The Vagus Protects the Heart. A. STEFANI.—Years of special study have convinced Stefani that the inhibiting innervation of the heart is a contrivance to protect it against the three chief causes of exhaustion: increased arterial pressure, dyspnea and high temperature. Danger from increased arterial pressure is averted as the vagus center is directly stimulated by the increase, and probably also indirectly through the depressor nerve. As the vagus center is stimulated the heart-beat is retarded, which in turn reduces the arterial pressure. In respect to dyspnea, the blood in this condition is incapable of restoring strength to exhausted muscles, but the stimulation of the vagus center by the dyspneic blood retards the heart and in this way reduces the amount of oxygen required by the heart, which can thus longer resist the deficiency of oxygen. Elevation of temperature has also a stimulating influence on the vagus center, as can be interestingly studied by irrigating the exposed medulla alternately with hot and cold physiologic solutions. The effect of temperature on the bulbar heart inhibiting center explains why a high temperature with a moderate pulse offers a better prognosis than a lower temperature with a more rapid pulse. As long as the inhibiting innervation is functioning well, the heart has little to fear from the high temperature of the blood. The vagus, he concludes, is the trophic nerve of the heart, increasing diastole, and causing the assimilative processes to preponderate over the dissimilative.

Tuberculosis and Pregnancy. E. CIOFFI.—Maragliano has stated that out of 188 cases of circumscribed tuberculosis, 34 died within twenty-one months, that is, 18 per cent., while the percentage of deaths among those who had passed through a pregnancy amounted to 94 per cent. These statistics are confirmed by Cioffi's experience of the excessive mortality among tuberculous parturients. He asserts that the persistence of fever and grave adynamia after childbirth, when other causes of infection are excluded, should suggest the idea of possible tuberculous lesions. In examining a tuberculous female it is well to bear in mind that the first manifestations of the disease may have coincided with a pregnancy. He also reaffirms Maragliano's statements (see JOURNAL, xxxii, p. 1253), that the pregnancy must be interrupted where tuberculosis is certain or suspected.

Il Policlinico, May 30.

Resection of the Cervical and Abdominal Sympathetic. RUGGI.—Ten cases of extirpation of the cervical sympathetic for glaucoma are reported, bilateral in four. The tolerance is remarkable, and also the rapid disappearance of the violent peribulbar pains. Ruggi recommends extirpation of the sympathetic in abdominal operations—the ganglia forming the plexus spermaticus, uterinus and ovarialis—as there are sensory spinal fibers in these ganglia which may keep up the pains after the corresponding organs have been removed. He even

considers that in many cases of hyperesthesia and crithism this intervention alone might be sufficiently effectual.

Nuova Rivista Clinico-Therapeutica (Naples), No. 5.

Influence of Bandaging the Extremities on Albuminuria and on the Arterial Pressure. BRUSCHINI.—Winding the lower extremities with elastic webbing for two to three hours has always produced a transient improvement in severe cases of albuminuria and permanently cured light cases—an extensive experience at De Renzi's clinic. The amount of urine at first diminishes but later returns to one-third above normal. The percentage of albumin in the urine gradually decreases during the bandaging and after, but returns to the previous proportion in twenty-four hours. The arterial pressure is materially increased during the bandaged period, falling later even below normal. The amount of albumin eliminated does not depend on the variations in the vascular pressure, but continues diminished after the bandage has been removed. This may be explained by the assumption that the rapid increase in arterial pressure regulates the circulation in the kidneys and acts on the renal innervation, which favorable effect lasts after the increase in the blood-pressure has subsided.

Societies.

Southern Minnesota Medical Association.—This Association held its annual meeting at Owatonna; secretary, W. T. Adams, Elgin. The next meeting will be at Winona.

Rock River Valley Medical Association.—The following officers were elected at the recent meeting of this Association, held in Dixon, Ill.: President, A. E. McBride of Sterling; vice-president, G. R. Proctor of Coleta; secretary, A. L. Miller of Dixon.

Huntington County Medical Association.—At the recent session of this Association, election of officers resulted as follows: President, H. C. Gemmell; secretary and treasurer, Ervin Wright. The next regular meeting will occur October 10, in Huntington, Ind.

Southwest Minnesota Medical Society.—The summer meeting of this society was held at Adrian, Minn., recently. The newly-elected president is G. R. Curran of Worthington; secretary and treasurer, H. D. Jenkes of Jasper. The January session will be held at Worthington.

Ontario Medical Association.—At the recent meeting of this Association the following officers were elected for 1899-1900, the Association to meet in Toronto again in 1900: President, J. E. Graham, Toronto—since deceased; first vice-president, Adam H. Wright, Toronto; second vice-president, M. I. Beeman, Newburgh, Ont.; third vice-president, R. J. Trimble, Queenston, Ont.; fourth vice-president, A. F. McKenzie, Monckton, Ont.; secretary, Harold C. Parsons, Toronto; assistant secretary, E. Hurlburt Stafford, Toronto; treasurer, George H. Carveth, Toronto.

Ontario Medical Council.—The thirty-fourth annual session of the Medical Council of this province met in Toronto July 4 and transacted business for the six succeeding days. The following is the list of officers for 1899-1900: President, W. F. Roome, M.P., London, Ont.; vice-president, William Britton, Toronto; registrar, R. A. Pyne, Toronto; treasurer, Wilberforce Aikins, Toronto. The fall examinations were fixed for the third Tuesday in November, 1899, at the college in Toronto, and those at the City Hall, Kingston, Ont., on the second Tuesday in May, 1900.

British Medical Association.

Annual Meeting, Portsmouth, Eng., August, 1899.

(From advance sheets of British Medical Journal.)

PLACE OF PHARMACOLOGY IN MEDICAL CURRICULUM.

DR. J. B. BRADBURY, in his remarks, said in part: For some time my mind has been exercised as to the proper place of pharmacology in the medical curriculum. So far as I

can make out there is a growing tendency for medical corporations—if we except the universities—to require less and less knowledge of the natural history, properties, composition, and action of drugs, from candidates for their diplomas; a condition of things much to be regretted. Personally I have no wish to revert to the state of affairs when candidates were expected to have a minute knowledge of the distinctions between the different species of senna, and of cinchona, etc.; but the danger now is that they may not be able to recognize senna at all, or to know the ingredients and doses of the most important pharmacopœial preparations. The consequence is, when settled in practice, that they are tempted to prescribe ready-made tabloids, elixirs, etc., the purity and the precise dose of the ingredients of which have no official sanction. Far be it from me to speak too disparagingly of these products of the chemist's ingenuity; in many cases they are most useful and valuable on account of their easy portability; but in other cases the therapeutic results would be more satisfactory if B. P. preparations were issued instead. And here may I say one word in praise of the new "pharmacopœia"? It is a model of what such a work would be—accurate, learned, and not overburdened with details. I am surprised, when I have to consult it, at the extent and variety of the information which it contains. The contents of such a book, so far as bear directly or indirectly on prescribing, should be thoroughly mastered by all medical students, and I would make such knowledge a compulsory part of the curriculum. Think for a moment of what is required of a medical man once started in practice. A considerable part of his work is writing prescriptions for his patients, and yet in respect of the knowledge of drugs and their actions his education is often most imperfect.

This brings me to the subject of pharmacology, or the action of drugs on the body in health and in disease. Is it too much to expect those who are daily to prescribe remedies to be acquainted with what is known of their actions? Certainly not. Well, then, how can this best be taught, and where in the student's course shall it come in? I think after anatomy and physiology, and alongside of pathology. I would make the first part of the final examination pathology and pharmacology—the sciences dealing respectively with disease and its treatment—and then the student should at the next stage be ready to apply the principles thus acquired to actual practice in connection with his clinical medicine, surgery, and midwifery.

The more intimately a student knows the action of the drugs he prescribes, the greater will be his success in treatment, and it is much to be regretted that some of the examining boards require a student to acquire this knowledge only in a haphazard way, or at a premature stage of his course. He can not appreciate physiologic action until he is possessed of the elements at least of physiology. On the other hand, he can not appreciate the importance of judicious prescribing, unless he has learned the nature and properties of the agents prescribed. These two considerations seem to me decisive as to the exact place in the curriculum at which pharmacology should be introduced. I believe I am correct in stating that every German university demands of its students a knowledge of pharmacology, and that the subject is regularly taught in these universities. It has been said that the medical student is already overburdened with subjects. That may be, but lighten some of the other less necessary subjects, and encourage him to give more attention to knowledge which when in practice he will daily and hourly be called on to use.

UNUNITED FRACTURE IN CHILDHOOD.

EDMUND OWEN, F.R.C.S., considered two questions: 1. Why is non-union after fracture of the tibia and fibula in children of comparatively frequent occurrence? 2. Why does its treatment by operation so often end in amputation? He said:

It is because of the frequency with which the tibia and fibula are involved in pseudarthrosis in children, that I suggest we should confine our remarks to ununited fracture in the leg bones, though there is no reason why the condition as affecting other long bones, notably the clavicle, humerus, and femur, should not be alluded to for purposes of illustration. I have met with non-union after fracture of the clavicle in a child; but, after all, the defect did not prove a very serious one.

The humerus is rarely the seat of pseudarthrosis in children, though in the adult it is often involved. So also with

the shaft of the femur; it is frequently affected in adult life but rarely in children, and the only case of femoral pseudarthrosis which I have met with in a child recovered after a long rest, without a cutting operation.

The two great differences between ununited fracture in the child and the adult are these, that in the child the false joint is generally in the leg, and that operative treatment is almost invariably futile.

Comparatively little attention has hitherto been directed to this subject, chiefly for the reason, I suspect, that the surgeons who had to deal with such cases could not publish a satisfactory result to their operative interference. Though why surgeons should publish accounts only of their successful cases I cannot understand, such practice being equally misleading and immoral.

So far as I know, the first essay directing special attention to the subject of ununited fracture in children was by Sir James Paget in *Studies from Old Case-books*, published in 1891. In it he gives brief records of three cases:

The first was that of an infant who broke her tibia and fibula from very slight violence; when she was 15 years old she was glad to have the leg amputated.

The second case was that of a baby who fell and broke its leg below the middle. "The fracture was at once well set, and every care was taken of it; the union gave way, and consolidation never took place, though scraping, excision, wiring, everything" were tried. The limb was eventually amputated.

In the third case a "bonesetter" broke the bent leg of a child, and the fracture did not repair in spite of a resort to resection and wiring, and in due course Dr. Snowcroft amputated the leg.

In the cases on which I have operated there was apparently no local impediment to the consolidation; the broken ends of the tibia forming a salient anterior angle at the junction of the middle and lower third of the leg, were in close apposition. No tendon or sequestrum interfered with them, and they were surrounded and connected by a considerable amount of fibrous tissue, which, unfortunately, failed to attain the higher development into bone.

It would be as interesting, as it is impossible, to know what is the exact state of the bone at the time of the fracture in those cases in which pseudarthrosis ensues. Does the fracture occur because there is some peculiar atrophic condition of the tibia and fibula at that spot? If this be the case, the failure of operation to remedy the defect is at once explained. Will the X-rays eventually help in the elucidation of this mysterious and interesting matter?

In some cases of pseudarthrosis in children the fracture occurs in utero or at the time of birth, but more often at a later period, and in many cases as the result of slight violence. In such circumstances, therefore, there might be but little to attract the attention of the mother or the surgeon to the injured leg-bone, and so the fracture might be neither recognized nor treated.

In the adult the chief cause of non-union after fracture is want of rest, and possibly this is one of the causes of the frequent occurrence of pseudarthrosis in the child's broken tibia; the fracture is not detected and not treated, and the child is carried about, the leg hanging over the mother's arm. Thus the weight of the foot constantly draws the lower end of the tibia backward, and the salient angle at the fracture is directed forward.

In the adult the humerus and femur are bones whose shafts are most often the seat of ununited fracture, and with them resection of the pseudarthrosis and wiring the freshened ends of the bone always results in consolidation. But in children non-union most often occurs in the tibia and fibula, and, so far as my experience goes, fibrous union is the best result that follows operative treatment. But as fibrous union of a fracture of the tibia and fibula is of no practical value, the operative treatment very often ends in amputation.

He then quoted Packard of Denver, and D'Arcy Power's table of 72 cases of ununited fracture of the long bones in children, of which 45 occurred in the tibia and fibula, giving a percentage of 62.5, and said:

As to the cause of the almost invariable failure of operative measures I regret to say that I have nothing definite to offer.

It has been suggested that previous to its being fractured the bone may have been the seat of an obscure affection somewhat allied to mollities ossium. All I can say is that, cutting down upon the seat of the fracture there was no remarkable softness of the bone. In the instances, however, in which I have operated long after the original injury there was an atrophic condition of the lower fragment of the tibia. The child's foot had been well enough developed, but the fragment between the ankle and the fracture has been poor and spindle-like, as in a case of infantile paralysis. Why should one bone be affected by any form of mollities ossium without other bones being affected, mollities being a general disease?

As to theories—what is wanted is a theory which shall at the same time explain the easy fracture of the bone from some slight injury; the absence of bony union whether the fracture be well treated or not; and the complete failure of those operative measures which can be depended upon for success in the treatment of pseudarthrosis in the adult.

The only theory which, so far as I can see, is able to answer all these requirements is that which invokes the influence of the trophic nerves. I am, therefore, going to suggest that leading up to the fracture there is some subtle disturbance in the anterior cornu of the grey crescent of the cord, inhibiting the due nutrition of the bone, and rendering it weak and friable, subsequently interfering with repair, and eventually frustrating the best endeavors of the operating surgeon. I would thus ally the condition to the molecular disturbance of the crescent which entails infantile paralysis, but one which exceeds its influence upon bone rather than muscle.

It would be interesting to know if the forcible straightening of bent bones—a very common operation in these times—has in many instances been followed not merely by delayed union, but by pseudarthrosis. Such an occurrence would, indeed, be a calamity.

In a large proportion of the cases the fracture has been the result of very slight violence. Is it not fair to assume that there was some antecedent weakness in that part of the bone? Admitting the pre-existence of such local weakness, it will not come as a matter of surprise that operative treatment ends in disappointment.

I see no reason why one should endeavor to attribute the fracture to any constitutional dyscrasia, such as rickets, syphilis, or tuberculosis. It is probable that in a large proportion of the cases the general treatment has been in such directions, but always with the same negative result.

In the heading of this paper I ask the question why the operative treatment of ununited fracture of the tibia is so often followed by amputation; and, in order to increase the chance of some satisfactory conclusion being arrived at, I will throw out these definite suggestions for discussion:

1. Why do the tibia and fibula of a child break as he is, for instance, pushing a chair along the carpet, whilst every other bone in his body is apparently sound?

2. Why, if the fracture is promptly discovered and properly treated, does it sometimes fail to consolidate?

3. Whether the fracture has been appropriately treated or not, how is it that the operative measures which suffice to cure pseudarthrosis in the adult fail miserably in the case of the ununited fracture of the leg bones of the child?

4. Is the diaphysis of the tibia, or the lower fragment, generally ill developed in these cases? If so, does this morbid condition help to explain the failure of the operative treatment? What is the explanation of this atrophic condition?

Lastly, has any operator ever established consolidation in the ununited tibia of a child? If so, will he kindly explain how he accomplished it? For my own part, I must regretfully confess that all my best efforts in that direction have ended in complete failure.

A PLEA FOR CONSERVATIVE GYNECOLOGY.

G. GRANVILLE BANTOCK, M.D., said in part: It was an idea of the late M. Péan's that a fibroid was essentially a malignant growth that must be removed some day, and some of the younger generation seem to have adopted that view. When the life-history of the uterine fibroid comes to be written, it will be seen how erroneous that idea is. A fibroid tumor does not necessarily interfere with impregnation, the full development of the fetus and its safe delivery, nor with the repetition

of the process again and again. Fallacious arguments have been drawn from the supposed analogy between the ovarian tumor and the fibroid, and because of the improved results which have followed upon early interference in the case of the ovarian tumor, it is maintained that a like result would follow in the case of the fibroid.

But it is impossible to establish any analogy between these two diseases. Who has heard of an ovarian tumor disappearing, except by the hand of the surgeon? On the other hand, who has not heard of fibroid tumors disappearing under various conditions, of which the essential element would seem to be an interference with the nutrition of the growth, as, for example, by the natural processes of the menopause and child-bearing, or by the removal of the appendages? Who, with an experience of ten or fifteen years, has not known fibroid tumors to become arrested in their growth and all symptoms cease, if, indeed, there were any; or observed tumors of considerable size become so quiescent as to render the risk of surgical interference unjustifiable?

Again, if a woman complain of pain in the pelvis—especially in either ovarian region—as the result of an abortion, chronic uterine congestion, or follicular disease of the cervix; or if she present symptoms attributable to the minor forms of derangement of the generative apparatus, she is deemed to require the removal of the appendages; and if she should be the subject of an uncomplicated retroversion which an ill-devised and ill-adapted pessary has failed to relieve, then she must undergo an operation, either by the vaginal or the abdominal route, for fixing it in position. I have seen many examples of all these, in which I have felt it my duty to advise against operation, and I do not know of a single case in which there has been reason for regret that that advice has been acted upon, while, on the contrary, I have positive evidence of its soundness in many cases. With regard to the case of uncomplicated retroversion, I have never seen the necessity for any operation, either that senseless method of fixing the organ by the vaginal route, or the more rational method—of course, on the assumption of its necessity—by the abdominal route. It would be taking a charitable view of the matter to say that errors of diagnosis are answerable for many mistakes in practice.

It was a maxim of the late Mr. Lawson Tait, to whose initiative gynecology owes so much, and who has left the impress of his genius indelibly stamped on the face of gynecology, "When in doubt, open the abdomen." But it was very much misunderstood. Mr. Tait did not mean that the abdomen should be opened to solve a doubt as to whether there was disease or not, but to ascertain the exact nature of a diseased condition of the existence of which there could be no doubt, which is a very different thing. I know that he shrank with horror from the practice of opening the peritoneal cavity and cutting a piece out of an ovary for microscopical examination and the purpose of diagnosis.

An idea of recent origin is this, namely, that the ovary secretes a something which is of service in the economy, and that whenever it is possible, in an operation involving of necessity the removal of only a part of the generative apparatus, one or both ovaries should be left. There is not an atom of evidence to support that idea. Yet there are those who do not hesitate to foud and urge the adoption of a practice on a pure and ridiculous assumption. It appears to have been assumed that because disease or loss of the thyroid gland—of whose function we know absolutely nothing definite—is sometimes followed by a certain train of symptoms, therefore the loss of the ovaries—of whose function we have definite knowledge—must be avoided because their loss will deprive the economy of something which the ovary secretes. Now the ovary was evidently devised for the purpose of perpetuating the species by providing an ova—of which each ovary contains a definite and limited supply—and for nothing else except it be to provide fees for their removal, not for their retention, and in the normal state, having discharged that function it atrophies, and like its neighbor the uterus, becomes not only a useless but a dangerous organ; for, as we only too well know, it is very liable to disease. In a very large proportion of cases disease attacks this organ long after it has served its purpose, and it seems to me rather one's duty to secure the removal of such an unsatisfactory appendage when opportunity offers

than to take steps for its retention. In my own practice I have had to remove both ovaries in a large number of cases. I have never willfully left an ovary when the uterus or its Fallopian tube has been removed; and over and over again patients, thus deprived of both these organs, have testified by word of mouth, confirmed by appearances, to a condition of good health, mental and physical, that had not been experienced for years previously, although these organs played no part in bringing about the disease which involved their removal. On the other hand, it has occurred to me to have to remove the second ovary after an interval of as many as eleven and even eighteen years. Surely the possibility of such an occurrence is a strong argument against the practice in question. Tait was much nearer the mark when he urged that the removal of the second ovary—as in the case of the appendages—should become a rule of practice, because of the frequency with which it was subsequently attacked.

(To be continued.)

Rocky Mountain Interstate Medical Association.

Salt Lake City, July 25-26, 1899.

(Concluded from p. 414.)

TREATMENT OF ACUTE CONJUNCTIVITIS.

DR. EDWARD JACKSON, Denver, called attention to the fact that under acute conjunctivitis are included, besides effects of eye strain and chemical and mechanical irritants, at least five distinct infections; and that successful treatment depends on exact diagnosis. Eye strain should always be eliminated. In all forms of infection complete cleansing of the conjunctiva at sufficiently short intervals is of greatest importance. For purulent conjunctivitis protargol is to be employed, with occasional applications of strong solutions of silver nitrate in the bad cases.

