade a most extraordinary memoir on "The Theory of two Suns." M. Latterade contends that the warm period which is demonstrated by the presence of tropical fossils in Sweden and Norway was produced by the proximity of a very powerful star which had given to the earth an immense quantity of heat, and which from that time has receded into the abysses of celestial space. M. Latterade contends that the *supplementary sun* has not disturbed the elements of the planets, because its attractive power was smaller than its warming power. He states, moreover, that the warming power does not vary according to the mass, like the attractive power. This communication was referred gravely to a committee composed of three members.—M. Champion sent a new memoir on nitro-glycerine, which he has studied with so much care during the investment of Paris. It is not only a very dangerous study, but also a very painful labour, as violent headaches are experienced by persons engaged in such operations. The whole of the memoir is worthy of being read attentively by working chemists. We will not try to analyse it, but merely mention two facts. Electricity is without action on glycerine as proved by Ruhmkorff, and explosion does not take place at 360° Fah. as supposed, but at 540° only.—M. Quatrefages presented an interesting memoir from M. Dareste, who is pursuing with constant success his studies on artificial monstrosities, produced by different operations on eggs during incubation. The learned physiologist examines the alterations produced in the blood, and finds the number of corpuscles is very small indeed under special circumstances.—Father Denza sent from Italy an account of the aurora borealis observed in Italy on the evenings of April 9, 10, 18, and 23. Father Denza mentions other auroræ boreales on the 7th, 12th, and 18th of June. This last display was very brilliant, and was accompanied with very great magnetical disturbances. It coincided, moreover, with great storms observed in England and other countries.—Baron Larey announced that Dr. Castano is just leaving France for a climatological and medical inspection of Denmark, Sweden, Norway, and perhaps Iceland, as well as the Faroe Islands.—In its secret sitting the Academy is discussing the titles of several candidates to fill the room of M. Lamé, who was mostly engaged in abstruse researches on the application of high mathematics to molecular physics during his whole lifetime. M. Puiteux was chosen as candidate in the first line. He will be certainly returned on the 10th. M. Lamé cannot have any fitter or more qualified successor.—M. Delaunay has published the result of observations for the month of June. The greatest excess of black bulb thermometer *in vacuo* exposed to the sun over the ordinary thermometer in the shade was 35½° Fah. on June 1, and the smallest on the 5th, when it was only 4°.

VIENNA

Imperial Academy of Sciences, May 11.—Dr. Neilreich communicated a critical revision of the species, forms, and hybrid forms of the genus *Hieracium* hitherto observed in Austria and Hungary. The author remarked upon the peculiar difficulty of deciding what constitutes a species among the Hawkweeds, and pointed that by one course, the number of species is inordinately increased, whilst the other diminishes it to an unnatural minimum. In his treatment of the Hawkweeds of Austria and Hungary he has adopted a middle course, namely, the establishment of what he calls "artificial species." — Prof. E. Linnemann transmitted a memoir on the simultaneous formation of propylic aldehyde, acetone, and allylic alcohol with acroleine, by the desiccating action of chloride of calcium upon glycerine.—Prof. F. Simony presented the conclusion of his memoir upon the glaciers of the Dachsteingebirge.—Prof. V. von Lang communicated a paper on the dioptrics of a system of centred spherical surfaces.—Prof. C. Jelinek communicated a note by Prof. Handl containing corections of errors in Kunzek's meteorological observations made at Lemberg.—Dr. von Monckhoven exhibited a blowpipe constructed by him for the production of the Drummond light, which permits the use of hydrogen, common gas, or alcohol as the combustible material. He also discussed some of the incandescent materials which may be employed, of which he seems to prefer white marble. Prof. Brühl transmitted three plates of the anatomy of the lice, intended for early publication, for the purpose of claiming priority in case of his results being hit upon by Dr. v. Graber, in his memoir on the same subject lately communicated to the Academy of Sciences.

*May* 16.—The following memoirs were communicated:—"Graphical determination of the stereographic and allied projections of the lines of the geographical sphere," by Prof. J. O. Streissler; "The pressure of water as a motor," by M. F. Schindler.—Director C. von Littrow presented a report upon the determination of the latitude and azimuth effected by Prof. E. Weiss at Dablitz.—M. F. Unferdinger communicated two mathematical papers, one upon four integrals, the other upon the theory of that spherical triangle in which one angle is equal to the sum of the other two.

## BOOKS RECEIVED

ENGLISH.—Mycological Illustrations: W. W. Saunders, W. G Smith, A. W. Bennett, part 1 (Van Voorst).—Darwinism Refuted: S. H. Laing (E. Stock).—A Treatise on Asiatic Cholera: C. Macnamara (Churchill).—A History of British Birds: W. Yarrell, edited by A. Newton, part 1 (Van Voorst).—The Census of England and Wales for 1871, Preliminary Report.

AMERICAN.—A Treatise on Diseases of the Nervous System: W. A. Hammond (New York, Appleton).

FOREIGN.—Das Leben der Erde: N. Humnel (Leipzig, Fleischer).—Die Grundsätze graphischen Rechnens, part 1: K. Von Ott (Prag, Calve).

## CONTENTS

THURSDAY, JULY 20, 1871

## *THE NEWCASTLE-UPON-TYNE COLLEGE OF PHYSICAL SCIENCE*

WE have apprised our readers from time to time of the progress of the arrangements for the proposed College of Physical Science in Newcastle. In our report of the meeting held on the 25th of March, at which the scheme was first publicly broached, we expressed an estimate of the administrative ability of the committee appointed to carry into effect the resolutions then adopted, which events have amply justified. A second public meeting was held in Newcastle on Saturday last to receive at the hands of the executive an account of their labours, and the Report now before us shows the energy which has been brought to bear upon a complicated and laborious task. Few who read the announcement of the first meeting—probably few even of those who were there present—supposed that the ship, of which the lines were then but talked of, could be ready at the expiration of little more than three months to launch and make her trial voyage.

We need not reprint the whole Report, as portions of it are merely the official announcement of arrangements already made public; but its contents may be briefly summarised. The Committee state that—

"At their first meeting it was found that the scheme had so far interested the general body of the inhabitants of the district, that very much more support would be forthcoming than was sufficient to provide for the six years' experiment; and as the University of Durham intimated that the promised aid (1,000*l*. per annum) would be made permanent if a capital sum could be obtained sufficient to secure the continuance of the support from the district, it was considered advisable to appeal to the public for 30,000*l*. This sum was mentioned not as being completely adequate to meet the expenses of a collegiate institution, but as providing sufficient funds for the commencement of such an undertaking."

Towards this fund 21,460*l*. has been obtained, together with three subscriptions each of 100*l*. a year, and a hope is expressed that within the next few months between 30,000*l*. and 40,000*l*. may be raised.

The election of Professors in Mathematics, Geology, Chemistry, and Experimental Physics, and the determination of the Committee to open the College in October are announced. It is recommended that the lecture fees should be such as may secure a large attendance of students and it is suggested that five guineas yearly for each course, and one guinea entrance, would be suitable to this end.

It had been agreed by the committee to propose the following Constitution. The governing bodies of the College to be:—firstly, the *Governors*, secondly, the *Council*.

1. The *Governors*; to be limited at first to forty-seven, of whom nine are to be *ex-officio* members of the body. Of the remaining thirty-eight, three are to be north-country Members of Parliament, and two Professors in the College. Nine are to be elected by subscribers to the fund, and the rest in different proportions by the Chapter of Durham, the Senate, the Convocation, the Municipal Councils of twelve northern towns, and the Scientific Societies of the district. Of the elected members one-third are to vacate their seats every two years, but are to be eligible for re-election.

2. The *Council*, which is proposed to "consist of fifteen members, including a Chairman, of whom five shall be members of the Chapter, Senate, or Convocation of the University of Durham; and of these one shall be the Warden, and of the other four at least two shall be members of the Senate; but all members of the Council shall be elected out of and by the Governors themselves. They shall be elected for five years, one-third of the number resigning their places every three years, but being re-eligible. They shall in all cases retain their appointment for two years."

This Council is to meet monthly, and to transact all the ordinary business of the College, arranging the periods of study and fees of the students, and to assume the general direction of affairs.

To a committee of this body, with which all the Professors shall be combined, is entrusted the more strictly academical administration and discipline, including the number and direction of the Professors' Lectures, subject to the general control of the Council.

In conclusion, it is proposed "that while steps are being taken to draw up the necessary documents and to proceed with the election of the Council in the terms of the Constitution, the government of the College shall remain in the hands of the Executive Committee, who shall act as the Council for the period of one year.

"At the invitation of the North of England Institute of Mining and Mechanical Engineers, the Literary and Philosophical Society, the Medical College, and the Natural History Society, occupying a group of buildings in a good situation already dedicated to scientific purposes, a suitable suite of rooms for the lectures, private rooms for the professors, laboratories, and offices, has been secured, which will be sufficient for the accommodation of the College for some years, when it is hoped the success of the Institution will be so secured that a sum of money sufficient to build separate and suitable accommodation will be easily procured."

It is almost needless to say that this report was well received and unanimously adopted, and that the meeting willingly accorded to the Executive Committee the proposed continuation of their powers for a year. In the discussion some remarks were made by gentlemen taking an active part in the labours of the Committee, which are worthy of note.

Mr. Lowthian Bell alluded to the present available accommodation for the College as insufficient, except for temporary purposes, and suggested the probable necessity for building at any rate new laboratories. He also bade the meeting to regard the four professorships already established as but a commencement, there being many other departments of Physical Science which must ere long be provided for, and made special allusion to the claims of Biology to representation.

It is true that another member of the committee with very pronounced political views, suggested that a chair of Political Economy should be the next subject adopted, but as he did not attempt to show the position of Political Economy in his scheme of physical science, it was scarcely thought necessary to argue the point.

In far wider spirit were the remarks of a subsequent speaker, who looked hopefully forward to the time when success in teaching physical science should enable them to enlarge the basis of the Institution, so as to include all the higher branches of a liberal education.

We have, on more than one occasion, advocated the addition of a Biological chair to the four already agreed upon, for it has seemed to us an anomaly that a School of Physical, or, to use the correlative term, Natural Science, should be without teaching in general Natural History, especially in a locality in which excellent facilities exist. But there is another view which has been prominently in our mind. If the College were intended to be a mere mining and engineering school, established to enable engineers and coal-viewers to educate their pupils with less labour and cost, its claim upon the general public would be small. It is due to the public that Science for its own sake,—Science with less direct reference to considerations of pounds, shillings, and pence, should be recognised; and in no way could this be so readily done, under existing circumstances, as by the establishment of a Chair in Biology.

We readily admit the pre-eminent importance of the subjects selected to commence with, and as willingly record our confidence that the Executive Committee will approach this as all other subjects with the single desire to do what is right.

Finally, we would make one comment on the attitude of Durham University. For many years past it has been regarded as almost hopeless to expect any active assistance in educational matters from that hitherto somewhat sleepy body. But with the new Dean seems to commence a new *régime*, and facts appear to bear out the testimony of many of the speakers at Saturday's meeting, that in all arrangements in connection with the new College, the University authorities have shown the widest liberality and unselfishness.

The vast importance of schools of this sort, and the prospect of a movement with a similar object in the West Riding of Yorkshire, renders needless any apology for reviewing with some detail this last addition to our scientific institutions.

## PERCY'S METALLURGY OF LEAD

*The Metallurgy of Lead, including Desilverisation and Cupellation.* By John Percy, M.D., F.R.S. (London: J. Murray, 1870.)

THE preparation of metallic lead from its several ores, amongst which galena stands foremost, presents to us processes and circumstances which, though generally simple, are amongst the most interesting and delicate in the whole range of productive metallurgy. It is therefore with even more expectation than attached to his former volumes on Copper, Zinc, and Iron that we opened Dr. Percy's present volume; and, in finding a copious and well-arranged compilation, we have not been disappointed, although we might have anticipated something more of original research.

It would, indeed, be improbable, with the great power of obtaining information directly from manufacturers necessarily belonging to the influence and position of a Professor at the Government School of Mines, that the result should be any other. Accordingly, the reader who desires to obtain a distinct and tolerably detailed though "bird's-eye" view of all the various forms of commercial metallurgy of lead (in humbler phrase of lead smelting) will here find a classified survey of it as practised in Great Britain, all over Europe, and in North America, with some notices of attempts made in South America. Of the very ancient lead-smelting processes of Asia, probably the earliest practised on a large scale in the world, and still believed to be in use in China and Japan, we do not find a word. Of recent methods in use in Japan there is a brief notice from Mr. Pumpelly at p. 384, and in China at p. 479.

The first one hundred pages are occupied with the physical and chemical properties of lead viewed from the metallurgical stand-point, one which we cannot but think is always essentially misty and unsatisfactory. The physics and chemistry of any metal ought to be the same to everybody, and it seems to us ought to be fully and accurately known before ever the student opens a metallurgical book. If that be admissible, then metallurgy proper has its limits advantageously defined and narrowed, and its treatises ought to be then divided into two distinct classes—the one like the small octavo volume of Rammelsberg (that most elegant and classic work, now several years published, but yet as true and valuable in almost every page as when it was wet from the press), which teaches the *principles* of metallurgy, that is to say, the principles of those reactions which occur in the established and fully-adopted processes of commercial metallurgy, without going into any details as to apparatus, furnaces, or criticism, as to whether this or that method or construction of plant be better or worse. The other, consisting *not* of any attempt to aggregate in one volume the details of manufacturing apparatus, of trying to tell all about the minutiæ, of all the diversities of all the commercial metallurgies in the world —which, we are compelled to say, is impossible within even the very diffuse limits taken by Dr. Percy—will best consist, we think, of *monographs*, such as those of M. Grüner, in the *Annales des Mines* of a year or two back, on this subject of lead. Each one of these monographs, with the necessary plates of illustration, should really, and in a genuinely practical way, exhaust one single national or special system of smelting of lead, or of some one other metal.

Such has been the plan almost universally adopted in Germany and France, and with results at once far more comprehensive, clear, and exact, than are practicable from the hand of any one man, however able, or in any volume though bulky, illustrated only by woodcuts however excellent, and those of Dr. Percy's present volume are remarkably clear and good.

For the practical and exhaustive description, in fact, of any single smelting process largely in commercial use, an atlas of folio copper plates, forming a volume in itself, is indispensable. The result of the contrary view of the metallurgist's descriptive task, is inevitably that want of balance, and yet incompleteness here and there, which characterise all these metallurgic volumes of Dr. Percy. Thus, for we feel bound to give an example to sustain our criticism, in his volume on Iron, Dr. Percy goes into the question of blowing machines, blast cylinders, and the like—a thing really as foreign to the metallurgy of iron as the theory and practice of building chimney stalks would be to that of lead;

and Dr. Pole, it appears, wrote for him the rather jejune algebraic investigation of the principles of such machines, which, when we come to examine it, we find is merely what we may find in any elementary book on pneumatics; and owing to the omission of all the *structural conditions producing loss of effect* in blowing machines, exists, in fact, as a mere parade of useless symbols, of no value to the constructor or the purchaser or the user of such apparatus.

Now we are wholly unable to see the necessity for thus cumbering with a needlessly hooked-on subject a book on Iron Metallurgy at all; but if otherwise, then it should have been gone into thoroughly, and in a way to be of real value to the constructor. To have done this, however, would have required some fifty pages or more, so that a far better mode, in our judgment, would have been to have simply confined the point to a reference to the great monographs which exist on this special subject, both theoretic and practical. Neither Dr. Percy nor Dr. Pole seems to have been aware of the fact that a quite exhaustive investigation of the theory of blowing machines (omitting none of the conditions of practice) and of high merit, was published as long ago as 1805, by Herr J. Baader, Counsellor of Mines of the Kingdom of Bavaria, and which was specially and by the authority of Napoleon I. translated into French and published in the *Annales des Mines* in 1809. There may be such a thing as apparent completeness, which yet is only the piling together of incongruity or of incompleteness.

But this want of the sense of balance and of relative importance is not confined to such collateral subjects of practice. Dr. Percy, in the volume here noticed, devotes nine pages to the physical properties of lead, in commencing, and of these we find four (under the head of Resistance to Pressure) are occupied with details of Coriolé's fruitless attempts in 1829 to construct weighing machines, whose indications were to be derived from the compression suffered by known volumes and forms of lead pieces—a subject as indirect and foreign to the physical properties as it is far away from the metallurgy of lead.

One statement made in this part of the volume is undoubtedly incorrect, where it is said, "by hammering lead becomes harder, but acquires its original softness by annealing." The actual fact is, that lead cannot be made harder by hammering, for its annealing temperature is so low (that of every metal being a function of its fusing point), and it suffers so large a deformation by reason of its softness when hammered, that enough heat is evolved by internal work to cause the metal to anneal itself,—in other words, never to become harder. This has been fully ascertained, and the fact has even been taken practical advantage of by those engaged in "drawing lead pipe" by the older methods, who are well aware that a hard pinch at first or rapid reduction in diameter in passing through the holes of the draw-plate, heating the lead, enables it to be drawn into finished pipe with a less total expenditure of power than if drawn slowly and with so gradual a reduction in diameter as that the lead should remain always nearly cold. Were the lead hardened here by a compression quite the same in effect as hammering, the very reverse must be the case. This volume comprises a very good account of the Pattinson process for separation of silver, and also of Parkes's zinc process. What can have induced Dr. Percy (who is, we believe, fond of scholarship) to employ such barbarous compounds as "lithargefication," "desilverisation," and "decopperisation," in place of "disargentation," "decuperation"? What would be thought of "desugarification" as a substitute for "desaccharisation"?—but these are matters of taste and no more.

The chapter on the ores of lead and that on the assay of lead ores are amongst the very best in the volume, which is beautifully printed with the clearest of type and paper, and with good indices. There are nine pages near the end devoted to poisoning by lead, which, though certainly not the metallurgy of lead, may prove of some use to those employing work-people in lead smelting or manufacturing operations; though we think here, perhaps, the wisest instructions might have been simply, "send the patient to the doctor." We have little confidence in amateur or improvised medicine on the part of "laymen," in such cases as lead-poisoning, at any rate. On the whole, though, as we have had to point out, this work of Dr. Percy's is not free from faults, it is, we think, in several ways the best of all those on Metallurgy which have appeared from under his pen, and in the collection and discussion of a vast array of facts is a noble volume, the very best that yet exists in English on its subject.

## NEWMAN'S BRITISH BUTTERFLIES

*An Illustrated Natural History of British Butterflies.* By Edward Newman, F.L.S., F.Z.S., &c. 8vo. (London: W. Tweedie, 1871.)

THE British Butterflies form a small but striking group of insects, and hence not only are they as a general rule the first objects on which the collecting spirit of the

RED ADMIRAL (*Pyrameis Atalanta*). Upper side.

Under side.

young entomologist is exerted, but they also offer one of the best means of commencing the study of entomology. Thus they are easily collected and preserved, their appearance is pleasing and often beautiful, their characters are generally very clear and distinct, so that the discrimination of the species is by no means difficult, and their

PAINTED LADY (*Pyrameis Cardui*).

Painted Lady. Var. 1.

Natural History is easily studied; whilst the small number of the species renders it an easy matter for the beginner to procure in a season or two by far the greater proportion of the known forms.

Although there are already many books treating specially of the British butterflies, some of them expensive, and others so cheap as to come within the reach of every one, we cannot blame Mr. Newman for adding one more to the number, especially as his work is distinguished by the great prominence given in it to the Natural History of the species. Upon this subject, as also upon the distribution of the species in Britain, Mr. Newman has long been publishing details from his own observations and those of other naturalists, in his periodicals the "Zoologist" and "Entomologist;" and the whole of the information thus accumulated is here summarised and supplemented with observations derived from other sources. Another useful feature in the present work is the insertion of notices, and frequently of figures of the more important varieties of each species, which will often relieve the young student from a state of puzzled suspense in the determination of his specimens. The classification adopted is founded, in its broad outlines, upon the preparatory states of the insects, but it leads pretty nearly to the same results as the system more generally followed.

The illustrations are very numerous, including figures of all the species and of both sexes when there is any difference either in the upper or lower surface. They are all woodcuts, and are generally well executed, as may be seen from the examples which we are enabled to give.

W. S. DALLAS

## OUR BOOK SHELF

*The Western Chronicle of Science.* Edited by J. H. Collins, F.G.S., Secretary to the Royal Cornwall Polytechnic Society. January to June, 1871. (Falmouth. Pp. 96.)

WE are glad to afford space for a short notice of this cheap scientific journal, which, although specially intended for the benefit of the mining population of Cornwall and West Devon, deserves a wide circulation in all our mining districts. Each monthly number contains one or two original articles, either on general subjects, as "The Practical Value of Scientific Knowledge," or giving descriptions of various forms of machinery, followed by notices of books, and a monthly chronicle of science. From one of the editorial articles on "The Practical Value of Scientific Knowledge," we learn that a good stoker may effect an annual saving of nearly 35*l.* per annum over a bad one, and that it is a common Cornish habit to hang heavy jackets, great coats, &c., on the lever of the safety valve of engines devoid of a pressure guage; while the farmers, with the view of giving their ground two good things at once, mix lime with their guano some days before spreading the manure. A very remarkable natural-history statement is made by Mr. Williams, of Hayle, in his paper on "Scientific Nursing." "I have (he says) in my possession a double chick, the produce of an egg laid by a barn-door fowl, one half being the natural species, the other half composed of the sparrow-hawk!" Until this remarkable chick appears *in propriâ personâ* at the office of NATURE, or, at all events sends us its photograph, we must, with much regret, decline to accept the fact.

*Medizinische Jahrbücher.* Herausgegeben von der K. K. Gesellschaft der Aerzte, redigirt von S. Stricker. Jahrgang, 1871, Heft I. und II. Mit 26 Holzschnitten und 2 lithographirten Tafeln. (Vienna: Braumüller; London: Williams and Norgate, 1871.)

THE two parts before us are the continuation, in a new form, of an old and valuable periodical, and, under Prof. Stricker's able editorship, its tendency, instead of being, as heretofore, chiefly clinical, will be so far modified as to embrace all the results obtained in the physiological laboratory. A glance at the table of contents is sufficient to prove the truth of this statement. Thus putting aside the first paper by Prof. Stricker, entitled "Pathology and Clinical Observation;" the rest, nine in number, are nearly all devoted to the results of microscopic research. Thus, Dr. Genersich contributes a paper on the Serous Canals of the Cornea; Dr. Heiberg one on the Regeneration of the Corneal Epithelium; Dr. Güterbock one on Inflammation of Tendons; Dr. G. F. Yeo one on the Structure of Inflamed Lymphatic Glands; Dr. Lang one on the First Stages of Inflammation in Bone; Dr. Albert and Dr. Stricker one on Surgical Fever, and the latter author another on the nature of the Poison of Pus, and so on. The journal leads off with a good start, and if it continues as it has commenced, will probably take up a leading position. We notice one or two of the papers that appear to be of general interest. H. P.

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Cotteau's "Echinides de la Sarthe"

A NOTICE of Cotteau et Triger's *Echinides de la Sarthe* in a recent number of NATURE (June 15, p. 120) is likely to convey a false impression of the accuracy of M. Cotteau, and throws considerable doubt on the value of his work. It is not often that French scientific men are as conscientious as he is in the examination of authentic types. There is hardly a collection of fossil Echini which M. Cotteau has not examined; and his thorough acquaintance with all that has been written on his subject, as well as his intimate correspondence with the principal echinologists, is a sufficient guarantee that no important memoir (such as Wright's monograph) could have escaped him. Anyone who will take the trouble of turning to Cotteau's work (p. 111) will find, under *Pseudodiadema hemisphæricum*, a notice of Dr. Wright's figure of the same species (so much superior, with many others, to Cotteau's?) and a reference to his description. Nor is this an isolated case. Throughout the work M. Cotteau discusses and criticises more or less the results of this very monograph, said to have been overlooked by him. The mistake Cotteau is accused of making of assigning to Desor instead of Agassiz the specific name of *Pseudodiadema hemisphæricum* is entirely unfounded. Referring again to p. 111., we find, as a synonym, *Diadema hemisphæricum* Agass. M. Cotteau, like many continental and American writers, does not interpret the notation of species as is required by the laws of the British Association, but for that reason he should not be accused of committing mistakes which his own writings show him not to have committed. M. Cotteau, in common with others, looks upon nomenclature simply as a matter of registration; and when M. Desor transfers to *Pseudodiadema* the *Diadema hemisphæricum* Agass., M. Cotteau writes, therefore, *Pseudodiadema hemisphæricum* Desor, and not Agassiz; he may be wrong, according to the principles of the writer in NATURE, but he has not, either in this instance or in the other cases alluded to, committed a mistake through ignorance of the subject. A. AGASSIZ

### Mr. Howorth on Darwinism

MR. HOWORTH sneers at "Survival of the Fittest" as an "identical expression" which "might have suggested itself even to a child," an axiom, in short, of which the truth cannot be disputed. This is satisfactory; but it is strange that he did not apply this axiom to his own theory, and see how they agreed together. He would probably admit, as another discovery "that might have suggested itself to a child," that *as a rule* the entire offspring of each animal or plant, except the one or two necessary to replace the parents, die before they produce offspring (this has never been denied since I put it prominently forward thirteen years ago). He would further admit, I have little doubt, that a great majority of animals and plants produce during their lifetime from ten to a thousand offspring, so that fifty will be a low average, but the exact number is of no importance. Forty-nine. therefore, of every fifty individuals born, die before reaching maturity; the fiftieth survives because it is "best fitted to survive," because it has conquered in the struggle for existence. Will Mr. Howorth also admit as self-evident, that this one survivor in fifty is healthy, vigorous, and well nourished, not sickly, weak, or half-starved? If he maintains that it is the latter, I shall ask him to prove it; if the former, then what becomes of his theory as an argument against Natural Selection? For, admitting as a possibility that his theory of the greater fecundity of the weak, &c., is true, how are these weak or sickly parents to provide for and bring up to maturity their offspring, and how are the offspring themselves (undoubtedly less vigorous than the offspring of strong and healthy parents) to maintain themselves? The one in fifty who survives to leave descendants will inevitably be the strong and healthy offspring of strong and healthy parents; the forty-nine who die will comprise the weaker and less healthy offspring of weak and sickly parents; so that, as Mr. Darwin and myself have long ago shown, the number of offspring produced is, *in most cases*, the least important of the factors in determining the continuance of a species.

I have thought it better to go thus into the heart of the question, rather than defend myself from the charge of dogmatism, for stating as a fact that the most vigorous plants and animals are the most fertile. I repeat the statement, however, referring to Mr. Darwin's observations, and especially to those in which he *demonstrates by experiment* that cross-breeding produces the most vigorous and luxuriant plants, which again produce by far the largest quantity of seed. The facts that wild animals and plants are, as a rule, healthy and vigorous, that the head of the herd is the strongest bull, and that weak and sickly carnivora are rarely found because they must inevitably starve to death, sufficiently refute Mr. Howorth's theory as against Natural Selection. If he can point to any district upon the earth where the animals and plants are in a state of chronic debility, disease, and starvation, I may admit that there his theory holds good; but such a district has not yet come under my observation, or, as far as I am aware of, been recorded by any traveller.

I still maintain (Prof. Jowett's authority notwithstanding) that the phrase "Persistence of the Stronger" does not truly represent "Natural Selection" or the struggle for existence;" and, though it may often be true, is not the whole truth. The arguments of Mr. Howorth from the history of savages will, I think, not have much weight, if we may take as an example his putting together as cause and effect the extinction of the Hottentots and their now obtaining enough to eat. ALFRED R. WALLACE

MR. ALFRED WALLACE directs attention to the gross error of supposing that "the struggle for existence means the persistence of the stronger," and correctly stigmatises this view of Mr. Howorth's "a pure misrepresentation."

It is, as Mr. Wallace remarks, very curious and even ludicrous, after all that has been said and written upon the matter, that anyone should fail to recognise the advantages to their possessor of "obscure colours," "cunning," "nauseousness," "bad odour," and other qualities superior to strength alone. The creature having these properties, at last brought to perfection through the operation of natural selection, acting through countless generations, will assuredly have the advantage in the battle of life over its less fortunate neighbours. It will survive in the struggle for existence. Having survived, is it not better that it should at once teach the world the law of its survival, and proclaim itself the fittest to survive, than that it should remain silent until those whom it has destroyed may rise from the dead and admit that their doom was deserved because they were not fit to live? LIONEL S. BEALE

MR. HOWORTH, it seems to me, has not chosen a very favourable time for so strongly maintaining the truth of Mr. Doubleday's theory, seeing that the recent census has shown that the population of England has increased not only with an increment absolutely greater than that shown by any previous census, but also—and this is still more important—with an increase proportionally greater than during the last decade. Yet never, surely, has luxury been so prevalent among us as during these last ten years. The evidence thus afforded will perhaps be deemed more conclusive than the argument of Mr. J. S. Mill, who invites those who may be inclined to accept Mr. Doubleday's opinions "to look through a volume of the Peerage, and observe the enormous families almost universal in that class; or call to mind the large families of the English clergy, and generally of the middle classes of England" ("Principles of Political Economy," bk. 1, ch. x., note). Mr. Howorth, however, states that "the classes among us who teem with children are not the well-to-do and the comfortable." If this statement were absolutely true, it would be of little service to Mr. Howorth, since it is in the classes referred to that prudential restraint acts with the greatest force, and the effects of this restraint, both direct and indirect, would have to be taken into account before his conclusion could be admitted. He further asserts that "a state of debility of the population induces fertility," since "where mortality is the greatest there is much the greatest fecundity." That births should be most numerous where the mortality is greatest, requires for its explanation no hypothesis respecting the fertilising power of debility. "The fact," says Malthus, "may be accounted for without resorting to so strange a supposition as that the fruitfulness of women should vary inversely as their health. . . . When a great mortality takes place, a proportional number of births immediately ensues, owing both to the greater number of yearly marriages from the increased demand for labour, and the greater fecundity of each marriage from being contracted at an earlier, and naturally more prolific, age" (vol. i., pp. 472, 473, 5th edit.). Man's reproductive power is always in civilised life more or less checked, and ready to be more or less exercised in proportion to the lessening by death of the restraining pressure.

THOMAS TYLER

MR. WALLACE, in replying to Mr. Howorth's objections to the theory of Natural Selection, points out that that gentleman first misrepresents Darwinism, and that having done so he does not employ the distorted doctrine as premisses to a further conclusion. But the second part of the criticism is not quite just. Mr. Howorth, after stating the Darwinism theory, introduces us to an order of facts which is at variance with that theory as apprehended by him; and not only does he do so, but he places an interpretation upon these facts which is utterly irreconcilable with the Darwinian theory as understood by its most able expositors. It is true that Mr. Howorth does not bring his interpretation of the facts he adduces and the theory of natural selection into such juxtaposition as to show their mutual contradiction; but a little consideration will enable Mr. Wallace to supply the missing links, and to see that in any generous construction of Mr. Howorth's letter, the real questions at issue are the correctness of the facts he adduces and the validity of the generalisation he makes from these facts. My object in writing is to direct Mr. Howorth's attention to Mr. Herbert Spencer's profound discussion of this subject, as it appears to have escaped his notice. This is the more surprising, since, on p. 111, vol ii. of "The Variation of Animals and Plants under Domestication," and to which Mr. Darwin refers him, there is the following marginal note:—"Since this MS. has been sent to press, a full discussion on the present subject has appeared in Mr. Herbert Spencer's 'Principles of Biology' vol ii., 1867, p. 457, *et seq.*" He is a bold man who undertakes to enlighten the public on a subject which Mr. Spencer has fully discussed, without first ascertaining what view that profound and original thinker adopts; and most certainly a fresh writer coming into the field ought to take up the discussion where an author of such eminence has left it. If Mr. Howorth will look at Mr. Herbert Spencer's "Principles of Biology," he will find in sections 78 and 79, an explanation of the process adopted by gardeners of cutting the roots, and "ringing" the bark of fruit trees. Section 355 explains the fact that fatness is often accompanied by barrenness. In a footnote at p. 483, vol. ii., he will find Mr. Doubleday's doctrine specially noticed, and the fallacies upon which it is based exposed; while in the chapters "On the Laws of Multiplication," vol ii., p. 391, *et seq.*, he will find the whole subject treated with a fulness and exhaustiveness which leaves little to be desired. Mr. Howorth will notice that Mr. Spencer does not deny Mr. Doubleday's facts, but that he places upon them an interpretation which brings them into harmony with the general theory of evolution, and with the special part of organic evolution which constitutes the Darwinian theory.

Newchurch, July 17 JAMES ROSS

---

I HOPE you will allow me a few lines to reply to Mr. Howorth.

I had thought Mr. Doubleday's essay was among the things of the past. There can be no question that his conclusions are not the conclusions of accomplished naturalists like Mr. Wallace, whose assertions are certainly as good, if not far better, than those of Mr. Doubleday.

Quoting Mr. Chadwick, Mr. Howorth again puts cause for effect. There can be no doubt that the death rate increases in a crowded country *pari passu* with the crowding, and that the crowding is the result of fertility. It by no means follows that the crowding produces fertility.

There is one way in which poverty and overcrowding tend to increase the birth rate. Many of the children of the poor die during the first few months of life, and hence the mother, being relieved of her offspring, ceases to secrete milk, and soon again falls pregnant. It is the death of very young children in crowded districts which so largely increases the mortality, and this, as we have seen, may tend to increase the birth rate.

The large percentage of deaths in early life amongst the ill-nourished and weakly renders these less likely to bear children than the strong. With regard to the large families of the poor so often quoted, I have grave doubts of the fact. I have for many years seen hundreds of poor families every year in the exercise of my profession of surgeon, and although I know many instances of ten or fifteen children having been born of one mother, in the majority not more than two or three reached adult age, and hence these produced no offspring in the second generation.

The most remarkably prolific woman who has come under my notice has had twenty-two children in twenty years, and she is still continuing to present her husband with blessings. She is one of the fattest women I know.

Amongst the rich and the well-to-do it is no uncommon thing for eight or ten children to grow to man's and woman's estate and to rear families. I know as many well-to-do persons with large families as poor people, and the living percentage is far greater in the former.

I am not aware that consumptive patients are so extremely prone to breed as Mr. Howorth thinks, certainly their children do not live to produce a second generation as a rule.

Examples of fecundity and barrenness amongst wild tribes are not much to the purpose, because there are so many disturbing influences. To take, however, Mr. Howorth's case, the Red Indian feeds ill enough and is thin enough, yet he is not fertile. The backwoodsman, with his vegetable diet, would be far more likely to grow fat, and is certainly far better fed and far stronger than the Indian, yet he is more fertile than the Indian, although by no means fertile. He has many hardships to undergo.

With regard to the Patagonian women and their belief that bleeding produces fertility, evidence is wanting as to the truth of their belief. We know many wide-spread beliefs are erroneous, for instance, most savages believe in rain-makers.

In conclusion, Mr. Howorth thinks that wild animals in captivity are sterile from over-feeding. If he will try and make them fertile by starving them, I think I may assert positively he will fail. Hence, I suspect, we must look for a deeper cause of barrenness in them. B. T. LOWNE

99, Guilford Street

## Recent Neologisms

IN using the word Mr. Ingleby objects to as hideous, I was not aware that I was coining a new one. If so, it was quite unconsciously on my part; but a word was wanted to express the property of being prolific, and if the choice lies between "prolificness" and "prolificacity," as I think it does, I am inclined to believe that the former will survive, as being the shorter, the easier to pronounce, and perhaps the less hideous, even though it may not be constructed on the best etymological principles. "Fertility" and "fecundity," which are often used, do not quite answer the purpose, although the latter has very nearly the same meaning. Our language must and will grow; and its growth will be determined by convenience rather than by grammatical rules. ALFRED R. WALLACE

---

DR. INGLEBY is in error as to the recent introduction of "survival," "impolicy," and "prolificness." All these words will be found in Chalmers's abridgment of "Todd's Johnson" (1820); the first with a reference to Sir George Buck, the second with one to Bishop Horsley, and the third with one to Scott (not Sir Walter). "Indiscipline" does not occur, but "indisciplinable" does, Hales being cited as the authority.

R. G.

---

IN his excellent custom of "registering the first appearance of new words and new phrases," Dr. C. M. Ingleby is surely very careless or superficial. He quotes "survival" as a new word introduced, he thinks, by Darwin. I have been familiar with it as long as I remember, and my life of careful observation has exceeded a quarter of a century. "Impolicy" is equally familiar, having had currency at least twenty years before the Franco-Prussian war, to which Dr. Ingleby accredits it. He will find both words, as well as "indiscipline," in "Webster's Dictionary," edition 1852, and probably much earlier on careful search. "To telegram" is clearly a vulgarism, rarely heard I imagine, and never seen in print. G. W. S.

---

## Fertilisation of the Bee Orchis

MR. DARWIN, in his "Fertilisation of Orchids," states his belief that the Bee Orchis presents a physiological difference from all other British orchids, and is habitually self-fertilised. I had, yesterday, an opportunity of observing a number of these plants in one of its abundant localities in Surrey, and at a time when fertilisation must have been completed. In every plant almost all the capsules were considerably swollen, and were loaded with apparently fertilised ovules. In most of the withered flowers, the remains of the pollinia were still visible in the position described by Mr. Darwin, hanging down before the entrance to the nectary, in immediate proximity to the stigma, and rendering it almost impossible to believe that the flower had ever been entered by any insect of considerable size, which must inevitably have carried away the pollinia with it. The fact that the Bee Orchis, the most "imitative" of all our native plants, is never visited by insects, is a very suggestive one. If, as might well have been assumed, the object of the "mimicry" is the attraction of bees, the device appears to have signally failed.

London, July 17 ALFRED W. BENNETT

### Saturn's Rings

As Lieut. Davies has thought it necessary to refer to your remarks about the satellite theory of Saturn's rings—and in so doing has named my work upon Saturn (which you had *only* referred to without naming) it may be as well for me to mention, that I nowhere in that work claim the theory as mine—and that, whenever I have seen it referred to as mine, I have as publicly as possible disclaimed all title to it.

Permit me to add, that, whatever opinion we form of Lieut. Davies's views, he deserves our thanks for bringing out a treatise so full of work, from cover to cover, as his "Meteoric Theories." Such examples are a good deal needed in these days.

8, Wellington Villas, Brighton RICHARD A. PROCTOR

### Ocean Currents

I FIND that Dr. Carpenter does not consider his experimen probative. Judging from the air of triumph with which, both in his lectures and writings, he has announced its success, I had certainly imagined that he did. But if not probative, what is it? Dr. Carpenter says it is only intended to be illustrative. What does it illustrate? It does not illustrate any currents formed in the ocean by differences of temperature; for it does not illustrate the differences of temperature to which he attributes these currents. In his letter in NATURE of July 6, he proposes an unwieldy modification of his former well-known experiment, but which still, I would submit, in no way avoids the difficulty to which I have called attention. He describes a strong freezing mixture applied to the surface through one-tenth of the length of a trough half a mile long, and heat applied to the surface also through one-tenth of the length, measured from the other end: between the cold and the hot surface there is, then, an intervening space of four-tenths of a mile, or 2,112 feet; that is to say, there is a thermometric gradient of about 50° in 2,000 feet, or 1° in forty feet. This is small enough, and we may perhaps doubt whether such a gradient could give rise to any appreciable movement; but it is 15,000 times greater than the gradient observed in the ocean, which is about 1° in 100 nautical miles; and any movement shown by an experiment which, in its details, bears no reasonable proportion to the reality, cannot be accepted as an illustration of a movement in the ocean.

Mr. Proctor, in the same way, speaks of his proposed experiment as an illustration; and, in the same way, I would say that the distortion produced by magnifying 6,000,000 times that particular detail on which he wishes to lay an emphasis, precludes our accepting it as an illustration at all. Mr. Proctor says that it is intended specially to throw light on the easterly and westerly movements; it is surely unnecessary for me to point out to him that any easterly or westerly movements, as illustrated in a cylinder such as he describes, revolving continuously and uniformly, are direct consequents of the outward or inward movement due to the differences of temperature, and are, therefore, in the strictest sense, dependent on the thermometric gradient. If, with a thermometric gradient of $\frac{1}{600000}$ of a degree in one foot, and with an angular velocity of 360° in 24 hours, Mr. Proctor succeeds in showing any appreciable movement, I and (I think I may add) many other readers of NATURE will be glad to learn the result. But this is, after all, the point I raised in my last letter (NATURE, June 29), and which Mr. Proctor considers would require many columns for its full discussion. I do not myself see that there is any room for discussion at all; and any difference of opinion that may exist can only be met by experimental demonstration.

Dr. Carpenter appears to wish to support his theory on "authority," and especially on that of the recent letter of Sir John Herschel. This is a point on which I touch with great reluctance; but I would point out, in the first place, that "authority" in matters of science carries very little weight; and, secondly, that Sir John Herschel, in the letter referred to, merely admits what he and everyone else have all along admitted, that hot water and cold, in juxtaposition, will establish a circulation. It was not for him, in a letter of private courtesy, to enter again on a discussion of the infinitesimal nature of the gradients—a discussion which he had already worked out very fully in his "Physical Geography."

But, leaving this consideration on one side, I maintain that, at the present time, the *onus probandi* rests with the supporters of the temperature theory. Its opponents have offered what is, at any rate, a rational, consistent, and tolerably complete explanation of all the known ocean currents; and they say, in so many words, that the explanation offered, in accordance with the theory of temperature and specific gravity, is neither complete, nor consistent with itself or with geographical observation. The theoretical objection of the infinitesimal nature of the thermometric gradients and of the differences of specific gravity, which has, indeed, formed the subject of these letters, is not one which I was inclined to put forward in any prominent degree. I preferred, and still prefer, to base my objection on the utter discrepancy between fact as observed, and fact as described by Captain Maury and Dr. Carpenter, in accordance with their theory.

I have elsewhere dwelt on this at great length, and do not intend to go over the same ground here, even if you were willing to afford me the space to do so; but this discrepancy, which actually and very markedly exists, does call attention to the thermometric gradients in the ocean; and when we find the same discrepancy between observation and description in the case of aërial currents, it leads to the conclusion that the infinitesimal nature of the thermometric gradients is as sound an objection to the temperature theory of atmospheric circulation, as it is to the temperature theory of oceanic circulation. I refer here to the last sentence but one of Mr. Proctor's letter. The last sentence, I must confess, I do not understand. I do not see what effects solar light can produce, or even be supposed to produce, on the depths of ocean, to which no light penetrates; still less do I see how to integrate them.

J. K. LAUGHTON

### Formation of Flints

IN your report of the discussion that followed the reading of my paper on Flint, before the Geologists' Association on June 2nd, Prof. Morris is said to have asserted that the views I suggested were first propounded by Dr. Brown of Edinburgh. I think the Professor must have been slightly misrepresented in this; at all events I must most decidedly decline to be coupled with Dr. Brown, or to allow myself to be associated with his very remarkable statements. These may be found in the Trans. Roy. Soc. Edinb., vol. XV. He asserts that carbon is transmutable into silicon; at p. 229 he says, "Carbon and silicon are isomeric bodies, and that the former element may be converted into a substance presenting all the properties of the latter." At p. 244, "3·04 grains of silicic acid were extracted from 5 grains of paracyanide of iron;" at p. 245, "5·4 grains of silicic acid were procured from 30 grains of the ferrocyanide of potassium," and "there were obtained 9,334 grains of silica from 3,240 grains of ferrocyanide, although some of the product was lost in two of the operations." The view I advocated as explanatory of the formation of flints was the *substitution* of silicon for carbon, not a transmutation, and I distinctly showed the source from which the silicon was derived. Dr. Brown's statements are so extraordinary that I could scarcely believe them serious. I find, however, in the same volume of the "Transactions" that they were most patiently examined and confuted by Dr. George Wilson and Mr. John Crombie Brown, and they say, "We tried the greater number of Dr. Brown's processes, and rejected them one after another without pursuing their investigation further, on finding they would not yield quantitative proofs of the conversion of carbon into silicon. The limited time, which from various circumstances we could devote to the subject, obliged us to follow this course; and the confident expectation we entertained till a recent period that each new process would supply what the rejected ones had failed to afford, led us to neglect noting many particulars of our early trials which otherwise we should have recorded. . . . In conclusion, we need scarcely say that we have been unable to supply any proof of the transmutability of carbon into silicon."

I have one more objection to make to the report. I did not say that flints were merely silicified sponges. I believe that such is the case with *some* flints, but certainly not with all. I hope you will find space for this rectification of manifest errors.

M. HAWKINS JOHNSON

379, Euston Road, July 11

### Affinities of the Sponges

MR. PARFITT seems to think that Mr. Carter has done Prof. Greene some injustice, because he has not referred to him as an original investigator of the Sponges, and he bases his opinion on the figures in Prof. Greene's "Manual of Protozoa," urging that the only difference between the forms figured by Carter in 1871, and those by Greene in 1859, is "the want of the funnel-shaped mouth, which seemed to have escaped the observation of Prof. Greene, probably owing to want of definition in the instrument used in the investigations." Allow me to point out that there is no pretence of originality in Prof. Greene's useful manual, that the figures alluded to are acknowledged (p. 85) to be copied from those illustrating the papers by Williamson and Dobie, and to express the opinion that much further research is necessary before the affinities of the sponges can be regarded as satisfactorily settled. When that day comes there is little doubt that a good deal of what is now guess work will require to be completely sponged out. W.

### Sun-Spot

WHILE watching the sun set over the hills to the west of Halifax, on the evening of July 17, my attention was called to an intensely black spot upon its southern hemisphere, almost vertically below the centre of the disc, which was visible to the naked eye. I may add that the evening was fine, but a thin mist was rising from the valleys, and that it was about five minutes before the sun touched the horizon that the spot was first seen. THOMAS PERKINS

## EDOUARD RENÉ CLAPARÈDE

AT the early age of thirty-nine, one of the most skilful, laborious, and honoured of European zoologists has been lost to Science in the person of Edouard Claparède. For the last three years his health has been such that his friends continually feared to receive the sad news which has at length come from Italy. In spite of a complication of pulmonary and cardiac disease, his indomitable spirit had kept the man at work to the last. Having taken up his residence in Italy for the benefit of his health, he produced during the last three years of his life a series of memoirs, so richly illustrated, and exhibiting such astonishing industry, that one would have fancied a man in full health and vigour was unequal to such abundant fertility. He once remarked to a friend, who expressed surprise that a man in his precarious state of health should work so hard, that he felt work was the only thing which kept him to life, if he left off working he should die at once. Claparède was a native of Switzerland, and a pupil of that great master of great zoologists, Johannes Müller. He could write French and German equally well, and consequently some of his researches are to be found published in the German periodicals, others in French in the Transactions of the Academy of Geneva. His earliest published work of large size is the "Recherches sur les Infusoires," which he produced in conjunction with his friend Lachmann, who unhappily died before it was completed. Though now to a great extent superseded by the later researches of Stein, Zenker, Cohn, and others, working with more accurate instruments, this treatise is one of classical importance, and forms the foundation of modern views on the Infusoria. Not long after the publication of this work, Claparède came to England, where he made the acquaintance of Dr. Carpenter, and spent a portion of the summer in his company in the Hebrides, working with the microscope, chiefly at the lower worms and annelids. From this expedition resulted a quarto publication, illustrated with plates (published by the Geneva Academy), giving accounts of new marine worms allied to the earth-worms, and many valuable observations on the Turbellarian worms. In conjunction with Dr. Carpenter, he also published some observations on the curious *Tomopteris onisciformis* in the Linnean Transactions. Attracted by the limicolous annelids, Claparède continued his observations on the forms of this group inhabiting the streams around Geneva; and his "Recherches sur les Oligochêtes," also published by the Geneva Academy, furnished zoologists with a very complete account of many of the anatomical and systematic differentiæ of these worms, till then almost entirely neglected and misunderstood. In this work the homology of the segmental organ with the reproductive ducts was demonstrated. The circulation of spiders, which he studied in the transparent young of the genus *Lycosia*, and the development of the freshwater gasteropod, *Neritina fluviatilis*, also about this time furnished occupation for his pen and pencil; and an elaborate work on the development of the Nematods, in which the important questions of the signification of the parts of the egg are discussed, was completed by him. In the collections of miscellaneous observations, always finely illustrated, which he from time to time published, such as "Glanures zootomiques," "Beobachtungen über wirbellosen Thiere," &c.," he recorded observations principally on the Annelids and free-living worms, which he made from year to year on the coasts of Normandy or the shores of the Mediterranean, and many strange forms, paradoxical marine larvæ, and unsuspected annectant genera, are briefly figured and described, which excite the interest of the zoologist, and awaken the desire to know more of them; whilst in other cases new modes of reproduction, new anatomical details, or physiological observations are related (for Claparède was no narrow zoologist) of rare and little known forms. The great work which he took in hand after his health had compelled him to reside in a warm climate during winter, was the study of the Annelids of the Bay of Naples. Under this title he has left two thick quarto volumes, illustrated by more than fifty coloured plates, consisting of anatomical and enlarged coloured drawings of these beautiful worms. Many new and curious forms were added by one winter's work to the known species of the Annelida; but his work is even more valuable for the anatomical and histological observations which are there recorded, and for the great critical ability displayed in dealing with the perplexing question of synonymy. M. Claparède appears to have found especial pleasure in doing justice to Delle Chiaje, who preceded him in the investigation of the fauna of the Bay of Naples; whilst he does equal justice to M. de Quatrefages, whose errors in a recently-published "Histoire des Annelées" he does not hesitate repeatedly in the course of his book to expose; whilst dedicating the first volume of his work to that distinguished French naturalist, and naming many new species in his honour. Whilst this splendid work on the Neapolitan Annelids was in press, M. Claparède also gave to the world some very interesting studies on Acarids (published in German), in which many new facts are detailed, and the Darwinian theory, in the manner of Fritz Müller, is shown to furnish a satisfactory explanation of the modification of dissimilar parts in different genera, to form identical organs. During the same period he also published in the *Zeitschrift für wiss. Zoologie* a memoir on the histology of the earth-worm, illustrated with nine coloured plates, which is certainly the most minute and careful piece of work which he ever produced. The structure of the nervous system and of the three "riesige Rohren-faden," soon to become very celebrated in zoological circles, are here for the first time fully described; and, indeed, the subject had been so slightly handled before that the whole work abounds with new matter. M. Claparède's last published paper appeared this year in the *Zeitschrift*, and as if to show that he did not intend to abandon himself to the study of one group, consisted of observations on the anatomy and reproduction of some marine polyzoa, illustrated by three coloured plates, drawn with his accustomed facility and grace. He has, we understand, left behind him ready for publication a large work on the Embryology of Insects, and an immense collection of microscopic preparations, of great value, of Annelids. Perhaps the most striking discovery recorded in any of M. Claparède's writings (which should however, be judged by the accumulated value of their immense number of anatomical observations) is one among those relating to the Annelids of the Bay of Naples. Claparède found that the *Nereis Dumerilii* lays eggs, sexually fertilised, which, on hatching, produce a worm which had been placed in quite a distinct genus (*Heteronereis*), and this worm lays similar true eggs, which produce sometimes a second kind of *Heteronereis*, or at other seasons the original form *Nereis Dumerilii* again. The difference between *Heteronereis* and *Nereis* is very great, and one extending into such details as the form of the setæ of the feet. At present this appears to be the only *real* case of alternation of generations on record, if, by "generations," we understand "sexual generations."