Mydriatics and cocaine should not be prescribed for acute conjunctivitis, since they are more likely to do harm than good. To aid in securing cleanliness of the conjunctiva, and to limit the danger from infection, all forms of the poultice, handage or compress should be carefully avoided.

DR. I. A. E. LYONS, Salt Lake City, has used weak solutions of cocaine, 1 to 1000, or 1 to 2000, in connection with boric acid, on account of its power to lessen congestion.

POINTS IN EYE WORK.

DR. R. F. LE MOND, Denver, dwelt on the important connections between eye lesions and brain disease. He believes that in astigmatism the degenerative changes often seen in the eye are for the purpose of relieving the strain that would otherwise fall on the brain.

OCULAR PROTHESIS.

DR. G. MELVILLE BLACK, Denver, called attention to the recent important suggestions of Snellen that artificial eyes should be made of different forms. The shell heretofore universally used was designed to be worn over a shrunken eyeball, and not to properly occupy the orbit after enucleation. There is also needed a concavoconvex form of artificial eye, to be worn over a small stump; and a double convex artificial eyeball to be worn after enucleation. Artificial eyes of these latter forms are not yet obtainable in this country. He has resorted to the expedient of filling in the cavity of the ordinary shell with a preparation of wax ("Gilbert's temporary stopping" used by dentists. This has proven very satisfactory, preventing the unsightly sinking of the artificial eye, and the accumulation of discharges and irritation of the conjunctiva by the formation of a vacuum behind it.

DR. EDWARD JACKSON thought this suggestion of great practical importance. It removes those objections to the operation of enucleation which has led to the trial of substitutes for it; such as the Mule's operation, which planned to keep a foreign body, the glass or metal sphere, permanently embedded in the tissues of the orbit.

GALL-STONES.

DR. I. B. PERKINS, Denver, found this subject of importance on account of the frequency of the occurrence of the condition, and the numerous, often obscure symptoms caused. He ascribed its greater frequency—of more than 2 to 1—in women to compression of the abdomen by dress, and a more sedentary life.

The distended gall-bladder must be distinguished from floating kidney, chiefly by its fixed position and fluctuation. He reported three cases in which operation had been necessary.

In closing the wound after operation, he sewed the gall-bladder to the abdominal wall with catgut. The stitches to close the parietal wound passed entirely through the abdominal wall; and those which came opposite the opening in the gall-bladder were introduced in this way: They were passed through the abdominal wall and into the gall-bladder. Then they were made to emerge from the gall-bladder before reaching the incision in it; and carried across the incision and made to enter the walls of the gall-bladder on the other side of the incision, and finally brought out through the abdominal wall. This made in effect, so far as the gall-bladder was concerned, a Lembert suture, inverting the lips of the wound so as to bring peritoneal surfaces in contact and secure prompt union.

In closing the wound at time of operation two or three stitches at the center of the opening in the gall-bladder were not tied. The wound was left open at this point, and packed to insure drainage. When drainage was no longer necessary, the surfaces were scarified and brought together and the stitches tied, without causing pain or requiring the use of an anesthetic.

DR. JOHN B. ROBERTS, Philadelphia, suggested that where a gall-stone was impacted in the common duct, the duct might be followed down to its entrance in the duodenum; and the duodenum opened opposite this entrance, a probe introduced into the duct, and the obstruction pushed back into the gall-bladder. The dilatation of the duct above the point of obstruction would commonly render this not difficult.

APPENDICITIS WITH ANOMALOUS POSITION OF APPENDIX.

DR. A. J. HOSMER, Salt Lake City, exhibited a boy operated for appendicitis, in whom no trace of appendix could be found through the usual right iliac incision; but a mass of inflammatory exudate could be felt far up and to the right. A median incision was made, and the gangrenous appendix removed from the midst of this mass. The colon seemed not to pass into the right iliac region at all. In this case pain was referred to the left side.

SUPRARENAL EXTRACT IN SURGERY OF EAR, NOSE AND THROAT.

DR. W. W. BULLETTE, Pueblo, Colo., read a paper on the value of this preparation, based on its use in 201 cases. He finds that it produces anemia of the tissue, reducing swelling, and preventing the hemorrhage that would otherwise obscure the field of operation. It also aids in securing local anesthesia, which is cut short by the hemorrhage that carries away much of the cocaine. Operations can thus be done without pain or loss of blood. There is little secondary hemorrhage, and no unpleasant effects. Since employing suprarenal extract cases presenting alarming symptoms of cocaine poisoning have been fewer. It reduces the dread of operations to a minimum.

BOTTINI INSTRUMENT FOR HYPERTROPHY OF THE PROSTATE.

DR. LEONARD FREEMAN, Denver, reported 8 cases operated on with this instrument. Of these, 5 were practically cured; 1 case improved at first, and continued to have no residual urine; but pain and frequency of urination were as bad as ever, and cancer was now suspected.

The instrument burrs grooves in the prostate. It consists of a platinum knife arranged like the male blade of a lithotrite; this is heated by the galvanic current, while any general burning of tissue in contact with the instrument is prevented by a stream of ice-water circulating through it. Operation with the instrument causes little pain or after bleeding.

Few men submit cheerfully to castration or even vasectomy. Bottini's operation causes no external wound. It can usually be done under local anesthesia. In the above cases general anesthesia was used once; and in two local anesthesia was not entirely satisfactory. The burned surfaces are practically sealed against absorption. The benefit is immediate. There are few relapses. The patient can move about within a day or two. The danger is less than by other modes of operation. Patients will submit to it when they would not submit to other operations.

MASTOID DISEASE.

DR. C. K. COLE, Helena, Mont., had seen sixteen cases of serious mastoid disease in the last twenty months, of which he reported four. These cases were essentially surgical, and should be seen by the surgeon. He advocated thorough open-

ing of the mastoid and irrigation with at least two to four quarts of hot sterilized solution. The periosteal incision is also useful in young patients. In extreme cases multiple openings are a rational procedure.

DR. W. W. BULETTE has found that mastoid disease followed acute otitis media; but with early paracentesis of the drum membrane, few will go on to the more grave condition. Heroic doses of epsom salts he has also found beneficial in preventing mastoid involvement.

DR. H. R. BULL, Grand Junction, Colo., recently met with two cases of mastoid disease following measles. He employed hydrogen dioxide as a cleansing agent in these cases.

TOXIC CAUSES OF INSANITY.

DR. HUBERT WORK, Pueblo, Colo., called attention to the generation within the body of poisons capable of causing mental alienation. Loss of weight and anorexia occur so constantly in connection with certain psychoses as to suggest a common cause. It is certain that insanities do result from prolonged digestive disturbances. Autoinfection from the alimentary canal may alone cause many cases. He reported four illustrative cases in which treatment directed to the source of the toxic influence brought about a cure of the mental symptoms. One was a case of digestive disturbances, cured in three months. The second was a case of rheumatism, cured in eighteen months. The third was a case of chronic cystitis, cured in four months. The fourth was a case of hepatic derangement, cured in two months by treatment of the hepatic disease alone.

Insanity is a symptom, and removal of its cause brings recovery. In no disease is proper medical treatment more needed at the beginning.

AUTOINTOXICATION AND BLOOD MORPHOLOGY.

DR. P. S. KEOGH, Salt Lake City, discussed the bearing of these subjects on the preparation of the patient for surgical operations. The older surgeons noticed that complications followed less frequently when the patient had been carefully prepared for operation by catharsis. Symptoms of indigestion and gastro-intestinal disease should always be carefully looked for. Examination of the urine might reveal a deficient elimination of solids. General anesthesia increases the danger from autointoxication by reducing the amount of oxygen in the blood. The examination of the blood, particularly with reference to the percentage of oxyhemoglobin, and leucocytosis, gives very important evidence regarding the patient's power of resistance.

GENERAL AND LOCAL INFECTION BY THE BACTERIUM COLI.

DR. J. N. HALL, Denver, reported two fatal cases of this form of infection. The organism, at first regarded as a harmless habitant of the normal alimentary canal, was now known to be one of the most important of the pathogenic bacteria. Probably the organisms designated by this name should be regarded as constituting an extensive group, presenting varying degrees of virulence, rather than as a single species. The first patient, after twenty-four hours' retention of urine, presented great numbers of the colon bacilli in the bladder. There ensued pleuritis, bronchopneumonia, pericarditis, a purpuric eruption, pyelitis, and perinephritis inflammation. In the second patient, also a male, there were numerous abscesses scattered over the body, and a purpuric eruption. The bladder was distended with acid, foul-smelling urine, containing sugar, and loaded with bacilli. Gas was generated in the bladder. The spleen was found septic, also the liver. The heart was large and fatty. There was nephritis, and a large abscess behind the upper end of the sternum.

EARLY DIAGNOSIS OF TUBERCULOSIS.

DR. A. M. HOLMES, Denver, made a plea for the early recognition of this disease, at a time when it was most curable. There are early evidences that the vital forces are impaired, which warn of danger, and if these are heeded recovery may be brought about. Impaired health, loss of appetite and weight, gastric disturbances, dyspnea and persistent cough should lead to careful and repeated examinations. The early examination of sputum is overrated. The bacteria may not be found. Concealed foci of infection may exist a long time before the bacilli find their way into the sputum.

"Cog-wheel respiration" he regards as an important early sign. Subnormal morning temperature is also an important symptom. Hemorrhage is not early in the disease; the study

of the blood is of greater importance than the study of the sputum, especially the examination of stained films, with differential count. There is no excuse for delay in the diagnosis of tuberculosis, for we have a certain test in the reaction produced by tuberculin. It begins with the injection of 1 mg. If no reaction follows, three days later 3 mg. are injected; and if this produces no effect 5 mg. may be tried. The injection is made in the evening and the reaction commonly occurs six to twelve hours later.

At the business meeting fifteen new members were elected, and Judson Daland and John B. Roberts of Philadelphia were elected honorary members. The following officers were chosen: President, Charles K. Cole, Helena, Mont.; vice-presidents, Leonard Freeman, Denver, and R. H. Reed of Wyoming; treasurer, Charles G. Plummer, Salt Lake City; recording secretary, Donald Campbell, Butte, Mont.; corresponding secretary, S. D. Hopkins, Denver. The next meeting will be held at Butte, Mont., the last week of August, 1900.

California Academy of Medicine.

July Meeting.

(Concluded from p. 415.)

INCUBATION PERIOD IN SYPHILIS.

DR. DOUGLASS W. MONTGOMERY brought up this subject, and said—The interval elapsing between the inoculation of the syphilitic virus and the appearance of the chancre seems to be subject to wide variations. This is unfortunate, as the physician is often obliged, in order to cover possibilities in foretelling the future, to keep an anxious patient, with a stricken conscience, a long time in suspense. Authorities disagree very widely. According to Max Joseph, for instance, this time of incubation varies between ten and forty-two days, with an average of three to four weeks. Personally, my impression is that this average of three to four weeks is too long; but impressions are not facts, and facts personally observed are very difficult to gather on this subject. Patients are inaccurate or unable to give the date of inoculation, or are often unable to give the time of the appearance of the chancre. The following is an instance where the observation was accurate and by a trained observer:

On July 10, 1894, a doctor who had been attending the meeting of the AMERICAN MEDICAL ASSOCIATION, held that year in San Francisco, came to me with a rosola of the body and limbs, and of the right palm and sole. There was a herpetic sore in the mouth, which, however, was not characteristically syphilitic, and there was some redness of the fauces and throat. There was also stiffness of the right masseter muscle, and some pain down to the margin of the lower part of the sternum, which was also thought to be muscular. Both right and left epitrochlear lymphatic nodules were enlarged, and there was a large packet of swollen lymphatic nodules in the left axilla. A diagnosis of syphilis was made, and the doctor then drew my attention to a dark red patch, about the size of a nickel, over the inner side of the lower extremity of the left ulnar, which he said was the site of an ulcer. He then told me that on May 15, while on the train, coming to San Francisco, he noticed in this situation a small sore which was painful and annoying, particularly because the edge of his cuff struck against it continually. This date is probably accurate, because while traveling one can by coincident circumstances be more precise about dates than in the ordinary routine of life, and, as before stated, the inconvenience caused by the edge of the cuff, drew early attention to the lesion. This small sore grew larger, and became covered with a black scab, and then swelling of the left epitrochlear lymphatics and of the nodules in the left axilla was noticed. Pronounced secondary lesions were first noticed on July 5, although for a month previous he had suffered from malaise and pains in the limbs. He said that shortly before leaving home, while circumcising a patient suffering from a venereal sore on the prepuce, he pricked himself in the arm with the point of the knife. On returning to his home in the Middle States, he consulted his books and sent me the exact date of the above-mentioned operation, which was April 29, 1894, or sixteen full days previous to noticing the sore on his forearm. In his letter he also said that the patient he then circumcised was, when again seen, suffering from the most virulent secondary symptoms he

had ever seen. The doctor had on April 29 circumsised a syphilitic patient, and during the operation pricked his arm slightly with the point of the knife. In the region of this puncture, on May 15, or sixteen full days after the operation, he noticed the sore, and on July 5 cutaneous symptoms were manifested. He consulted me July 10. There can be no doubt that this lesion on the arm was a chancre; its existence before general manifestations appeared, together with the large packet of enlarged lymphatic nodules in the axilla, were in themselves excellent evidence of this. In addition was the fact of his having abraded himself with a knife which he had used in circumsising a patient with a venereal sore, who broke out shortly afterward with symptoms of virulent secondary syphilis.

DR. DUDLEY TAIT—I do not think there is anything positive as to the period of incubation; I think it a very variable quantity. I have personally studied this matter a little, and that is the result of my own observations, as well as the opinion of most authorities. I remember two patients who presented excellent opportunities for observation, as they were both infected extragenitally. The first patient was a girl who had been kissed on the neck by a young man infected with syphilis; she had recently suffered a slight burn on the neck, at the site of the kiss, and this was not quite healed up at the time. Nineteen and a half days after the kiss a sore appeared at this point, and became an ulcer. I did not make a correct diagnosis at the time, but after curetting tried to graft over the ulcer. In making the skin slices from the arm of the lover of the girl—himself uninfected—I infected him with syphilis, which first appeared eighteen days after the operation, and was a beautifully typical case. A third case of infection occurs to me, in which the patient was in all probability infected in a barber shop by a slight cut with a razor. Though two other cases of syphilitic infection are reported from the same barber shop, the source of infection with this man is not absolutely clear, for the reason that he was then living with a woman who had had syphilis, and she may have kissed him on the cheek at the site of an abrasion. The time in this case, and the two others from the same shop, was twenty days.

DR. S. J. HUNKIN—In the cases just mentioned by Dr. Tait I should think the average period of incubation as mentioned by Dr. Montgomery was substantiated; they were all from eighteen to twenty days.

DR. TAIT—There are cases on record where the period of incubation has been as great as 100 or 110 days.

DR. MONTGOMERY—There can be no doubt that the time of incubation is a variable one. I remember some interesting cases in point reported in the *Lancet* some years ago. Some soldiers had had themselves tattooed by a person who was afflicted with syphilis. In the process he dipped the needle with which he made the tattoo punctures into his saliva. The men could all be carefully watched, and the time before the appearance of the chancre in some of them was quite extended; one man went for eighty-nine days before the chancre made its appearance on his arm. There are also some cases reported in which the period of incubation was very short. I believe Taylor mentions one case in which the chancre appeared on the patient after two or three days.

Chicago Academy of Medicine.

Regular Meeting, June 23, 1899.

(Continued from p. 116.)

With reference to pulmonary tuberculosis, the presence of immunity here is one of considerable importance, from the fact that so many persons during some period of their life are thrown in contact with persons who have consumption and die of consumption. This may be either through their relationship with such persons in schools, boarding-houses, or from marriage, by constant and prolonged contact for months or years, during which they show absolutely no evidence of infection. They are apparently perfectly healthy and live a long time afterward without any affection, while subject to this constant contagion during the period of their existence. For this reason I believe there is considerable natural immunity in tuberculosis. The majority of tubercular infections become most highly developed at about the time that maturity results.

They are not so evident except in the form of bone tubercularis and some special forms in the spine itself. But I think at the beginning a large number of cases of pulmonary tuberculosis, considering that phase of it, have their beginning in the child life of the individual, and I am also of the opinion that tuberculosis may remain latent for a considerable period when some circumstance, as an unusual exertion, or an intercurrent disease, may furnish an opportunity for the tuberculosis, consumption more particularly, to become active and for the individual to have a sudden extension of the disease and die within a short period.

Now, as to the relation of the child to tuberculosis and measures for its prevention in after life: If tuberculosis begins during child life we should, as far as possible, prevent the individual from coming in contact with tubercular material. We should not feed children on milk of tubercular cattle, because I do not believe it is necessary to have intestinal infection from the simple fact that tubercular milk is used. On the other hand, it is fairly clear to my mind from reasoning on the subject, that tubercle bacilli can live in the intestinal canal and pass into the circulation and become localized at some distant part of the body without any infection of the intestinal canal at all. We find by inoculation experiments on animals, injecting tubercular milk under the skin at different points that we can produce a localized tuberculosis in the spleen, the liver, and in the lungs. The same is true of pigs fed on the milk of cows that have tuberculosis. There is frequently no infection of the intestinal canal, but we have tuberculosis of the liver and of other internal organs with, at times, tuberculosis of the lungs. For that reason, the food should be one that is free from tuberculosis. This is a question by itself, and even a large one, as far as cattle affected with tuberculosis are concerned.

Another point of great importance is that children who represent a condition of immaturity, apparent defects in natural immunity, should be selected as special examples for training toward the development of their natural immunity. We have all forms of physical examination as persons become older. When children start in school there is no attempt made at physical examination. That is a point of considerable importance, as brought out by Dr. Scott, and those children who appear to be lacking in natural immunity should be selected from the pupils for special courses of development along those lines, to guard against the possibility of developing those diseases later in life. We know the good effect of sanatoria and climatic changes on individuals when they are actually infected with tuberculosis. What, then would be the possibilities in individuals or children who show what is generally looked on as a tubercular tendency, that is, absence of robustness, failure of natural immunity, if they are placed under similar conditions to those individuals who are actually infected with tuberculosis and who recover. Then, if that can not be done, as far as tuberculosis is concerned, gymnastic work and special training should be had, so that there shall be a complete elimination of the effete products of the body, keeping everything clean, because we know bacterial infection is especially prone to take place where there is a nidus allowing bacteria to remain for a certain length of time, sometimes longer in the case of one form of bacterium, sometimes shorter in the case of others. The bacillus of tuberculosis may remain for a considerable time at one point, and then under suitable conditions develop and begin its serious work. In the child, if taken in hand in a proper manner and given a proper course of training, so that the areas of least resistance in the body are renovated, the chance of tuberculosis developing in after life is greatly lessened, and the chances for developing a strong man or woman in the end are very much more certain than if the child has to educate itself and care for itself in after life.

MENTAL AND NERVOUS ASPECTS.