Whilst working so largely as an original observer, M. Claparède occupied himself also in reviewing the labours of others from time to time in the *Archives Suisses* published at Lausanne. Though holding the title of Professor in the Academy of Geneva, we believe he never (certainly not of late years) gave any public lectures on zoology; yet that he was admirably fitted for such work, had he thought fit to devote his time to it, is evident from the admirable style of his writings, especially the reviews and criticisms published in the *Archives Suisses*. His criticism of Mr. Wallace's views on the Descent of Man is known to our readers. Having access to the French world of science as a speaker and writer of the French language, and being thoroughly familiar with German writings and thought, both from education and continued association, M. Claparède appears to have taken an honest delight in every now and then dealing a severe blow at some one or other of the French naturalists who might venture to exhibit superficiality or dishonesty in his field of study. Dujardin is roughly handled in the "Recherches sur les Infusoires;" Rouget also, who appears to have personally resented the correction. Balbiani's researches on the development of the aphides are made the subject of special investigation by M. Claparède, who, three years since, studied the embryology of a species of aphis at Naples solely with the view of testing some extraordinary statements then recently advanced by the French doctor, and came to the conclusion that they were utterly unfounded, and that M. Balbiani had not done justice to the work of his predecessors, which conclusions he stated in very plain language. The attack on M. de Quatrefages, gracefully made and richly deserved, was perhaps the most entertaining. For M. de Quatrefages, charged to present to the French Academy the work which was dedicated to him, and in which, while his good work was appreciated, his errors were exposed, thought it advisable to reply to some of M. Claparède's criticisms, and displayed some temper, and even hinted that the dedication was objectionable. The sequel to this is to be found in the dedication of the second volume of the "Annélides du Golfe de Naples." It is dedicated to Delle Chiaje. Perhaps, says M. Claparède, were he alive he would object to this dedication; he would see with regret many of his errors pointed out; although so much of his work is here confirmed, human vanity would suggest to him to refuse the dedication of a work, to which, however, posterity considers he is justly entitled. It is, he concludes, easier sometimes to dedicate a book to a dead than to a living man.

The ardent naturalist, the accurate observer, the brilliant artist, the keen critic, the lucid exponent, has ceased his work, but has left a name which may well cheer the most faint-hearted among us—even those who feel to want the physical vigour of their fellows—for it is to be remembered that the works which do most honour to the name of Edouard Claparède were the labours of a dying man.

E. R. L.

## ALEXANDER KEITH JOHNSTON, LL.D.

A MEMOIR of Mr. Johnston would be the record of a life laboriously and successfully devoted to the spread and popularisation of a single science. Mr. Johnston's first maps, the result of a walking excursion through the north of Scotland, appeared in 1830, and were issued in a Traveller's Guide-Book. His first large work was the "National Atlas," folio, on which he was assiduously engaged for upwards of five years, having projected and drawn the greater part of the maps (forty-five in number) and written nearly all the names they contain with his own hand. This work went through many editions, and was considered the best of its time.

Having, in the course of his residence in Germany, been much interested in the writings of Ritter, Humboldt, and Berghaus, on Physical Geography, and having learned that Humboldt had expressed a desire to see an English physical atlas constructed in a manner suited to the taste of the British public, and on a scale sufficient to admit of entering fully on the details of physical phenomena, Mr. Johnston visited Germany in 1842, travelling from Hamburgh to Vienna, collecting materials for such a work, and making arrangements for an extensive correspondence.

Previous to the commencement of Keith Johnston's Atlas, Physical Geography was an unknown term in Britain. Hence it was predicted that the work would be a failure, and it required great faith to enable him to persevere in his self-imposed task. He was unfortunate in his first publisher, who was not able to do much with so expensive a work; however, the first edition was sold off, and a second was called for, and published in 1856. The two editions occupied Mr. Johnston ten years of the best period of his life. These writings procured for him, in 1850, a Fellowship in the Royal Society of Edinburgh.

In 1850 appeared the first edition of his "Dictionary of Geography, Descriptive, Physical, Statistical, and Historical," 1 vol. 8vo., on a new plan, embracing numerous facts in the different branches of science not before noticed in similar works.

In 1851 the author constructed a Physical Globe of the earth, thirty inches in diameter, showing in colours its Geology, Hydrography, Meteorology, &c. &c. For this, the first Physical Globe ever drawn, the medal of the Great Exhibition of 1851 was awarded. The globe was not intended to be published.

Between 1851 and 1855, he constructed and published for educational purposes four Atlases, royal 8vo.—namely, General, Classical, Physical, and Astronomical, and one Elementary Atlas, small 4to. All these have been improved, some of them re-engraved, and as many as from five to thirty editions of each have been published, of 1,000 copies each. In 1852 he prepared an Atlas of Military Geography to accompany Alison's "History of Europe," 1 vol. 4to. This work was most favourably reviewed, and commended by military men.

In 1855 was commenced the "Royal Atlas of Modern Geography," on which the author brought to bear the geographical experience gained during the labours of a quarter of a century.

In 1865 the University of Edinburgh conferred on him the Honorary Degree of Doctor of Laws.

During the last four years Mr. Keith Johnston was engaged in the production and increase of a complete series of geographic works for schools.

From the brief notice which appeared in our last number, it will be seen that Mr. Johnston may be said to have died in harness, his active labours having been carried on till the close of his life.

## PAPERS ON IRON AND STEEL

### V.—THE BESSEMER PROCESS (*continued*)

In the previous papers I have described the phenomena presented during the different stages of the blow, and have endeavoured to explain the chemical actions upon which they depend. The next stage, that of adding the molten spiegeleisen to the iron which has been fully acted upon by the blast, also presents some interesting phenomena which have not hitherto been fully examined.

In a paper on "Burnt Iron and Burnt Steel," read before the Chemical Society 6th April last,* I showed that the "burnt iron" of the workman is really what its name implies, viz., iron which has been more or less oxidised throughout its substance, and that "burnt steel" is quite different,—that the presence of combined carbon in sufficient quantity effectually protects iron from oxidation by heat.

These conclusions are strikingly illustrated in the Bessemer process. In spite of the excessively high temperature and the abundant supply of oxygen during the blast producing most violent combustion of the material in the converter, I have found no "burnt iron" during the early or middle stages of the blow. This only appears at quite the latter stages when the carbon is nearly all burnt out. At the termination of the blow, the material left in the converter is burnt iron of a very exaggerated type in all cases where the burning out of the carbon has been carried to its full extent.

Mr. Bessemer failed in his attempts to produce malleable iron by his process, and all subsequent attempts have equally failed, even when the very finest qualities of hæmatite pig-iron have been used. I am not aware that any explanation of this has yet been given, but have no doubt that it depends upon the principle above stated, viz., that some combined carbon is absolutely necessary to preserve the iron from oxidation, and thus, as the carbon is removed, the iron begins to oxidise throughout, and we have an incoherent mixture of iron and particles of oxides, which crushes under the hammer or the rolls, is neither malleable nor ductile.

The degree of rottenness depends upon the extent to which the blow has been carried, and the iron thus produced varies from a quality which simply cracks at the edges when hammered or rolled, to a mass that crushes into granules like a piece of coarse sandstone. If inattention or some hitch in the machinery prevents the immediate turning over of the converter, and the blow is continued a few minutes too long, the amount of oxidation is so considerable that the mass in the converter loses its fluidity, and becomes a spongy and pasty mixture of melted iron and infusible oxide, which is rather troublesome to the manufacturer.

By the simple method described in the paper above-referred to, I have been able at once to detect the presence of entangled particles of oxide in the midst of the iron remaining in the converter at the end of the blow. They are even visible on the fracture of overblown iron.

The presence of this free oxide explains some otherwise inexplicable phenomena which accompany the pouring of the spiegeleisen. A furious ebullition of the molten metal takes place, jets of burning carbonic oxide spurt up violently from all parts of the surface; the converter is filled with the blue flame which pours forth from its mouth, producing the weird illumination I have already described. The outpouring flame so completely occupies the whole dimensions of the mouth of the converter, that no air can possibly enter, and thus all the oxygen required for the combustion which is going on must be derived from the material inside the converter. Some of the carbon of the spiegeleisen is thus burning at the expense of the oxide of the original charge, and this oxide is thereby reduced.

The sole function usually attributed to the spiegeleisen is that of converting the iron into steel; but if the above be correct, it performs, in addition to this, the important service of reducing the free oxide of the rotten burnt iron, and thereby rendering it malleable. We shall now understand why Mr. Bessemer and others have failed to produce malleable iron by directly oxidising the silicon, carbon, &c., of the pig-iron in the converter. It may be asked how then does the puddler remove the carbon from pig iron? My answer is simply that he does it by a far less violent process of oxidation; that towards the end of his work when the iron is "coming to nature," *i.e.*, when the proportion of protecting carbon has become very small, he takes especial precautions by closing the dampers, and otherwise diminishes the rate of oxidation as much as possible, and thus he is able to work down to less than $\frac{1}{10}$ per cent. of carbon without burning his iron.

The more violent oxidising agency of the Bessemer blast demands a greater quantity of carbon for the protection of the iron, and accordingly it is found that about 0·25 per cent. is the minimum limit of carbon which is practically obtainable without sacrifice of malleability. I have determined the carbon of many hundreds of samples of Bessemer steel which has been specially made as "mild" as possible, where it was a primary object to reach the minimum proportion of carbon, and have never found any sound metal to contain less than 0·20 per cent. The usual range of this (which is sometimes called "Bessemer metal" being scarcely steel although not true iron) is from 0·25 to 0·30 per cent. of carbon. I do not here speak of the limits of absolute possibility, but of the practical limits of the process as at present conducted.

I should add that, in the course of subsequent working the proportion of carbon is reduced, but the extent of this reduction is very variable, depending on the number of re-heatings, the amount of surface exposed, and the kind of furnace in which the reheating is conducted. By using a reducing flame the oxidation of the carbon may be wholly prevented, but in the ordinary reheating or mill furnace and in the exposure of rolling, &c., a certain amount of oxidation commonly occurs. Rails and tyres usually contain two or three hundredths per cent. less than the ingots from which they were made, thin plates and sheets lose a larger proportion, even as much as one-tenth per cent. in extreme instances. I have removed the whole of the carbon from the surface of a hard steel plate by exposing it for several days to the low red heat of an annealing furnace.

W. MATTIEU WILLIAMS

* An abstract of this paper will be found in NATURE, April 20, p. 497.

## THE CAUSE OF LOW BAROMETER IN THE POLAR REGIONS AND IN THE CENTRAL PART OF CYCLONES

In none of the treatises on Meteorology or Physical Geography is there to be found any satisfactory explanation of the observed low barometer in the polar regions, or in the centre of a cyclone. Observations show that in the Antarctic region there is a permanent depression of more than one inch below the average height nearer the equator, and in the Arctic region a depression of about half that amount; and also that for several days frequently the barometric pressure of the central part of a cyclone is one or two inches less than that of the exterior part. Mr. Buchan, in his excellent treatise on Meteorology, attributes the low barometer in the polar regions to the effect of the vapour in the atmosphere. If the amount of vapour in the polar regions was greater than in the equatorial, this effect, so far as it would go, would be in the right direction; but just the reverse is the case; for it is well known that the amount of vapour in the warm equatorial region is much in excess of that in the cold polar regions. Attempts have also been made, without success, to account for the depression in cyclones by the effect of centrifugal force.

By whatever cause so great a difference in the barometric pressure in the different regions might be produced, it may be shown from the principles of dynamics that the equilibrium would be restored in a very short time, if there was not some constant force tending to drive the atmosphere from the polar regions towards the equator, or from the centre of the cyclone to the exterior, and to keep it in that position. Such a force may be found in the influence of the earth's rotation. In a paper by the writer in the *Mathematical Monthly* in 1860, published in Cambridge, U.S., a full abstract of which was also published in the January No. of *Silliman's Journal* for 1861, the following very important principle was demonstrated:—In whatever direction a body moves on the surface of the earth, there is a force arising from the influence of the earth's rotation, which tends to deflect the body to the right in the northern hemisphere, and to the left in the southern hemisphere. This force, which is the key to the explanation of many phenomena in connection with the winds and currents of the ocean, does not seem to be understood by meteorologists and writers on physical geography. We see it frequently stated that the drift of rivers and currents of the ocean running north or south always tends to the right in our hemisphere, and that a railroad car running north or south presses to the right; and this is the case. But the same is true, and to exactly the same amount, of a current or of a railroad car running east or west, or in any other direction.

The amount of this deflecting force, when the velocity of the body is small in comparison with that of the earth's rotation, is expressed by $2 \cdot \frac{1}{289} \cdot \frac{v}{n} \cos \theta \, g$; in which $v$ is the lineal velocity of the body relatively to the earth's surface, $n$ that of the earth's rotation at the equator, $\theta$ the angle of polar distance, and $g$ the force of gravity. If the velocity is expressed in miles per hour, the expression in round numbers becomes $\frac{v \cos \theta}{150{,}000} g$; that is, for each mile of velocity per hour, the force is $\frac{1}{150{,}000}$ of gravity, multiplied into the cosine of the polar distance. Hence a railroad car on the parallel of 45° north, running in any direction at the rate of forty miles per hour, presses to the right with a force equal to about $\frac{1}{5{,}000}$ part of its weight.

The effect of this deflecting force upon what Mr. Stevenson calls the barometric gradient is easily estimated. Since the strata of equal pressure of the atmosphere, so far as this force is concerned, must be perpendicular to the resultant of this force and gravity, the sine of inclination of any such stratum to the earth's surface must be $\frac{v \cos \theta}{150{,}000}$, and the change in barometric pressure for any given distance is equal to the weight of a column of atmosphere of a height equal to the change of level of the stratum of equal pressure, and of a density equal to that at the earth's surface. The barometric gradient, then, as expressed by Mr. Stevenson, for any distance $d$ expressed in miles is $\frac{v \cos \theta \, d}{5 \times 150{,}000} \times 30$ inches; putting five miles for the height of a homogeneous atmosphere, and thirty inches for the pressure at the earth's surface. Round numbers are used throughout, since it is only the order of the effects we wish to determine, and not their exact amount.

According to all observations, there is a steady and very strong wind blowing all around the earth in the middle and higher latitudes of the southern hemisphere, with a velocity of at least twenty-five or thirty miles per hour at the surface of the ocean, and this is perhaps much greater in the upper strata of the atmosphere. If at the parallel of 50° we suppose the velocity of the wind $v$ to be thirty miles per hour, the preceding expression of the barometric gradient for a distance $d$ of 5° or 350 miles, using the cosine of 40°, is 0·33 inches of mercury. By reference to § 113 of Mr. Buchan's Meteorology, it will be seen that the barometric gradient for that parallel is only 0·28 inches for 5° of latitude, and that this is about the maximum gradient in the southern hemisphere. Hence a velocity less than 30 miles per hour at the surface of the sea, especially if we suppose that it increases in the higher regions, is sufficient to account for this maximum barometric gradient; and, according to observations, 20 or 30 miles per hour for the wind in that region is no unreasonable assumption. The eastward velocity of the wind in the different latitudes being known, and, consequently, the corresponding barometric gradients, the difference of barometric pressure between any parallel near the pole and one toward the equator, is readily obtained by integration. As the wind near the equator is toward the west the deflecting force there is *toward* instead of *from* the pole, and hence the greatest barometric pressure is about the parallel of 30°, and there is a slight depression at the equator. The deflecting force and the consequent depression are small, then, on account of the small value of $\theta$ near the equator.

Since there is more land and mountain ranges in the northern than in the southern hemisphere to obstruct the eastward motion of the atmosphere, its velocity is not so great, and consequently the polar depression is much less there than in the southern hemisphere. According to Mr. Buchan the barometric depression in the Arctic regions is much greater in the northern part of both the Atlantic and Pacific oceans, than it is in the same latitudes on the continents. The explanation of this is, that the eastward velocity of the atmosphere over the oceans being much greater than it is on the continents, where it is obstructed more by friction and mountain ranges, the force driving the atmosphere from the poles toward the equator is less, and consequently the barometric pressure is less in the northern part of both oceans than it is on the continents in the same latitudes.

Upon the relative strength of the forces tending to drive the atmosphere from the poles towards the equator, depend the positions of the equatorial and the tropical calm belts. This force being strongest in the southern hemisphere on account of less resistance from friction and mountain ranges, the mean position of the equatorial calm belt is a little north of the equator, and the positions of the others a little farther north than they would otherwise be. The prime motive power also in both hemispheres being the difference of density of the atmosphere between the polar and the equatorial regions, arising from a difference of temperature and of the amount of aqueous vapour, during our summer when this difference is less than the average in the northern hemisphere, and greater in the southern, these calm belts are forced a little north of their mean positions. Of course, just the reverse of this happens during our winter; hence we have an explanation of the annual variations of the positions of these belts.

In the case of cyclones, the atmosphere at the earth's surface being forced in from all sides towards the centre, by the force arising from a difference of density of the atmosphere in the central and exterior parts, it cannot, on account of the deflecting force which has been explained, move toward the centre, without, at the same time, receiving a gyratory motion around that centre. Neither can it have a gyratory motion without also having a motion towards that centre, since in that case there would be no force to overcome the frictions of gyration. Hence, neither the radial theory of Espy, nor the strictly gyrating theory of Reid and others, can be true, though either of them may be approximately so in special cases. But the gyratory part of the motion is not caused by the motion of the atmosphere from the north and south only toward the centre of the cyclone, as stated by Mr. Buchan and others, but equally by the different parts moving in from all sides, since in whatever direction they move toward the centre there is the same deflecting force, either to the right or the left according to the hemisphere.

The motion of the atmosphere being in a spiral toward and around the centre of the cyclone, the deflecting force depending upon the earth's rotation, at right angles to the direction of motion, being resolved in the directions of the radius of gyration and tangent, the latter overcomes the friction of gyration, and the former causes a pressure from the centre, decreasing the height of the strata of equal pressure in the cyclone, and consequently diminishing the barometric pressure. The barometric gradient of a cyclone is estimated in precisely the same way as in the case of the hemispheres, using for $v$ the lineal velocity of gyration obtained by resolving the real motion into the directions of the tangent of gyration and of the radius. It has been seen that a velocity of 30 miles per hour gives a barometric gradient of $\frac{1}{3}$ of an inch in 350 miles on the parallel of 50. A gyratory velocity therefore of 100 miles per hour would give a barometric gradient of one inch of mercury in about 300 miles. The velocities of gyration being known at all distances from the centre of motion, and consequently the barometric gradients, the difference of barometric pressure between the centre and the exterior, so far as it depends upon the gyratory motion, may be obtained by integration. The effect of the centrifugal force of the gyrations is generally only a very small quantity of a second order, in comparison with the other, and the effect of it is entirely insensible, except in the case of small tornadoes, when the gyrations are very rapid close around the centre.

In all the preceding estimates of the barometric gradient, it should be understood that the results belong merely to the force depending upon the earth's rotation, and to this must be added the part belonging to a difference of density of the atmosphere, which in the case of cyclones increases the gradient, but diminishes it in the case of the hemisphere. For the general motions of each hemisphere form a cyclone, with the pole as a centre; but having the denser instead of the rarer portion of the atmosphere at that centre. Hence the motions in any vertical plane through the centre are reversed, and it becomes what has been called an anti-cyclone.

Cambridge, Mass. WM. FERREL

## RECENT MOA REMAINS IN NEW ZEALAND

II.

THE Moa's neck with the integuments attached, the discovery of which was announced in my communication dated April 3, has since then been forwarded to this Museum for examination by Dr. Thompson, and the following particulars may not be without interest to your readers.

The total length of the specimen is 16·5 inches, and includes the first dorsal and last six cervical vertebræ with the integuments and shrivelled tissues enveloping them on the left side. The surfaces of the bones on the right side, where not covered by the integuments, are free from all membranes and other tissues, but are quite perfect and in good preservation, without being in the least degree mineralised.

The margin of the fragment of skin is sharply defined along the dorsal edge, but elsewhere it is soft, easily pulverised, and passes into adipocere.

The circumference of the neck of the bird at the upper part of the specimen appears to have been about 18 inches, and the thickness of the skin about $\frac{1}{16}$ of an inch.

The only indication of the kind of matrix in which it had been imbedded was a fine micaceous sand, which covered every part of the specimen like dust, there being no clay or other adherent matrix. On removing this sand with a soft brush from the skin, it was discovered to be of a dirty red-brown colour, and to form deep tranverse folds, especially towards the upper part. The surface is roughened by elevated conical papillæ, from the apex of some of which springs a slender transparent feather barrel, never longer than half an inch. On the dorsal surface a few of these quills still carry fragments of the webs, some being 2 inches in length. From these it appears that the colour of the feather barbs was chesnut-red, as in Apterix Australis, but that each barrel had two equal plumules to each quill, as in the Emu and Cassowary, and in this respect differed from the Apterix, the feathers of which have not even an accessary plumule. On the other hand the barbs of the webs of the feathers do not seem to be soft and downy towards the base as in the Emu.

From the direction of the stumps of the feathers, it is evident that the portion of the neck which has been preserved is that contained within the trunk of the body, and which, in the natural position, has a downward slope, the conical end of the specimen being where the upward sweep of the neck of the bird commenced, which accounts for the absence of the trachea with its hard bony rings, none of which are found among the soft parts which have been preserved.

The integument was easily removed by dividing the few threads of dried tissue by which it was attached. The shrivelled-up soft parts thus displayed could not be clearly distinguished, but may be grouped as follows:—1. A strong band of ligamentous tissue connecting the spinous processes. 2. Inter-vertebral muscles and ligaments. 3. A sheath diverging from the lower part as if to enclose the thorax. The only bone besides the vertebræ was attached to this sheath by its tip, the other extremity being articulated to the first dorsal.

Respecting the nature of the circumstances to which this remarkable specimen owes its preservation, I can only conjecture that the body of the bird must for a considerable period have lain on its side in water or a swamp, and that the portion immersed was thoroughly macerated, while the exposed parts were desiccated and shrivelled up; and that subsequently the whole remains were embedded in dry sand.

As a fact of some interest connected with the history of the Moa, I should mention that in December last, Archdeacon Williams informed me of the discovery of a series of enormous bird-foot marks on the surface of a layer of sand beneath a bed of alluvium at Poverty Bay. The specimens he collected for me have unfortunately gone astray, but others have been placed in the Museums in Auckland and Napier, and I have just seen a pencil rubbing from the latter, taken by Mr. Cockburn Hood, which leaves no doubt that they are the footprints of a bird like the smaller-sized species of Dinornis, the largest of these footprints being about eight inches in length.

JAMES HECTOR

Colonial Museum, Wellington, New Zealand, May 15

[We exceedingly regret that we are unable to reproduce woodcuts of the beautiful illustrations by which Dr. Hector's article is accompanied.—ED.]

## NOTES

WE are glad to learn that our anticipations last week with reference to the Australian observations of the Total Solar Eclipse of December next are being realised. The Royal Society of New South Wales is organising an expedition to Cape Sidmouth, a little south of Cape York. The President of the Royal Society of London has arranged that a few instruments of the newest construction shall be sent out from this country.