DR. JAMES G. KIRKMAN—The relations of childhood to adult defect and disease are, from a psychiatric and neurologic standpoint, determined by three factors: heredity, the reaction of the organization to the periods of stress, and the results of disease and environment after birth. The development of man after birth is marked by periods during which certain important functions are, so to speak, learned by the organ, or other functions pass into disuse. The infant is a being

wrapped up in its instincts of self-preservation. The primary ego is predominant, and the child is an egoistic parasite. Development of a complex mental state tends to check a simple explosive propensity in accordance with the well-known law of evolution from the simple homogeneous to the complex heterogeneous with a loss of explosive forces. The forebrain is a checking apparatus against the lower and more instinctive natural impulses. The higher its development, the greater its tendency to subordinate the particular to the general. In training the infant, the difference between its explosion of anger and egotism and expressions of suffering or need must be recognized. Many a mother, by taking the child up when it cries, irrespective of the cause of the crying, has laid the foundation of that future selfishness which develops into the egotist who keeps within the law, or into the criminal who passes beyond it. With this training, conscience begins to assume its priority, the forebrain acts as a check on the purely vegetative functions, and the secondary ego develops to take precedence over the primary. If, as already stated, through lack of training, the checking functions are weakened, disordered predominance of the natural instinct occurs, and, when totally lost, a criminal appears who opposes the ethical order of society, a parasite of the worst kind, who not only lives on his host, but destroys him in so doing. During this period of stress the child expresses the fatigue of its nervous system by restlessness, which often finds expression in crying and explosions of temper with motor expressions even extending to convulsions. The balance between the system can only be secured by full development of all the checks—which are the latest and best acquirement of the race. The seeming suffering consequent on the period of the first dentition, however, often leads, through misguided albeit natural sympathy, to simulation of the primary ego of the child and hence to the retention of the child at a period of mental development that implies an arrest of the mind and moral faculties. This arrest implies, during the subsequent period of the second dentition and of puberty and adolescence, increased training to eradicate tendencies springing from the unchecked primary ego. Otherwise these render the child unsuited to his mental and moral environment. The seeds of what is afterward cruelty toward animals, playmates and relatives are often sown by the attention given to the invalid infant during the troubles resultant on the constitutional evolution of the first dentition. The child mentally is in the condition of primitive man, who was the center of the universe, owned everything, but feared nothing except the unknown. The mental state of the infant at this time, as later, resembles, so far as the fear of the unknown is concerned, the mind of the savage and the animal. A lion which would face a man will run away from a suddenly-opened umbrella. The child, like the savage, does not distinguish between its dreams, its beliefs, and actual perceptions of the senses. This is healthily shown in the way it regards its doll, and unhealthily—unless corrected, by an instinct of refuge-taking in the arms of the nurse or parent—in its fear of the unknown. This unknown, until quite late, does not include death, but some occult trifle. As any condition of disease or disorder interfering with the balance which makes up the nervous system creates uncertainty, as this mental uncertainty increases fear of the unknown, the child during the period of the first dentition accumulates a mass of fears which dominate its mental life unless corrected by refuge-taking and training in like manner as such fears do primitive man, the persecutory delusional lunatic or the neurasthenic. The two last, through denudation of checks acquired during infancy by illness, have returned to the condition of man and the child. In proportion as the infant is surrounded by judicious care during this period, and not by maudlin sympathy which defeats its own objects, will the fear of the unknown be so controlled as to render easy the child's training during subsequent periods. During this period, training should be directed to developing the tendency to the full effect of refuge-taking by limiting this to occasions. While the spoiled child is often the offspring of a defective, its defects are decidedly increased by the training given by its defective parent. Maudlin sympathy, whether for animals, children or invalids, is an expression not of the secondary ego, but of the lowest primary, a mere pose to secure personal gratification at the least possi-

ble expense. It tends to develop its own likeness in the persons to whom it is applied. Good wine makes very sour vinegar. Parental affection of the defective is thus very often worse than neglect. Expressions of either the disorder or the passions of the child during this period are generally motor. The child cries, whether from anger or unsatisfied desire, in a convulsive manner accompanied by marked motor manifestations almost approaching convulsions. Like the primitive races, convulsive pantomime repeats or adds to speech. These two conditions are so intermingled that while on the one hand physical treatment of the conditions underlying convulsive tendencies will cure them, or hygiene will prevent them and thus prevent explosions of anger and egotism to which they give rise; so, on the other hand, will mental and moral treatment of the egotism and anger prevent convulsive tendencies. The humoring of the supposed invalid child at this period has the same bad effect as the humoring of a chronic invalid. As the child does not distinguish clearly between its suddenly-conceived thoughts and what it sees, hears or feels, hallucinations may occur. Some of them are regarded as lies, some are ridiculed, others are humored, all of which procedures tend to fix these hallucinations in the mind to be retained in after-life.

The second period of stress is marked by the important maturity of the jaws and teeth, but while the stress of development is as great during this period as during the last described, it is not so obviously related to the development of the teeth as in popular opinion to be ascribed to that cause alone. The factor, therefore, which tended to interfere with training during the first period of stress is not so obviously present. Sympathy for the child during the second period of dentition is much less maudlin and its judicious exercise is much more frequent.

The second period is marked also by developments in the alimentary and other systems. A species of contest for existence has resulted between the central nervous system and the other systems whose effects are felt during the next period of stress. During this period, provided the struggle for existence goes well, the average child does not display any special disorder, but if, from inherited or congenital defect, development of the system does not proceed equally, then evidences of stress occur. Among the nerve expressions likely to result from this stress are the following:

Neuroses.—Convulsions, nervous laughs, nervous coughs, spasmodic hicough, spasmodic sneezing, stuttering, tics, neuralgia, chorea, epilepsy, somnambulism, ecstasy and hysteria.

Psychoses.—Hallucinations, anomalies of character, aberrant sentiments—love jealousy, anger, pessimism—imperative conceptions—pure; attended by impulsive acts (arson, suicide, destructiveness, homicide, alcoholism, theft, rape, non-criminal acts)—idiotcy, imbecility, night terrors, mania, acute confusional insanity, melancholia, transitory frenzy, stuporous insanity, katatonia, moral imbecility, paranoia, periodical insanity.

In many respects these nerve expressions of stress are remains of the imperfect training of the first period; in part, they are evidences of that precocity which is an expression of premature senility. The struggle for existence between the higher nervous system and the ordinary functions of the body partially results in victory for the latter. In man from about the third year onward further growth, though an absolute adaptation to and environment, is to some extent growth in degeneration and senility. It is not carried to so low a degree as in the apes, although by it man is to some extent brought nearer to the apes, and among the higher races the progress toward senility is less marked than among the lower. The child of negro races is scarcely, if at all, less intelligent than the Caucasian child, but while the negro as he grows up becomes stupid and obtuse, the Caucasian man retains much of his child-like vivacity. In the highest human types, as represented in men of genius, there is a striking approximation to the child type. The average man of genius is comparatively short and large-brained—the two chief characteristics of the child. His general facial expression, as well as his temperament, recalls the child. The aim, therefore, of education at this time should be directed to the creation of a system of

balance which would prevent that operation of the law of economy of growth whereby a too much stimulated nerve being weakened, the rest of the organs gain at the expense of the organ controlled by it. Neglect of this principle checks further growth or unduly precipitates the approach of the next period. This is shown in some of the nerve expressions of stress. It is evident that imperative conceptions sometimes take a form connected with the continuance of the race which should not appear in the ordinary course of events until after the onset of the next period of stress, between 14 and 25. As the third great period of stress is marked by development in the bony structures, especially connected with the teeth and jaws, the systems connected with these not unnaturally affect the skull and face and set in action causes which, if not duly balanced with the system as a whole, tend to check brain growths or developments as to associations.

The three periods described are not inaptly designated the period of the first dentition, the period of the second dentition, and the period of puberty. The last, albeit better designated as just described, could also be entitled the period of the third dentition, since in it the dentition is finally completed, the wisdom teeth appearing, if at all, during its close. During this period the bones of the pelvis which enclose the structures devoted to the continuance of the race are finally perfected. The period is marked by the contest between two great functions, one intended for the continuance of the race, the other for the systematization of the various intellectual and other checks for the benefit of the individual which have been acquired during the first decade and a half of life.

In consequence of this struggle, the mind, which, during the previous period had acquired somewhat of a balance, has new factors introduced which create for the time being a consciousness of instability that underlies the doubting tendency so often present during this period. The imperative conceptions described as occurring during the previous period, are now more frequent and more likely to be attended by impulsive acts. Furthermore, the imperative conception is less likely to be dominated by a healthy, suddenly acquired conception. For this reason suicide, homicide and other imperative acts are much more frequent during this period than during the preceding. The introduction of the potent influence of the great instinct of the race is also a disturbing factor, especially as this instinct can be aggravated by local disorder apparently without relation to it. In the previous period many of the impulsive acts were committed without consciousness of their moral significance. In the present period this moral significance is extended even to acts not ordinarily regarded as coming within the scope of ethics. This mental state is often unduly encouraged because of the belief that it is an expression of ethical significance, whereas it is but an additional evidence of egotism to be discouraged. For this reason, an undue struggle for class position breaks down the individual since the worry engendered by possible failure destroys the balance between the different mental faculties. It is worry, not study, which is the cause of the many nervous and mental difficulties resulting at this period.

The influence of disease, of improper food and environment may even in congenitally sound individuals produce any of the neuroses and psychoses already mentioned.

SCHOOL STRAIN OF CHILDHOOD IN ITS RELATION TO ADULT DISEASE AND DEFECT.

PROF. COLIN A. SCOTT.—School strain falls on those who are least able to bear it. The first thing in considering this question is the defectives. During the last year under the auspices of the Chicago school board, I conducted a series of examinations, directly and indirectly, of 8750 school children. This is only a small percentage of the children of our public schools of Chicago, but the percentage of defectives among this number was about 18 per cent. of those examined. The defects that were sought for, in the first place, were those of the eye and of the ear, and in the second place, such nervous defects as could be observed by the teacher in the ordinary course of school events, and such as a slight or superficial physical examination could detect. The problem was to adapt school work to the condition of the children, as well as to make it of service in assisting the children. Slight defects of hearing I find are exceedingly common. I have full descriptions of hundreds of cases. A concrete case will be of advantage.

A pupil was observed by his teacher to be careless in his work; he was not as far advanced in his grade as the rest of the boys. He did not pay very close attention to what was being done; he threw things around, made considerable noise but when spoken to sharply, paid attention. This case was referred to me. After hearing the description, the first ques-

tion I asked of the teacher was whether she had tested the hearing of the child, and she said she had not done so. On examination, by the teacher, it was found that this boy was partially deaf in both ears, although the deafness was not recognized either by the parents or any of the teachers before a special examination was made to reveal it. In such a case the boy did not need the services of an oculist to reveal the fact that he was hard of hearing, nor do many of the cases. This in my opinion is the function of the teacher. The teacher or parents, more particularly the teacher, should be able to observe these defects, although it is admitted that for treatment or a more careful diagnosis we must obtain the services of members of the medical profession. It requires a specialist to make a thorough examination to determine whether a child has defective hearing or not; still, teachers can make use of the watch-test for determining varying degrees of acuteness of hearing. As a result of this method there are hundreds of cases that have been recognized and whose condition in the school has been improved.

In the examination of the eyes we have the same necessity for examination on the part of the teacher. President Harper, of the University of Chicago, told me that until he was 12 years of age the world was to him a dim and misty place; that neither his parents, his teacher, nor physician knew that he was astigmatic. It seems to me, we need more strenuous efforts made to open the eyes of the public as to the importance of some recognition of the ordinary defects of childhood.

The other defects, those of the nervous system, are more difficult of recognition by the teacher. There are many children in the schools who are somewhat like the case I saw a few days ago. I observed a lesson which was being taught by an enthusiastic teacher to an enthusiastic class. There was apparently nothing lacking to a superficial observer. I watched the children carefully, and I saw many cases similar to the one I am about to describe.

A little girl during the first twenty minutes of the lesson was all excitement. She listened to the teacher very attentively; her face was flushed. During that time I saw two distinct flushes pass over her face. She surpassed her companions in answering the questions of the teacher. But at the end of twenty minutes she collapsed. Her head drooped, she put her thumb in her mouth, gazed vacantly, then tried to arouse herself, but to no avail. She had passed through a condition of irritable weakness to one of considerable exhaustion, both phases of undue fatigue. I asked the teacher if she had observed this child, and she said she had not particularly. She had noticed, however, that the child was very bright, and answered questions much better than any of the other pupils. She had not observed the flushes or other signs.

Now, it seems to me, if the eyes of the teachers were opened to the significance of these observations, it would have a great effect on the development of children in school. It would also have an indirect effect on children other than those who are defective. Our present examination system of education is arranged like a series of hurdles, over which our pupils are expected to pass, cart horses and race horses alike. Such a system is not best adapted to develop the brain of the child. It overtaxes and strains the nervous system, producing injurious effects. School studies should be arranged in such a way that the work is adapted to each individual pupil whether it results in the passing of a definite examination or not. The aim is to round out the development of the child, making as symmetrically developed an individual as possible. In this connection the most important discovery in child-study is what I have been accustomed to call by the name of "nascent periods." In the mental life of the child there are periods which are favorable for the growth of certain organs or combinations of organs. We know that the heart, for example, has different periods of growth, partly independent of the rest of the body. The same is true of the liver as well as other organs. Growth in height follows the same law. There are distinct periods when growth in height is accelerated. A similar periodicity is observed with respect to mental activities and, as Flechsig shows, with different groups of brain fibers. These nascent periods are important to observe, and I have studied some of them with care. (Illustrations were given.) It requires a long time to settle this matter scientifically, in such a way as to be helpful, to determine the limits of each nascent period, and what it is that grows out of it. There is a fertile field for investigation in this line, extending from the intellectual into the emotional and moral qualities. I have considerable data on that matter. All of these things are materials which concern the proper education of the child. Teachers and educators are becoming interested in child-study, and are beginning to realize its importance.

(To be continued.)

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 10 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting, of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Those new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 19, 1899.

BRAIN WEIGHT AS INDEX OF INTELLIGENCE.

Opinions regarding the weight of the brain being an index of intelligence have fluctuated within wide limits. Before the days of cerebral localization there were many physiologists who believed that an individual's intelligence was directly proportionate to the total weight of the encephalon. A large brain meant large mentality. As the encephalon began to be more closely investigated and the post-mortem records were more carefully compared, it was discovered that large brains were not always possessed by those who exhibited the highest intelligence. In fact some of the greatest thinkers in the world were the owners of brains much below the average in absolute weight and size. This apparently upset the earlier physiologic dicta in regard to mind activity being dependent on the physical brain. The discussion at once assumed two aspects. Some physiologists frankly declared that mind was not solely a product of brain function, but that it was an entity dependent for its manifestation on the brain, but nevertheless quite separate and distinct from the latter. Scalpel and alembic might analyze the brain, but they could do nothing to explain the mind. These views characterized the metaphysical physiologists. The materialistic physiologists, on the other hand, took the ground that the mind was solely and *in toto* a product of brain activity, and that accordingly it must follow that a large mind necessarily presupposes a large brain. In attempting to harmonize their views with the apparently contradictory observation that many of the most intelligent men were the possessors of undersized brains, these physiologists were again divided into two camps, as it were; some taking the

ground that the cellular richness of the cortex, including its convoluted development, was the real indicator of intelligence irrespective of the total brain weight, while the others maintained that the total brain weight was the potential indicator though not necessarily the actual one. The latter insisted that a large brain represented large capacity for mentalization, and that the brain, like the muscles, was capable of development, and the greater that development so much the greater will be the resulting mentalization. Its potentiality, according to these physiologists, rather than its manifested activity is what is shown in its total weight.

The average weight of the encephalon of a well-built European is about 1380 grams. As an argument in favor of brain weight being an indicator of mental power, real or potential, it is instructive to recall that Bismarck's brain, the largest on record, was calculated to have weighed about 1867 grams; while the actual weight of Cuvier's was 1830, Byron's 1807, Kant's 1650, Schiller's 1630 and Dante's 1420. It is unfortunate that in most of these instances the total body weight was not at the same time estimated, for that might have had some bearing on the question. Many of these large brains, as for instance those of Cuvier and Rubenstein, were associated with early hydrocephalus, which would seem to argue in favor of brain development as an antecedent of mental activity if not of actual mental development. So many brilliant thinkers have been hydrocephalic that we are forced to think that the expansion of the skull by reason of which the brain was later on enabled to grow, was an advantageous circumstance, in the enhancement of the individual's mental potentiality.

As an illustration of great mental power with a total low brain weight, Gambetta is often cited, as his brain weight was below those of the average. It should be noted, however, that the speech-area of this great orator was uncommonly well developed, a fact which leads us to immediately ask the questions, what is intelligence? How much of it do great thinkers actually possess and exhibit? What relation does it bear to the special cortical areas whose functions we are now acquainted with? and do these special areas exhibit an increase in size and weight always in correspondence with the respective forms of special intelligence? Taking all these questions into consideration it would seem that brain weight, not *in toto* but in part, is after all an index of intelligence. Unfortunate is it that the variety of intelligence revealed by individual great thinkers has not been taken more into consideration when their brains were being examined post-mortem. It is exceedingly rare, if the phenomenon ever does happen, for a man to manifest a universal intelligence equally strong and exalted in all directions. His brilliancy is more apt to shine in one special department of knowledge, and all his other acquisitions or natural powers will be subsidiary to this. In his "Intellectual Life" Hammerton goes so far even as to say that a man can not possess two languages, certainly not three, with equal accuracy, for as one be-

comes more and more facile therein the other loses! Hence, intelligence, great as it may be in some individuals, is after all a more or less limited mental phenomenon. If this be so, the character of that intelligence should be given due consideration in the study of brain weight as its indicator. Many brains have been studied from this standpoint, and to a remarkable degree there has been observed a constant increase in size and weight of special parts that bear a relationship to the kind of superior intelligence manifested. Great artists, for example, in whom the visual imagination is highly developed, have been found to show a corresponding increase beyond the average in size and weight of the representative visual center in the occipital lobe.

The pendulum is thus swinging back again and in a newer but somewhat different sense, brain weight, including brain development with convolitional and cellular increase, is shown to be more or less of an index of intelligence.

DILATION OF STOMACH DUE TO COMPRESSION OF DUODENO-JEJUNAL JUNCTION BY MESENTERIC ARTERY AND ROOT OF MESENTERY.

P. A. Albrecht¹ describes two cases in which uncontrollable vomiting and dilation of the stomach, and other symptoms of ileus, developed soon after operations on parts of the body not in direct connection with the abdominal organs. In the post-mortem examination of both these cases, it was found that the dilatation of the stomach ceased promptly at the superior mesenteric artery, and that there was no organic stricture of the duodenum at that point. In the second case it was found that when the mesentery was pulled down, then the superior mesenteric artery became tensely stretched over the duodenum, so that the latter was flattened out from before backward against the spinal column. The small intestines were crowded down into the true pelvis; but there were no adhesions which would hold them in the pelvis.

In 1842 Rokitansky suggested that intestinal obstruction might result from the pressure of one part of the intestine on another. Glenard pointed out that the duodeno-jejunal junction may become compressed by the mesentery and that the superior mesenteric artery is accompanied by a number of bundles of connective tissue, which form the real suspensory ligament or root of the small intestine. If the small intestine should sink into the true pelvis, then a weight equal to about 500 grams would pull on this ligament at the duodeno-jejunal junction.

Kundrat describes several cases in which he found the stomach and duodenum greatly dilated, the small intestine crowded down into the pelvis, and complete compression at the duodeno-jejunal junction by the mesentery. He believes that the cases are due to the peculiar form of the mesentery. Schnitzler also describes two cases, in one of which the duodenum was

completely obliterated by a band, which proved to contain the superior mesenteric artery.

Albrecht calls attention to the fact that the ascending part of the duodenum, at the point of the superior mesenteric artery, is usually not round but flat, and that when the finger is placed in the duodenum under the artery, and the small intestine pulled down into the pelvis, the lumen of the duodenum becomes smaller. Albrecht believes that an overfilled stomach, especially when previously dilated, would press on the small intestine, and that in consequence the superior mesenteric artery would compress the duodenum against the spinal column and cause a true mechanical obstruction so that fluid would be unable to escape and enormous dilatation of the stomach and duodenum would result, which would only tend to aggravate the condition. In the same way chronic dilatation of the stomach might also become an indirect cause of obstruction of the duodenum. The paresis of the stomach which results after narcosis and surgical operations may be assumed, with Albrecht, to lead to similar results.

The principal symptoms of this form of obstruction of the stomach and duodenum are the following: profuse vomiting, the vomitus containing bile but not feces; great distension in the region of the stomach, but absence of intestinal meteorism. The previous history of dilatation of the stomach would be important. There would also be found dulness above the symphysis, owing to the compression of the small intestines crowded into the pelvis. Albrecht believes that a number of cases which die apparently as the result of acute gastrectasia belong to this category of ileus.

As regards treatment, then, gastrectasia should be remedied, as a prophylactic measure; during the acute attack the patient should be put in the knee-chest position, so as to liberate the small intestine from the pelvis, and the stomach should be emptied.

ORIGIN OF DERMOID CYSTS OF OVARY.

In the June issue of *Progressive Medicine* Dr. John G. Clark presents an interesting review of the recent research of Kroemer concerning the histogenesis of the so-called dermoid cysts of the ovary. As the final result of his review of the literature and of his study of twelve cases, Kroemer reached full agreement with Wilms, who was the first to offer any proof of the ovulogenous development of these tumors. The theory which has ascribed these tumors to inclusion of the ectodermal layer, in the early growth of the embryo, has never been satisfactorily proven. The principal objection to this theory is that ovarian dermoid cysts do not correspond to the type seen in the superficial parts of the body, where dermoids undoubtedly come from the ectoderm, because they contain only those tissues which are found in this layer. Arnsperger¹ reaches the same conclusions as Wilms and Kroemer. One of the tumors which formed the basis of Arnsperger's investigation was as large as a goose egg.