IT perhaps is not so generally known as it ought to be that the Emperor of Brazil, now in this country, is an enthusiastic astronomer, and has an appreciation of the value of science which places him in the highest rank among reigning sovereigns. During the last week he has visited the Royal and Mr. Huggins's Observatory, and in a long interview with Mr. Lockyer has discussed the bearings of the recent solar discoveries.

The *Pall Mall Gazette* states that the Emperor Napoleon is about to visit Mr. R. S. Newall, whose magnificent refractor has already been described in these pages.

The Royal Commission on Scientific Instruction and the Advancement of Science adjourned on Tuesday last till November. We are informed that the publication of some of the evidence already taken may shortly be expected.

The first General Meeting of the approaching session of the British Association at Edinburgh will be held on Wednesday, August 2, at 8 P.M., when Prof. Huxley will resign the chair, and Prof. Sir William Thomson will assume the presidency, and deliver an address. On Thursday evening, August 3, at 8.30 P.M., there will be a Discourse by Prof. Abel on some recent Investigations and Applications of Explosive Agents; on Friday evening, August 4, at 8 P.M., a Soirée; on Monday evening, August 7, at 8.30 P.M., a Discourse by Mr. E. B. Tylor on the Relation of Primitive to Modern Civilisation; on Tuesday evening, August 8, at 8 P.M., a Soirée; on Wednesday, August 9, the concluding general meeting will be held at 2.30 P.M.

We are glad to notice the step recently taken by the Committee of St. Mary's Medical School, in establishing Scholarships in Natural Science, open to public competition. Through the very proper action of the Governors of the Hospital, the share of school fees formerly paid to the charity has been appropriated to the improvement of the school. By this means the Committee has been enabled not only to provide a tutor to assist the students in the practical portion of their work, but also to establish three Scholarships in Natural Science, each of the annual value of 40*l.*, and tenable for three years. The first of these, and an annual exhibition of 20*l.*, will be awarded by open competitive examination in September next. The tendency of these Scholarships will be to favour what we have so often advocated, the acquisition of a proper amount of scientific knowledge pre vious to entering upon a regular course of medical study.

The *Lancet* states that the Council of the College of Surgeons of England have withdrawn their opposition to that portion of the scheme of the College of Physicians which provides for the selection of examiners by a central Board composed of the representatives of the various licensing bodies and universities, and have agreed to give up the power of specially nominating examiners in special subjects. Thus the main difficulty in coming to an agreement upon the question of a conjoint examination has been removed. The Apothecaries' Hall will probably be left out in the cold.

The number of successful candidates at the recent Matriculation Examination at the University of London was 242, of whom only 30 passed in honours. This shows a larger proportion of failures than on any previous occasion, notwithstanding that the novel practice was introduced of optional questions, only a certain proportion being expected to be answered in some of the papers.

The Anniversary meeting of the Quekett Microscopical Club will be held on Friday the 28th inst., at 8 P.M., at University College, Gower Street.

The first number is issued of the "Journal of the Anthropological Institute of Great Britain and Ireland," being the first substantial result of the union of the two old societies, the Ethnological and the Anthropological Societies. We are glad to see this evidence of the concentration of power thus effected.

The Annual Meeting of the British Horological Institute was held on July 11, Mr. John Jones, vice-president, in the chair. The report of the Council for the past year was read by Mr. Henry Moore, resident secretary. One of the most interesting features of the report was the fact that the Baroness Burdett Coutts has, agreeably to that line of action for which she has been distinguished, volunteered a prize for the best essay on "The Balance Spring and its isochronal Adjustments." The Astronomer Royal, Sir C. Wheatstone, and Mr. James F. Cole will be the judges. The attention of the Lord Mayor, the head of the guilds of the City of London, bodies entrusted with power specially to promote purposes similar to those aimed at by the Institute, has been attracted by the efforts of the Institute, and he has promised to distribute the prizes to the successful students in horological drawing. Lectures were delivered in the past half year by Mr. Perrell, Mr. Herrmann, Mr. Charles Frodsham, and Mr. John Jas. Hall. The following are the chief officers elected for the ensuing year:—President: Mr. Edmund Beckett Denison, LL.D., Q C. Vice-presidents: Mr. C. I. Klaftenberger, E. D. Johnson, and John Jones. Treasurer: S. Jackson.

The Government of Bavaria has been long engaged in the publication of a History of Science in Germany. The following volumes have already appeared:—Bluntschli's History of Political Law; Kobell's of Mineralogy; Fraas's of Agriculture; Peschel's of Geography; Lotze's of Æsthetics; Benfey's of Philology; Raumer's of German Philology; Kopp's of Chemistry; and the following are in preparation:—Zeller's of Philosophy; Bursian's of Classic Philology; Bernhardi's of Military Science; Wegele's of History; Stintzing's of Jurisprudence; Karmarsch's of Technology; Gerhard's of Mathematics; Jolly's of Physics; Wolf's of Astronomy; Ewald's of Geology; Hirsch's of Medicine and Physiology; Carus's of Zoology. When may we look for anything of the kind from our enlightened Government?

With the July number of the Journal of the Franklin Institute of Philadelphia, Dr. W. H. Wahl becomes sole editor.

We have received the Catalogue of the Iowa State University for 1870-71. The students are divided into law, medical, normal, and academical departments, the students in all the departments, except that of law, being of both sexes, and some of the instructors being also ladies. The full course of instruction in the academical department occupies five years; during the first three years nearly the same course of study is followed by all the students; during the last two years the course is elective, either literary or scientific. The University is wholly sustained by endowments and state appropriations, the fees even for the medical classes being merely nominal. Good opportunity appears to be afforded for the practical study of natural and physical science, and the "School Laboratory of Physical Science," edited by Dr. G. Hinrichs, the Professor of Physical Science, is published at the University.

*Les Mondes* prints a list of the new taxes imposed by the French Government on articles of consumption and commerce.

An additional excursion of the Geologists' Association took place on the 10th and 11th inst. to Warwick and neighbourhood. The sections of the Lower Lias were examined, and the extensive quarries worked for material for hydraulic cement were visited. A special object of interest was the insect-beds occurring in the Lias at Wilmcote, near Stratford-on-Avon.

We learn from the *Journal de Méd. de l'Ouest*, and *Bull. Génér. de Thér.* that Dr. Weir Mitchell, from observations on the bite of the rattlesnake, and MM. Gicquain and Viaud Grand-Marais, from observations on that of the viper, have arrived at the conclusion that the application of carbolic acid immediately on the receipt of the injury prevents both local and general poisoning. The pure acid however, if applied in too great quantity, is liable to produce sloughing, and even dangerous symptoms; hence it is best used in the proportion of two parts of acid and one of alcohol. Given internally, or applied to the wound at a late period, it produces no effect. It is believed to act, not by neutralising the poison, but by causing contraction of the small vessels, and thus preventing its absorption.

THE following interesting account was published in *Notes and Queries* of August last year without eliciting any reply. Mr. Alexander Williams writes :—"As the Commissioner for Western Australia of the International Exhibition of 1862, I received from the Colonial Committee at Perth several specimens of native shields. The long narrow form of these implements of defence is common to all the Australian colonies I believe, but I cannot say whether the ornamentation is uniformly the same. But among the Swan River nation it consists of an oblong pattern (following the shape of the shield) composed of border within border, traced in different coloured paint. The late Mr. Christy called my attention to the exact similarity of these shields to those used by the natives of Central Africa—a similarity not only in shape and pattern but actually in the succession of colours in the pattern. How is this to be accounted for? It is possible (and no other theory seems admissible) that it is purely an accidental coincidence. It is perhaps not difficult of belief that the native mind in two races in all respects so utterly distinct should have hit upon the same shape and form of weapon to meet and throw off the common spear. It is even not very surprising that savages unacquainted with 'lines of beauty' should adopt the same crude form of ornamentation, but it is somewhat startling I think that they should have used apparently the same pigments, and very extraordinary as it appears to me that they should have adopted precisely the same succession of colours."

WHILST we have been literally overwhelmed with rain in this country for the last three months, it is interesting to hear that in Tientsin in China there was so little snow in the winter, and hardly any rain has fallen since, that the peasantry are complaining of the want of water, and consequent injury to the crops.

A SEVERE earthquake shock is reported from Brooklyn and Staten Island, New York, on the 19th of last month at about 10 P.M. No great amount of damage was done, and the motion appears vertical rather than horizontal in character.

THE *American Journal of Science* gives a long report of the severe earthquake at Oaha, Hawaian Islands, on February 18 of this year. It commenced at about 11 minutes past 10 P.M., and lasted about a minute. The direction of motion was vertical, with a rocking movement N.E. and S.W. The usual roaring sound preceded the earthquake and was heard far out at sea. No earthquake wave is reported from any quarter, although the earthquake itself seems to have been felt on all the islands more or less severely. No unusual volcanic action is reported. Slight shocks were also felt on the 22nd and 24th of the same month. It should be noticed that a severe earthquake is reported from Chile on the 25th, and shocks were noticed in Peru on the 22nd and 23rd of February.

THE existence of certain plants only in limited districts is one of the most remarkable points of interest in connection with the problem of the distribution of species. Mr. Moggridge, in his valuable "Contributions to the Flora of Mentone," figures a very elegant species of *Leucojum*, of which no drawing had hitherto been published. "It is believed to have but one habitat on the face of the earth, claiming only a small strip of rocky shore reaching from Nice to about two miles east of Mentone. *Leucojum hyemale* grows in a stony soil, and out of the cracks of the hardest limestone rocks at Port St. Louis, Cape Veglio, on the way to Monaco, and at some height on the Aggel mountain, besides other less abundant localities." We are not aware whether this species has been introduced to English gardens, but it would be a very desirable acquisition. At Mentone it flowers in April.

THE Ant-eating Woodpecker (*Melanerpes formicivorus*) a common Californian species, has a curious and peculiar method of laying up provision against the inclement season. Small round holes are dug in the bark of the pine and oak, into each one of which is inserted an acorn, and so tightly is it fitted or driven in, that it is with difficulty extracted. The bark of the pine trees, when thus filled, presents at a short distance the appearance of being studded with brass-headed nails. Stowed away in large quantities in this manner, the acorns not only supply the wants of the woodpecker, but the squirrels, mice, and jays avail themselves likewise of the fruits of its provident labour.

DR. GEORGE STUCKLEY gives an interesting account of the Western Mole (*Scalops Townsendii*), which occurs in the Oregon and Washington Territories. He kept a specimen for some time in a box, at the bottom of which was a quantity of rich black loam. When disturbed it instinctively endeavoured to escape by burrowing in the earth of the box, using its long-pointed nose as a wedge to pioneer the way. The excavation was performed by its broad stout hands, which, surmounted with their long sharp claws, seemed admirably adapted for the purpose. The fore paws were worked alternately as in swimming, the hind feet acting as propellers. Although the earth in the box was soft and friable, it was nevertheless a matter of astonishment to see how rapidly the little creature could travel through it. When he slept it was in a sitting posture, with the body curled forward and the neck strongly bent, so that the nose rested between the hind legs. He thus assumed the shape of a ball, evidently his ordinary position when asleep.

THE cultivation of the poppy in China, which has been more than once prohibited by Imperial edicts, appears to be increasing everywhere, and becoming a profitable trade. In Szechuen, where the climate is warm and the season early, two crops at least are produced on the same ground annually. The seed of the poppy is sown in February, the plants flower in April, and the fruits are so far matured by the middle of May, that the juice is collected, and the stalks removed and burnt directly after, but previous to this the second crop, which may be either Indian corn, cotton, or tobacco, is sown, so that almost by the time the poppy is cleared from the field the new crop makes its appearance. The profit derived from the cultivation of the poppy is not only the result of a fair market value and a ready sale, but also from the fact that much of the work in the plantation, especially the gathering of the juice, can be done by the children of the family. The scratchings or incisions being made in the capsules in the morning, the juice which has oozed out in the course of the day is collected in the evening, and after simply exposing it to the sun for a few days it is ready for packing. The seed not required for sowing is used for food.

## *ON THE RECENT SOLAR ECLIPSE**

I.

MY duty to-night, a pleasant one, although it is tinged with a certain sense of disappointment, is to bring before you the observations which were made of the recent eclipse in Spain and Sicily, to connect them with our former knowledge, and to show in what points our knowledge has been extended. In these observations, as you know, we had nothing to do with the sun as ordinarily visible, but with the most delicate phenomenon which becomes visible to us during eclipses. I refer to the Corona.

### *General Notions of the Corona*

Let me, in the first place, show you what is meant by this

* A Lecture delivered at the Royal Institution, Friday, March 17, 1871

term, and state the nature of the problems we had before us. I have here some admirable drawings, which I will show by means of the lamp, of the eclipse that was observed in 1851 by several astronomers who left England in that year to make observations in Sweden, where the eclipse was visible. You must bear in mind that the drawings I shall bring to your notice were made in the same region, at places not more than a few miles apart.* The first drawing was made by an observer whose name is a sufficient guarantee for its accuracy—I refer to Mr. Carrington—*and when the sky was absolutely free from clouds.* In the next diagram you will see the corona is changed. The bright region round the sun is no longer limited to the narrow border of light round the dark moon, as seen by Mr. Carrington, but it is considerably expanded. The third gives still a greater extension, although that picture was drawn within a quarter of a mile of the place where Mr. Carrington's was taken. And lastly, we have a drawing made by the present Astronomer Royal, of that same eclipse, *through a cirrostratus cloud* as unlike Mr. Carrington's as anything can possibly be. So that you see we began with a thin band of light about the moon, which would make the corona a few thousand miles high, and we end with a figure which Mr. Airy graphically likens to the ornament round a compass-card, and which gives the corona a height equal to about once and a half the sun's diameter.

I will next bring before you some drawings made during the eclipse of 1858, which was not observed in European regions, but in South America by two first-rate observers—one, M. Liais, a French astronomer, who was stationed at Olmos, in Brazil; the other, Lieutenant Gilliss, who was also there as a representative of the American Government, and observed some thousand miles away in Peru.

I will throw on the screen the appearances observed by these gentlemen, and I think you will acknowledge the same variations between their results, as to degree, while in one case we get a perfectly new idea of the phenomena—a difference in kind. I would especially call attention in the Olmos drawing to those extraordinary bundles of rays of wonderful shapes, which you see are so much brighter than the other portions of the corona. Such forms have been seen in other eclipses, but they are somewhat rare. The drawing made by Lieutenant Gilliss bears the same relation to that made by M. Liais as Mr. Carrington's did to the Astronomer Royal's; so that we may say that we not only get variations in the dimensions of the corona as seen at different stations, but that we furthermore get a strange structure introduced now and then in our drawing in regions where absolutely no corona at all exists in the other.

So much by way of defining the phenomena and giving an idea of the eye observations generally.

Let me now attempt to show you how the phenomena observed in the last eclipse bear upon the results which had been previously accumulated by means of telescopic and naked-eye observations, and by means of the polariscope and spectroscope.

## I.—Telescopic and Naked-eye Observations

### *a.—A Part of the Corona is undoubtedly Solar*

The first use I propose to make of the telescopic and naked-eye observations of last year is to show you a photographic copy of an admirable drawing made by Mr. Brett, who, though unfortunate enough to see the sun only for a very short time, was yet sufficiently skilled to make good use of that brief period. This drawing will bring before you the fact that even when a large portion of the sun remained unobscured by the moon, Mr. Brett was enabled to see a dim ring of light round the unobscured portion, which since the year 1722 has been acknowledged, beyond all question, I think I may say, to represent something *at the sun.* It was observed in 1722 round the uneclipsed sun, and in more recent times by Mrs. Airy in 1842, and by Rumker $1\frac{1}{2}$ minute before totality in 1860, not to mention other instances. Therefore we have one observation made during this eclipse, confirming the old one, that in the corona there is a region of some small breadth at all events which is absolutely solar, and which it only requires a diminution of the solar light to enable us to see. This, then, we may look upon as the known; now let us feel our way gradually outwards.

### *b.—Rays, or Streamers, are added at Totality*

The drawings made in all the eclipses which have been carefully recorded bring before us quite outside this narrow, undoubtedly *solar region*, observed before totality, as I have shown, and also by Mr. Carrington, and by Lieutenant Gilliss during totality in 1851 and 1858, extraordinary appearances of a different order. While in fact we have a solar ring from 2′ to 6′ high, we have rays of all shapes and sizes visible outside, in some cases extending as far as 4°, and in all cases brighter than the outer corona on which they are seen, the rays being different in different eclipses, and appearing differently to different observers of the same eclipse, and even at the same station. Here is a copy of a drawing made by M. Rumker of the eclipse of 1860, and I show it for the purpose of calling your attention to the fact that the two curious rays represented in it belong to a different order of things from those which we see in the rest of the corona. From the beginning to the middle of the eclipse the east rays were the most intense. In the next drawing, which was made by the same observer, you see something absolutely new; and now the western side of the corona is the most developed; we have a new series of bright rays, and altogether it is difficult to believe that it is a drawing made by the same observer of the same eclipse.

The third drawing is a representation of the same eclipse by M. Marquez, who observed with a perfection of minute care which has scarcely ever been equalled: I bring it before you to show that the rays he saw were altogether differently situated. We may conclude then that the rays, although extremely definite and bright—as bright or brighter than the other portions of the corona which are visible before totality, they being *invisible* before totality—appear different to different observers of the same eclipse, and to the same observer during different *phases.*

### *c.—They Change from Side to Side*

I have already said that M. Rumker observed that from the beginning to the middle of totality the rays on the *east* side of the sun were longest and brightest, and that from the middle to the end of totality the rays on that side of the sun where the totality ended were longest and brightest.

We will now carry this observation a step further, by referring to three drawings made by M. Plantamour in the same eclipse, that of 1860. In the first drawing we have the beginning of the total eclipse as seen in the telescope; with the naked eye naturally we should get the sun disappearing at the east or left-hand side, the moon moving from west to east; in the telescope things are reversed, and we have it right instead of left: and here we have the same thing that M. Rumker observed, namely, that when the eastern limbs were in contact, bright rays (M. Plantamour saw three) were visible on the side at which the contact took place. When the moon was half way over the sun, *two* rays of reduced brilliancy were observed on that side, not necessarily in the same position as *those* first observed, but one of *these* has been abolished altogether; and on the other side of the sun, where totality was about to end, we have three rays gradually suggesting themselves: at the end of totality the rays visible at the commencement are abolished, and now instead of them and of those seen at the middle of the eclipse, we have a bran new set of rays on the side of the moon from whence the sun is about to emerge.

This observation I need hardly say is of considerable importance in connection with the fact that from the year 1722 almost every observer of a total eclipse has stated that there is a large increase of brilliancy, and an increase of the size of the corona on the side where the sun has just been covered, or is just about to emerge.

Now, what was there bearing on this point in the recent observations? I have here three drawings, which, though roughly done, you will see are of great importance side by side with those of M. Plantamour. These are drawings which have been sent in to the Organising Committee by Mr. Gilman, who lives in Spain, and who took considerable interest in the eclipse, and sent the results of his observations to England with the eclipse party when they came home; and it is of importance that you should see everything that Mr. Gilman has done. If you agree with this explanation of the square form of the corona, which was observed in Spain this year, it will explainl the quadrangular form observed in the corona in a good

* Mr. Carrington observed at Lilla Edet, on the Grota River. The Astronomer Royal observed at Göttenburg. The second drawing referred to was made by Pettersen, at Göttenburg; the third by a friend of the Rev. T. Chevalier, at the same place; and I might have added another by Fearnley, taken at Rixhöft, in which the corona is larger than in any of the others. The series is most instructive. See Mem. R. A. S. vol. xxi.

many previous eclipses. Mr. Gilman says that at the commencement of totality—let me remind you, the commencement was determined by the disappearance of the sun at the east limb of the moon, which is east in Mr. Gilman's drawing, as he was observing with the naked eye—the commencement, he says, was determined by the corona flashing out very much like a capital D. You see on the black board exactly the outline, and you will at once mentally associate one half of the diagram with the rays observed by M. Plantamour, and the other half, in which there is a nearly perfect ring of light round the moon, with the corona observed by Mr. Carrington all round it in a cloudless sky. At mid-eclipse Mr. Gilman also observed the corona, sketched out its outline carefully, and found rays coming out on the opposite side, adding themselves on to the perfect ring first seen there. Opposite the two salient angles he observed at the commencement of totality—represented by the top and bottom of the upright stroke of the capital D—there were two others; *the corona now appeared square*, and then, just before the end of totality came on, the two corners first seen were observed to disappear altogether, leaving nothing but a perfect ring, and where, at the beginning of the eclipse, nothing was seen but a perfectly round ring, the two exactly similar forms on the opposite side shot forth, and you got a D reversed (ᗡ). Mr. Warrington Smyth, who drew a square corona, saw the light flash out into the corona before the end of totality, and believes that all the angles of the square were not visible at one and the same time.

Here, then, you have observations of exactly the same character as those of M. Plantamour, to which I have referred. In the drawings of both are shown the inner part of the corona, which you saw growing in the observations of 1851, to which were added the strange forms observed in 1858. You have these strange variations positively growing at the same place and the same time, in the same and in different eyes. Obviously there must be very much that is non-solar, call it personality, atmospheric effect, or what you will, connected with it. We have added to the stable the unstable. The question is, to what is this unstable portion due?

*d.—They are very variously represented*

I will now refer to other drawings of the late eclipse, which were made in Sicily. For some reason or other, which I do not profess to understand, the corona, which appeared in Spain to be square, and to Mr. Gilman like a D at the beginning, and like a D reversed (ᗡ) at the end,—to all those with whom I have conversed who saw it in Sicily, it appeared as round as you see it here, in this drawing made by Mr. Griffiths; and, instead of being square, we had sent to us all sorts of pictures, a large number of them representing a stellate figure. Here is a drawing made by a Fellow of the Royal Society, on board one of Her Majesty's ships (the *Lord Warden*) which were trying to save the poor *Psyche* at Catania. In this we have perfectly regular rays drawn from every region of the sun, some long, some short, but similar rays are almost invariably opposite each other; but in the interior, inside these rays, the corona is just as it was observed by Mr. Griffiths at Syracuse. I now show you a drawing made by an American gentleman at sea, between Catania and Syracuse, with one ridiculously long ray, a ray as long as was seen by Otto Struve in 1860. Other drawings were made, even on board the same ship, so unlike each other, and so bizarre, that I need only refer to them as showing that there at all events must be some personality. We have then to account for the variations between the observations made in Spain and those made in Sicily. I regret that we have not a third order of difficulties to contend with, as doubtless we should have had if observations had been made by Mr. Huggins' party in North Africa.

*e.—The Rays are accompanied by a Mass of Light.*

These changes of the rays from side to side are accompanied by, and are perhaps to a certain extent due to, the bursting forth of brilliant light in their neighbourhood, where the limbs are nearest in contact. This was first observed by Miraldi in the eclipse of 1724, and has frequently been recorded since. Mr. Warrington Smyth, to whom I have before alluded, states that he noticed this in the last eclipse, and the photographs, I think, have recorded it; but as there is some uncertainty on this point, I need only suggest it.

*f.—Long Rays are seen extending from the Cusps before and after Totality*

So far I have referred only to the rays visible during totality, but long rays were seen when a crescent of the sun was visible in 1860 and 1868 by Mr. Galton and Mr. Hennessy. Mr. Brett caught the same phenomenon last year; but as the sky was cloudy the commencements of the rays only were seen, appearing like delicate brushes in prolongation of the cusps. These observations are of great value, *as no one for one moment imagines that these rays are solar*, and yet they are very like those seen during totality.

*g.—Sometimes Dark Rays, called Rifts, are seen instead of Bright ones*

Those rays to which I have referred are, however, not the only kind of rays that are observed. At times are seen, as it were, openings in the corona; the openings being of the same shape as the rays, that is, expanding as they leave the dark moon, and opening more or less exactly as the rays do. Like the rays also they are sometimes very numerous; in other eclipses they are few in number. Let us take the eclipse observed in India in 1868. Several drawings made there showed the corona as square as it was drawn in Spain last year; others as round as it was seen in Sicily; but the eclipse was not observed only in India, it was observed at Mantawalok-Kelee by Captain Bullock, and at Whae-Whan, on the east coast of the Malayan Peninsula, by Sir Harry St. George Ord, Governor of the Straits Settlements. In the former place we had rifts expanding rapidly as they left the sun—one forms an angle of 90°, the sides of another being *parallel*—separating patches of corona, which in some places extends $2\frac{1}{2}$ diameters of the moon from the sun.

At Whae-Whan we are told that at one particular moment of the eclipse "it was noticed that from several points in the moon's circumference darker rays emanated, extending to a considerable distance into space, and appearing like shadows cast forth into space by something not very well defined;" these dark rays afterwards "diminishing."

Now let us pass on to the eclipse of 1869. In two drawings made by Dr. Gould, in which the changes in the bright bundles of rays come out in a most unmistakable way, we get similar rifts, which changed as violently as did the rays; while in another drawing made by Mr. Gilman, the whole corona is furrowed by narrow rifts in all regions lying between violet, mauve-coloured, white, and yellowish white rays!

Now, what have we bearing on this point in the recent observations? No rift was *seen* in Sicily; one rift was recorded by the sketchers in Spain, but more than one rift was photographed in both places. We must remember, however, in thus bringing eye-sketches and photographs into comparison, first that the eye too often in such observations retains a general impression of the whole phenomenon, while the plate records the phenomenon as it existed at the time at which it was exposed; and secondly, that we know that the plates record chemically, while the eye records visually. We are dealing with two different kinds of light.

I will show you two photographs on the screen. Although the lucid intervals were very rare, we were fortunate enough to get one photograph of the coronal regions in Syracuse, and one in Spain. I now show you the photograph made by the American party in Spain. You see here that, probably owing to a cloud, we get a certain amount of light driven on to the dark moon, and you also see the indications of the rifts. This photograph was taken with an instrument with a small field of view, so that the most important parts of the corona were rendered invisible by the instrument itself.

Lord Lindsay, who also photographed in Spain, recorded no rifts.

In the other photograph, taken at Syracuse, the result is better. We have the equivalent of the rift in the photograph I showed you before. The instrument was extremely unsteady, and the definition not so good as it would have been if Mr. Brothers had had a good opportunity of displaying his skill. We get other fainter indications of other rifts here and there, and the question whether these rifts agree in the photograph taken in Spain with those in that taken in Syracuse is one of great importance; and it is to be hoped that before long it will be set at rest. Some observers think they agree; others think they do not.

But there is an important consideration based on that photograph, to which I must draw your particular attention. I have shown you the photograph as it may be thrown on the screen; but in the photograph itself there are delicate details which it is impossible to reproduce. The dark portions in the corona indicated in the copy I have shown you are merely the bases of so many dark wedges driving out into space, like their prototypes in the Indian eclipse. It is Mr. Brothers's opinion, I believe, that all you see on the screen round the dark moon, all that enormous mass of light, nearly uniform in texture, and these beautiful broad rays between the rifts are really and absolutely parts of the solar corona. I confess I do not wish to commit myself to such an opinion. We want more facts, and the *onus probandi* lies with those who insist upon that view, and I have yet to hear an explanation of them on that basis.

*h.—The Corona sometimes seems to be Flickering or Rotating.*

We now come to the next point. Time out of mind, that is, for the last two centuries, the corona has been observed to be flickering, waving, or rotating, moving in every conceivable way and direction. In 1652 it was described as "a pleasant spectacle of rotatory motion." Don Antonio Ulloa remarked of the corona observed in the eclipse of 1788, "It seemed to be endued with a rapid rotatory motion, which caused it to resemble a firework turning round its centre." The terms whirling and flickering were applied in the eclipse of 1860. This extraordinary condition of things was also thoroughly endorsed by the late observations. It certainly exists, and is among the observations we have to take into account. When I saw an officer of one of the ships at Catania, I asked him if he had taken a drawing of the corona. "No," he said. I asked him, "Did you see any rays?" "Yes." "Then why did you not make any drawing of them?" His answer was, "How on earth could you draw a thing that was going round and round like a firework?" This was not the only observation of the kind, and the tendency of such observations I need hardly say is to strengthen a belief in the unstable, and therefore uncosmical, nature of their rays.

Is this variation of light due to the brilliancy of the corona, and the rapid change of the rays, which is one of the results which comes out clearest? In 1842 the brilliancy of the corona was stated to be insupportable to the naked eye. A similar remark was made to me by several of those officers who saw the last eclipse in Sicily. J. NORMAN LOCKYER

(*To be continued.*)

## SCIENTIFIC INTELLIGENCE FROM AMERICA*

PROF. LEIDY has lately announced to the Philadelphia Academy of Natural Sciences the existence of some new fossil mammals from the Tertiary formations of Wyoming Territory. One was a tower jaw, discovered by Dr. J. Van A. Carter in the vicinity of Fort Bridger. The animal to which it belonged was as large as a hog, but was more nearly allied to the rhinoceros or tapirs. It was especially remarkable for the possession of a large pair of front teeth, resembling, both in form and construction, the incisors of the beaver. The name proposed for it was *Trogurus castoroideus*, or the beaver-toothed gnawing-hog. Another of the fossils indicates a carnivorous animal, a contemporary of the former, and about the size of the gray fox. The animal was related to the weasel and canine families, and was called *Sinopa rapax*, the former name being that applied by the Blackfeet Indians to a small fox. Prof. Leidy also exhibited photographs of the lower jaw of the American mastodon, recently received from Prof. W. C. Kerr, State Geologist of North Carolina. The jaw was found in Lenoir County of that State. It belonged to a mature male, and was of special interest from its retaining both tusks, as well as the molar teeth.—Among objects of great ethnological import are the aboriginal inscriptions or carvings upon rocks, which are met with in North America and elsewhere, and are sometimes of a very remarkable character. Ordinary copies of such inscriptions, unless they be photographs, are rarely of sufficient accuracy to be of much value; and those of our readers who are likely to come across such inscriptions may like to know a method by which an absolutely perfect fac-simile can be made. This process has been applied with much success in copying carvings in Egypt and other places, and it will be equally serviceable in our own country. For this purpose the inscription is to be first well cleaned from dust or mud by means of a hard, stiff brush; stout, unsized paper is then to be wetted rapidly, but uniformly, in a tub of water, and applied to the inscription, and forced into the irregularities by repeated and forcible strokes with a hard brush, an ordinary clothes-brush being as good as any for the purpose. If the stone be clear of dust, the paper adheres, and, when dry, falls off, forming a perfect mould of the inscription. If the carving be deep or broad, it is sometimes advisable to apply several sheets of paper, one after the other, brushing over the surface of one with glue or gum before applying the next, so as to obtain, when dry, a firm body. By making a plaster cast of the paper relief thus prepared a fac-simile of the inscription will be obtained.—The present year seems to be marked with a great deal of activity and enterprise in researches connected with the natural history and physics of the deep seas, especially on the coast of America. We have already referred to the enterprise proposed by the Coast Survey, of sending a steamer, especially adapted to this purpose, around Cape Horn to the California coast, on a ten-months' journey, to be accompanied by Professor Agassiz and Count Pourtales, and a corps of assistants, all prepared to make observations and collections on the most perfect scale. The expense of the scientific work will, it is understood, to the amount of 15,000 dollars, be defrayed by Mr. Thayer (the same gentleman who supplied the funds for Professor Agassiz's expedition to Brazil), a sum which will probably enable Professor Agassiz to accomplish his object in the most perfect manner.—Professor Verrill and party, from Yale College, will also, it is expected, prosecute an exhaustive research into the deep sea and littoral fauna of the Vineyard Sound and the adjacent waters, in connection with the inquiries of the United States Commission of Fish and Fisheries relative to the decrease of the food fishes of our coast. Corresponding researches will also be carried on in the deeper waters of Lake Michigan, where, it may be remembered, the interesting discovery was made last year of crustaceans and fish of marine types at a depth of 300ft. and over. The inquiries this year will be under the immediate direction of Dr. Stimpson and Mr. Milner in a still deeper part of the lake, and it is not at all improbable that discoveries of the highest interest will be made.—The Arctic expedition of Captain Hall will also undoubtedly do its part in the general work, as the naturalist of the party, Dr. Emil Bessels, has had large experience in such labours, and is practically conversant with the fauna of the arctic seas from his connection with the Spitzbergen expedition of 1869.—At the June meeting of the California Academy of Sciences the subject of inviting the American Association for the Advancement of Science to meet in San Francisco in 1872 was discussed, and the treasurer was instructed to call upon the trustees, and to solicit the co-operation of the Chamber of Commerce in taking measures toward this object. The meeting for the present year will be held in August next in Indianapolis, and a large attendance is expected, especially of Western members, to whom the places of meeting in the East have generally proved too remote to suit their convenience.

* Communicated by the Scientific Editor of *Harper's Weekly*.

## SCIENTIFIC SERIALS

THE *American Naturalist* for June contains no article of very striking value, though several of interest in special subjects. Dr. Elliott Coues contributes an account of the yellow-headed blackbird, *Xanthocephalus icterocephalus*, first described by Prince Buonaparte in his continuation of Wilson's Ornithology.—An article on Cuban Seaweeds, by Dr. W. G. Farlow, includes outline drawings of a number of distinct types.—Dr. Lebaron describes a new species of moth, the larva of which is extremely destructive to young apple trees, which he calls *Tortrix malivorana*, or the Lesser Apple Leaf-folder.—Mr. E. L. Greene contributes June Rambles in the Rocky Mountains, with special reference to their flora.—From Dr. Henry Shimer we have "Additional Notes on the Striped Squash Beetle," and from Prof. W. H. Brewer, "Animal Life in the Rocky Mountains of Colorado."—A larger space than usual is occupied by Reviews, among which is one of Mivart's "Genesis of Species," comparing the views of the author with those of the American writers, Cope and Hyatt.

THE first article in the *Journal of Botany* for June is an important one, by Prof. A. H. Church, on Sugar in Beet-root, with a record of investigations on the effect of the amount of rainfall in the development of the sugar.—Dr. Henry Trimen discusses the question, "Is the Sweet Flag, *Acorus calamus*, a Native?" showing that it was unknown in this country before 1596, and that it was not till about 1660 that it was reported as a wild plant from Norfolk. The plant appears to be originally a native of south-east Europe.—Prof. Dickson has an article on the Phyllotaxis of *Lepidodendron*, and the allied, if not identical, genus *Knorria*.—Mr. A. G. More continues his Supplement to the "Flora Vectensis;" and the Rev. Jas. M. Crombie his additions to the British Lichen-Flora.

The number for July contains Mr. Ernst's "Jottings from a Botanical Note-book," and concludes Mr. A. G. More's "Supplement to the Flora Vectensis." Dr. Trimen contributes some notes on plants observed in Jersey and Guernsey in April. There are several other short papers and notes of special interest to British botanists.

OF the *Bibliothèque Universelle et Revue Suisse*, one of the most valuable of continental periodicals, whether we consider the quality of its original articles, or the admirable extracts of scientific memoirs which it contains, we have just received the part published on May 15, which forms the commencement of a new volume. The first and most important of the three papers contained in it is on the action of magnetism on gases traversed by electrical discharges, by MM. A. de la Rive and E. Sarasin, in which the authors describe a long series of experiments made by them, leading to the following conclusions:—1. The action of magnetism exerted only upon a portion of an electric jet traversing a rarefied gas, causes an augmentation of density in this portion. 2. This action exerted upon an electric jet placed *equatorially* between the poles of an electro-magnet, produces in the rarefied gas an *augmentation* of resistance proportional to the conductivity of the gas itself. 3. On the contrary, it causes a corresponding *diminution* of resistance, when the jet is directed *axially* between the two magnetic poles. 4. When the action of the magnetism is to impress a continuous movement of rotation upon the electric jet, it has no influence upon the conductivity if the rotation be in a plane perpendicular to the axis of the iron cylinder detaining the rotation, and diminishes it considerably if the rotation takes place so that the jet describes a cylinder round the axis. 5. These effects do not seem to be due to variations of density, but to perturbations in the arrangement of the particles of the rarefied gas.—A second paper is an excellent abstract and discussion by M. Emile Gautier, of the observations of solar protuberances, made at Rome by Prof. Respighi; and the third consists of an account of geological, meteorological, and archæological explorations made in the province of Constantine (Algeria), by M. Tissot.

THE first part of the twenty-third volume of the *Zeitschrift der deutschen geologischen Gesellschaft*, containing the proceedings of that society for the months of November and December 1870, and January 1871, includes one paper which will be of especial interest to British geologists, namely, "Some Geological Sketches from the East Coast of Scotland," by Prof. F. Zirkel, extending over 124 pages of text, illustrated with four plates. In this paper the complicated geology of the islands of Arran, Mull, Iona, Staffa, and Skye is discussed in considerable detail, and the author winds up with a description of the east and west section of the north of Scotland. Another long paper is the first part of a geological description of the annular mountain of Santorin, by M. K. von Fritsch.—M. C. Struckmann describes the *Pteroceras* beds of the Kimmeridge formation at Ahlem, near Hanover, which he divides into three series (upper, middle, and lower), indicating the characteristic fossils of each deposit. M. R. Richter publishes a fourth notice on the Thuringian slates, for which he claims an Upper Silurian age, an opinion here supported chiefly on the evidence of Graptolites. The author discusses the affinities of the Graptolitidæ, and adopts an opinion expressed by Leuckart (MS.) that this group is to be regarded as nearly allied to the Bryozoa. The author describes a new genus, *Triplograptus*, the chief character of which is that the canal has three vertical rows of alternating cells, of which the type is *T. nereitarum* (Richt.), and also as new species *Diplograptus pennatulus* and *Monograptus crenatus*. These and some other species are figured in the plate accompanying the memoir. A new species of *Nautilus* (*N. veles*) is also described and figured in this paper (p. 243). From M. Emanuel Kayser we find a notice of the occurrence of *Rhynchonella pugnus* with traces of colour in the limestone of the Eifel (Devonian), to which is appended a tabular list of those fossil shells on which traces of colouration have been observed.

## SOCIETIES AND ACADEMIES

### LONDON

Geological Society, June 21.—Joseph Prestwich, F.R.S., in the chair.—R. J. Watson, W. T. Scarth, Gen. A. C. Bentinck, and John Brooke were elected Fellows of the Society.—"On some supposed Vegetable Fossils," by William Carruthers, F.R.S. In this paper the author desired to record certain examples of objects which had been regarded, erroneously, as vegetable fossils. The specimens to which he specially alluded were as follows:—Supposed fruits on which Geinitz founded the genus *Guilielmites*, namely, *Carpolites umbonatus* Sternb., and *Guilielmites permianus* Gein., which the author regarded as the result of the presence of fluid or gaseous matter in the rock when in a plastic state; some roundish bodies, which, when occurring in the Stonesfield slate, have been regarded as fossil fruits, but which the author considered to be the ova of reptiles, and of which he described two new forms; and the flat, horny pen of a Cuttlefish from the Purbeck of Dorsetshire, described by the author as *Teudopsis Brodiei*, sp. n. Mr. Seeley remarked on the compressed spheroids found in so many rocks, that there was a difficulty in accepting the view of their originating in fluid vesicles, though he was unable to suggest any other theory by which to account for them. He observed that the eggs from the Stonesfield slate closely resemble those of birds, and that it was of the highest interest to find such eggs in strata containing so many remains of ornithosaurian forms, such as *Rhamphorhynchus* and *Pterodactylus*, of which genus probably these were the eggs. Prof. Rupert Jones fully recognised the ingenious explanation of the bubble-formed limited slickensides, that looked so much like possible fossil fruits, and Mr. Carruthers's masterly treatment of the other specimens. But he wished that the author would take up the subject exhaustively, and define the nature of other supposed vegetable fossils, such as the so-called fucoids, *Palæochorda*, *Palæophyton*, *Oldhamia*, &c., many, if not all, of which Prof. Jones thought to be due to galleries and other tracks made by Crustaceans. Prof. Ramsay had known many instances of such blunders as those pointed out, made, not by experienced geologists, but by those unacquainted with the science. Though he had never regarded the flattened spheroids as fossils, he was unable to account for their presence in the clay-beds of different ages. Mr. Hulke inquired whether Mr. Carruthers considered the limited slickensides common in the Kimmeridge shales as due to gaseous origin. He remarked on the rarity of Pterodactylian remains as compared with those of other Saurians in the Wealden beds, in which the presumed eggs of Pterodactyls were found. Mr. Seeley did not regard the Wealden egg as being that of a Pterodactyle. Mr. Carruthers, in reply, remarked that the local slickensides mentioned by Mr. Hulke differed in character from those to which he had referred.—"Notes on the Geology of part of the County of Donegal," by A. H. Green, F.G.S. In this paper the author described the geological structure of the country in the neighbourhood of the Errigal Mountain, with the view of demonstrating the occurrence in this district of an inter-stratification with mica-schist of beds of rock, which can hardly be distinguished from granite, the very gradual passage from alternations of granitic gneiss and mica-schist into granite alone, and the marked traces of bedding and other signs of stratification that appear in the granite, to which the author ascribed a metamorphic origin. He also noticed the marks of ice-action observed by him in this region, and referred especially to some remarkable fluted bosses of quartzite, and to the formation of some small lakes by the scooping action of ice. Mr. Forbes stated that none of the facts of this communication were new, but he dissented altogether from the conclusions arrived at by the author in regarding these rocks as originally of sedimentary origin, and for the following reasons: (1) That this district has been studied in detail by Mr. Scott and Prof. Haughton, who declare the rock to be undoubtedly intrusive, as it not only sends out veins into the neighbouring strata, but also encloses fragments of the rocks through which it has broken. (2) Because the author starts from the idea that if such rocks are found to lie conformably on beds of undoubted sedimentary origin, it is a proof of their being themselves sedimentary or stratified,—a conclusion which is totally unwarranted, since there are innumerable instances, not only of beds of lava or other igneous rocks being conformable to fossiliferous strata, but of their also being found intercalated with such beds even for considerable distances. (3) The strata, so far from being proved by him to be of truly sedimentary origin, are of a most questionable origin, since they are neither in themselves fossiliferous, nor can they be correlated with any containing fossils as proofs of true sedimentary deposition; and the description of his section is sufficient to show this; for although it looks well on paper on a scale of three feet to the mile, the author has so little confidence in it that he is not even certain as to which is the top or bottom of the section on which so much generalisation is based. (4)

That a parallel structure equally, if not better developed than any occurring in the gneiss of Donegal, is common to many volcanic rocks, as in a specimen laid before the meeting, in which this parallel foliated structure due to crystallisation-layers is so well developed as to make it appear exactly like a stratified rock, and even split along these lines, and this, although the product of volcanoes still active is found for great distances both overlying conformably and intercalated between beds of the Cretaceous and Oolite formations. Mr. Scott was unwilling to accept the section given by the author as satisfactory. He agreed, however, as to the bedded appearance of the granite, and to the masses lying in general conformably with the lines of stratification of the country. The nearest spot at which fossiliferous rocks occurred was separated from the beds described by the whole width of the county of Tyrone, though some presumed Eozoonal forms had been found at a less distance. He was not prepared to believe in the original absolutely fused condition of granite, nor in there being two distinct forms under which it occurred.—"Memoranda on the most recent Geological Changes of the Rivers and Plains of Northern India, founded on accurate surveys and the Artesian well-boring at Umballa, to show the practical application of Mr. Login's theory of the abrading and transporting power of water to effect such changes," by T. Login, The author commenced by referring to the general conditions of the surface of the country under consideration, and to the evidence afforded by it of a great decrease in the amount of rainfall, and a great change in the nature of the rivers. His object was to show that the superficial deposits of the plains of India were formed by the action of mountain streams, the deposits being irregular transversely, but exhibiting a uniform section longitudinally, in a curve which the author believed to be a true parabola, as indicated by Mr. Tylor. The connection of this with the author's theory as to the transporting power of water was indicated. The author also showed that the beds of the large Indian rivers are rising rather than being lowered, and pointed out that this was in accordance with his theory.

### Halifax, Nova Scotia

Institute of Natural Science, May 8.—Mr. J. Matthew Jones, F.L.S., president, in the chair. Mr. Frederick Allison read a paper entitled "Results of Meteorological Observations at Halifax, Nova Scotia, for 1870." The temperature of January had not been approached since 1863. Mean pressure was great. Cloud was scanty, and winds strong, N.W. prevailing. Very large total precipitation, due to heavy rain, the snow-fall being deficient. No fog, and but five days' sleighing during the whole of January. Strong east gales at the close of the month. February was nearer to normal temperature. Mean pressure very light. Cloud far exceeded that of January and its own average. Prevalent wind, N.W., strong. Great precipitation, nearly doubling the average amount, and especially large in rain. One fog, and sleighing from the 1st to 25th. On the 9th strong east gale in morning, and blowing at night from the west. March bore much the same relation to normal temperature as did February; but the minimum of the year, 6°, occurred on the 12th of that month. Pressure still extremely light. Cloud in decided defect. Prevalent wind N.N.W., with mean force great. Precipitation, both of rain and snow, small. Only one fog. Eleven days of sleighing. Three gales, all more or less eastwardly. Wild geese (*Anser Canadensis*) passed over on their northerly migration on the 19th. Peach, trained against a south wall, blossomed on the 24th. The American robin (*Turdus migratorius*) appeared on the 30th. April was warm. Pressure 29·743, but ·001 below an eight years' average. Cloud still deficient. A peculiar direction of wind was prevalent—E.S.E. Mean force small. Precipitation close to average; rain being abundant, but snow only one inch. Five fogs recorded. First thunder and lightning this year on the 12th. One short gale from E.S.E. Frogs (*Hylodes Pickeringii*) first heard on the 8th; and May flowers (*Epigæa repens*) in full bloom on the 12th. The mean temperature of May was a little less than average. On the 30th 80°·2 was reached. Mean pressure a little light. A very bright month, with only 3·19 inches of rain, the average being 4·33. Snow inappreciable, the latest falling on the 24th, and melting as it fell. Four fogs. Thunder and lightning on the 9th and 12th. The garden cherry blossomed on the 23rd, and the humming-bird (*Trochilus colubis*) was first seen on the 18th. June was slightly cool, somewhat low in pressure and decidedly bright. Only 1·69 inches of rain fell. Mean velocity of wind but 8·8 miles per hour; direction W.S.W. Three fogs noted. No frost after the 24th of the preceding month, either at five feet high or on the surface of the earth. Thunder and lightning twice. The apple blossomed on the 6th, and red clover same date; horse-chesnut on the 2nd; wild strawberries ripe on the 20th. Grass mowing began about Halifax on the 30th. July temperature was 1°·85 above the average. On the 24th 91°·5 was marked. The mean of six equidistant observations on 25th, 75°·27, being the warmest day recorded at this station for at least twelve years. Mean pressure low. Great want of cloud. Light winds; direction S. 59° W.; velocity 8·1 miles per hour. Rain, 3·21 inches, being much above average. Four fogs. Thunder and lightning twice. August was warm also. Mean pressure almost identical with July, being 29·659. Very little cloud. Wind, resultant direction, N. 77° W. Mean velocity 10·5 miles per hour. Rain scanty, giving but 2·20 inches. Fogs three. Thunder and lightning thrice. September mean temperature 57°·20, having fallen 7°·60 below August. On the 30th exactly 32° was registered by grass minimum; but atmosphere never descended to freezing point. Mean pressure still low, and cloud also deficient. Wind, resultant direction N. 15° W., and mean velocity only 10·6 per hour. Rain, half an inch less than average. Three fogs. Hoar frost on the 30th. Thunder once. Lightning twice. Three gales. October had a mean temperature of 48°·14. Mean pressure 29·825. Still a quantity of cloud, though October is frequently a bright month in Nova Scotia. Resultant direction of wind N. 42° W., and mean velocity 12·45 miles per hour. Heavy rainfall, and eight inches of snow. One fog. Three gales from N.W., S.S.W., and S. First frost, five feet above ground on the 26th; temperature having been above 32° 155 days. Measurable snow on 31st. The mean temperature of November remained above the average. The whole pressure again small. The month was rather less cloudy than usual. Resultant direction of wind N. 87° W., and mean velocity only 10·75 miles per hour. Rainfall large, 5·67 inches, and snow depth great, 7·7 inches. Three fogs. Three gales, N.W., S S.E., and S.E. Meteors on the night of the 14th. December was very mild. Mean temperature 30°. Pressure very low. Much cloud. Resultant direction of wind N. 76° W., and mean velocity 11·6 miles per hour. Rain was heavy, and snow small, though containing larger amount of water than average. One fog. Four days' sleighing. On Christmas Eve thermometer reached 4°·6, minimum of month. After noting the cyclone of the 3rd and 4th of September, Mr. Allison proceeded to connect it with the gale of the 7th moving in the Bay of Biscay, in which the *Captain* foundered. Giving the following figures from a mass of observations, to show the storm path:—S.S. *Robert Lowe* at sea, lat. 43°2′ N., long. 65°3′ W., September 4, 4 A.M., bar. 28·700; wind 25lb. per square foot. Halifax N.S., lat. 44°39′ N., long. 63°36′ W., September 4, 9.30 A.M., bar. 28·952, 6 to 7 A.M.; wind velocity 65·7 per hour, and reaching 70 miles in gusts, fully 24·5lb. per square foot. Glace Bay N.S., about 250 miles from *Robert Lowe*, E.N.E., bar. 3 P.M. 29·333; wind 3 P.M. 86 miles per hour. This storm was travelling at direct rate of about 23 miles per hour in this longitude, its speed being accelerated as it progressed eastward. It would be due, with its south-eastern edge, in diminished force probably, in Bay of Biscay on evening of 6th of September. From these and other data a world-wide system of telegraphic storm warnings was urged.—Another interesting paper, "On the Meteorology of Glace Bay, Cape Breton, N.S.," by Mr. Henry Poole, was also read.