¹ Hammerton: Intellectual Life, Part III, Letter viii.

² Virch. Arch., 1899, 156, Heft 2.

¹ Virch. Arch., 1899, 156, p. 1.

and grew in the right ovary of a woman 27 years old. The special feature of this tumor was a complete trachea, and also structures which correspond to the stomach and intestines, as well as a distinct head region. The development of this entodermal tube was especially interesting, because the individual parts of which it was made up maintained the same relationship to each other as in a rudimentary embryo. The growth originated entirely from the ovary. In two other cases he also found distinct entodermal elements. The number of instances of so-called dermoid cysts of the ovary in which entodermal elements and rudimentary organs of various kinds, including more or less fully developed brains and retinal epithelium, as well as true optic vesicles, rudiments of ears, cranial nerves, ganglia, a quite complete medullary tube, as well as the remarkable observation of Kroemer of a sympathetic plexus within the muscular wall of an intestinal tract, are becoming quite numerous. As already indicated, dermoid cysts usually develop from the inside of the ovary; in a few instances the tumor has been attached to the ovary by a thin pedicle. As pointed out by Kroemer, these formations are neither simple tumors nor cysts, but consist of a cystic portion and of the varied embryologic elements enumerated. The changing form of the cystic portion, and in the growth of the dermoid itself, gives rise to the variability in the general appearance of the tumor. According to the views advanced by Wilms, Kroemer, and Arnsperger, the cystic portion of these growths is of follicular origin, while the embryologic parts are of ovulogenous development. In an observation by Lee a dipinnate dermoid maintained the same relationship to the follicular cavity as the ovum to the follicle. Sutton made the same observation in the case of a dermoid cyst in the ovary of a mare. Kroemer likewise made out a similar relationship of the tumor to the follicle in two cases. The epidermal lining of dermoid cysts, therefore, appears to be derived from the ectoderm of the ovum. It would, therefore, seem that a dermoid cyst of the ovary in reality represents an ovum, and that the cyst is the more or less successful result of parthenogenesis. Kroemer points out that it is hardly correct to attribute the development to parthenogenesis proper, because this is a normal process in lower plant and animal life for the propagation of species, while in this case it was a distinctly pathologic process, in which the growth, differentiation of organs, etc., are atypic and occur without any definite law. The dermoid cysts of the testicles are explained by Wilms in somewhat the same manner. In this case the various portions of organs and tissues are derived from pathologic growth of the sperm cell. It has been suggested that these tumors be designated as embryoma, and it is thought that the development of the structures from the single ovum or sperm cell is greatly hindered, because of the confinement in the small space of cyst, so that only rudiments of embryos are developed. In what manner the ovum or sperm cell is stimulated to this anomalous growth is at present entirely mysterious.

CURATIVE VALUE OF GYNECOLOGIC OPERATIONS IN INSANITY.

The effect of disorders of the reproductive organs in causing or perpetuating mental disorders in women has been for a long time a vexed question among practical alienists. A certain proportion, probably the majority, are dubious as to the importance of this factor; many see objections to any very general extension of gynecologic surgery in asylums except where absolutely necessary. On the other side, we have some ardent enthusiasts who see in gynecologic diseases one of the chief active factors in the mental disorders of women. An article in the July issue of the *Dominion Medical Monthly* is in evidence of this; it is one of several that have recently emanated from Canadian sources maintaining the necessity and importance of gynecologic work in the insane. The author, Dr. Ernest Hall, has no hesitation in stating his convictions. He writes, however, with the heat of the reformer when he speaks of the opposition of "vested prejudices and conventionalities" that must be disturbed, and of dyeing the chariot wheel of progress red with the "political and official life blood of those who affirm that present methods are adequate." His statistics, so far as he gives them, however, are of interest; out of 70 female insane patients, 33 of the most intelligent and favorable cases were selected for examination; 30 of these cases were found fit cases for operation and 7 were operated on with the result of three cures, mental and physical, 2 improved, 1 death, and 1 with the result still in suspense. He tabulates 12 cases, the above being included, from which a better estimate of the strength of his position can be made. One of the twelve is noteworthy, a cure of melancholia of ten years' standing by double castration. One of the other two cases cured was insanity of only three weeks' standing, and the other of only a little over a year. It seems quite within the range of possibility that the production of an artificial menopause might have sufficient effect to materially modify the patient's mental condition, but as none of his cases has yet been over seventeen months under treatment, there still remains some rational basis for reservation of opinion as to the permanent cure, and the results are possibly less startling than he claims. The personal equation of the physician needs to be taken into account in the case of the estimate of the cure or improvement of the insane, as has long since been pointed out by Pliny Earle and others. This element has to be considered to some extent in any case, and all the more if the physician has enthusiastic views on any special theory or mode of treatment. On the other hand, we have the varying opinions among gynecologists and our knowledge of the variations of practice among them.

Insane women are not capable of deciding for themselves, and the physician's responsibility is therefore increased in their case. It is not remarkable, therefore, that asylum physicians should be cautious in advocating any general gynecologic crusade among their patients.

It is, moreover, unjustifiable to assume, as does Dr. Hall, that they are guilty of what is practically criminal neglect in not so doing. The opinions of experienced alienist physicians and neurologists not in accord with those of Drs. Hall, Bucke, Rohé and others on this subject also do not go for nothing in this matter; they are certainly numerous enough and sufficiently eminent in the profession to carry weight. The introduction of women physicians into hospitals for the insane, for the special duty of gynecologic work, has met some of the demands of the reformers, but these are by no means unanimously enthusiastic over the value of operative gynecology in the treatment of insanity in females. It is easy to suppose that any considerable operation may affect the mental condition temporarily for the better, as it does the attacks in epilepsy, but that enough permanent improvement can be brought about in this way may possibly be as dubious in the one case as in the other. It can hardly be said to have been proved as yet.

Considering all these facts, it seems safest to say that while an insane woman has as good a right to be relieved of needless suffering as any other, yet there are obvious reasons why judicious conservatism is advisable in the practice of gynecology in the insane.

AN EDITORIAL OVERSIGHT.

In its issue of August 5, the *N. Y. Medical Record* editorially gives credit to the American author, Dr. Leonard Corning, for priority in the method of local anesthesia by intraspinal injection, a method lately rediscovered by Bier of Keil, and published by him in the *Deutsche Zeitsch. f. Chir.* last April. The recognition is an excellent thing and the editorial prominence given it by the editor of the *Record* is altogether admirable, but it comes a little late. If he had thoroughly perused an up-to-date journal and read Dr. Matas' review of the progress of surgery in our souvenir issue of June 3, he might have given it in his editorial on June 24, on "A New Method of Anesthesia." Not only was Corning's work noticed in Dr. Matas' paper above, but also the fact that it antedated the "so-called methods of Oberst and of Bier." We are not surprised that in some things foreigners are fourteen years behind this country, but American editors ought not to be caught napping even if they do make honorable amends for it later.

THE DEVIL AS A HEALER.

Joseph Wilhoff of Chicago is in custody charged with obtaining money under false pretenses. He posed as a "Doctor," claiming to cure by the aid of the devil, his silent but active partner. Like all other supernatural healers, including the followers of "Mother" Eddy and "Father" Dowie, no ailment was too serious for his skill, provided there was money forthcoming, but it had to be "down on the nail,"—no pay, no cure. The trouble with Wilhoff, however, was that he went out of the beaten path; so long as he only swindled people out of their money with his pretense of healing, all went well, but when he began to fling around incantations, spells, and hoodoos among the superstitious Germans who composed his clientèle, the trouble began to brew. He, it

appeared, not only convinced his dupes that he could cure diseases with the aid of the devil, but that he could raise hades generally with their temporal affairs, and finally some of them rebelled. The principal difference between this impostor and others at present notorious is chiefly in the sheep's clothing affected by the latter. There is, or should be, as good a case against them for obtaining money under false pretenses as against this open and avowed ally of his satanic majesty. It may appear more respectable to some people to take the sacred names in vain to promote frauds, than to use that of the devil, but it is in every way blasphemous and more morally criminal. It is, moreover, infinitely more harmful, as the devil naturally has but a small following that believes him capable of doing them any good. If Wilhoff is convicted, why not Dowie and the mercenary followers of "Mother" Eddy.

THE PLAGUE.

Fear has been expressed in various newspaper editorials and despatches, that the appearance of plague in Egypt is only a precursor of its invasion of Europe—not that there will be an inefficient quarantine against Egyptian infected ports, but that the steady advance westward of the disease, of which its foothold in Egypt is only an indication, is not likely to be checked unless more rigid and concerted international measures are adopted to check its progress. The Mecca pilgrimage is stated as one great source of danger, and a still more eastern gateway is said to be afforded through the Persian Gulf, where the English sanitary regulations are said to be sadly neglected. It is certain that the range of the epidemic has been widened, increasing the possible sources of contagion, and that a rigid sanitary cordon on land is much more difficult to make effective than a quarantine at seaports, and for this reason the possibility of the pest reaching and ravaging Europe is to a certain extent increased. We have already expressed an opinion that the peril is not as great as some have feared, and we see no reason to retract it. The conditions of the past are not likely to be reproduced, and it must be remembered that the plague has been actually in Europe six or eight times during the present century, without its repeating the history of the invasions of the past. Readers of Kinglake's "Eothen" will remember the description of his entry into the plague-stricken city of Cairo. In those days, while quarantines were rigid in spots, the general rules of sanitation were far behind what we have to-day, and Europe was, it may safely be said, far more vulnerable to attack than at the present. That it then escaped is a good augury for the future. It is quite possible, even probable, that there may be local footholds of the plague along the Russian and Turkish borders in Asia, or that it may appear, through some oversight, in some poorly-watched European port, but the chances of its spreading from such foci are not great. There are like dangers on our own coasts. It may be carried to San Francisco by way of Japan or China, but it will be our own fault if it gains a serious foothold. The need of vigilance is great at all times, but fear is irrational and unwarranted. As it is, the risk does not justify the sensational newspaper articles and despatches that have appeared.

VOLUNTARY VS. COMPULSORY NOTIFICATION OF CONTAGIOUS DISEASE.

In 1895 the Chicago Department of Health inaugurated the plan of allowing physicians to "assume the responsibility" of enforcing precautionary measures against the spread of contagion in cases of diphtheria and scarlet fever. In other words, it made the notification of these disorders voluntary instead of compulsory. The results of this policy are reported in the *Monthly Bulletin* of the Department, for June, which is just in print. In 1894, the last year under the compulsory system, the total notifications of diphtheria were 1921, and the total deaths recorded from the disease, 1293, making an apparent death-rate from diphtheria of 67.3. In 1897 the cases reported were 3103, and the deaths 726, and in the first six months of 1899 the reported cases were 1726, as against 1304 for the corresponding period in 1897. Of all infectious reportable diseases, the total figures were 4380 to 1760 for the same periods respectively. These statistics are far better than labored arguments in favor of voluntary vs. compulsory reporting. As Commissioner Reynolds says: "The ordinance requirement of uncompensated professional service by physicians in the report of their contagious disease cases had not only been a demonstrated failure, but the tactless efforts to enforce the provision had alienated a most valuable ally of any health department. Now, more than ever before in its history, this Department is in touch with the physicians of the city, more fully than ever it receives the information from them necessary to success in its efforts to restrict the spread of the communicable diseases and to protect and promote the public health." It might be added here that the statistics further show that in the first half of 1897 the Department disinfected premises in 419 cases, and supervised 223 contagious disease funerals. In 1899, during the corresponding period, 2096 premises were disinfected and 380 funerals supervised. Figures speak louder than words, and while they may be misused, in this case no question can be raised as to their significance.

A MEDICOLEGAL QUESTION.

Last week a lawyer was fined fifty dollars and sentenced to thirty days in jail for practicing law without a license. During the trial it developed that he had practiced in the courts of Chicago for years; that he had a diploma from a law school, but had not been admitted to the bar. Editorially, the *Chicago Evening News* comments on the verdict as follows:

As to this decision no one interested in the dignity of the bar and the cause of justice will demur. It may be added, however, that the fact that this ignorant and incapable lawyer practiced ten years in the criminal and justice courts of Chicago before his right to the honors and emoluments of the profession of the law was questioned is not altogether creditable to the courts in which he practiced nor to the bar of which he was supposed to be a member. It is encouraging to note, however, that the Chicago Bar Association has at last taken the duty in hand of determining who are properly members of the legal profession in this city. The association will render a needed and valuable service to itself and the people by looking after other alleged members of the legal profession whose ignorance of law and the ethics of the bar are

continually bringing the latter and also the administration of justice into disrepute. It is possibly, occasionally, that even a regularly admitted lawyer may resemble necessity in knowing no law, but that is not the rule. There should be a weeding out of these alleged lawyers.

To all of this we say "amen." But we would like to ask, if the question is not considered too impertinent, why people should not be protected against medical pretenders who are "turned loose to prey upon the people" just as much as against legal frauds? If the Chicago Bar Association is doing a good thing in weeding out "alleged members of the legal profession," why is it not a good thing when an organization of medical men attempts to rid the community of dishonorable advertising frauds, faith curers, Dowieites, magnetic healers and the various hordes of vampires, who, under the cloak of religion, pseudoscience, and other pretexts, prey on the people? If not, is it because life and health are of less importance to the individual than his money? Is it of more importance that the criminal should have an educated lawyer to defend or prosecute him than that an individual suffering from disease should have an educated physician to attend him? Will the *News* and the other Chicago newspapers, which are rightly endorsing the Chicago Bar Association in its action, in the same manner endorse the Chicago Medical Society should it attempt to rid the city of alleged "doctors" and charlatans who infect it? In other words, is it not just as important to have honorable and educated physicians as it is to have honorable and educated lawyers? And if so, do not physicians deserve the support of newspapers in their efforts to keep the standard of their profession high and honorable, as much as the lawyers in their efforts to keep up the dignity of the legal profession, even though in the case of physicians it might result in the loss to the newspapers of some advertising patronage?

Medical News.

DR. L. NAPOLEON BOSTON, Philadelphia, has gone to England and will be away for several weeks' rest.

THE RUSSIAN authorities have ordered the disinfection of all the mail arriving from places suspected of being infected by the plague.

SEVERAL cases of smallpox are reported from Windsor, Ont., and the three cases in the smallpox hospital in Toronto are now nearly well.

PROF. GRASSI has been granted, by the Board of Public Health in Italy, a sum to defray the expenses of further research on malaria.

THE LOUISIANA State Board of Health has sent Dr. J. J. Bland to Hampton, Va., to report on the yellow fever outbreak at that point.

THE SURGICAL clinic at Leipsic will have a centennial celebration in October, when a bust of Professor Thiersch will be installed on the city hospital grounds.

PROF. MAX VON FREY, the well-known physiologist, is to take the place of Professor Fiek, who has retired from active professional life, in the Würzburg Medical Faculty.

As we go to press we learn that Justice Everett has imposed a fine of \$100 on Mrs. Bratz, the disciple of the "Divine Healer," Dowie, referred to in last week's *JOURNAL*, page 423. The case is to be appealed.

At EASTON, Pa., recently, a man gained entrance to the Easton Hospital under the pretense that he came to make an inspection of the electric wires, and stole money from many of the patients.

THE ANTI-RABIES service at the Constantinople bacteriologic institute, according to *Presse Med.*, July 20, has been placed in charge of Dr. Marie, summoned from the Paris Institut Pasteur for the purpose.

THE SUPERINTENDENT of the Kings County Hospital, N. Y., has made the complaint that the new civil service rules have so crippled the working of the institution as to seriously interfere with its service.

A COMMITTEE has been appointed by the Delaware County Institute of Science, organized in 1833, to prepare a memorial of the life and works of the late Dr. Daniel G. Brinton, which is to be preserved in the archives of the institute.

A SEVERE fire broke out in a branch of the Royal Lunatic Asylum of Aberdeen, Scotland, July 31. The building was damaged nearly \$25,000. Over 200 patients were in the building at the time but all were removed in safety.

E. H. STARLING, F. R. S., has been appointed Jodrell Professor of Physiology in University College, London, to succeed Prof. Schäfer, whose removal to Edinburgh we recorded in these columns several weeks ago. Prof. Starling is lecturer on physiology in Guy's Hospital.

A COUPLE of internes at the Hospital Pelegrin, Bordeaux, recently fought a duel with pistols discharged simultaneously at twenty-five paces, resulting in the perforation of the femoral artery and bladder and the death of one of the combatants, the son of a physician.

FEW SCIENTISTS receive such assistance in their research as Dr. Vatchef of Bulgaria, in his study of the Slavic type. The authorities have ordered exact measurements and physical details to be recorded according to his instructions, of all the native soldiers in the army.

WE LEARN from the *Medical Record* that a boy was recently arrested in New York City for spitting on women's skirts, and was fined for disorderly conduct. He had several times been apprehended for the same cause, and seems to derive gratification from indulgence in this impulse.

DR. ANNA S. FULLERTON, who has been practicing medicine for many years in Philadelphia, has decided to go to India where she will engage in special work, under the supervision of an interdenominational board. Among her duties will be the preparation of young women for the practice of medicine.

THE JAPANESE are keeping up their efforts in trying to make their country an enlightened one. The government recently ordered that vaccination and revaccination would be compulsory. All children must be vaccinated before the tenth month, and revaccinated at 6 and again at 12 years of age.

ANTHRAX is prevalent among cattle near Listowel, Ont. The Ontario Provincial Board of Health has ascertained that the existence of the disease is due to the polluted water below the tannery and woolen mills of that town. To remedy the evil, the Town Council has undertaken to devise a scheme for sewage disposal.

DR. THOMAS LOTHROP, who has for twenty years been at the head of the editorial department of the *Buffalo Medical Journal*, has transferred his interest to Dr. William Warren Potter, who becomes owner and editor-in-chief. The *Journal* enters on the fifty-fifth year of its publication with the addition of Dr. Nelson W. Wilson

as assistant editor, and Dr. Maul J. Frye of Buffalo, as associate editor.

AN ASSOCIATION for the promotion of public hygiene has been organized in Germany, by V. Leyden, Rubner and other prominent members of the profession, and officials. Lectures, meetings, circulars, everything tending to educate the people in matters of hygiene is included in its scope. It is to have branches in every community.

NIEBUHR states that the first mention of the plague in history has been recently deciphered on a clay brick dating from 1380 B. C. It is a message from the king of Alashja to the Pharaoh Amcnophis, apologizing for the smallness of his tribute a certain year, as all his officials had died "by Nergal's hand." Nergal was the pestilence god.

DR. J. C. WEBSTER, who has been appointed successor to the late Prof. James H. Etheridge, Rush Medical College, Chicago, was married recently in New York to Miss Alice Lusk. The ceremony took place in All Souls' Church, being conducted by the Rev. Dr. B. Heber Newton. Dr. and Mrs. Webster have gone to Europe on their honeymoon.

ACCORDING to the *British Medical Journal*, the will of Mr. Lawson Tait, dated April 6, 1893, has been proved; the whole of the testator's estate has been valued at £9,571, 13s, 10d—\$17,850—and his personal estate at nil. He left all his property to his wife, absolutely. The amount given is certainly much below what he was supposed to be worth.

IN A report on the water sources of New York State, just completed by George W. Rafter of the United States Geological Survey, it is stated that the Croton watershed, contains thirty-one ponds and lakes, with a total storage amounting to 75,569,000 gallons. When completed it is estimated that the Croton water system will supply 280,000,000 gallons daily.

FAY CONNOR, 11 years old, died in Chicago last Sunday, while under treatment by the "Christian Scientists." Just before death took place a physician was called who immediately recognized the disease to be diphtheria. The girl had been allowed to go out among her playmates and neighbors until too weak to leave her bed, and even then no efforts were made to isolate or prevent the spread of the disease. A coroner's jury investigated the case, and simply returned a verdict to the effect that death was the result of diphtheria. No one was censured, or blamed in any way because the laws of Illinois recognize these faddists as practitioners.

DR. T. G. RODDICK, Montreal, has just returned from an extensive tour of all the provinces in the Dominion of Canada, where he has been addressing the different medical societies and at the same time feeling the professional pulse in regard to "Dominion Registration." In British Columbia, Manitoba and the Northwest Territories there has been displayed on the part of the profession a gratifying unanimity of opinion in favor of the scheme. British Columbia, however, was a little bit suspicious. There they appeared to be afraid that the scheme, if adopted, might open the door to practitioners of the cheap diploma stamp.

It is expected that within a few days anthrax in Pennsylvania, where it has prevailed to a limited extent, will be stamped out. Over 2000 cattle have been rendered immune by artificial serum, and so far none of these have been affected. The rule adopted by the Board of Health of Pennsylvania is to give three inocu-

lations as follows: First a mild dose of serum is given, to be followed within five days by a stronger dose, and two weeks later by a third dose of still greater antitoxic power. It is believed that by this treatment immunity is conferred, the duration of which lasts one year. No accidents have followed the inoculations.

SIX COLORED persons in Philadelphia, who have been exposed to smallpox, were recently taken to the Municipal Hospital where they have been restrained. The question as to whether they could be kept in quarantine, was agitated, and a writ of habeas corpus directed against Dr. William M. Welch, physician in charge of the Hospital. When the matter came up for hearing, Dr. Welch stated that: "The parties were detained for the usual period of incubation to pass, which may be a little more or less than two weeks." The judge therefore dismissed the writ applied for and decided that the health of the public necessitated their remaining in the Hospital.

FAKE "HEALERS" IN ENGLAND.—In England last month a man was sentenced to one month's, and his wife to six weeks' imprisonment, for having unlawfully and wilfully neglected their little girl of 5 years of age. The child died of pneumonia, no physician having been called to attend her. The defendants were members of the sect called Peculiar People. They were originally prosecuted for manslaughter, but as no physician would go on the witness-stand and swear that the patient could have been saved, this charge was dropped, and the lighter charge of cruelty substituted. The cruelty consisted in allowing the child to suffer the severe pain of the disease, when it might have been relieved. The *Lancet*, from which we obtain the above facts, thinks the sentence much too light, believing that while persons may torment themselves for conscience' sake, their unlucky offspring should not be compelled to suffer. In this country it would be considered that the age of reason had dawned if this much of a sentence could be inflicted. Another case recorded by the *Lancet* shows that the rights of a similar class of healers are also being sadly infringed on in England. One Rev. Stephen Shepard Maguth, who claimed to be a LL. D., but whom the *Lancet* inelegantly dubs "an ass," gave up preaching and started out as "a scientific medical botanist and hygienic and dietetic adviser in all ailments." And for this he got two months' imprisonment.

Therapeutics.

Iodipin.

Iodipin is an organic combination of iodine with sesame oil, in which the former has united with the fatty acids of the oil. Being in the form of a liquid it is absorbed by the body, and, like other fats, it is in part deposited in the liver, bone-marrow, and subcutaneous connective tissue, and in part disintegrated. The greater portion of the iodipin leaves the body in the form of potassium iodide, and a varying amount appears in organic combinations. Klingmüller (*Berlin Klin. Woch.*, June 19, 1899, p. 540) reports the results of some observations upon the use of iodipin by subcutaneous injection, made at the clinic of Neisser at Breslau. Such a mode of treatment is a special advantage for patients who will not or can not take iodine by the mouth, and especially the insane. It was first found by experiments upon animals that the drug thus employed was non-toxic. Thirty-six patients were treated and received two hundred and twenty injections of a 10 per cent. preparation. No unpleasant effects were observed even when 20 c.c., the equivalent of 30 grains of iodine, were injected daily. Five injections were made

on successive days in cases in the hospital, but with longer intervals in ambulant cases. Subsequently additional injections of a 25 per cent. preparation were made, with equally satisfactory result. Not only was the iodine deposited in the subcutaneous tissues, slowly absorbed and distributed, but all of it was necessarily taken up and rendered active. Iodine appeared in the urine in from three to five days after the treatment was begun, and its excretion continued for several weeks, while with other preparations the iodine appears earlier and the period of elimination is much shorter. To overcome objection to the lateness of appearance, the slowness of absorption and tardiness of elimination of the drug when given subcutaneously, when a speedy effect is desired, it may be given by mouth simultaneously. The subcutaneous method of injection of iodipin has the further advantage of being painless, convenient and cheap. The injection is best made strictly into the subcutaneous tissues between the skin and the muscle, and preferably into the gluteal or interscapular tissues. The specific activity of iodine was manifested after subcutaneous injection of iodipin in the same degree as when other iodine preparations, and especially iodipin, were administered by the mouth. The results in typical cases of gummatous destruction were most favorable.

Finally, the subcutaneous use of iodipin was unattended with symptoms of iodism. As a result of his experience Klingmüller warmly commends the use of iodipin, and for the following reasons: 1. It exerts the specific action of iodine upon tertiary syphilis. 2. The organism is kept for a longer time under the influence of the action of iodine than with the use of hitherto employed preparations of iodine. The subcutaneous administration has the following advantages: 3. None of the drug is lost. 4. The organism disintegrates the iodine introduced slowly and regularly. 5. Iodism, with its unpleasant secondary effects, does not occur. 6. Absolute dosage is rendered possible. 7. The treatment is rendered possible for patients who for any reason will not or can not take iodine—the insane; after operations—the unconscious. 8. The body may be kept under the influence of iodine for weeks, or even months, by repeated courses of a few injections.

Facial Paralysis Cured by Salicylate of Sodium.

Following are the symptoms of a patient, in a case mentioned by Catrin, of paralysis of the seventh cerebral nerve: Paralysis of the muscles of the face, diminution of the salivary secretion, disturbances of hearing and taste, and downward deviation of the eye when attempts were made to close it. Catrin, believing the trouble to be of a rheumatic origin, put his patient upon sodium salicylate, 30 grains per day, and gradually increased this dose until 60 grains per day were taken. This was continued for two weeks, and then was gradually diminished. Altogether, the patient took the drug three weeks. Sensation began to return on the sixth day of the treatment. The patient could completely close his eyes in two weeks, and all disturbances of sensation vanished. There was no longer any trace of the trouble in three weeks.—*La Presse Med.*

Hydrochloric Acid in Gastric Acidity.

Gastric acidity is said by Reid to be best treated by hydrochloric acid. He says (*Mercer's Arch.*): "Wegeler and Hemmeter, among recent authors, bear witness to the powers of HCl as a stomachic or stimulant to the peptic glands. Hemmeter also quotes Riegel and Reichmann and Mintz as having reported cases of gastric acidity in which the restoration of HCl was effected by a more or less prolonged dosage with the same acid. Hemmeter gives twenty drops of the diluted HCl, in appropriate cases, in two ounces of water every half hour, beginning fifteen minutes before meals and continuing it till half an hour after the meal. He has frequently seen excellent results from this method, and believes that the motor function

of the stomach, as well as the glands, is favorably influenced—a view which my own experience confirms. My practice has been to give much smaller doses. I direct the patient usually to begin with a dose of four or five drops of the dilute HCl, given after each meal in this way: The amount prescribed, which is gradually increased if necessary up to ten, or exceptionally, even to twenty drops, is added to half a goblet of water, which the patient is directed to take in small sips at frequent intervals during an hour or an hour and a half. In cases of complete or nearly complete anacidity the sipping of the diluted acid is begun immediately after the meal, but in other cases not till the meal has been over for half an hour. In this way the amylaceous portions of the food are given time for the action of the saliva. I was led to adopt this gradual method of administering the acid through having observed a number of cases with absence of free HCl, in which the patients complained of a marked burning in their stomachs after taking quite small doses of the remedy. This apparent intolerance of the drug was overcome entirely by having it taken gradually in small sips, and the results eventually were quite as gratifying as in other cases in which no such disagreement occurred."

Neuralgia.

- R. Tinct. aconiti
- Tinct. colchici seminis
- Tinct. cimicifugæ
- Tinct. belladonnæ ãã. ʒi
- M. Sig. Six drops every hour until relieved. —Metcalf.

INTRACTABLE NEURALGIA.

- R. Croton chloralis. ʒi
- Glycerini
- Syrupi aurantii ãã. ʒi
- M. Sig. One teaspoonful as required. —E. P. Hurd.

CHRONIC NEURALGIC HEADACHE.

As an alternative to diseased nerves, in chronic neuralgic headaches, etc.:

- R. Zinci phosphidi. gr. 1/40
- Ext. cannabis indicæ. gr. 1/8
- Ext. nucis vomicæ. gr. 1/8
- Sodii arsenatis. gr. 1/64
- Quinine sulphatis. gr. 1/2
- Ext. aconiti radici. gr. 1/10
- M. Ft. tab. No. i. Sig. One such at 10 a.m. and at 4 and 9 p.m. —Henry J. Kenyon.

NEURALGIC HEADACHE.

- R. Antipyrin. ʒiiss
- Acetanilid. ʒss
- Camphor monobromate. ʒi
- Caffein. ʒss
- Phenacetin. ʒi
- M. Div. in chart No. xx. Sig. Take one and repeat in one hour if unrelieved. —E. C. Wendt.

INTERCOSTAL NEURALGIA.

- R. Tinct. gelsemii. gtt. c
- Syrupi simplicis. ʒiiss
- Aquæ destil. ʒvi
- M. Sig. One or two teaspoonfuls two or three times daily. —Cheron.

Caution—If the heart is feeble this formula should not be employed.

Brown-Séguard's prescription for neuralgia is as follows:

- R. Ext. hyoseyami
- Ext. conii ãã. gr. xl
- Ext. ignatiæ
- Ext. opii ãã. gr. xxx
- Ext. aconiti. gr. xx
- Ext. cannabis indicæ. gr. xv
- Ext. stramonii. gr. xii
- Ext. belladonnæ. gr. x
- M. Sig. Divide into sixty pills.

- Camphore pulv ãã. ʒi
- Morphinæ sulphatis. gr. ii
- Chloroformi. m. xl
- M. Sig. m. xx the dose. May be used locally. —Bartholow.

TRIGEMINAL NEURALGIA.

- R. Tinct. aconiti. ʒiiss
- Tinct. gelsemii ad. ʒi
- M. Sig. Ten drops every twenty minutes, as directed.
- Directions—Take every twenty minutes until pain is relieved; not, however, to exceed eight doses, and stop earlier if any tingling is felt in the tips of fingers. —H. B. Whitney.

Influence of Morphin on Evacuation of Urine.

Acute or chronic intoxication with morphin causes difficulty in the emission of urine, or complete retention in some cases. In recent experiments on guinea-pigs, *Monch Med. Woch.*, No. 26, the administration of morphin abolished the sphincter reflex until the urine accumulated in such amounts that rupture of the bladder walls was produced, preceded by the appearance of more or less blood in the urine from the extravasation of blood caused by the stretching of the walls.

False Croup.

For this, Dr. F. C. Rogers recommends apomorphin in doses of gr. 1/40 to 1/50 by the mouth in a little water, repeated every fifteen or twenty minutes until symptoms are relieved. This dose is for a child 5 years old. One or two doses are usually sufficient to check the attack without producing vomiting.

Constipation with Scanty and Defective Bile Secretion.

- R. Acidi arseniosi. gr. i
- Hydragryi chloridi corrosivi. gr. i
- Pulveris ipecacuanhæ. gr. ii
- Hydragryi chloridi mitis. gr. xvi
- M. Div in tab No. xv. Sig. One or two tablets daily. —W. H. Porter.

HABITUAL CONSTIPATION.

In the habitual constipation of delicate persons with feeble digestive organs:

- R. Ext. cascara sagradæ. gr. ii
- Ext. nucis vomicæ. gr. 1 4
- Ext. belladonnæ. gr. 1 3
- Pulveris capsici. gr. 1/2

M. One such tabloid after food once daily should be taken; increased, if necessary, until two tabloids are taken thrice daily. This dose should be maintained until the habit of regular action is established, when the number should be gradually reduced and at length discontinued. Remedy the lack of fluids in the body by giving an abundance of water, either hot or cold. —Cutter.

Deaths and Obituaries.

IRVING C. SCHUREMAN, M.D., Albany, N. Y., 1869, died at his home in Tom's River, N. J., of cardiac disease, August 6, aged 59 years. He was a Civil War veteran, and a member of several fraternal orders. A widow and four children survive him.

JOHN M. FLETCHER, M.D., Bowdoin, Brunswick, Me., 1869, died at his home in Belfast, Me., August 7, aged 73 years. He had been governor and afterwards treasurer of the state.

NATHANIEL WILSON LEIGHTON, M.D., Bowdoin, 1857, and New York Medical College, 1858 (now extinct), died at his home in Brooklyn, N. Y., August 12, in the 60th year of his age.

JAMES F. JUDD, M.D., Jefferson, 1897, died in Philadelphia, August 5, aged 38 years. He was born in England.

H. STANGEWALD, M.D., born in Dresden in 1829, and a graduate of the University of Vienna, died at his home in Nunana Valley on June 1, after a practice in Hawaii covering about forty years.

B. T. Crompton, M.D., Corydon, Ky., died August 10, aged 29 years. . . . N. S. Freeman, M.D., Charleston, Ill., August 7, aged 70 years. . . . John T. Ireland, M.D., Lower Marlboro, Md., August 4, aged 60 years. . . . James T. Johnson, M.D., Huntsville, Ala., August 9, aged 68 years. . . . Kline W. Lynn, Cortland, Ohio, August 7, aged 29 years. . . . G. L. McClain, M.D., Arlington, Ga., August 1. . . . W. H. Seaton, M.D., Indianapolis, Ind., August 6.

A Combined Stomach Tube and Douche.

BY J. W. BELL, M.D.

Professor of Clinical Medicine and Clinical Diagnosis, Univ. of Minn.
MINNEAPOLIS, MINN.

The pressing need of a more satisfactory method of securing thorough gastric lavage, as well as a more efficient means of treating atonic conditions of the gastric mucosa and muscularis is my only apology for calling attention to a new combined gastric-tube and douche. The instrument consists simply of an inflow tube equal in size to two-fifths of the lumen of the entire tube, ending in a perforated jacket. This perforated jacket, corresponding to the last four inches of the gastric end of the tube, contains some seventy-two very small openings through which the water issues in very fine streams or a coarse spray with a force corresponding to the pressure or height of the column of water in the inflow tube. The outflow tube, corresponding in size to three-fifths of the lumen of the entire tube, simply performs the functions of an ordinary stomach-tube, draining the stomach of its contents, thus enabling the

small streams issuing from the small openings in the jacket to come in contact with and thoroughly cleanse all parts of the gastric mucosa. The perforated jacket is the only portion of the instrument original or new. This jacket proved a very troublesome problem for our rubber workers to solve, and allow sufficient space for the outflow. After many failures, extending over a period of nearly two years, they finally succeeded in making a satisfactory instrument. The following points are claimed for it:

1. The instrument is simple in construction and durable.
2. It thoroughly and efficiently cleanses and disinfects the stomach.
3. By means of the douche we are able to stimulate and tone the gastric mucosa and muscularis.

Miscellany.

Important Symptom in Chloroform Narcosis.—Lehmann states that if the eyelids close as the effect of the anesthetic is felt, the probabilities are that the narcosis will proceed smoothly. But if the eyelids remain partially or entirely open, or reopen if closed, trouble may be anticipated.—*Memorabilien*, July 19.

Right to Ride on Sidewalks.—Whatever may be said as to general rules of law prohibiting vehicles, including bicycles, on sidewalks, the supreme court of Iowa declares, in *Wheeler vs. City of Boone*, that it has yet to learn of any general or local law prohibiting the use of carriages operated by hand on sidewalks for the convenience of those unable to walk; and no law, it holds, should be given such effect by construction.

Criminal Abortion with no Vagina.—W. A. Freund recently served as expert in a case in which the woman was condemned to prison for feticide. There was no vagina and the uterus opened into the urethra, which was much dilated. Conception and expulsion of the uterus occurred per urethram. The abortion followed an injection into the bladder with criminal intent.—*Wiener Klin. Woch.*, July 20.

The Speculum Outside of the Office.—Our exchanges are copying the suggestions of Dr. Groussin, that the inconveniences of examining with the vaginal speculum without a table or chair for the purpose, can be obviated with a couple of stout cords, each tied into a loop made of a napkin. The loops are fitted over

the knees, and the other end of the cord attached to the upper hinge of a door, or to a nail or screw driven in for the purpose, one on each side. The knees can thus be held flexed and in the correct position to facilitate examination.

Voluntary Overexertion.—The term "voluntary overexertion," in a policy of accident insurance, the supreme court of Nebraska holds, *Rustin vs. Standard Life and Accident Insurance Company*, means conscious or intentional overexertion, or a reckless disregard of consequences likely to ensue from great physical effort. For example, it can not be said as a matter of law, it maintains, in applying this doctrine, that the slight elevation of a 300-pound weight by a strong man accustomed to lifting is voluntary overexertion.

To Be Determined by Board.—Whether a diploma presented by one who desires a certificate authorizing him to practice medicine is from "a medical institution in good standing," the supreme court of Ohio holds, is to be determined, in the first instance, not by the court, but by the board of medical

registration and examination. An institution incorporated for the purpose of "the education of suitable persons in the art and science of curing diseases by the use of air, baths, electricity, heat, magnetism, massage and all other resources of nature," it further holds, in *State vs. Hygeia Medical College*, does not offend against the law of its creation by imparting instruction concerning the administration of drugs.

Serotherapy in Pseudomembranous Conjunctivitis.—Pes found antidipteria serum remarkably effective in 13 cases—9 with Loeffler's bacillus pure and 4 associated—and warmly advocates its use to prevent tardy complications (paralysis of the ocular muscles), and facilitate the expulsion of the pseudomembrane, both as a preventive and cure, even when bacteriologic investigation is not possible.—*Revue Gen. d'Oph.*, July 31.

Tendon Suture in Injury from Circular Saw.—The saw had cut into the soft parts of the arm to the bone, and the wound had healed with the hand and fingers contracted, and the slightest movement exquisitely painful. Seven months later Gedeon reopened the wound and united the severed tendon stumps with silk sutures. In a month the pains had entirely disappeared and the hand and fingers had recovered full working capacity.—*Memorabilien*.

Not Bound to Have Amputation.—As a result of a casual difficulty in a saloon one man shot another in the leg, just above the knee. Nine days thereafter the man so shot died. The man who fired the shot was convicted of manslaughter. In affirming the judgment, the court of criminal appeals of Texas holds, *Franklin vs. State*, that the refusal of the man shot to have his limb amputated could not be imputed to him as gross neglect or manifestly improper treatment. The physician's opinion that the man would have gotten well had he permitted the amputation, the court considers, was more or less speculative on his part. It did not understand the physician to say that in every case where the main artery of the leg is penetrated or cut, and the party does not immediately bleed to death, blood poisoning is bound to follow; and, unless such be the case, it declares, it could scarcely be said that the deceased was guilty of gross neglect or manifestly improper treatment by taking the chance of saving his limb, although he may have refused to take the advice of the physician in the matter.

Unlicensed Experts.—After a careful consideration of the subject, the court of appeals of New York says, in the case of *People vs. Rice*, that it has reached the conclusion that if a

man be in reality an expert on any given subject belonging to the domain of medicine, his opinion may be received by the court, although he has not a license to practice medicine. But such testimony, it goes on to state, should be received with great caution, and only after the trial court has become fully satisfied that on the subject as to which the witness is called for the purpose of giving an opinion he is fully competent to speak. Here, there was testimony adduced that the witness in question was a manufacturer of medicines, and the publisher of medical books, and the author of a medical book used throughout the United States by practicing physicians, and that he had pursued a study of medicine and of nervous diseases in connection with the course of study of medicine. Whether he had pursued this study one week or one year did not appear, or whether he has ever read an article on the subject of insanity. Let alone studied the subject, did not appear. Nor was the subject of his book given, and therefore the court thinks that presumably it was not relating to insanity, so long as it was the object to qualify him as an expert on that subject. Such being the case, the court not only holds that he was not *prima facie* competent to express an opinion as an expert on the subject of insanity, because he had not been licensed to practice medicine, but insists that it is clear that, under the circumstances, the trial court was right in refusing to permit him to give his opinion as an expert on the subject of insanity. If he was an expert, it adds, that fact was not shown.