### Paris

Académie des Sciences Morales et Politiques, June 24.—M. Jules Simon in the chair. Notice was given of the death of M. Ramon de la Sagra, a Spanish gentleman who had been a great traveller in America, and was well known as a botanist.—M. Egger read some pages of his great work "On the Progressive Development of Infants."

July 8.—M. Paul Janot in the chair. Notice was given of two letters received from M. Henry Martin, a member of the National Assembly, and M. Filon, an inspector of the Academy of Paris, both contending for the seat left vacant by the late M. Pierre Clement, who wrote, many years ago, a history of the *Revocation de l'Edit de Nantes*, vindicating Protestantism, and published many articles in the *Journal des Economistes*, in support of free trade policy. The contest will be severe, as M. Henry Martin is very popular, being the author of a History of France. M. Filon is a gentleman of a wider intellect, and has written a Comparative History of France and England. The election will take place on the 22nd.

**Académie des Sciences**, July 10.—M. Claude Bernard in the chair. Notification was received of the death of M. Haidinger, the keeper of the great aerolitic collection at Vienna and a correspondent in the section of mineralogy. —The public sitting, which, according to the rules, was held before the secret one, was rather long and interesting. M. Puiseux was unanimously elected a member of the section of geometry (this honour is very seldom paid to any member). M. Puiseux belongs to the scientific staff of the National Observatory. He was much praised many years ago by Cauchy for his calculations on variations of weight and of its effects. He was a contributor to Lionville's *Journal de Mathematiques*.—M. Boussingault described some experiments showing that water is not liable to freeze irrespective of the degree of cold to which it is submitted, as long as it is not allowed to expand in order to change into ice. It is the complement of the celebrated Florentine experiment. M. Boussingault exposed water to $-13°$ Cent. enclosed in strong steel tubes as used for rifled guns, without any congelation taking place. On unscrewing the steel end of the barrel, the congelation was instantaneous. The fluidity of the water was made manifest by small steel spheres, which moved freely inside the guns during the whole process, and would have been stopped by congelation. A very long conversation took place between M. Boussingault and several members who proposed many objections, to which he found ready answers.—M. Saint-Venant read a long report on a memoir presented by M. Maurice Levy on several Equations showing the internal movements of molecules when a ductile body is submitted to external pressure.—M. Faurneyron was a French engineer of great reputation, known by the invention of "turbines" or hydraulic wheels. He bequeathed to the Academy a certain sum in the funds to give a 40*l*. prize to the best memoir on Practical Mechanics every two years. The Academy appointed a committee of five of its members to draw up a programme for the next competition. The competition is to be open to all, irrespective of nationality and qualification, except to the members of the different French academies.—M. Brown, the astronomer at the celebrated Trevandum Observatory, read a most important note on the "Diurnal Lunar Variation," which he proved has sometimes to exceed the solar variation. The law is illustrated by calculating the maximum Every day there are two maxima of lunar action. In June, when the moon is on the 6th and 18th horal meridian, in December on the 0th and 12th, and in the intermediate months on the intermediate meridians, according to progressive changes. The excursions are greater when the moon is nearer to us (perigee), and when the passage of the moon to the maximum meridian is by daylight. This difference is very great, the *nocturnal* max. reaching only $\frac{1}{3}$ of *diurnal* max. The law is worth the most serious consideration, as connections between variations of magnetism and temperature are becoming every day more and more frequent. It may lead to the discovery of the lunar influence on meteorology, which discovery will be *initium sapientiæ*.—M. W. de Fonvielle sent a note discussing certain singular phenomena which were observed in Scotland during the stormy periods of June 18 and July 18. The facts were quoted from the *Scotsman*, an Edinburgh paper. The note was printed in the *Comptes Rendus*. The author is anxious to see if "mirages," as observed on the Isle of Man, can be considered as having been a presage of the stormy weather. He wrote also upon certain accidents, showing that it is dangerous to move metallic objects during thunderstorms. M. Chapelas presented the results of observations made during twenty years (1848-1868) on 39,771 meteors, out of these 23,481 were observed in summer when the nights are short, only 2,145 in winter when the nights are long. The mean direction is S.S.E. The numbers of meteors vary in *inverse ratio* with their magnitude:—1st magnitude 2,497, 2nd magnitude 3,918, 3rd magnitude 7,137, 4th magnitude 8,847, 5th magnitude (an exception to the rule) 8,050, 6th magnitude 9,322 (very slight augmentation). He says, moreover, it shows that falling stars are more frequent in high altitudes. It is true, assuming falling stars to be essentially of the same magnitude, and differing only apparently from distance.

RIGA

**Society of Naturalists**, February 1.—Prof. Schell discoursed upon the importance of water-levels on the coasts of the Baltic provinces, and described some anemometers. — M. Schroeder communicated a notice relating to the avifauna of the Baltic provinces, in which he mentioned several species to be struck out of or added to the previously published lists. He made the total number of species, 272.—Baron F. Hoyningen-Huene communicated a continuation of his phænological observations, during the year 1870, containing a report on natural phenomena observed from March to October.

PHILADELPHIA

**American Philosophical Society**, April 1.—Prof. Cope made remarks on the Vertebrata obtained in the Port Kennedy bone cave by Chas. M. Wheatley, stating the number of species to be forty-two. The Mammalia were referred to orders, as follows:—Edentata, 6 species; Rodentia, 14; Insectivora, 1; Chiroptera, 1; Ungulata, 8; Carnivora, 4; total, 34, of which about half are new to science. Birds and Reptiles, 8 species. He made remarks on the nature and origin of the post-pliocene fauna, the origin of the caves, and possible topographical history of the country in that connection.—Pliny E. Chase read a paper on "Resemblances between Atmospheric, Magnetic, and Ocean Currents."—Lieut. Dutton presented some views on regional subsidence and elevation, and mentioned the physical changes produced by the metamorphism of rocks as an agent in changing the contour of the earth's surface. The obliteration in specific gravity produced by change of chemical constitution of interior rock strata was an important cause of the elevations and subsidences of the earth's crust, generally overlooked.

## *MR. CROOKES ON THE "PSYCHIC" FORCE*

WITH a boldness and honesty which deserve the greatest respect, Mr. Crookes has come forward as an investigator of those mysterious phenomena which have now been so long before the public that it is unnecessary to name them, more especially as their generally received name is very objectionable.

Two things have contributed to retard our knowledge of these strange events. In the first place, until lately few men of name have been associated with their occurrence, so that outsiders have not had the facts put before them in a proper manner. In the next place, we are inclined to endorse the remark of Mr. Crookes, that men of science have shown too great a disinclination to investigate the existence and nature of these alleged facts, even when their occurrence had been asserted by competent and credible witnesses.

Before adverting to the results obtained by Mr. Crookes, a few words may be said about our mode of procedure in accepting testimony.

Let us suppose that a man comes before us as a witness of some strange and unprecedented occurrence. Here it is evident that we are not entitled to reject his testimony on the ground that we cannot explain what he has seen in accordance with our preconceived views of the universe, even although these views are the result of a long experience; for by this means we should never arrive at anything new. Our first question is manifestly one regarding the man's moral character. Is he an honest and trustworthy man, or is he trying to deceive us?

Let us assume that we have convinced ourselves of his honesty; we are then bound to believe that *he thought he saw* what he described to us; not necessarily, however, that the occurrence which he described actually took place. Convinced, already, that he is not deceiving us, we next question whether he may not be deceived himself. Let us, however, assume that, upon investigation, the circumstances are such that collusion of any kind is out of the question, and that the man is neither trying to deceive us, nor that it is possible that he himself can have been deceived by others. Even yet we have an alternative in our judgment of the event. The phenomenon may be *subjective* rather than *objective*, the result of an action upon the man's brain rather than an outstanding reality. For nothing is more certain than the occasional occurrence of such strange impressions; and the cat or the dog or the skeleton by which the patient is haunted is frequently recognised even by himself as having no external existence. Of late years we have been able to produce instances of this depraved consciousness almost at will. The author of these remarks considers it certain that the electro-biologist has frequently caused them. The unimpeachable character of the patient, combined with the fact that he has sometimes pronounced water to be wine, or a snow storm to be taking place in a room, can only be accounted for on the supposition that he has been put into a peculiar state, during which his evidence of events is utterly worthless. But beyond the bare fact, we know next to nothing of the laws that regulate this action, nor can we tell under what conditions one man is capable of influencing another, or whether a man or body of men may not be capable of influencing themselves.

To come now to the class of events which Mr. Crookes has witnessed. It is greatly to his credit that he has come forward so frankly and honestly; and since he has begun to investigate the peculiar class of facts, we are sure that he will consider it his duty to continue the investigation in such a way as to convince those men of science who may not themselves be able to take up the question—outsiders in fact. Mr. Crookes will, we are sure, not object to a few critical remarks honestly made with the sole view of finding out the truth, and we would therefore express a wish that, in order to facilitate operations the experiments should in future be conducted by only by such men as Mr. Crookes himself, and that it should always be absolutely superfluous to investigate whether machinery, apparatus, or contrivance of any sort, be secreted about the persons present. We should thus start from a higher platform, and the investigation would gain in simplicity, although perhaps something might be lost in the marked nature of the results obtained.

Allowing, however (as we are disposed to allow), that things of an extraordinary nature are frequently witnessed on such occasions, yet we are by no means sure that these constitute external realities. The very fact that the results are uncertain, and that, as far as we know, they have never yet been obtained in broad daylight before a large unbiassed audience, would lead us to suspect that they may be subjective rather than objective, occurring in the imaginations of those present rather than in the outward physical world. Nor can this doubt be removed by any precision of apparatus; for what avails the most perfect instrument as long as we suspect the operator to be under a mental influence of the nature, it may be, of that which is witnessed in electro-biological experiments? The problem is, in fact, one of extreme difficulty, and we do not see how it admits of proof, provided the influence cannot be exerted in broad daylight and before a large audience. There is, however, a cognate phenomenon which admits of easy proof. We allude to clairvoyance, and have in our mind at the present moment a man of science who if not himself a clairvoyant has yet the power to command the services of one who is. Now, were he at once to communicate to a journal such as NATURE, in cipher if necessary, the knowledge derived through the influence, giving the proof afterwards when obtained in an ordinary manner, the public would soon be in a position to judge whether there is any truth in the influence or not.

It is, in fact, somewhat hard upon the writer of these remarks and some others who are disposed to allow the possibility of something of this nature, but have not the opportunity of investigating it, that those who have will not satisfy the public with a convincing proof.

B. STEWART

## *TYNDALL'S FRAGMENTS OF SCIENCE*

*Fragments of Science for Unscientific People.* By Prof. Tyndall, LL.D., F.R.S. (London: Longmans: 1871.)

THIS volume is a reprint of a number of detached essays, lectures, and reviews, by Prof. Tyndall, published at various times and in various places during the last ten years. Besides a few shorter pieces collected at the end, there are in all thirteen articles. These consist of two classes of a totally distinct nature. The larger number constitute considerably the greater bulk of the volume, deal entirely with scientific subjects, and are of a special scientific nature. The remainder deal either directly or indirectly with the question of the opposition or concordance of science and religion. To this question, Prof. Tyndall brings that same remarkable clearness and definiteness of statement which characterises his writings on purely scientific subjects. It is a highly desirable thing for all parties that it should be distinctly stated what are the issues, in their ultimate form, to which our various hypotheses may lead. Prof. Tyndall, from the scientific side, makes this statement clearly and distinctly. He views an hypothesis, so to speak, in its widest generalisation, and does not shrink from it or its consequences. If, he would say, you hold these or those views, then this is what they *must* imply, and what, if these views be true, you *must* come to; and so you need not be afraid, and if you hide it from yourself you only cloak the truth in the one case, or hinder the exposure of error in the other. As an example, let us take the statement of the Natural Evolution hypothesis in the lecture on "The Scientific Use of the Imagination" (page 163 of the present volume). Speaking of the evolution of the present world from a nebulous mass he says:—

"For what are the core and essence of this hypothesis? Strip it naked, and you stand face to face with the notion that not alone the more ignoble forms of animalcular or animal life, not alone the nobler forms of the horse and lion, not alone the exquisite and wonderful mechanism of the human body, but the human mind itself—emotion, intellect, will, and all their phenomena—were once latent in a fiery cloud. But the hypothesis will probably go even further than this. Many who held it would probably assent to the position that at the present moment all our philosophy, all our poetry, all our science, all our art—Plato, Shakspeare, Newton, Raphael—are potential in the fires of the sun. We long to learn something of our origin. If the Evolution hypothesis be correct, even this unsatisfied yearning must have come to us across the ages which separate the unconscious primeval mist from the consciousness of to-day. I do not think that any holder of the Evolution hypothesis would say that I overstate it or overstrain it in any way. I merely strip it of all vagueness, and bring before you, unclothed and unvarnished, the notions by which it must stand or fall."

"Fear not the Evolution hypothesis," he says further on, "steady yourselves in its presence in the ultimate triumph of that truth which was expressed by old Gamaliel when he said, 'If it be of God ye cannot overthrow it; if it be of man it will come to nought.'" This is the true scientific spirit; and the beautiful daring with which Prof. Tyndall launches upon an unknown sea trusting to this guiding principle, is an instance of that noble faith which has lived through all phases of the human mind alike in scientific and unscientific ages. To have a faith in something seems to be the ultimate necessity of all humanity. Let all of us beware how we call that faith, as it exists variously in each of us, false.

Prof. Tyndall always writes in a beautiful, clear, and pointed style. Not the least excellent part of it, and that which probably as much as anything else constitutes him the great scientific teacher he is, is his unbounded power of apt illustration. He carries this into every subject with which he deals. As an example, take the following from page 58 of the article on "Miracles and Special Providences:"—

"The mind is, as it were, a photographic plate, which is gradually cleansed by the effort to think rightly, and which when so cleansed, and not before, receives impressions from the light of truth."

Again, at page 101 we find the following:

"We live upon a ball of matter 8,000 miles in diameter, swathed by an atmosphere of unknown height. This ball has been molten by heat, chilled to a solid, and sculptured by water."

There is the touch of a master's hand in the way in which these few words "fling us the picture of the fight," and enable us vividly to realise that which they would have us realise.

Prof. Tyndall, however, has evidently given less attention to spiritual than to natural questions. Indeed, it is not to be wondered at that a man now-a-days should not have time to pay attention to everything. It is sometimes, however, to be lamented, though perhaps hardly to be wondered at, that a man should write about too much. The articles of a purely scientific character consist of two on "Radiative and Radiant Heat," one on "The Light of the Sky," and one on "Dust and Disease."

The articles on the "Life and Letters of Faraday" will well repay the perusal of those who have not already read them in the *Academy*, and will even well merit a re-perusal, as everything does which gives us any insight into the character of that great and child-like man.

The last of the series is a lecture on Magnetism, addressed to the teachers of primary schools, at the South Kensington Museum. Prof. Tyndall tells us, in a short introduction to it, that he had at first some doubts as to the propriety of its insertion. "But, on reading it," he says, "it seemed so likely to be helpful that my scruples disappeared." We are exceedingly glad that it has been so. The lecture is a beautiful example of true teaching, and of that excellent union of logic and experiment which is the true education which physical science is so well calculated to supply.

JAMES STUART

## *DALL'S BRACHIOPODA OF THE UNITED STATES COAST SURVEY*

*Report on the Brachiopoda obtained by the United States Coast Survey Expedition, in charge of L. F. de Pourtales, with a Revision of the Craniidæ and Discinidæ.* By W. H. Dall. (Bulletin of the Museum of Comparative Zoology, at Harvard College, Cambridge, Mass.) With two plates. (Cambridge, U.S., 1871, 8vo.)

THIS is another important instalment of the published results of the deep-water dredgings made by our Transatlantic cousins and friends in the Gulf of Mexico. The first was issued in 1869, and consisted of a Preliminary Report on the Echini and Starfishes, by Prof. Alexander Agassiz. A report by Dr. Stimpson on the Crustacea procured in the same expedition is announced as nearly ready; and that distinguished zoologist has also undertaken the still greater charge of a report on the Mollusca. It is impossible to over-rate the impulse which will be every where given by such explorations to the study of marine Natural History.

We are now entering on quite a new phase of research, and commencing a survey of the hitherto unknown world beneath the waters. Regarded not merely in a biological, geological, or physical aspect, but also as a basis of sound education, these investigations ought not to be neglected by any civilised nation, especially by Great Britain, which, it is hoped, will never cede her well-earned maritime prestige, and her laudable ambition of discovery. This has been forcibly urged as a duty on the Government in an admirable article which appeared in the *Spectator* of the 22nd of July. In the pages of NATURE (meaning, of course, the present periodical, and not the mythical book to which fanciful writers are wont to allude), some of the results obtained in our deep-sea explorations of the North Atlantic and Mediterranean have been already noticed; and next year will in all probability inaugurate an expedition on a more extensive scale, and worthy of this rich and intellectual country. Sweden has performed her part most nobly, by sending out, in 1869, the *Josephine* frigate for the exploration of the sea-bed lying between the coast of Portugal and the Azores, and this year a corvette and tender to Baffin's Bay and Davis's Straits. Russia despatched, last year, a frigate to New Guinea for a similar purpose, under the scientific charge of an experienced naturalist, Mr. N. M. v. Maclay. We are now informed on good authority that Drs. Noll and Grenacher, two German naturalists, are projecting a dredging expedition along the coasts of Portugal and Morocco to the Canaries. Even France, in the midst of her troubles, devoted some of her energy and vast resources to the peaceful object of dredging in the lower part of the Bay of Biscay, under the personal superintendence of the Marquis de Folin, the Commandant at Bayonne. In Canada a Government schooner has been lately placed at the disposal of the Natural History Society of Montreal for dredging the deeper part of the Gulf of St. Lawrence. But the United States, not content with the laurels she had gained in the Gulf of Mexico, has this year promoted two separate expeditions; one, under the charge of the veteran and celebrated Professor Louis Agassiz, and Count Pourtales, to proceed along the south-eastern coasts of the Atlantic from Bermuda, through the Straits of Magellan to the Galapagos and San Francisco, dredging all the way; and the other, under the charge of Mr. Dall, the author of the Report above cited, has already gone from California to the Aleutian Islands.

The Brachiopoda, which form the subject of the present Report, are usually considered an abnormal class of the Mollusca; although some systematists place them in another group or sub-kingdom, the Molluscoidea, along with the Tunicata and Polyzoa. Mr. Morse, an American naturalist, has recently endeavoured to show that the Brachiopoda are Annelids. This is a very debateable matter of classification. I am, for one, disposed to let the Brachiopoda remain among the Mollusca, to which they appear to be allied through the *Anomia* family. Their mode of reproduction, bivalve shells, and general habits, evince a much closer affinity to the Conchifera than to the Tunicata, Polyzoa, or Annelida. Other points of resemblance between the Brachiopoda and the three last-named groups may savour of analogy, not of homology. The author has executed in a most scientific and conscientious spirit the somewhat difficult task allotted to him; and he has contributed much valuable information to our scanty knowledge of the life-history of these remarkable animals. I regret that I cannot accept his conclusions as to the difference of certain so-called species (*Terebratula vitrea* and *cubensis*, *T. septata* and *floridana*), nor as to the generic value of *Terebratulina* and *Waldheimia*. But this is not the place for discussing such questions. That part of the Report which treats of the *Craniidæ* and *Discinidæ* is equally well done, and the plates are capital.

J. GWYN JEFFREYS

## OUR BOOK SHELF

*The Year-Book of Facts in Science and Art.* By John Timbs. Pp. 288. (London: Lockwood and Co. 1871.)

*Annual of Scientific Discovery, or Year-Book of Facts in Science and Art for* 1871. Edited by John Trowbridge, S.B., aided by W. R. Nichols and C. R. Cross. Pp. 349. (Boston: Gould and Lincoln. London: Trübner and Co. 1871.)

THE opinion that we expressed on a former occasion regarding the relative value of these Year-Books, remains unaltered. Mr. Timbs, as of old, still wields the scissors and the paste-brush with unabated zeal, and his Year-Book for 1870 presents all the faults of its predecessors. Considering that "Science and Art" are not the only subjects to which Mr. Timbs devotes his attention, but that a new book on (we may almost say *of*) "Popular Errors," or on "Curiosities," seems to be always springing from his fertile pen, his "Year-Book" does him no discredit, although non-critical readers may wonder at some of the "Facts," as well as at some of the omissions, which they encounter. Why he should place "The Entozoa Egg," (on which we suspect his ideas are somewhat obscure,) "Protoplasm," the "Germ-Theory of Disease," and "Sleep," under the head of "Natural Philosophy;" or "Snuff Taking: a Preventive for Bronchitis or [and?] Consumption," under that of "Chemical Science," we cannot pretend to say; but, possibly, the following paragraph, taken from the heading "Astronomy and Meteorology" may afford a clue to his mysterious system of classification:—"Dr. F. G. Bergmann has projected from his own consciousness the beings from which the human race developed itself. Their name is 'Anthropiskes,' and they lived in Central Africa. They developed out of apes," p. 265. The appalling idea cannot be repressed that the intellect o our venerable instructor in "Science and Art" must be fai ing from over-work, so as to lead him to confound Anthropology with Astronomy!

The American Annual has the great advantage over its British rival of being compiled by men who understand the subjects on which they are engaged. The editor, John Trowbridge, S.B., is Assistant Professor of Physics in Harvard College, and one of his assistants, W. R. Nichols, is Assistant Professor of Chemistry in the Massachusetts Institute of Technology. The subjects embraced in this volume are nearly the same as those included in Mr. Timbs's Year-Book: Mechanical and Useful Arts, Natural Philosophy, Chemistry, Natural History or Biology, Geology, and Astronomy and Meteorology, being common to both, while the present work has additionally Geography and Antiquities, and the English annual makes Electricity a separate subject.

Unless the editor enters more fully in future volumes into the subject of "Geography and Antiquities," we should recommend the suppression of this department. On the present occasion it is simply compiled from the proceedings of the Geographical Section of the British Association, and does not contain a reference to *Petermann's Journal*, to the French or German Geographical Societies, nor even to the American Geographical Society.

With this exception the "Annual of Scientific Discovery" is entitled to our earnest commendation. The editor and his assistants have done their work well, and the only editorial slip that we have noticed is the insertion of the same paragraph in two separate departments (see pp. 122 and 208). The "Notes of the Editor" at the commencement of the volume are, as in preceding years, especially deserving of praise, and indicate in a comparatively short space the progress of science for the year.

*Mycological Illustrations, being Figures and Descriptions of New and Rare Hymenomycetous Fungi.* Edited by W. Wilson Saunders, F.R.S., F.L.S., and Worthington G. Smith, F.L.S., assisted by A. W. Bennett, M.A., B.Sc., F.L.S. London large 8vo., tab. lith. pict. 24. (London: John Van Voorst, 1871.)

THOSE who have made the longest and most intimate study of Fungi are most sensibly alive to the fact that it is almost impossible to name species, especially those belonging to the genus Agaricus, without figures derived from the authors themselves to whom they are attributable, or at least made under their immediate inspection. It was therefore a great boon to mycologists when Prof. Fries, a student of some sixty years' standing, determined to deposit in the museum at Stockholm figures of a large portion of those species, described by himself, which have a softer texture, and are with difficulty preserved for the herbarium; copies of many of which, and frequently the original sketches, have from time to time been kindly transmitted to this country, while the illustrations themselves are in the course of publication. Five fasciculi have already appeared under the title "Icones selectæ Hymenomycetorum nondum delineatorum," containing fifty plates, several of which comprise two or more distinct kinds; and it is much to be hoped that increasing years will not prevent the venerable mycologist from continuing his indispensable work, supplementing, as it does so nobly, the "sveriges ätliga och giftiga svampar," which furnishes a hundred plates, of which several are critical species, though, from the nature of the publication, the greater number are well-known forms.

We have now before us a work of much importance in the same direction, which, though not sanctioned by so long a study or such numerous treatises, must ever be of considerable weight from the unusual artistic talent of Mr. Worthington Smith, to whom, in conjunction with Mr. Wilson Saunders, the illustrations are due. He has not, however, rested entirely on his own knowledge of the subject as regards the determination of species, but has very wisely obtained help where it was possible to do so. In general the species are very correctly determined, but we venture to make one or two observations where some doubt exists, a matter of no surprise in so very complicated a subject.

Fries has just published a figure of his *A. polius* which is very different from that in the work before us, and which agrees with what we have ourselves always considered that species. *Boletus pachypus* is certainly not the plant of Fries as figured in his work on esculent and poisonous fungi. We have no right to criticise *A. junonius*, as it has the sanction of Fries himself, but we cannot help remarking that it does not at all resemble the figure in the "Svensk Botanik." As regards Cortinarii it is most desirable that the young state should always be figured. *Cortinarius caninus*, for example, is much brighter in colour at first. The figure clearly represents an older condition. The least satisfactory figure is that of *A. hydrophilus*, which differs from the usual form in not having a fistulose stem. There are some errors, whether clerical or otherwise, which call for a stricter revision in future numbers of the Latin phrases.