Physician's First Duty.—The first duty of American physicians is to join the AMERICAN MEDICAL ASSOCIATION and attend its meetings. It is hardly necessary to repeat what we have so often urged, that the ASSOCIATION is the gravitational center about which gather the unitizing tendencies and powers of the profession. It is plain to every one that our professional disunity is at present our greatest curse, and that it is the fundamental cause of our powerlessness in the face of the evils besetting us. Quackery, medical humbug, sectarianism, the nostrum shame, a hundred pseudomedical journals up for sale, and innumerable spawnings of medical delusions and fanaticisms—all these exist by our leave, and almost solely because of our disorganization. Far more than this, our awful death rate is almost the direct product of this same lack of unity. We have the knowledge whereby the American death-rate could be reduced one-half, but we have not the power to reduce it. We have not the power because we have no professional voice, no corporate unity, by which we can turn our knowledge into active prophylaxis, through the law-makers and administrative officers of the national state, and civic governments. If our population numbers now 70,000,000 and there are 10 unnecessary deaths each year per thousand, it follows that there are 70,000 deaths each year due to that professional negligence which is in reality a crime. We can not understand the logic of those who have no interest in medical sociology and public hygiene (preventive medicine) and who labor year after year in the hope of discovering the pathology of some rare disease, or the treatment of special diseases. We have, of course, no intention of underrating the value of abstract scientific study, for we know that ultimately all professional progress and power come from such science. But it is certain that at present scientific knowledge has outrun practical application, and we question only the logic of the sad neglect of actually saving lives in our extreme interest in the knowledge of how to save them. To effect this actual saving, it need hardly be added, is, however, the serious and earnest desire of the great bulk of the profession; what, then, hinders, if we do really know how to do it? There are many subordinate hindrances, but outweighing all combined is the fact we have emphasized, our professional disorganization. We can not turn our knowledge into facts, because we have no representative organization through which the whole body can speak, and by which influence may be brought to bear upon the social and governmental forces

so negligent and even scornful of general life-saving.—*Phila. Med. Jour.*, August 12.

London.

(Special Correspondence.)

BRITISH MEDICAL ASSOCIATION.—The event of the week—and for that matter, the only midsummer event—in medical circles, was the meeting of the British Medical Association, which concluded its sessions at Portsmouth this afternoon—August 5. The transatlantic visitor could not but be impressed, however, with the fact that out of over seventeen thousand members, the register indicated an attendance of less than nine hundred and, further, that of those in attendance but relatively few seemed to find their way either to the general sessions or to the meetings of the sections. This could not be attributed to the committee on arrangements, for each member and visitor alike was given, not only a copy of the daily journal, but a guide-book and all necessary information relative to places and times of meetings. It may be said, indeed, that the work of the always hard-worked committee of arrangements could not well have been improved upon. If, therefore, the small registration had any particular significance it was that the meeting was held in the south end of England, to reach which required a journey of at least several hours—never of a whole day—but even this is a very formidable affair to the average English practitioner. On the other hand, if there seemed to be a lack of interest in the proceedings the fact was to be explained by the close proximity of Cowes and the Royal regatta, the attractions of which could not be resisted even by your correspondent. London representation was, as usual, conspicuous chiefly by its relative absence. The few distinguished gentlemen who came down from the metropolis—quite two hours away—tarried long enough to deliver themselves of their appointed tasks and scurried back to town in eager quest of guineas, or else to the Pyrenees, the Alps, or the fjords of Norway, in no less eager quest of pleasure. It may be added that so far as pleasure was concerned there was but little occasion to quit Portsmouth or South Sea—save to escape the disagreeable heat—for what as between warships and barracks and gunwharfs and military and naval hospitals, all so dear to British hearts—entertainments were launched with necessary impetus and éclat. A garden party given one afternoon by the Mayor of Portsmouth in the beautiful grounds of the borough asylum, was a delightful success, while those—a half dozen or so—given by distinguished citizens on their private grounds, to limited numbers, contributed equally to the pleasure of those who were fortunate enough to secure tickets. It was a conspicuous fact, work in all the sections was abandoned at 1 o'clock, and the afternoons given over entirely to social enjoyment. This impressed me as vastly more desirable than our own intensely work-a-day fashion of running our Sections morning, noon, and sometimes at night, as if the welfare of creation were resting on us and had to be settled, finally and definitely, before the President could announce a *sine die* adjournment of the AMERICAN MEDICAL ASSOCIATION.

America was as usual represented at the meeting. Among the more conspicuous guests from our own country was Dr. Daniel Lewis of New York, the editor of the *American Medical Review of Reviews*, whose interest in medicine is exceeded only by his enthusiasm for yachting. Dr. Ernest Laplace of Philadelphia was an interested participant in the proceedings of the surgical section. Dr. James Tyson, the distinguished professor of medicine at the University of Pennsylvania, was among the more notable of American visitors. Drs. Bill, Brainard, Cole, Cushing, Hirschfelder, de Schweinitz, Hubbell, Reed, Kipp, Hutchinson, Lewis, McCrae, Snow and Jackson were the other American names on the guests' register. I have not alluded to Dr. Osler in this connection, who, by virtue of his former Canadian residence is a member, and who took an active part in the proceedings, and who, *on dit*, entertains very definite

London ambitions—a fact which, if well founded, will bring but little comfort at John Hopkins, where he has rendered such conspicuous service.

One familiar with the work of the AMERICAN MEDICAL ASSOCIATION can not but be impressed with the important functions exercised by the Council of our sister organization of Great Britain. This body—the Council—consists of nearly a hundred members, and exercises, *ad interim*, practically all the functions of the Association—indeed, it exercises a sort of veto power over the general organization in view of the fact that elections to membership in the Association seem to be made at the time of the meeting subject to subsequent action by the Council. In this way, no doubt, much more careful discrimination can be exercised in the selection of members than by the delegate and loose credential system in vogue in America.

The report of the Council for the present year indicates a membership of 17,746. As the total revenues were £42,924, and as the membership fee is a pound, it would seem that the *Journal* has a comfortable income from other quarters of £25,178. The expenditures are, however, very heavy, as they leave a balance of less than £5000. As a trustee of our *JOURNAL*, and one much interested in its success, I feel that the financial statement submitted at the Columbus meeting was very satisfactory, as compared with the one just submitted at Portsmouth. Another important fact relating to the welfare of the *British Medical Journal* is also found in the report of the Council. This relates to the continued organization of branches in different parts of the Empire: One has been organized at Perth in West Australia, which with the other five Australian branches furnishes an aggregate membership of 1109. The branches of South Africa and other colonies are reported as being "everywhere large, active and useful." Thus it becomes apparent that by a wise system of organization, the profession of the Empire is essentially unified and put into position for the effective protection and advancement not only of its own interests but those of the public that come properly within the purview of medical men. Other topics discussed in the report of Council are: "the library," which now contains 37,000 volumes; "instruction in tropical diseases;" "tuberculosis;" a controversy with the "London Chamber of Commerce;" various parliamentary questions; and obituary notices. It would seem from this that the functions of Council are varied and important. I feel that I can best illustrate their importance by giving one or two instances in detail. The London Chamber of Commerce made a grave accusation against the probity and integrity of the profession to the effect that "secret commissions" were received by medical men. The Council at once took up the question, demanding the facts on which it could proceed to punish offenders, but the London Chamber of Commerce was unable to furnish them, and as a consequence the imputations have fallen flat.

There is no system of medical registration in India, a fact which has been taken up with the Indian and Colonial office by the Council, with the prospect that the evil may be remedied. A more striking example of the beneficial influence of the Council is indicated in the following paragraph, taken from the report: "A complaint having been received from the Jamaica Branch that the Legislature in that colony had passed a law which compelled medical practitioners to notify infectious diseases under a penalty of 40s., but had failed to provide any payment for the duty thus imposed, the President of Council wrote to the Colonial Office, and again received a reply from the Right Honorable J. Chamberlain, stating that the Governor of Jamaica had been instructed to introduce a law to provide for the payment of fees to medical practitioners for notifying infectious diseases and to protect them from any legal consequences of such notification."

There is to-day, in the United States, a striking need for a legislative committee so constituted that by virtue of its representative character it can speak for and in the name of the

great medical profession. Such a committee, to be effective, must be as small as may be consistent with its representative character. One might imagine such a committee made up of the president of the AMERICAN MEDICAL ASSOCIATION and the president of each state medical society, if each state medical society were only a branch—an integral part—an organic and constituent unit of the national organization—but such important changes must come slowly. The watchword with the AMERICAN MEDICAL ASSOCIATION, however, must be organization, organization, and still, organization!

It is manifestly out of the question to deal in detail with the proceedings of the Portsmouth meeting. Naturally keen interest centered in the annual address of the President, Dr. Ward Cousins, given in abstract in the *JOURNAL*, August 5, p. 355.

It was but natural that a discourse of such high ethical conceptions should not be appreciated by the lay press. The *Standard*, for instance, true to those instincts which permit it to become the avenue for the advertisement of nostrums whose effects are but little if any short of criminal, wrote an editorial review in which it sought to throw dust in the eyes of the public by carping against the medical profession, that it had not yet solved the millennium. Of course the medical, and for that matter the discriminating lay public, readily understood that the criticism was prompted by the counting-room. There was a sort of melancholy comfort, however, in observing this antagonism, for to an American it served to exemplify the companionship of misery. It must be admitted, however, that in the matter of prostituting their columns to the fabrications of nostrums, the reputable English papers are less serious offenders than are publications of corresponding position in the United States.

One of the most important contributions to the proceedings was by Prof. Alexander Ogston (see p. 474, ¶ 143), of the University of Aberdeen, who offered some severe strictures on the present status of the medical science in both the army and the navy. The revelations were in the nature of a surprise to one who had learned to look on all sorts of military and naval preparations in England as being in a state of perfection. To learn, therefore, that an under secretary for war had openly admitted that, in the event of a sudden precipitation of hostilities, making it necessary to organize two army corps, the government would not be in a position to furnish the requisite medical contingent, was certainly a communication from beyond the realm of the expected. Much fault was found with the rank and quarters furnished medical men, with the restrictions placed on them with regard to private work while on garrison duty, with the hospital accommodations, especially in the navy, with the pernicious habit of keeping surgeons for long periods at ports remote from the centers of medical progress, and with the policy. The address was received with profound attention and will doubtless result in a new task for the parliamentary committee.

My participation in the work of the sections was restricted to the section on gynecology, which was presided over by the distinguished Dr. George Granville Bantock of London—the Beau Brummel of the metropolitan profession. The late Mr. Lawson Tait was sorely missed, and his untimely demise was the occasion of many heartfelt regrets. On one day there was a discussion on the treatment of fever following delivery, with special referenceto serotherapy, opened by a carefully prepared paper by Dr. Herbert Spencer—manifestly a coming man. The discussion which ensued was participated in more especially by the distinguished successor of Leischman, Prof. Merloch Cameron of Glasgow, and by Prof. Mere Madden of Dublin, with the result, so far as I could determine, that the case as presented on the affirmative side by Dr. Spencer, was interesting as set forth, was important if true, but that it at present lacks confirmation. On another day Mr. Bland Sutton presented his well-known views on ovulation and menstruation in

their relation to the menopause. This he did in his graceful and masterly style by way of opening a discussion on the natural menopause as compared with: 1, that induced by the removal of both the uterine appendages and, 2, that induced by the removal of the uterus without the uterine appendages. There was but comparatively little discussion following the essay, but the lull seemed much like that which precedes the storm that one inevitably provokes when one has the temerity to entertain views at variance with those of general acceptance.

CHARLES A. L. REED, M.D.

Canada.

(From Our Regular Correspondent.)

August 12, 1899.

CANADIAN MEDICAL ASSOCIATION.—What promises to be the most successful meeting in the history of this Association is that which convenes in Toronto on August 30, as noted in the JOURNAL of August 12. An important discussion on "Dominion Registration," in which the Canadian practitioner in every part of the Dominion is vitally interested, will be introduced by Dr. T. G. Roddick of Montreal. Delegates will be present from every province in Canada, pledged to support this movement. The pathologic museum, in charge of a committee with Dr. A. Primrose of Toronto as chairman, will add much to the interest of the meeting. Already a great many specimens have arrived, and others are being rapidly contributed. The social part is being well looked after by a committee of arrangements with Dr. A. Jukes Johnson as chairman and Dr. Charles R. Dickson as secretary. This will include a garden party and musicale in the Normal School—where the meeting is to be held—and on its beautiful lawns, on the evening of the first day; a "tea" at the Royal Canadian Yacht Club (Island clubhouse); a smoking concert, tendered by the City Council, on one of the large vessels of the Niagara Navigation Company; and a visit to the Industrial Exhibition with reserved seats for members and their lady friends, in the grand stand, offered by the Industrial Exhibition Association. Besides, there will also be numerous private entertainments.

POST-MORTEM WITHOUT AUTHORITY.—A case which has excited considerable interest and discussion in Ontario, and which has just been decided in favor of the defendants, was that of Davidson vs. Drs. A. H. Garratt, H. B. Anderson and W. H. Harris, all well-known practitioners in good standing in Toronto. Having been called suddenly to see the wife of the plaintiff, Dr. Garratt had at once responded, only to find the woman dead on his arrival. He telephoned the coroner and was subsequently instructed by that officer, through the same medium, to perform a post-mortem examination. Taking with him Drs. Anderson and Harris, they proceeded to the residence and were admitted by the plaintiff's own son. The heart only had been examined when the husband entered and demanded their authority. The Ontario laws require this in writing, but custom was otherwise, so the doctors had no written authority. The coroner had previously withdrawn his warrant for an inquest, but had not notified Dr. Garratt of his action. Hence, suit was entered for damages to trespass on land, and in the assize court \$600 and costs assessed against the defendants. An appeal was immediately taken in the High Court (Divisional). Here the verdict in the lower court was reversed, the appeal granted with costs, and the action dismissed with costs. Counsel for plaintiff argued that because the law was consistently ignored in the matter of written authority from the county attorney to the coroner, and further from the coroner to the doctor performing the post-mortem, custom superseding it, it was no excuse for the physicians doing as they had done. This, Justice Rose of the High Court considered nonsensical and perfectly ridiculous, and thought that when a doctor was ordered by a coroner to perform a post-mortem he should do it, and not go scurrying around hunting up the law on the subject.

END OF MONTREAL CLINICAL SOCIETY.—The Montreal Clinical

Society *non est inventus*. For several years past the Society has been in a declining condition. This was no fault of the officers; they were full of enthusiasm, but the rank and file had lost interest, so it was decided to close up its affairs. The idea was subsequently carried out in a very happy manner. The last general meeting took the form of a supper in Elm Hall, Westmount, where forty-five members gathered, and, amid a glorious carnival of refreshment, sang their death song.

MEDICAL MEETINGS AND DOMINION REGISTRATION.—Down by the sea, in the maritime provinces—New Brunswick, Nova Scotia, Cape Breton and Prince Edward Island—all the annual meetings of the societies have been held. They proved successful in every respect. In his annual address before the Medical Society of Nova Scotia, held in the Normal School Building, Truro, the president, Dr. John McMillan of Pictou, advocated a very important issue—one which forces itself on the consideration of the profession in that section of the Dominion, viz., the need of a properly organized statistical bureau, and the establishment of a sanatorium for the treatment of tuberculosis. A more efficient regulation of vaccination than at present in vogue, was ably contended for by Dr. Jones of Halifax, and an animated discussion ensued on the subject. The Maritime Medical Association meeting was well patronized, and an excellent program presented. Nova Scotia especially sent a large delegation to this meeting, while P. E. I. was not far behind in the point of numerical representation. It was the ninth annual meeting, and opened on July 12 in the Legislative Assembly, (Charlottetown, P. E. I. Dr. Robert T. Morris of New York delivered an address on "Peritoneal Adhesions," while Dr. James Bell's (Montreal) contribution of "Several Unusual Cases in Abdominal Surgery with History and Treatment" added somewhat to that gentleman's reputation as one of Canada's foremost surgeons. The address of welcome was delivered by Lieutenant-Governor McIntyre, a medical man; and the occupant of the mayor's chair in Charlottetown, who contributed much to the social entertainment of the visitors, is also a member of the profession. The garden party at Government House; the pleasant excursion on the harbor; and the dinner at the Hotel Davies reflected much credit on the local committee of arrangements. Dr. Roddick was present at all the meetings, advocating "Dominion Registration." Dr. MacNeill, president of this Association, in referring to this subject, spoke of the good work that the eleven medical colleges in Canada were doing in medical education, and said that for years past the Canadian Medical Association had been endeavoring to educate the people as well as the profession, on the necessity of having one qualification for all Canada. He stated that at the last meeting of that Association, in Quebec, P.Q., the basis of uniformity of curriculum was agreed on, and Dr. Roddick was intrusted with the matter to perfect and complete. We look to him as the Cæsar to lead us across the provincial Rubicon, and have established in Canada—what? The University of Canada or the College of Physicians and Surgeons of Canada? Or the Dominion Medical Council? By the accomplishment of this scheme, students graduating and having obtained licenses to practice in one province will be spared the examinations and the expenses of further examinations and licensing in other provinces.

DEATHS FROM PUERPERAL FEVER.—Some little attention to statistics in regard to puerperal fever in the Province of Ontario may be interesting. During 1897, in an urban population of 436,996, there were 9,037 births, and 29 deaths from this disease, a mortality-rate of 0.32 per 1,000. In the cities of Brantford, Windsor, Chatham and St. Thomas there were no deaths from this disease, while in Guelph the rate was 0.77; Stratford, 0.74; Ottawa, 0.7; Belleville, 0.66, their respective birth-rates to 1,000 living persons being respectively 23.1, 13.2, 27.1, and 14.3. Hamilton makes a good showing with a percentage of 0.01; London, 0.18; Toronto, 0.26. In the whole province, out of 47,323 births, 185 deaths are reported from this dis-

case, one death from puerperal fever to 255 births. The greatest number of deaths from puerperal fever in 1897 occurred in parts of Ontario where the confinements took place without medical assistance. As for instance, in Algoma, four deaths occurred. Here something like 52 per cent. of the labors were unattended by physicians. In the county of Brant no deaths occurred, and only about 3.1 per cent. of the births were unattended by physicians. So also in the county of Bruce, 20.72 per cent. of the labors were unattended by physicians, and there were seven deaths recorded. Contrasting the rural with the urban population, the total deaths occurring in cities registers 15.67 per cent. The urban population is 19.13 per cent. of the total provincial population.

Queries and Minor Notes.

REJECTIONS FOR TOBACCO HEART.

OMAHA, NEB., August 9, 1899.

To the Editor:—Was there an official statement or authenticated report published stating the cause of rejection by our army recruiting officers, among applicants who desired to join the ranks of the Spanish-American War? I have scanned the index of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION in vain, yet I certainly read some place that about 90 per cent. of the rejections were based on tobacco heart. If published, where can I find it? If not published, how can I get the facts?

J. M. A.

ANSWER:—The above query we referred to an official in the office of the surgeon-general, who replies as follows: "No official statement or authenticated report has been published stating the cause of rejection by our army recruiting officers among applicants for enlistment during the Spanish-American War. It is doubtless whether a full tabulation of all the causes of rejection will ever be made. The papers relating to volunteers were filed in the adjutant-general's office, and that office has but little concern for the condition of men who were not accepted. Certain of the papers relating to regulars were filed in the office of the surgeon-general and as it has been customary for this officer to present in his annual reports tabulations of the causes of rejection among candidates for enlistment, he will probably have such a table in his forthcoming report. That 90 per cent. of the rejections were based upon tobacco heart may have been an exaggerated expression of the experience of some medical examiner who had but a few cases before him. The annual report of the surgeon-general for the year ended June 30, 1898, gives the recruiting statistics for the previous calendar year. From these we learn that of 3492 rejections, 363, or a little over 10 per cent., were occasioned by diseases of the circulatory system. To what extent tobacco heart may have figured in the causation of the 362 rejections is not known, as the tabulation does not go into specific details."

BRONCHIAL CALCULI.

CHICAGO, August 14, 1899.

To the Editor:—In re your remarks on bronchial calculi (JOURNAL, Aug. 12, 1899, p. 434), if your correspondent will consult Hoffmann, *Krankheiten der Bronchien*, in "Nothnagel's Spec. Path. u. Therap." Wien, 1896, pp. 38-64, he will find a fair résumé of our existing knowledge of this affection, together with reference to a few articles in the literature.

EDWARD F. WELLS, M.D.

The Public Service.

Movements of Navy Medical Officers.—Changes in the medical corps of the U. S. Navy for the week ending August 12, 1899:

Medical Inspector J. R. Waggener, promoted to medical inspector from April 3, 1899.

Medical Inspector T. H. Streets, promoted to medical inspector from April 16, 1899.

Surgeon T. A. Berryhill, promoted to surgeon from April 9, 1899.

Surgeon E. P. Stone, promoted to surgeon from April 16, 1899.

P. A. Surgeon J. M. Moore, ordered to the Vermont, August 10.

Asst.-Surgeon B. L. Wright, detached from the Vermont and ordered to duty with the 2d marine battalion for Manila, P. I., and on arrival at Manila to report to the commander-in-chief of the Asiatic Station for duty.

P. A. Surgeon W. F. Arnold, granted extension of sick leave for one month.

Surgeon G. Pickrelle, authorized to drop middle initial of name.

P. A. Surgeon G. Pickrelle, detached from the Baltimore and ordered to the Monterey and to the Cavita Naval Station.

Asst.-Surgeon H. H. Haas, detached from the Oregon and ordered to the naval hospital, Yokohama, Japan, for treatment.

Marine-Hospital Changes.—Official List of Changes of Station, and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended August 3, 1899.

Surgeon Eugene Wasdin, to proceed to National Soldiers' Home, Va., for special temporary duty.

P. A. Surgeon G. M. Magruder, so much of Bureau order of July 31, 1899, directing P. A. Surgeon Magruder to proceed to Hampton, Va., revoked and directed to proceed to Richmond and Newport News, Va., for special temporary duty.

P. A. Surgeon C. P. Wertenbaker, to proceed to Hampton, Va., and report to Surgeon J. H. White for special temporary duty.

P. A. Surgeon A. C. Smith, leave of absence granted by Bureau letter of June 20, 1899, revoked and directed to rejoin station at Norfolk, Va.

P. A. Surgeon W. G. Stimpson, so much of Bureau order of July 31, 1899, directing P. A. Surgeon Stimpson to proceed to Fort Monroe, Va., revoked, and directed to proceed to Newport News, Va., and report by wire to Surgeon J. H. White Hampton, Va., for orders.

P. A. Surgeon Rupert Blute, to proceed to Columbus City, Washington, for special temporary duty.

P. A. Surgeon E. K. Sprague, leave of absence granted by Bureau letter of July 27, 1899, revoked.

P. A. Surgeon W. H. Wickes, leave of absence granted by Bureau letter of July 27, 1899, revoked.

Asst.-Surgeon R. H. von Ezdorf, to report to Surgeon J. H. White at Hampton, Va., for special temporary duty.

Asst.-Surgeon L. D. Fricks, relieved from duty at the South Atlantic Quarantine Station and directed to proceed to Hampton, Va., and report by wire for further orders.

Asst.-Surgeon F. J. Thornbury, relieved from duty at New York, N. Y., and directed to proceed to Baltimore, Md., and report to the commanding officer for duty and assignment to quarters.

Acting Asst.-Surgeon L. C. Dean, granted leave of absence for fourteen days from August 4, 1899.

Acting Asst.-Surgeon L. F. Gibson, granted leave of absence for ten days.

Acting Asst.-Surgeon R. H. McGinnis, granted leave of absence for three weeks from August 7, 1899.

Acting Asst.-Surgeon W. H. McE. Martin, granted leave of absence for thirty days on account of sickness.

Acting Asst.-Surgeon A. W. Smith, to proceed to Fortress Monroe, Va., and report to Surgeon W. J. Pettus, for special temporary duty.

Sanitary Inspector John C. Rodman, granted leave of absence for four days.

Hospital Steward W. W. Kolb, to proceed to Hampton, Va., and report to Surgeon J. H. White for special temporary duty.

Hospital Steward F. H. Peck, to proceed to Fortress Monroe, Va., and report to Surgeon W. J. Pettus, for special temporary duty.

Hospital Steward H. E. Davis, to proceed to Baltimore, Md., and report to commanding officer for temporary duty.

Temporary Hospital Steward E. T. Olsen, relieved from duty at Chicago, Ill., and directed to proceed to Wilmington, N. C., and report to commanding officer for duty and assignment to quarters.

RESIGNATION.

Acting Asst.-Surgeon S. C. de Krafft, resignation accepted to take effect July 15, 1899.

APPOINTMENTS.

B. W. Goldsborough of Maryland, appointed acting asst.-surgeon, U. S. Marine-Hospital Service, for duty at Cambridge, Md.

Temporary Junior Hospital Steward Egil T. Olsen appointed junior hospital steward from May 29, 1899.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended August 12, 1899:

SMALLPOX—UNITED STATES.

Kentucky: Louisville, July 26 to August 2, 5 cases.

Louisiana: New Orleans, July 22 to 23, 3 cases.

Massachusetts: Boston, July 29 to August 5, 1 case.

Ohio: Columbus, July 29 to August 5, 1 case; Dayton, July 29 to August 5, 1 case.

Washington: Spokane, July 22 to 29, 2 cases.

SMALLPOX—FOREIGN.

Belgium: Antwerp, July 8 to 22, 45 cases, 2 deaths.

Brazil: Rio de Janeiro, June 15 to 30, 32 deaths.

Colombia: Panama, July 25 to August 1, 1 case, 1 death.

Egypt: Cairo, June 24 to July 15, 7 deaths.

England: London, July 5 to 15, 1 case.

Greece: Athens, July 15 to 22, 11 cases, 3 deaths.

India: Calcutta, June 24 to July 1, 1 death.

Netherlands: Rotterdam, July 15 to 22, 1 case.

Russia: Odessa, July 5 to 22, 9 cases, 4 deaths; St. Petersburg, July 8 to 22, 15 cases, 6 deaths.

Turkey: Erzeroum, July 8 to 15, 2 cases.

YELLOW FEVER.

Brazil: Rio de Janeiro, June 15 to 30, 15 cases.

Cuba: Matanzas, July 13 to 20, 1 case, 1 death; Matanzas, July 26 to August 2, 1 case, doubtful; Santiago, July 15 to 22, 12 cases, 2 deaths.

CHOLERA.

India: Calcutta, June 24 to July 1, 7 deaths.

PLAGUE.

Egypt: Alexandria, from outbreak to July 9, 65 cases, 32 deaths.

India: Calcutta, from June 24 to July 1, 6 deaths.

Straits Settlements: Penang, January 1 to June 30, 42 cases, 33 deaths.

CHANGE OF ADDRESS.

Burnard, H. W., from 9139 to 9215 Commercial Ave., Chicago.

Cuthbertson, W. M., from 189 41st St. to 453 53rd St., Chicago.

Fisher, Geo. C., from 3000 Indiana Ave to 6303 Monroe Ave., cor. 63d St., Chicago.

Holman, Carl Johnson, from Granite Falls, Minn., to the Norwegian Lutheran Hospital, cor. Thomas and Francisco Sts., Chicago.

Kirby, H. W., from Airbratt, to Paris Block, Cripple Creek, Colo.

Knowles, W. F., from Hotel Berkeley to 220 Clarendon St., cor. Newberry St., Boston, Mass.

Louis, Surg. Major D. T., from Philadelphia, Pa. to Division of Cuba, Havana, Cuba.

Lova, I. N., from 3507 Olive St. to 4661 Maryland Ave., St. Louis, Mo.

McCormack, J. R., from Philadelphia to Montgomery, Pa.

Malsburg, C. E., from 23 East 11th St. to 1631 Sycamore St., Cincinnati, Ohio.

Marshall, O. R., from Moody to Gidley, Texas.

Muller, F. P., from 428 Kearney to 1016 Sacramento St., San Francisco, Cal.

Newton, C. S., from Altamont to Winfield, Kan.

Shields, W. B., from 493 1/2 Maryland to 453 1/2 Olive St., St. Louis, Mo.

Spangler, C. F., from York to Kane, Pa.

White, S. C., from Sandwich, Ill. to Kansas City, Mo.

Whalen, C. J., from 225 Dearborn Ave. to Luzerne Hotel, Station A, Chicago.

HYDROTHERAPY.

A NEW BATH FACILITATING ITS USE IN PRIVATE PRACTICE.*

BY A. C. HAVEN, M.D.

LAKE FOREST, ILL.

RÉSUMÉ.

Brief history of the Use of Water in Medicine.
Prejudice against Water, and Reasons.
Physiologic Action of Water—Cold and Hot.
Therapy—All Hyperpyrexia, etc.
Contraindications.
Technic.
Exhibit of New Bath.

The remedy I wish to exalt to-day is no new substance, compounded in German laboratory by processes of synthesis, but an original product, direct from the hands of the Creator; utilized first by Adam, recognized and recommended by all the illustrious followers of Esculapinus to the present day; even used by the Great Physician, Jesus Christ, who commanded the leper to go bathe in the river Jordan and be made whole. Yet with all these unparalleled recommendations, water is largely neglected by the busy practitioner of to-day, for the easier prescription which the druggist may compound. One hundred years ago Cullen sang the praises of cold water, and Brand of Stettin, Von Ziemsen, and our own Baruch, and many others have fought nobly to win it a place in our pharmacopeia. But their success has only been partial. Why has it not been complete? Surely not because the remedy does not meet the expectations of those who give it a fair trial. But it is such a common, every-day remedy with such an ordinary name. Sometimes I think if it were given its chemical name of protoxid of hydrogen, it would rise in the estimation of the profession.

Then, for a long time it was utilized by quacks, who did not use it scientifically, and recommended it as a "cure-all," thereby prejudicing the honest physician against it. Another cause of failure is because of a monstrous error which has deeply saturated the minds of the laity; and many otherwise learned physicians, too, are afflicted with the same paralyzing fear of "catching cold" from the use of water. The very remedy most potent in preventing colds is accused of producing them. Nansen and his crew had no colds in the Arctic regions. Only when they reached civilization did colds appear. Zymotic influences undoubtedly figure in their etiology. How absurd then to allow this illogical reasoning to deprive us of a powerful and beneficent remedy.

Sometimes I think a great part of the race are victims of true hydrophobia. I had occasion to recommend a bath to a patient recently and was electrified with the

response: "I don't know as it would make any difference, Doctor, but there has not been a drop of water on my body for twenty years."

The more formidable objection is the *time* required for the proper use of this remedy. Many argue that water is all right for hospitals where time is abundant, and helps many; but the fact that water is almost universally used in hospitals, argues that this remedy will accomplish what other drugs fail to accomplish, else why should hospitals go to all this trouble and expense? And a remedy which works such marvelous results in hospitals is a good thing for physicians generally to understand and use, and the chief purpose of this paper is to prove that the remedy can be applied to private practice without the loss of too much time, and without great inconvenience. I shall try to show how the patient in the country farm-house and the crowded city tenement may receive the blessings of this unequalled remedy.

Still another reason why the bath is not more often used by the private practitioner is due to a lack of appreciation of the physiologic action of such baths. To be sure baths are useful for cleansing purposes, and they also reduce bodily temperature, but baths are more potent as therapeutic remedies than that. Briefly, a cold bath stimulates all the nerve-centers, liberating new nervous energy, and thereby stimulating all the functions of the body and greatly improving the patient's resisting power against disease. The heart is powerfully strengthened, not weakened, as many suppose. The kidneys act vigorously after a bath, and experiment has proven the urine far more toxic after than before a bath, showing elimination of the poisonous ptomaines. The lungs, too, do their part, as respiration is powerfully stimulated by the cold bath, increasing the supply of oxygen and the exhalation of poisons. The skin is another channel of elimination that is greatly augmented by the cold bath, and bed sores are far less liable to appear. In fine, the cold bath fortifies the patient in his struggle against disease, stimulating the vital functions and hastening the throwing off of the poisonous ptomaines and their products. No other remedy can approximate it in usefulness at times. Nor do the baths inhibit the use of other therapeutic measures; they simply co-operate with them.

Hot baths, too, have their own distinct physiologic action, quite different from the cold. The warm bath numbs the terminal nerve-fibers, rendering them less sensitive, and thereby producing a sedative action. Baths over 105 irritate the vasoconstrictors, resulting finally in paralyzing them, dilating the peripheral vessels and raising internal temperature.

As to therapy, all hyperpyrexia are far more readily controlled by cold baths than by any other known remedy. Phenacetin and other coal-tar derivatives weaken heart action, if long used, and the patient merely dies with a normal temperature. Whenever delirium, restlessness and insomnia appear, the cold bath is indi-

* Presented to the Section on Practice of Medicine at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus Ohio, June 6-9, 1899.

cated. Cyanosis and signs of collapse are urgent symptoms demanding the use of the warm bath with cold affusion over the head and shoulders, with gentle friction. This will often rescue the sufferer from the very jaws of death, in a manner unknown to any other therapeutic measure.

If, for any reason, I can not use cold baths in typhoid fever, I confess I feel my patient has had only half a chance of recovery. The mortality has been reduced from 25 per cent. to almost nothing, when the baths are properly administered. In the last two years I have treated some forty cases without a single fatality.

It is in typhoid fever that the cold bath is seen in all its perfection. Its results are almost magical. Until some true specific, some antitoxin, is discovered, which will abort the disease, I shall continue the use of the cold baths in typhoid fever, in the belief that I am thereby giving my patient the safest and best treatment. Many lives might annually be saved, were this treatment more universal. I cannot understand why it is not the rule, the orthodox treatment in private, as well as hospital practice, unless it be that the busy practitioner feels he can not spare the time and labor necessary. It is not as difficult as many suppose, and even if it were, the results warrant the extra effort.

The exanthemata have long been treated with the initial warm bath. Strange to relate, the cold bath, with friction, is far more effective in bringing out the rash, and, contrary to old ideas, will not suppress the eruption. When high temperature and marked nervous symptoms appear in the exanthemata, nothing approaches the cold bath in quickly benefiting the little patient.

You are all familiar with the sedative effect of the hot bath in uremia, in convulsions of all kinds, and in cerebrospinal meningitis, and of its benefit in rheumatism and many chronic complaints which time forbids me alluding to.

The modern treatment of pneumonia in children demands the use of the warm bath, which not only reduces fever, quiets nervous symptoms, insures sleep, but tones up the heart action, thus facilitating recovery greatly. Bronchitis, too, in children is greatly relieved by the timely use of the warm baths. The list might be extended, but my object is merely to show that baths are no mean power for good, and should not be neglected or rejected.

The contraindications to the use of the bath are far less than are usually supposed. When rest is imperative, as in pleurisy, peritonitis, perforation or hemorrhage in typhoid, baths are best discontinued. A certain chilly sensation or even cyanosis of the body does not contraindicate their use, but cyanosis of the face is an indication of danger. Syncope may cause their cessation. Atheromatous cases and angina pectoris contraindicate hot baths.

As to technic, ten or fifteen minutes usually suffices, but one point I would emphasize in the cold bath, viz.: *friction*, which is absolutely necessary, over the surface of the body, insuring reaction and preventing internal congestions. The neglect of this is fatal to the good effects of the cold bath.

I do not recommend the bath as a "cure-all." It is merely a powerful remedy in combating disease which I feel is not as generally used or appreciated as it should be. It is one of many remedies which should belong to every physician's armamentarium, be he hospital, city or country practitioner.

The bath I have devised is cheap, enabling many to

use it. It is portable, no larger than an ordinary hand-satchel when folded, and can be carried by the nurse or physician. It can be operated by one attendant, as no lifting of the patient is necessary. It is simple, with nothing to get out of order. It consists of a canvas strap, encircling the head-board of the bed, the ends of the canvas belt fastened by a simple catch, so that the belt may be drawn taut, another canvas belt of similar design for the foot-board, two rings, twenty-six inches apart in each canvas strap, a rubber sheet hemmed at both sides, in which slip ropes, on the ends of which are four snaps. The patient is rolled on the sheet, the four snaps are caught in the four rings, and the tub is ready for the water. It is emptied by lowering one corner, and finishing with a small piece of rubber hose used as a syphon. When not in use it folds up in a small cotton bag.

A still simpler modification can be made with a rope tied firmly around a head-board, another around a foot-board, and two parallel ropes connecting them, and three yards of common table oilcloth, fastened by a dozen clothes-pins to the rope. *

In my judgment, there is no excuse for the busy practitioner neglecting a remedy that will do for his patient what no other drug will do. My one wish in writing this paper is to forcibly call your attention to the fact that this common, every-day, despised, neglected, yet potent remedy, *water*, should be used, and can be used, by every physician who truly has the good of his patient at heart.

PNEUMONIA.

ITS COMPLICATIONS AND SEQUELAE*

BY R. B. PREBLE, M.D.

CHICAGO.

(Concluded from p. 446.)

ENDOCARDITIS.

Aufrecht states that the frequency of acute endocarditis as a complication of pneumonia seems to vary with time and place. He personally has seen but one case. Netter reports 9; Weichselbaum 6, and Sello 6. According to the tables given by Jurgensen, it occurs in 0.2 per cent. of the cases in Vienna and Stockholm; in 0.9 per cent. of the cases in Basel. Sello's 6 cases were in 750 cases of pneumonia, making 0.8 per cent. Banti found 2 cases in 27 autopsies; Netter 2 in 26 autopsies. Netter has had a personal experience with 55 cases of ulcerative endocarditis, of which 23 were due to pneumococcus, and of this 23, 16 were associated with pneumonia.

The endocarditis may be either verrucose or ulcerative, but is usually the latter. Any condition which debilitates the patient—alcoholism, pregnancy, and the age between 30 and 60—predisposes to the occurrence of the pneumonic endocarditis. The date of onset cannot be accurately determined in many cases, but usually it is a late rather than an early complication. It presents some interesting contrasts to other forms of acute endocarditis. One-seventh of the cases collected by Netter were on the right side. This is three times the proportion found in the more common forms of endocarditis. The basal valves, aortic and pulmonary, are more often affected than the auriculo-ventricular. Another point is that while the vegetations are often large, emboli are

*Presented to the Section on Practice of Medicine, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

infrequent. The endocarditis may begin during the course of the pneumonia, in which case the symptoms are easily overlooked, at least until the pneumonic symptoms disappear. More commonly, however, the pneumonic symptoms end in the usual way, and after a shorter or longer period of apyrexia, the fever reappears and the course runs similar to that of any other acute endocarditis. The clinical course does not present any marked differences from the pyogenic endocarditis, but in general the fever is more regular, the duration is longer, and the emboli are less frequent. The mortality is very high, and more than half these cases die within the first month. Recovery may occur, as is illustrated by Case 4, in whom it seemed reasonable to believe the endocarditis pneumonic. We must also mention the frequency with which endocarditis is associated with meningitis, seven-ninths of the cases of endocarditis showing meningitis, while only one-third of the cases of meningitis show endocarditis.

ARTHRITIS.

Arthritis is not a common complication of pneumonia. Vogelius, in 1896, could find but 11 cases, including 2 of his own, in which a complicated arthritis was demonstrated as due to the pneumococcus. Netter collected 18 cases. In 4156 cases of pneumonia reported from the various German clinics, there are only 6 cases of arthritis. The arthritis may occur at any time during, after, or even before, the development of the pneumonia. The process is usually monoarticular, and in the upper extremities, where it affects the larger joints oftener than the small. If it occurs before the pneumonia, or after the crisis, it causes manifest constitutional symptoms beginning with a chill. If during the course of the pneumonia, there are only the local joint changes, swelling, redness, pain, with serofibrinous or purulent fluid in aspiration of the joint. Such joint changes are extremely serious, for they are local manifestations of general infection, which almost always causes death.

Joint pains are more common than the arthritis, and, like it, are more often monoarticular, and usually in the upper extremities. Netter found 17 cases of polyarthralgia and 35 cases limited to one joint. There may be no demonstrable changes in the joint, and the pain may be but transient, or there may be redness and swelling, and fluid in the joint. Such cases may recover on simple fixation even after weeks.

Suppuration in the soft parts has been seen repeatedly, but presents no special symptoms. There may be one or many such foci in any case. In general, the infectious complications occur in combination rather than singly. I have been able to find no references to suppurative panophthalmitis as complication of pneumonia, although I have personally seen two instances of it.

The following cases may be cited as illustrations of this complication:

CASE 7.—Dennis G., aged 33, entered Feb. 6, 1899. Family and personal histories were without interest. During the early part of January he had had la grippe, and on January 23 had a chill; since then he has been worse. He had more or less diffuse pain, especially marked in the right side, and pain in the right side increased by breathing, also pain in the right shoulder and all the joints of the left arm. He had some cough, nausea, vomiting; anorexia, constipation, insomnia.