Thirty species are illustrated in the twenty-four plates, the figures for the most part leaving nothing to be desired. Far the greater part of them have either not been figured before, or the published figures are not satisfactory. We may mention as peculiarly good *Cantharellus radicosus*, *Agaricus atro-cæruleus*, which reminds us of Gould's drawings of infant coots and waterhens; *A. lignatilis*, and *Gomphidius glutinosus*. We trust that this very useful and acceptable work will command such a sale as to ensure its continuance. The materials in the hands of the editors are almost inexhaustible, and are daily increasing.

Since the above was written, a letter has been received from Prof. Fries containing some kindly worded criticisms, the most important of which are subjoined. The least observation from a person of such wide experience must be welcome to every genuine mycologist, and to none, we are assured, more so than to the authors of the work before us. *Cortinarius callisteus* = *A. ferrugineus* Scop., agreeing exactly in habit with the plant of Fries but differing in colour. *A. polius* = *A. fumosus*. *Boletus pachypus* = *B. amarus* Fr. *C. cærulescens* = *C. cumatilis* Fr., *species valde variabilis*. He adds, "the price is so moderate that it excites my admiration. Your admirable work has been received with singular pleasure. It contains three interesting species quite new to me: *Cantharellus radicosus*, *Agaricus adnatus*, and *Agaricus polystictus*."

M. J. BERKELEY

## LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his Correspondents. No notice is taken of anonymous communications.*]

### Mr. Howorth on Darwinism

WILL you allow me to reply to the various letters which appeared in your last number in answer to one from me? I gratefully welcome their general courteousness. Postponing the consideration of Mr. Wallace's letter, I come to Dr. Lionel Beale, the relevancy of whose arguments, and especially of the lugubrious moral attached to them, I fail to understand. It seems to me to be so incoherent and rhetorical that it is far beyond the reach of reply.

Mr. Tylor refers to the last census as disproving my position. He says the population has increased enormously, and yet our age is characterised by its luxury. These statements are correct. But the argument deduced from them has a missing link. The luxury of the upper strata of society has increased with its wealth, but the numbers of the pauper class have been increased in the same rate. In considering the published returns of the Poor Law Board, I am compelled to admit that the increased luxury has been limited to the surface of society, and that its lowest ranks have been correspondingly recruited, and to admit the force of Mr. Doubleday's argument, that the population of England under the Tudors was stationary because of the generally diffused wealth, while that of Ireland in the last century was increasing at an enormous rate, because it was steeped in poverty and want. I am not arguing about individual cases, but about general laws. Now, in Lancashire, where the increase has been so marked, I have it on the authority of owners of mills that the indigenous stock of the county, which is thrifty and well off, is not an increasing element, but is being replaced by the children of the Irish, or semi-Irish blood, from the poorer quarters of the large towns, among whom prudential restraint (which is surely a very visionary *causa causans* in any event) cannot be said to have much influence. At Rome, Venice, Basle, and in France, where the aristocratic class was not limited by primogeniture, it was always dying out, and was only recruited by fresh creations (see the details in Doubleday, chapter iv. *passim*). In all these cases we can appeal to figures, and not to a superficial survey of a Peerage, or the limited area of our own acquaintance.

The particular passage quoted by Mr. Tyler from Malthus has been conclusively answered by Doubleday (chapter vi.), and it is useless to repeat his arguments, which on this point I consider to be unanswerable.

Mr. Lownes repeats the odd charge of Mr. Tait against me, that I put the cart before the horse. The latter gentleman, whom

I have not yet answered, cited against me the elementary case of capons and other creatures of that ilk. They are entirely beside the question. It is as reasonable to quote them in this discussion as to conclude that all chaste people must be cowardly and effeminate because mutilated animals are so. He also said that I mistook the whole rationale of the question, and that it is infertile creatures that grow fat, and not fatness that causes sterility. The only test of the question is the one I have not shrunk from applying in this argument (which, by the way, has not to do so much with the fat as the hearty and strong). This test is that in a great number of cases we can make strong and vigorous but sterile plants and animals fertile by starving or bleeding them, which proves that it is not the organs that are defective, but that the creatures are too hearty.

The experience of Mr. Lownes on the fecundity of consumptive patients, and of the poorest classes as compared with the richest, is at issue with that of the doctors and midwives whom I have access to, and of all the authorities I know whose opinions are based upon statistics.

I am not sure that I understand the second and third paragraphs of his letter. Whichever way the problem is put, I am satisfied if it be admitted that in the more crowded and squalid portions of our towns, the population as a rule is more fertile than in the less crowded neighbourhoods. The case he cites of poor women losing their children early and ceasing to give milk, and, in consequence, soon becoming pregnant again, is counterbalanced by the fact that among the richest the proportion of those who suckle their children is small, and this not because of fastidiousness, but because they secrete little milk. Mr. Lownes once more drags out the Indian and the backwoodsman, but he has overlooked the answer I gave to Mr. Wallace in my former letter, which needs no alteration to meet the case as he has put it. It is the case of the meat-eaters against the vegetable-feeders, the strong and hearty and active against the comparatively stolid and low-conditioned, and as in such cases all the world over the former are not so fertile as the latter. Mr. Lownes objects to savages being cited, because of qualifying circumstances; he may as well say that it is not fair to test natural selection by wild animals, but only by domesticated ones. His treatment of the case of the Patagonian women is convenient but flippant. Mr. Lownes' experience in breeding both cattle and sheep and fowls and in rearing plants must be extremely limited, or he would hardly have made so rash an assertion as that contained in his last sentence. The starving of plants and animals to induce them to breed is one of the elementary axioms of both gardeners and stockkeepers.

I now come to Dr. Ross's letter, which, although somewhat patronising in parts, is altogether more to my taste than some others. He has properly referred me to Mr. Herbert Spencer, but I am afraid of venturing into his book, for fear that I should open upon myself the floodgates of Evolution. It is not the general problem of Evolution about which we are now at issue, but that limited form of it called Natural Selection. It is satisfactory, however, to find that, according to Dr. Ross, Mr. Herbert Spencer admits the main facts upon which my argument is founded. His doing so is quite a relief after the jaunty manner in which some of your correspondents have spoken about the matter. To speak of its being late in the day to be now defending Mr. Doubeday, to tell one that "what one says is ludicrous," "a monstrous error," &c., &c., is surely a sign that the crowing of the Gallic cock has been mistaken for more substantial arguments. I am very sorry that Mr. Spencer's book is not in my library, and that I cannot meet with it at the Manchester Free Library or Mudie's, so that until I am aware of Mr. Spencer's arguments I cannot say how far they affect the position I maintain. If the facts are admitted, as Dr. Ross says they are, I confess that I cannot see any other interpretation of them than the one given by Mr. Doubleday. Will Mr. Ross do me the favour of pointing out what other explanation they are capable of?

Mr. Wallace has misunderstood me if he thinks me capable of sneering at the good and sound work that has been done by himself for many years, the value of which I am as conscious of as I am of the worthlessness of mere Olympian dogmatism. Sneers are only justifiable in answer to contempt, and if he feels aggrieved with any of my words I withdraw them.

Mr. Wallace says my criticism of the phrase Survival of the Fittest is satisfactory. In regard to the phrase I used, and for which I was severely flouted by Mr. Wallace, he says it is unknown to Darwinians; that may be, but it can hardly be said to be unknown to Mr. Darwin himself. Speaking of the problem of the conversion of varieties into species, the latter says: "The inevitable result is an ever recurrent struggle for existence. It has been truly said that all nature is at war, the strongest ultimately prevail, the weakest fail, and we well know that myriads of forms have disappeared from the face of the earth" ("Variation of Animals and Plants under Domestication," i. 5). Let me especially commend this extract to Dr. Lionel Beale, for whom I entertain the profoundest respect, notwithstanding his vituperation of myself.

I find a difficulty in meeting Mr. Wallace's latest arguments, because they are entirely *a priori*, and Mr. Wallace asks me to admit as premisses the very thing I dispute, namely, the relative sterility of strong and hearty animals and plants. I cannot see the relevancy of his quotation of the effects of cross-breeding to the present argument, unless he means to infer that crosses are more vigorous and stronger than pure bred animals, on which position I should like to be furnished with a little evidence. Again, I cannot test the supposititious problem put by Mr. Wallace as to the strongest individual of an animal's progeny eventually being the stem-father of the race. He takes for granted that it is, and in doing so begs the question. I can only say the only experiments I know do not favour Mr. Wallace's *a priori* view, and that in the cases we can experiment upon, not the least satisfactory of which is the case of man himself, the condition most favourable to fertility, as I have quoted many examples to show, is that of comparative depletion.

Mr. Wallace, as before, is spare of instances. I can only extract two *bonâ fide* ones from his letter. He tells us the strongest bull leads the herd; this proves nothing, unless we are to infer from it that his progeny is the most numerous, and that the biggest and strongest therefore survive. I prefer to quote Mr. Darwin himself where I can. If Mr. Wallace's instance be worth anything, how does he account for the following: "The decrease in size of the Chillingham and Hamilton cattle must have been prodigious, for Prof. Rutimeyer has shown that they are almost certainly the descendants of the gigantic *Bos primigenius*. No doubt this decrease in size may be largely attributed to less favourable circumstances. Yet animals roaming over large parks and fed during severe winters can hardly be considered as placed under very unfavourable conditions" ("Variation of Animals and Plants under Domestication" ii. 119). What Mr. Darwin says of the wild cattle is equally true of the reindeer kept by the Laplanders compared with the wild ones on the Samoyede tundras, of the red deer of our larger forests compared with the skeletons of red deer from the turbaries, and is, perhaps, generally true of semi-wild races where man has not intervened with the special object of increasing the size by breeding from the largest individuals only.

In regard to the carnivora, I know of no reliable facts. I am not proposing the monstrous paradox that those animals which are so weak, diseased, or decrepid that they cannot sustain life at all, are the only ones that keep up the succession of the animal world. The toothless tigress, who cannot kill her food and is starving, will most certainly not be the mother of a long race. She can do nothing but die. But I say that, judging from analogy, it is probable that the lean and comparatively ill-fed tigress will breed more freely than the man-eater supplied with regular and abundant food.

The banks of the Chinese rivers and the rough country in the south and south-west of Ireland are both inhabited by teeming populations, remarkable for their poverty and fertility, and remarkable further for sending out immense colonies, which supplant wherever they go, in Mantchuria, in Songaria, in Glasgow, in Manchester, in New York, the strong hearty, indigenous races. This being so (and I only quote these two as examples of a whole class), when Mr. Wallace asks the question, "How can weak and sickly parents provide for and bring up to maturity their offspring, and how are the offspring themselves (undoubtedly less vigorous than the offspring of strong and healthy parents) to maintain themselves?" I can only reply that they actually do so: *Veni, vidi, et credi.*

I must correct a wrong impression that Mr. Wallace has got hold of. In this controversy I have no theory; my only theory is that Natural Selection is an ingenious but fallacious explanation of the varieties of life.

I cannot understand Mr. Wallace's last sentence if it be meant for an argument; while if it is only a *jeu d'esprit* and witticism, it requires a commentary to tell us where the point is.

Lastly, I will consider Mr. Wallace's reiterated complaint that I have only treated of what is in most cases the least important factor in determining the continuance of species. Let me turn very briefly to another of these factors put prominently forward by both Mr. Wallace and Dr. Beale, namely, "Obscure Colour."

We are not arguing about exceptional and individual cases, we are dealing with a general law, applicable or supposed to be applicable to the great majority of cases. Can it be said gravely that obscure colour has tended to the preservation of particular forms of life to the exclusion of others, not in a few exceptions, but as a general biological law?

Daylight, it will be admitted, is more likely to disclose an object than darkness. If we compare diurnal forms of life with nocturnal ones, we ought to find, if I read the tendency of the Darwinian argument rightly, that in the daylight when a sombre, obscure, or indifferent colour, would be of great service to hide an object, that there are a much smaller proportion of conspicuous forms of life abroad than at night when there would be no such need for obscurity, and a bright colour might be worn with impunity. Is such the fact?

Again, if we compare the animals and plants that live in tropical climates, where the light is intense, with those found in temperate and severe ones where the light is not so great and objects are not so prominent, do we find that the former has a comparative monopoly of conspicuous objects, or do we find rather that the reverse is the case, and that all the brightest objects we know in nature—the parrots, macaws, humming birds, butterflies, orchids, &c.—are found in the greatest profusion in the tropics, while we proverbially console ourselves for the absence of colour in our birds by boasting of their singing, and hang the beetles of Brazil in necklaces round our sisters' and wives' necks, while we crush our sombre representatives of the same class under our heels? Is it not equally true of the sea? In the Mediterranean, for instance, do not the brightly decked out gurnards and mullets far outnumber the dingier fish, while on the banks of foggy Newfoundland the sober tinted cod and ling are the prevailing types? In the former we have the clear blue water that washes round Sorrento pierced through and through by the blazing sun, while in the latter we have everything gloomy except the fisherman.

If we separate the animal world into flesh eaters and vegetable eaters, we ought to find, if this theory be true, that the former (which as a rule are not themselves the prey of other animals) are more conspicuous than the latter, since they have less reason for adopting a secret costume. But is it so? Are the hawks and owls and carnivorous beetles as classes more conspicuous than their victims? Is it a not fact that the most beautifully coloured creatures are as a rule the most helpless, weak, and accessible; that those animals which are supplied by nature with weapons of defence or are strong and can defend themselves, are as classes more obscure in colouring than those not so protected, and that the same rule applies to plants which are poisonous, nauseous, or protected by thorns? If these facts be true in the great majority of cases, we have another factor in Mr. Darwin's theory which is not satisfactory, and the cases quoted to support it become mere exceptions, which, by being exceptions, disprove the particular law he is maintaining. This letter has already exceeded reasonable limits, and I must postpone a further consideration of this and other objections to another occasion.

Derby House, Eccles HENRY H. HOWORTH

---

MR. HOWORTH'S objections to the theory of Natural Selection have been fully answered. I therefore wish to direct attention to another objection which has been recently advanced, and which has not, so far as I know, been specially refuted. The objection is stated by its author in the following terms:—"And it has been affirmed that to 'the primitive properties of molecules' and 'Natural Selection' may be referred all the varying forms and structures known to us, as well as all the phenomena of the living world. But such terms explain nothing. By their use further inquiry is discouraged, and the mind bent upon investigating the secrets of Nature is misled at the very outset. Can any one of these very pretentious phrases be resolved into anything more than the statement of a fact or facts in the form and language of an explanation? Natural Selection is the formation of species, and species are produced by Natural Selection. Crystallisation is the formation of crystals, and crystals are produced by the operation of crystallisation."

This passage is extracted from p. 58 of "The Mystery of Life"—a little work by Dr. Beale, which was published a few months ago. Dr. Beale has a keen appreciation of the "ludicrous." He thinks Mr. Howorth's misrepresentation of the Darwinian theory "very curious and even ludicrous," and in the closing sentence of his letter in NATURE, he appears to have a bit of fun to himself which ordinary mortals cannot understand; and if he can prove that Natural Selection is a mere abstract statement of the fact that species are in some way or other formed, the Darwinian theory is the most "ludicrous" ever presented to mankind. Probably Mr. Wallace may take a different view of the subject, and he may even think that the objection is more ludicrous than the theory; at any rate, no harm can result from bringing Dr. Beale and the champions of Natural Selection face to face, so that stricter tests than the "ludicrous" may be applied to ascertain whether the truth lies in the theory or in the objection. JAMES ROSS

Newchurch, July 24

---

THE last paragraph of Mr. Howorth's letter in NATURE of July 13 reminds me of a fact which I have often noticed, and which is, I suppose, well-known to botanists, viz. that certain creeping plants which root at the joints, flower sparingly unless the sprays are so disposed that they cannot take root. I refer especially to the *Lysimachia nummularia* (larger moneywort or "Creeping Jenny"). This plant blossoms comparatively little when allowed to trail in the moist soil which is its natural *habitat*, and in which alone the leaves look healthy and thriving. A spray trained off the flower bed on to a flag-stone, or a plant grown in a pot so as to hang over the edge and not be able to take root, will look sickly, but will be covered with flowers. I think I have noticed the same thing in connection with the periwinkle.

Gardeners cut off the runners of strawberries and the suckers of fruit trees to increase the crop, because, as they say, runners exhaust the plant.

But is not the case, rather, that the possibility of continuing its own life by taking root at the runners makes the plant's constitution, as it were, lazy about propagating its kind?

It is, perhaps, worth noticing that the cutting off the runners or suckers does not in any way weaken the plant, or cause it to become sickly, but it does prevent the indefinite prolongation of the individual life.

THE OWNER OF A "WEED GARDEN"

## Recent Neologisms

WRITING, as I did, from a little Midland village, where access to an English dictionary was impossible, I am not surprised to find that three words, which I treated as recent coinages, were only re-introductions. *Survival*, *impolicy*, and *indiscipline*, are all so naturally formed, that, whether old or new, they are "welcome to stay." My end was answered by putting a brand on Mr. Wallace's *prolificness*, by way of contrast. If he is bent on using that monster, he will help to naturalise it by spelling it with *ck* (instead of *c*) like *thickness*. But surely he is not driven between the Scylla and Charybdis of *prolifickness* and *prolificacity*, when *prolicity* is staring him in the face. For my part, I pray that the whole family will (to quote Sylvester again) "shake swift wing," and be no more seen. By-the-bye, I find the verb to *handwrite* in the *Quarterly Review*, April 1871, p. 332. That is a good, if not a new word, and well deserves re-introduction.

C. M. INGLEBY

## The British Association and Local Scientific Societies

IT is to be regretted that the British Association does not exert its influence in stimulating local scientific societies towards greater efforts for the formation in their museums of collections representing the Geology and Natural History of their respective neighbourhoods, so that they might constitute local monographs. Such a system, combined with a central museum in London, representing an epitome of the collections throughout the country, would tend to the advancement of science with greater rapidity and accuracy than at present, when the provincial museums are little better than overstocked curiosity-shops, and with no recognised plan of arrangement which is greatly wanted. In general there is little space for additions of importance, from the fact that the museums already contain large miscellaneous collections, unconnected with the neighbourhood, and of little use to anybody. Many valuable private collections exist throughout the country, representing the geology, &c., of various localities, which are eventually too often dispersed and lost to the district where they would be most useful and instructive. Private collectors would probably show more public spirit, if greater zeal and better judgment were shown by local societies.

F. G. S.

### Science Teaching in Schools

In the number of Nature for April 20, there is an article containing an account of a "Plan for Teaching Science in Ordinary Schools, submitted to the London School Board by Mr. J. C. Morris."

I will ask you to give me a little space for some details respecting an educational experiment I made in 1867, 1868, and 1869. My object was to test the value of a plan much resembling that referred to. By means of circulars, addressed to more than a hundred of the London clergy, I obtained permission to have the children in seven large schools instructed in science. Four competent teachers put their services at my disposal. One of these gentleman is now chemist in iron works, two are art masters, and the fourth, having obtained one of the Whitworth Scholarships, is a student at Owen's College. I mention these facts to show the sufficiency of their knowledge. Three of them had had considerable experience in teaching. Twenty-two classes were formed, the total number of pupils exceeding 800. The principal subjects taught were chemistry, geology, physical geography, practical geometry, and mechanical drawing. The lessons were from one to two hours in duration on two days in the week at each school. But my plan differed from Mr. Morris's, inasmuch as thirty-five to fifty-five lessons were generally given in a subject before proceeding to a new one. He suggests that "a single teacher could get through three or four subjects annually, so that in two or three years he would have completed the full course in each school." This plan would give from twenty-two to thirty lessons per subject if I rightly understand his meaning. We fixed a small fee, but seldom obtained it, as we found that any attempt to press for payments would have reduced very materially the numbers in the colleges. The pupils were frequently examined, and those who appeared likely to satisfy the minimum requirements of the science department were sent in to the May examinations.

The following are some of the observations I made at the time :—

1. Few of the children appeared to obtain anything like sound and comprehensive knowledge of the facts the teachers put before them.

2. The great majority failed to express clearly on paper any ideas which an oral examination showed they had gained.

3. Most of them appeared to forget a subject within a few weeks after the discontinuance of instruction, or the substitution of another branch of science. The utter forgetfulness shown by whole classes was sometimes almost startling.

4. The papers worked by the girls at the examinations were superior to those produced by the boys, showing a more intelligent knowledge of the subjects they had been taught. This fact may, however, have resulted from accident, as comparatively few girls received instruction.

T. Jones

The College, Stony Stratford

### Ocean Currents

Mr. Laughton does not seem to observe that the subject of Ocean Currents involves several distinct issues, which may be discussed apart from each other. It is, of course, obvious that if the temperature explanation of the vertical circulation fails, then no illustration of the horizontal circulation, if founded on the temperature theory, can be really effective. But it is admissible to inquire separately whether the horizontal circulation *would* result from a vertical circulation such as the temperature theory suggests. For an objection has been urged against the theory on account of the nature of the horizontal circulation (see Herschel's "Physical Geography.") The express object of the experiment I have suggested is to show that this particular objection is unsound, or rather to illustrate the theoretical considerations argued in my essay on the Gulf Stream in the *Student* for July 1868.

But even in so far as my suggested experiment, like the similar one carried out by Dr. Carpenter, illustrates the production of a vertical circulation, I deny that Mr. Laughton's objection is valid. It is quite unnecessary to have a thermometric gradient resembling that in the terrestrial oceans. Whether Dr. Carpenter's view be correct, according to which the Arctic regions are the place where the Ocean Currents have their birth, or whether the view I have advocated be preferable, that the chief source of the oceanic circulation is to be recognised in the effects of tropical and subtropical heat, it is clear that we are rather concerned with the integrated effects of one or other cause (or of both causes combined) than with the amount by which temperature increases per mile of distance towards the equator. As I have already remarked, I conceive that any reasoning by which the contrary could be maintained would subvert the accepted and surely sufficient explanation of the trade and counter-trade winds. (The experiment described in illustration of this explanation in Daniell's Meteorology is open to much graver objections than Mr. Laughton has urged against Dr. Carpenter's experiment) And I note that here Mr. Laughton agrees with me, except that on the strength of his thermometric gradient he is as ready to give up one theory as the other, whereas I see no objection to retaining both.

The very word "gradient" should suggest the true answer to Mr. Laughton's reasoning. A gradient of one in ten (say) will produce little velocity in a rolling body traversing such an incline for a distance of only a few feet, but if the incline be a few miles long the body rolling down it would acquire a velocity exceeding that of our swiftest express trains. Or again, suppose Dr. Carpenter, desiring to illustrate the subject of springs of water, employed a conduit-pipe inclined 45 degrees to the vertical, would it be any valid objection to the illustration to urge that in most natural springs the water gradients are very much less? He could surely answer that the principle of his illustration was in no way affected by this circumstance, for if the water-gradients in nature are small, they act over a much longer range than could be employed in his experimental illustration. So with Mr. Laughton's temperature-gradients; they are very small indeed, but their action extends over a very great distance; and as in the two former cases the total fall measured vertically is to be looked upon as the true cause of the resulting motions, so I conceive that the total difference of temperature between Polar and Equatorial waters is to be considered in discussing the temperature theory of oceanic circulation.

I note, by the way, that "solar light" (by misprint or through a *lapsus calami*) was substituted for "solar heat" in my former letter. I did not think it necessary to correct this earlier, as I imagined the error would mislead no one. Like Mr. Laughton I "do not see what effects solar light can ever be supposed to produce," on the ocean, at least, in producing circulation.

I venture to remind Mr. Laughton that Dr. Carpenter's position in this matter is very different from his or mine. *We* have theorised on this subject, whether with more or less soundness time will show. But Dr. Carpenter has brought striking and important facts to our knowledge; and *if* there has been "an air of triumph both in Dr. Carpenter's lectures and writings" about ocean currents, he has had better cause for triumph than the mere success of a lecture-room experiment could have afforded him.

Richard A. Proctor

Brighton, July 21

### Western Chronicle of Science

I would beg to be allowed one or two remarks with reference to the very favourable review of the "Western Chronicle of Science" which appeared in last week's Nature.

It is not a "common Cornish habit to hang heavy jackets, great-coats, &c., on the lever of the safety-valve," and the farmers do not, *as a rule*, "mix guano with lime a few days before applying the manure." The editor has seen both these absurdities performed, and has used them as beacons to warn young men what to avoid. I may also remark that Mr. Williams's Paper is on Scientific *Mining* and not Scientific Nursing.

Falmouth, July 22 J. H. Collins

### Formation of Flints

Nothing can be more annoying to a reporter than to find he has not satisfied those whose statements it has been his duty to condense. I have therefore carefully examined the report to which Mr. Johnson takes exception in his letter to you of the 11th inst., and I regret that I am unable to acknowledge any error.

If Mr. Johnson will be good enough to consult some of those who were present at the meeting to which he refers, he will, I think, be more inclined to admit the accuracy of the report.

The Writer of the Report

## *NOTES*

THE arrangements are now completed for the session of the British Association, to commence on Wednesday next; and we may fairly expect a successful meeting. The large number of foreign *savants* who have announced their intention of being present will add greatly to the interest of the meeting, and the inhabitants of the pleasant Scottish capital seem determined to display to the utmost their well-known hospitality, both in a public and private capacity. The President's Address, as we have already announced, will be delivered on Wednesday evening at 8 o'clock; and at the first meeting of the General Committee, at 2 P.M. on the same day, the Presidents, Vice-presidents, and Secretaries of each Section will be appointed. On Thursday morning at eleven, the different sections will assemble in the rooms appointed for them, for the reading and discussion of reports and other communications; and the sittings will be resumed at the same hour each day till Tuesday, August 8. All further information may be obtained by those wishing to be present from the local secretaries, 14, Young Street, Edinburgh.

THE Emperor of Brazil has signified his intention of being present at the approaching meeting of the British Association.

THE Indian Civil Engineering College at Cooper's Hill will be opened by the Secretary of State and members of the Council of India on Saturday, August 5th.

WE have great pleasure in recording the inauguration of an effort to raise a memorial to the memory of the late Prof. William Allen Miller, and desire to call thereto the attention of all our readers who appreciate the valuable contributions to science for which we are indebted to that eminent chemist. The committee consists of Dr. Miller's fellow-professors at King's College and fellow-labourers in science, with the Rev. Principal Barry as chairman, Profs. Bentley and Bloxam, and Messrs. Cunningham and Tomlinson as secretaries, and Prof. Guy as treasurer. The intention is to raise a fund to be devoted, first, to the preparation of a bust or portrait of the late Dr. Miller, and, secondly, to the institution of a prize or scholarship in connection with King's College, and bearing his name. The ordinary amount of subscription is to be one guinea, and the list of subscribers will be published without any statement of the amounts subscribed.

THE International Congress of Prehistoric Anthropology and Archæology, which was last year postponed on account of the war, will be held this year at Bologna under the presidency of Count Gozzadini, and with Prof. Capellini as organising secretary. The sittings will commence on the 1st of October, and will continue during the following week. Mr. John Evans, F.R.S., of 65, Old Bailey, has consented to receive the subscriptions of English members, the amount of which has been fixed at ten shillings, and the payment of which entitles the member to the volume of proceedings.

THE President and Council of the Royal Geographical Society have addressed a letter to the Vice-Chancellors of the Universities of Oxford and Cambridge on the subject of the teaching of Physical and Political Geography. They observe that in the scheme now under the consideration of the Universities for the examination of boys between the ages of sixteen and eighteen from all the first-grade schools of England, neither branch of geography is included in the list of subjects out of which the boys are at liberty to choose any five for examination. They point out that geography has always been regarded as an essential, though subordinate, element of liberal education, and that it has been more and more frequently selected as their subject by candidates who pass the examination of the Science and Art Department of South Kensington. They hope that the Universities may see reason to repair the omission in the scheme above alluded to, and that they, by this and other means, will not only rescue geography from being badly taught in our schools, but will raise it to an even higher standard than it has yet attained.

THE examiners in the School of Law and Modern History at Oxford have given notice that at the next examination in December, Geography will form an important branch, and that papers will be set in the Honours Examination on this subject alone.

BY the appointment of Mr. Alexander Herschel to the Professorship of Experimental Philosophy at the Newcastle College of Physical Science, a vacancy occurs in the chair of Natural Philosophy at Anderson's University, Glasgow. Applications must be sent to the secretary by the 26th of August.

IN a letter to the *Athenæum*, the widow of the late Prof. De Morgan invites those who possess letters or other mementoes of the illustrious mathematician to lend them for the purpose of preparing a biography.

PROF. MARSH, of Yale College, has just started out on a second expedition for scientific exploration and discovery in the far West, which we trust will be still more fruitful in interesting results than the first one which brought to light so many extraordinary forms of fossil animals, that have been briefly described by him in the *American Journal of Science*, and referred to from time to time in our pages. His party for the present season will consist of thirteen besides himself, embracing quite a number of his companions of last year, and it is his intention to spend five or six months in searching the cretaceous and tertiary strata of the Rocky Mountain region and the Pacific coast for vertebrate fossil remains. With the experience of the past year and ample facilities, he expects to make very extensive collections.

THE New York Commissioners of Fish and Fisheries seem unwearied in their efforts to stock the waters of the State with the best varieties of fish. Among other results obtained by them, has been the hatching out during the past season of 3,000,000 shad eggs, or three times the total catch of the Hudson River. They have also bred several millions of white-fish, a million of salmon-trout, while of such fish as the black bass, pike, perch, and other varieties, they have supplied large numbers to those who would take and protect them. The period of their appointment will expire in the course of a year; but by that time, even if the commission should not be renewed, they will have made a most important impression upon the subject of the production of the fresh-water food supply.

COLLECTORS of scarce works in Natural History, curiosities, stone implements, rare specimens, &c., should not neglect the opportunity of inspecting the collection of a well-known collector, which will be sold at Thurgood and Giles's Auction Room, 7, Argyll Street, Regent Street, on July 31st and three following days; and will be on view two days before the first day's sale.

THE old adage about civilisation, or at least science, softening manners, is certainly being exemplified just now in France. M. Paul de Saint-Victor having given utterance to a violent tirade of undying hatred against Prussia, M. de Quesneville thus replies in the *Moniteur Scientifique*:—"L'humanité veut qu'on oublie; l'interêt des peuples, qui sont tous frères, la raison, le bon sens, tout nous dit que dans cette guerre qui vient de finir, la France, qui a succombé, doit chercher sa revanche, non dans la puissance de la force brutale, mais dans sa régénération sociale, et qu'elle doit demander à son génie de prouver sa supériorité dans les sciences, dans les lettres, et dans les arts, et que ce doit être là sa seule vengeance. C'est par là que la France est vraiment invincible, c'est par là qu'elle doit rester la grande nation, la nation aimée et préférée, et non dans une lutte d'obus et de chassepots." Noble words these, and full of the most rare form of generosity, that of the vanquished towards the victors; a fitting response to the note of reconciliation given forth by the venerable Baron Liebig, to which we referred some weeks since.

NORFOLK has always been noted for its devotion to ornithology. The "Transactions of the Norfolk and Norwich Naturalists' Society for 1870-71" contains several interesting and useful papers, among which we may especially mention "On the Ornithological Archæology of Norfolk," by T. Southwell, "On a Method of Registering Natural History Observations," by Prof. Newton, "A Natural History Tour in Spain and Algeria," by J. H. Gurney, and "On Certain Coast Insects found existing inland at Brandon, Suffolk." The author of this last paper believes that these species must have survived for several thousand years, since the great valley of the fens was submerged. The insects found are peculiar to coast sand-hills, the nearest of which are at a distance of forty miles; and yet, "in spite of their isolation and alteration of condition, the species are as true and as clearly defined as those of our present coast."

MR. W. G. M'IVOR, Superintendent of the Cinchona Plantations of the Bengal Government in British Sikkim, has published a lengthy report, of which the following is an abstract:—"The plantations are situated in the Valley of Rungbee in the Himalayas, about thirteen miles from Darjeeling, which seems admirably adapted for the growth of cinchona. The climate is very moist, being rarely free from rain. Nevertheless the state of the plantations is reported as very unsatisfactory; the plants have nothing like the luxuriant foliage which characterises those grown in Southern India on the Nilgheries. They seem to thrive for three or four years at the most, and then become diseased." Mr. M'Ivor says that trees of equal height do not produce so much bark as in the South of India, being of more slender growth, and the bark being thinner.

A GREAT demand for the English sparrow in various parts of the United States has induced their importation from England and Germany in large numbers; but in many instances where this has been done in large cages, most of the birds have died on the passage. In one instance, where four hundred were placed in two cages, only seven were safely landed in New York. Persons who have given this subject their attention, advise that the importations be made in long low cages, known as store cages, which are two or three feet long, about nine inches high, and twelve from back to front, with perches within two inches of the bottom. In a cage of this kind three or four dozen can, it is said, be readily transported, provided they be supplied with proper food, as well as with sand and fine gravel and plenty of water.

M. WURTZ has announced to the French Academy of Sciences that a young chemist in his laboratory has succeeded in transforming lactose, or the uncrystallisable sugar of milk, into dulcose or dulcine, the sugar of mannite, which may easily be obtained in very beautiful crystals, by the successive reaction of hydrochloric acid and sodium-amalgam.

M. FELIX PLATEAU has recently undertaken a number of experiments to determine the question whether the cause of the death of fresh-water animals when removed to sea water, and of marine animals when removed to fresh water, is the difference in the density or in the chemical constitution of the water. His observations were made mostly on various species of Articulata; he found that those fresh-water species which possess an aërial respiration can survive the change to salt water, while those which possess only a branchial and cutaneous respiration die quickly. By experimenting on water made denser by the solution of sugar, M. Plateau came to the conclusion that the density of the water is not the destructive agent, but a portion of the salts held in solution. The chlorides of sodium, potassium, and magnesium, he found to be very quickly fatal to fresh-water species, while the sulphates of magnesium and calcium had no prejudicial effect. In the same manner the death of marine animals in fresh water appeared due to the giving off of sea-salt from their bodies to the surrounding fluid. All these facts he believes explicable from the laws of endosmose and diffusion.

"A KEY to the Natural Orders of British Wild Flowering Plants," by Thomas Baxter, is designed to provide an "easier, although perhaps less scientific, method of identifying the orders of British Wild Flowering Plants than is generally found in analytical keys." There is no royal road to botany, and we doubt whether it is any real advantage to the student to sacrifice scientific in favour of superficial characters.

A CORRESPONDING member of the Glasgow Natural History Society, having been lately in Panama, has contributed to a local journal in the latter city an interesting account of the ants of the country. He describes a curious covered way or tubular bridge. In tracing one of these covered ways he found it led over a pretty wide fracture in the rocks, and was carried across in the air in the form of a tubular bridge of half an inch in diameter. It was the scene of busy traffic. There was nearly a foot of unsupported tube from one edge of the cliff to the other.

MR. THWAITES, in his "Enumeration of Ceylon Plants," says that from the large extent of forest land which has been and is now being appropriated to coffee cultivation, there is little doubt that some of the indigenous plants will in time become exceedingly rare, if not altogether extirpated, or exist only in the Botanic Garden, into which as many as possible are being introduced. The obtrusive character, too, of a plant brought to the island less than fifty years since is helping to alter the character of the vegetation up to an elevation of 3,000 feet. This is the *Lantana mixta*, a verbenaceous species introduced from the West Indies, which appears to have found in Ceylon a soil and climate exactly suited to its growth. It now covers thousands of acres with its dense masses of foliage, taking complete possession of land where cultivation has been neglected or abandoned, preventing the growth of any other plants, and even destroying small trees, the tops of which its subscandent stems are able to reach. The fruit of this plant is so acceptable to frugivorous birds of all kinds that, through their instrumentality, it is spreading rapidly, to the complete exclusion of the indigenous vegetation from spots where it becomes established.

## *METEOROLOGICAL OBSERVATORIES*

IN the part of the Quarterly Weather Report of the Meteorological Office just issued, for January—March, 1870, the following information is given with regard to the observatories from which the observations are recorded, accompanied by the illustrations which the courtesy of the committee enables us to reproduce. As correct an idea as possible is thus given of the value of the thermometrical and anemometrical observations published by them, and the local influences which may exert an effect in each case.

VALENCIA.—The observatory is situated close to the shore on the south side of the island, about three miles from the open sea.

The anemograph is on the roof of the house, which is two stories high. Its exposure is fairly good, for although it is situated in a valley, with hills of the height of about 1,000 feet to the south and south-east of it at a distance of three miles, and with a slight hill about 700 feet high distant three-quarters of a mile on the north-west of it, the country towards the other points of the compass is quite open, and the situation for wind is as favourable as can be obtained on that very rugged coast. The only point from which the wind is materially deflected or checked by local influence is the north-west. The house is an ordinary dwelling house of small size.

The thermograph is on its north side, facing due N.W. ½ N., and on the first story. The bulbs of the instruments are at a height of twelve feet above the ground, and about twenty feet above the sea level. The exposure is very good, as there are no buildings or trees in the vicinity to affect the readings.

ARMAGH.—The observatory is on a rising ground close to the town; it is situated in the centre of an ordinary garden and pleasureground, containing trees and shrubs of moderate size.

The anemograph is erected on the roof of the house, and raised seventeen feet above it, and is thoroughly well exposed to all points, excepting that the country about is undulating and fairly well wooded, which has the effect of retarding the motion of the air.

The thermograph screen is erected on the north side of the meteorological observatory; the bulbs are at the distance of four feet from the ground, and about 206 feet above the sea level. The exposure of the screen is good, though there are trees and shrubs about it. However,

VALENCIA

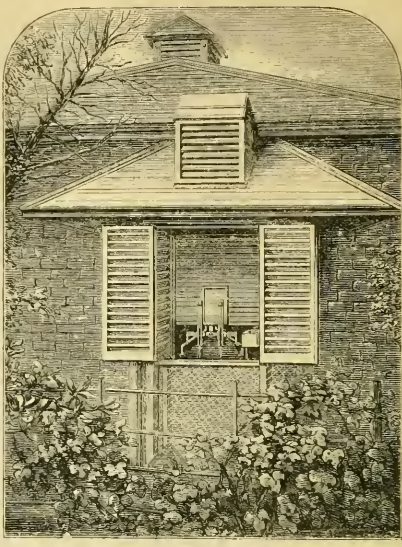
Dr. Robinson has satisfied himself by an independent series of observations that the record taken in the screen gives the true temperature of the place.

GLASGOW.—The instruments are at the astronomical observatory, which is placed on a slight rising ground at the west side of the town, and commands a clear view of the horizon in all directions. It occupies a central position in the valley of the Clyde, which is about 16 miles in breadth at that place. The bounding hills to the north are about 800 feet in height, those towards the south are about 400 ft. high.

The prevailing south-westerly winds sweep along the estuary of the Clyde and reach the observatory without much interruption.

The exposure both of the anemograph and of the thermograph screen is very satisfactory. The former is on the roof of the building, the latter is attached to the north wall of the tower in which the equatoreal is placed. The bulbs are 7 ft. above the ground, and about 190 ft. above sea level.

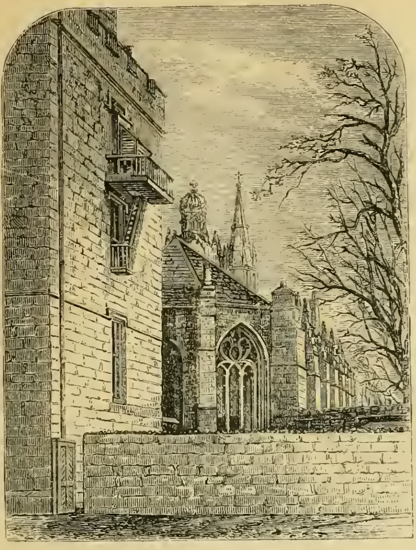
ABERDEEN.—The observatory is at King's College in Old Aberdeen, and lies on a plane gradually rising from



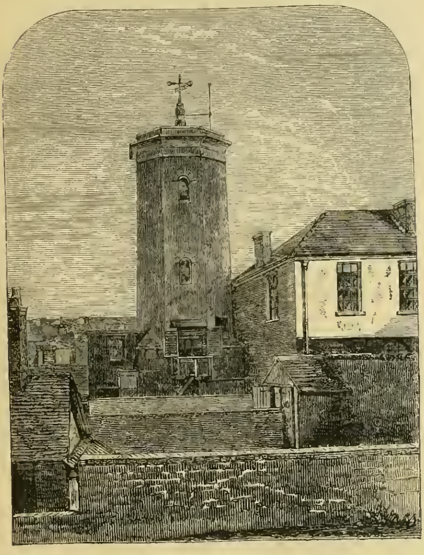
ARMAGH

GLASGOW

the sea, from which it is distant about a mile. There are no irregularities of surface in the vicinity, excepting the two river valleys of the Dee and Don, which are not of great importance. The ground immediately about the buildings is 46 ft. above the mean sea level.



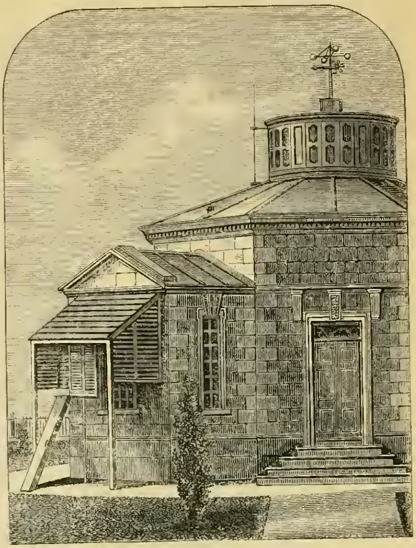
ABERDEEN



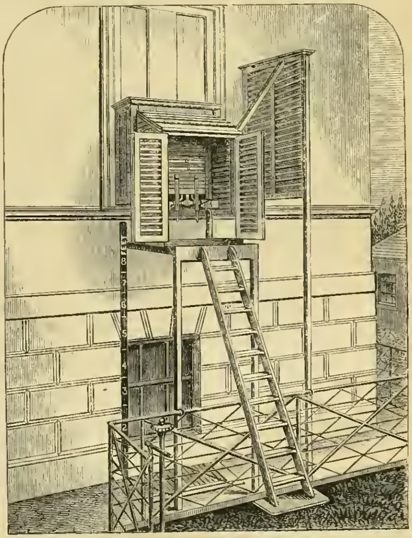
FALMOUTH

The anemograph is erected on the roof of the building, at a height of 72 ft. from the ground. It is well exposed on all sides.

Great difficulties were encountered in obtaining a site for the thermograph screen. The north side of the college



STONYHURST



KEW

is almost entirely occupied by the chapel. One wall of the building in which the physical cabinet and lecture-room are situated also affords a north aspect, but unfortunately there are trees growing at a short distance from it, which would entirely check the free circulation of air about the instruments were the screen set up at the usual elevation of about 6 feet above the ground.

Accordingly the window on the second story of the building was selected. It affords a free exposure to the north, but is at a level of 41 ft. above the ground, and about 87 feet above the sea level.

This elevation will of course exert a considerable influence on the thermometrical observations recorded.

FALMOUTH.—The establishment of an observatory at this station was beset with considerable difficulties; the building in which the Royal Cornwall Polytechnic Society holds its meetings was unsuited to the purposes of a meteorological station. Accordingly a tower was erected at the south-east corner of the bowling green, on the top of one of the hills on which the town is built.

The anemograph is on the summit of the tower, well exposed on all sides; but from the fact that the ground in the neighbourhood is uneven, the hill sloping rapidly down to the harbour, it seems probable that the force of the wind is not quite true, especially when it is easterly.

The position of the thermograph screen is far from being quite satisfactory; however, a better exposure could not be obtained. The screen is attached to the north wall of the tower, at an elevation of 11 feet above the ground, and about 200 feet above sea level.

It will be seen that there is the wall of a dwelling house at no great distance to the westward, which may possibly affect the instrument by radiation, and also interfere with the free circulation of the air.

STONYHURST.—The observatory stands in the centre of the college garden, which is on a gentle slope facing S.S.E., 381 feet above sea level. The anemograph stands on a cylindrical roof 12 feet in diameter and 4 feet 5 inches in height. The total height of the cups above the ground is 30 feet.

The country around, including the college grounds, is wooded, but not very thickly so, and the trees are in general small.

The nearest trees whose height could materially influence the anemograph are at a distance of about 200 yards, bearing from N. by W. to N. by E.

The main building of the college is placed at the N.W. of the observatory, at a distance of 193 yards, its angular height above the roof of the observatory being 1° 37′, and bearings from N. by W. to W.N.W.

The nearest hill is the Longridge Fell, whose nearest point is about two miles from the college. It extends from N. by W. to W. by N., and its highest point is 4° 1′.

Pendle Hill is at five and a half miles distance E.N.E.; height 2° 5′. Between these hills the country is very open. To the eastward there are hills at about four miles distance, height about 1°. To the S. and S.W. the land is low.

It will be seen from this that the anemograph is fairly well exposed to the different points of the compass.

The thermograph screen is attached to the north wall of the observatory, the bulbs are at an elevation of 7 ft. above the ground. The exposure is good.

KEW.—The observatory is situated in the old Deer Park at Richmond. It is a small building, which is well exposed to the wind, excepting on the west side, where there is a row of trees distant about 150 yards, which must materially affect the velocity of the wind. The country about is also well wooded.

The anemograph is placed on the dome.

The thermograph screen is attached to the north wall of the observatory within ten feet of the west end of that wall, at a height of ten feet above the ground, and about fifty above sea level. Its exposure is good.

We hope to take another opportunity of reviewing the volume itself.

## ON THE RECENT SOLAR ECLIPSE*

(*Continued from page* 233)

### II.—POLARISCOPIC OBSERVATIONS

WITH regard to the polarisation experiments, by the kindness of Mr. Spottiswoode I am enabled to show you, in a very clear way, the *raison d'être* of the polariscopic observations made during this and former eclipses; but the polariscopic ground is a wide one, and it is not my intention to cover it to-night.

I have had this arrangement of lamp, reflector and prisms made so that you may see how the polariscope can determine the percentage of reflected light at different angles, and the direction of reflection. Assume this lamp to represent the sun, let this reflector close to the lamp represent a particle near the sun, reflecting light to us, we shall naturally have the light reflected at a much larger angle than if the reflector were close to the screen representing a particle in our own air. Having this idea of the angle of reflection in your minds, and the fact that the larger the angle under these conditions the more the polarisation, if you take this lamp, as I have said, to represent the sun, and this mirror to represent any particle, of whatever kind you choose to imagine, it is clear that in order to get the maximum polariscopic effect from that particle, you must have it so situated that it will reflect light at a considerable angle to the beam coming from this lamp.

Now it is clear that in order to polarise the beam most strongly, I must place the reflector close to our imaginary sun. If I so place it as to represent a particle in our own atmosphere, the angle will be so small that the polarisation of the light will hardly be perceptible.

Here is our sunlight, which we will polarise at as great an angle as we can, by placing the reflector close to the imaginary sun, and send it through this magnificent prism which Mr. Spottiswoode has been good enough to place at our disposal; and in the path of the beam I will place an object so that you determine whether there is polarised light. [Experiment.] You see there is considerable brilliancy in those colours; their brilliancy depending upon the amount of polarisation.

Now if, instead of having our reflector close to our imaginary sun to represent a particle in the sun's atmosphere, we place it near the screen to represent a particle in our own, in which case the angle is extremely small, the brilliancy of the colours will entirely disappear. You see it has disappeared. The colours, as colours, are distinguishable, but their brilliancy has gone.

That is the rationale of the polariscopic observations, which have been made on the occasion of the last eclipse with more elaboration than they ever were before. If we found the corona to be strongly polarised, this was held to be a great argument in favour of the corona being a real solar appendage, an argument strengthened if the polarisation was also found to be radial. At present, however, a great many of the observations that have been made have not been received, and those that have been received are as discordant as those obtained in former eclipses, and therefore my account is an imperfect one, because I have not had an opportunity of discussing all these observations. Indeed, if I had, I should hesitate to give an opinion on the subject. When Mr. Carrington saw that small corona in 1851, and Mr. Gillis saw that small corona in 1858, neither of them traced any polarisation whatever; but when M. Liais saw that large corona in 1868, which was invisible to Mr. Gillis, he in his turn saw an immense amount of polarisation, which led him to believe that the corona was solar, the whole of it, rays and everything included, and that we had an indication of a solar atmosphere two or three times higher than the diameter of the sun; that is, an atmosphere two or three millions of miles in height. This observation is not in accordance with the general conclusions from the drawings I have shown you; and let me add that the assumption of reflection at the sun is not without its difficulties, and that we have not yet traced reflected sunlight, even when the strongest polariscopic effects have been observed.

### III.—AIRY'S AND MÄDLER'S CONCLUSIONS AS THE RESULTS OF THE PRE-SPECTROSCOPIC OBSERVATIONS

Before passing to the spectroscopic observations, I will state the conclusions at which the Astronomer Royal and M. Mädler arrived after the observations of 1860 had been gathered together.

The Astronomer Royal, in a lecture delivered before the British Association at Manchester in 1861, stated that the assumption of an atmosphere extending to the moon explained the observation of Plantamour, which could, he thought, be explained

* Lecture delivered at the Royal Institution, Friday, March 17, 1871.

in no other way, and he held also that the polarisation experiments seemed to show the same thing. The Astronomer Royal was content to find the reflection, which so many now insist must be at the sun, taking place somewhere between the earth and moon.