Examination showed an intelligent and well-nourished adult, breathing rapidly and noisily. He had marked icterus, erythema over the sacrum, left shoulder and elbow, with some superficial erosion. Right chest: Dulness below the eighth dorsal spine, extending forward to the axilla; over this area lessened breath and voice sounds; farther forward, pleural friction. Left chest: Below the third spine dulness, tubular breathing, bronchophony and crepitant râles. Heart, nervous system and abdomen were negative. The joints of the right foot, left knee, elbow, wrist and left second metacarpal

phalangeal joint were red, swollen, painful, and tender. Temperature was 100 in the axilla; pulse 96; respirations 28. Temperature ranged from 98 to 101; pulse from 96 to 130; respirations from 28 to 48 for forty hours, until death. Smears and cultures made from the left wrist and from the blood show pneumococci.

Diagnosis: Pneumonia of the left lower lobe, right sided pleurisy with effusion, and multiple arthritis due to pneumococci. No autopsy.

CASE 8.—D. R., a watchman, entered March 8, 1899. Two months before he was in Ward 4 with typhoid and pneumonia, and was transferred from there to the contagious ward with erysipelas. Finally he recovered and left the hospital ten days. Five days ago he had repeated chills and became delirious, and now complains of pain in the right knee and left shoulder.

Examination showed a well-developed, but emaciated adult, breathing rapidly, very deaf. The heart and left lung were negative. The right lung showed signs of consolidation over the right upper and part of the middle lobe, with friction in the lower part of the axillary region. The liver extended three finger-breadths below the costal arch and was tender. Urine, 1010; contained a large amount of albumin, granular and epithelial casts. Joints were tender, and there was swelling of the right knee and left shoulder. (For temperature, pulse and respiration see curves.)

Case 8.—Pneumococcus pyemia.

March 10, abscess on the back was opened, and pneumococci found in the pus.

March 13, abscess on the scrotum; pneumococci found in the pus.

Patient died one week after entrance.

Diagnosis: Pneumonia with multiple abscess in the soft parts, with multiple arthritis; nephritis.

CASE 9.—Child 14 months of age, seen with Dr. Prince. Eight days before the patient was seized with convulsions, and when seen by Dr. Prince had pneumonia of the left lower lobe. Three days later it had swelling of the left hand. When seen by me on the eighth day of the illness, there was a circumscribed pneumonia of the left lower lobe. There was a circumscribed red, tender, and painful swelling in connection with the left humerus just above the elbow-joint, and swelling and redness of several small joints of the left hand. I advised removal to the hospital, where the patient was placed in the care of Dr. Oelster, to whom I am indebted for the subsequent history.

The swelling of the left humerus was opened and proved to be a periostitis due to the pneumococci. Several other abscesses developed later in other parts, and were opened in the

course of the following weeks. The child had also, a few days after entrance into the hospital, a return of the pneumonia, and several weeks later had an otitis media. No examination of the blood was made. Eventually it made a complete recovery.

Diagnosis: Lobar pneumonia, with subsequent pyemia due to the pneumococcus.

OTITIS MEDIA.

Otitis media is a rather common complication, the infective agent reaching the middle ear by extension through the Eustachian tube. It may be unilateral or bilateral, and occurs more frequently in children than in adults. Ball illustrates by personal cases the fact that many of the general cerebral symptoms seen in meningitis may occur in otitis media following pneumonia. There was headache, vomiting, delirium, restlessness, fever, and coma, all disappearing promptly after the rupture of the tympanum. None of these cases presented any focal symptoms.

Turning now from the complications in which the infective agent travels along blood or lymph vessels or ducts, let us take up those where the extension is direct, such as pleurisy and pericarditis.

PLEURISY.

Pleurisy is by all odds the most common complication; so common, in fact, as scarcely to deserve the name of complication, for it occurs whenever the pneumonic process reaches the surface of the lung. The exudate is usually fibrinous, and limited to the pleura covering the pneumonic area. Such cases can be recognized only by the pain which they cause, and sometimes by friction also. Cases where the exudate is largely serous, causing the accumulation of fluid in the chest in sufficient amounts for recognition, are less common, their frequency being indicated by the following table:

	Pneumonia Cases.	Pleuritis.	Per Cent
Vienna	5738	298 exudativa	5.2
Stockholm	2616	104 do	4.0
Basel	230	35 do	15.3
Aufrecht	1501	89 serous and purulent	5.9
Sello	750	65	8.7
Grisolle			12.6
Dunst in Vienna (1857-61)			15.8

When we recall that at least 400 c.c. of fluid are necessary before fluid can be demonstrated in the adult chest, it is evident that many cases are overlooked. The percentage of cases in which there is a large effusion is small, about 1 per cent., according to Sello.

The pleuritis may precede or follow the pneumonia, the former being the decided exception. In 57 cases in which Sello demonstrated the presence of fluid by exploratory puncture, only 2 were at the beginning of the pneumonia, 31 during the pneumonia and 24 after the crisis. It usually appears about the fourth or fifth day of the pneumonia. Such a pleurisy has but little effect upon the clinical course of the pneumonia, and does not, according to Huss, materially increase the mortality, only 0.8 per cent., according to him. Jurgensen agrees with this, but quotes statistics from Basel, where the mortality of pneumonia with pleurisy was double the average mortality. When the pleurisy follows the pneumonia, there is no constancy about the clinical course; there may be no temperature, or there may be days of high and remittent fever when the fluid is serous.

The diagnosis of pleurisy with effusion complicating the pneumonia is dependent entirely upon physical signs, the distinctness of which is proportional to the amount of fluid. In some cases the signs of fluid are so marked as to entirely obscure the signs of the pneumonia. In making the diagnosis more attention should be paid to pressure symptoms, such as dislocation of the heart, de-

crease in size of Traube's space, than to intense dulness with loss of vocal fremitus and breath and voice sounds. The latter signs, as already stated, are absent in cases of massive pneumonia also.

The diagnosis of the nature of the fluid can be made by exploratory puncture only, and this should always be made, irrespective of the degree or type of the fever, if the signs of fluid persist for any length of time after the resolution of the pneumonia, in order to demonstrate or exclude the presence of an empyema.

EMPYEMA.

Empyema is by no means a rare outcome of the meta-pneumonia pleurisy, and like the other complications, varies in frequency from time to time and place to place. Aufrecht found 23 empyemas in 1501 cases of pneumonia; i. e., 1.5 per cent. Sello found 34 in 750 cases, which is 4.5 per cent. In general, empyema is more apt to follow severe and prolonged pneumonias, although there are exceptions to this rule. Cases ending by crisis are not often followed by empyema. Sello found this only once in 34 cases. Empyema is not common after 30 years of age. Of 286 cases collected by Netter, 215 were under 30; in Sello's table 15 were under 30 and 27 under 40. Two-thirds of the empyemas tabulated by Sello were on the left side, a rather striking observation when one recalls the greater frequency of right-sided pneumonia.

The development of an empyema brings no symptoms which are characteristic. The fever of the pneumonia falls gradually, and there may be a period of complete apyrexia, varying from a few days even to a few months in duration; but, as a rule, the fever of the pneumonia passes gradually over to that of the empyema. There is no constant type of this, for the fever may be continuous, intermittent, remittent or hectic. Occasionally there is no temperature at all. Chills are exceptional. Edema of the chest wall is sometimes seen, but less often than in other forms of empyema. The meta-pneumonic empyema is peculiar in the frequency with which it ruptures into the bronchus; something like 25 per cent. of the cases do so, according to Netter. Such rupture occurs most frequently in the third or fourth week, and while it may, it does not often cause a pneumothorax. The diagnosis can be made by exploratory puncture only.

The bacteria found in the pus are most often the pneumococcus alone; less often the pneumococcus with pus cocci; next the pus cocci singly or in combination, and sometimes the fluid is sterile.

PERICARDITIS.

Pericarditis is a far less frequent clinical complication than it is an accidental post-mortem finding. The following are the statistics:

	Pneumonia Cases.	Pericarditis.	Per Cent.
Vienna	5738	27	.5
Stockholm	2616	22	.9
Basel	230	9	3.9
Wurtzburg			.54
Sello	750	7	.9

Osler found 5 in 100 autopsies; Banti in 5.4 per cent. of the autopsies, and Netter in 8 per cent. of the autopsies.

Pericarditis may be due to direct extension, or to metastasis by the blood-channels; the former is the rule. We would, therefore, expect the pericarditis to be more common with left-sided pneumonia, especially of the upper lobe, and this is a fact. Jurgensen says that in all his personal observations there was pneumonia of the left upper lobe. Diehl states that resection has a marked influence upon the frequency of pericarditis and menin-

gits, basing his opinion upon the following figures: In 17 fatal cases treated by venesection he found meningitis 3 times and pericarditis 5 times, while in 22 fatal cases treated with tartar emetic these occurred but once, and in 14 fatal cases treated by dietetic measures they did not occur at all. In other words, after venesection he found pericarditis in 29 per cent. of the autopsies, to contrast with the 5 to 8 per cent. found by Osler, Banti and Netter.

The difficulties in the way of clinical recognition of the pericarditis are numerous and are mainly due to the presence of the neighboring pneumonia or pleurisy. The diagnosis of the pericarditis here, as elsewhere, depends entirely upon physical signs; therefore, while there may be subjective symptoms in the way of precordial distress and pain, with an increase or prolongation of the constitutional symptoms of the pneumonia, there is nothing characteristic about these which would suggest the development of the pericarditis. When there is a pneumonic area bordering upon the heart, or a large effusion in either pleural sac, the pericardial friction is the most reliable sign. If neither of these is present, the diagnosis is easily made by the physical signs common and usually marked in pericarditis.

The appearance of the pericarditis is always a very serious matter, for it has a marked effect upon the mortality, the patients dying either from the severity of the pneumonic process or from cardiac insufficiency. The amount and character of the exudate is not a matter of indifference, for most of the cases which recover are examples of dry pericarditis. If the patient survives the acute stage, we find exactly the same general condition seen in the pleurisy, the only difference being in the physical findings. If there is fluid in the pericardium, it may be either serous or purulent, and here, as with the pleurisy, if the signs of fluid persist for any length of time, no matter whether they are accompanied by constitutional symptoms or not, exploratory puncture of the pericardium should be made to determine the character of the fluid.

In the third, or toxic, group of complications we include those complications mainly nervous and renal which are apparently not due to direct infection by the pneumococcus, and for which the fever *per se* does not sufficiently account. Many of these were formerly referred to the increase in temperature, but the often marked disproportion between their intensity and that of the temperature has led to the theory that they and the fever are different results of a common factor.

Certain nervous symptoms are common in pneumonia, and it is only when present in an unusual degree that they need attract attention as complications. In children pneumonia, like other infectious diseases, frequently begins with general or local convulsions. Such an onset, especially when combined with vomiting and marked stiffness of the neck, is alarmingly suggestive of meningitis. Such symptoms of cerebral irritation are not common in adults, in whom it is shown by delirium. Delirium is a common manifestation of pneumonia, and varies in type from a low muttering delirium to one of wildest excitement. There are certain factors which predispose to the development of delirium. There can be no doubt of the fact that this and other cerebral symptoms are more marked when the pneumonia is in the upper lobe. Heinze, in 317 cases of pneumonia, had 98 with severe nervous symptoms, and of these 40.17 per cent. had pneumonia limited to the upper lobe, and 25.5 per cent. limited to the lower lobe. It is not plain why upper-lobe pneumonias should be more often delirious

than others, but it has been suggested that the infiltrated and swollen upper lobe presses upon the veins returning the blood from the brain. In this way the nutrition of the cells is lowered, and they are exposed to more intense action of the toxins in the circulating blood. Anemic or debilitated individuals are prone to delirium, because of the more easily disturbed equilibrium of the poorly-nourished brain-cells. This is the explanation of the greater frequency of delirium in cases treated by venesection. Alcohol, also, is an important factor in the development of delirium, which in these cases does not differ from the common delirium tremens. The frequency depends entirely upon the class of the patient. Huss puts it at 6.9 per cent. of the cases, while in 5738 cases from Vienna only .9 per cent. showed it. Aufrecht had 5.3 per cent. The 100 cases previously referred to as tabulated by me in 1893 make a still worse showing, with 9 per cent.

A far less frequent nervous manifestation is the occurrence of cerebral palsy, hemiplegia, monoplegia and aphasia. I do not here refer to such cases as are due to organic lesions, such as hemorrhage, softening or meningitis, but to those cases in which the transient course or the negative post-mortem findings prove the absence of an organic lesion in the ordinary sense of the term. Numerous instances of such paralyzes have been recorded by Huxham, Lépine, Macario, Stephan, Charcot, Chantemesse, Aufrecht and others. Most of these have been in patients past 60 years; in 20 of 28 cases collected by Bouloche, but still there are numerous instances in adults and even in young children. Such a paralysis may come on at any time during the course of pneumonia. It may, indeed, precede the lung changes, but, as a rule, comes on during the second or third day of the disease, which may be severe or mild. The paralysis may come on suddenly without premonitory signs, but is often preceded by headache, fullness, formication over the area later paralyzed, or there may be, as in the cases reported by Moizard, Jacksonian convulsions. The paralysis takes the form of a hemiplegia or monoplegia, or there may be aphasia with paralysis of the face and arms. Accompanying the paralysis there may be delirium or coma, and Cheyne-Stokes respiration, with weak and irregular pulse. The paralysis exactly resembles the common form, except in its course. The symptoms all disappear in the course of a few hours or days.

The explanation of these cases is not clear. Lépine, believing that these pneumonic paralyzes occurred only in the aged, referred them to atheromatous changes in the cerebral blood-vessels with resultant circulatory disturbances, merely precipitated by the pneumonia. Stephan, because of the examples of this form of paralysis in adults and children, whose vessels were not atheromatous, discarded Lépine's explanation, and referred them to the effects of the pneumotoxins upon the brain-cells or their circulation, comparing them to the monoplegias and hemiplegias sometimes seen in uremia, and not due to demonstrable anatomical lesions. Atheroma, high temperature, malnutrition and heart weakness are merely adjuvant causes.

All authors agree that this complication occurs most often with pneumonia of the upper lobes. Aufrecht believes that the pneumonia of the upper lobe, by lessening the influence of the negative respiratory pressure of the thorax, retards the return-flow of the blood from the brain, and leads to the development of cerebral edema, which may be partial and cause a hemiplegia or a monoplegia.

The following case is an interesting example of such a monoplegia:

CASE 10.—E. S., aged 2½ years, was seen with Dr. Urheim, May 22, 1899, after a few days of illness of indefinite character. He had a temperature ranging about 103, with swelling of the glands of the neck; no vomiting nor eruption. May 24, a small patch, half an inch in diameter, appeared on one tonsil. No culture was made. One thousand units of antitoxin was given. The throat cleared up, but the temperature continued, reaching 105 on the 26th. About this time retraction of the head and rigidity of the neck were noted. The child was conscious at this time, taking nourishment freely and retaining it. Pulse was strong, but rapid. On May 27, there suddenly developed a complete paralysis of the left arm; no paralysis elsewhere; no disturbance of the sensorium except stupor; no convulsions; pupils equal and reactive to light. When seen by me May 30, paralysis of the left arm had completely disappeared; the neck was less stiff, the head not retracted, there were no paralyses, sensorium was free, and there was consolidation of the right upper lobe. Temperature per rectum was 100.9. Examination was otherwise negative. The child made a complete recovery.

RENAL COMPLICATIONS.

Albuminuria is of frequent occurrence in the course of pneumonia. Jurgensen states that daily examination of the urine would probably show the presence of albuminuria in all cases. More definite statements are made by the following:

	Cases.	Per Cent.
Fraenkel and Reiche	356	albuminuria in 42.6
Rosenstein	130	albuminuria in 23.1
Crämer	66	albuminuria in 44.9
Startz	259	albuminuria in 42.5
Bleuler	121	albuminuria in 52.1

The frequency varies in different groups of cases. The age of the patient is of influence, as is shown by the table of Fraenkel and Reiche, who found albuminuria much less frequent in children than in adults. It is influenced, also, by the extent of the pneumonia, increasing in frequency with the extent. One lobe showed 38.8 per cent.; two lobes, 53.9 per cent.; three or more, 54.1 per cent. Of 175 fatal cases, 60.57 per cent. showed albuminuria; 36.5 per cent. of 535 cases ending by crisis, and 43.9 per cent. of 240 cases ending by lysis. The character of the epidemic also has a marked influence upon the frequency, and this, I believe, will account for the marked difference in the percentage given by different authorities. Hyaline and granular casts are very often found associated with the albuminuria, but definite figures as to their frequency could not be found. Authorities agree, however, in the opinion that these are not to be interpreted as due to an accompanying nephritis, but are the result of degenerative changes in the kidney.

The line between such cases of albuminuria of this class and a true nephritis can not be a sharp one, but the criterion of Aufrecht, while not exact, is practical. The urinary changes due to simple renal degeneration should disappear within three or four days after the crisis, and if they persist longer they may be regarded as due to a complicating nephritis. That nephritis is by no means a common complication is shown by the following table:

	Cases.	Nephritis.	Per Cent.
Vienna	5738	66	1.2
Stockholm	2616	52	2.0
Zürich	500	13	2.6
Fraenkel and Reiche	956	6	.53
Wagner	150	4	2.6
Rosenstein	130	3	1.7
Aufrecht	1501	16	1.0

Personally in 100 cases I found one acute nephritis and one acute exacerbation of the chronic. This makes 11,690 cases, with 160 cases of nephritis, i. e., 1.4 per cent.

The older explanation that the renal changes are due to temperature must be given up, because there is no relation between the fever and the albuminuria. The cur-

rent theories are that they are due either to the action of toxic bodies formed by the pneumococcus, or to direct action of the cocci excreted through the kidney. The changes found post-mortem in most cases exactly resemble those found after intoxication with certain inorganic bodies, and in other infectious diseases where they are believed to be toxic. However, numerous authors have demonstrated the pneumococci in the kidneys. Fraenkel and Reiche found them in 22 of 26 cases examined for this purpose. It seems probable that both theories are correct.

Nephritis may appear at any time during the course of the pneumonia, or may precede or follow it. It has no manifest effect upon the evolution of the disease, and does not, as a rule, cause any symptoms other than the urinary changes. Réndu reports a case of pneumonia complicated by nephritis in which the critical polyuria failed to appear when the pneumonia ended by crisis. Uremic symptoms are rare, but occasionally headache, insomnia and vomiting are seen. Edema, local or general, occurs, but it is exceptional. The nephritis is, then, feared not because of any symptoms which it causes, but because it is an expression of an intense infection or intoxication. Wagner notes the frequent splenic tumor, the early heart weakness and marked nervous symptoms as an expression of this same intoxication.

The prognosis is grave. Nauwerk lost 7 of 14 cases. Of Fraenkel and Reiche's 6 cases, 2 recovered, one disappeared, and 3 were discharged with nephritis, and one of these died ten months later of nephritis. The cases last for a few weeks to months, and end either in recovery or death, with an occasional exception in which the nephritis becomes chronic. Leyden, Fraenkel and Reiche, and Eisenlohr each report one instance of this.

The list of abnormal outcomes or sequelæ of pneumonia is not so long, and will include only the delayed resolution and induration, abscess and gangrene.

Sometimes after pneumonia has ended either by crisis or lysis and the constitutional symptoms have disappeared, examination shows that the lung has undergone no change; the patient may continue to improve and the lung remain unchanged for weeks and even months, and then gradually undergo resolution. There is no sharp line between these relatively favorable cases of delayed resolution and the much more serious cases of organization and induration. The cases of induration are characterized by three groups of symptoms: 1, continuation of the temperature; 2, the persistence of the signs of consolidation of the lung, and, 3, the gradually increasing deformity of the chest, due to the retraction of the forming fibrous tissue. The fever of the pneumonia passes gradually over into a prolonged and atypical even hectic fever, which persists for weeks or months, and is accompanied by all the constitutional and nutritional symptoms resulting from such a fever, irrespective of its cause. The cough continues, and the expectorate gradually loses its pneumatic character and becomes mucopurulent. Examination of the chest shows the persistence of the signs of infiltration of the lung, and gradually there are added to these the changes resulting from retraction. Usually one does not wait long for the latter. Personally, I have seen but three instances of such post-pneumonic induration, and in all the signs of retraction began to appear within the first month.

The changes resulting from retraction require only the briefest description, for they do not differ from those seen in cases of retraction from other causes. The affected side becomes smaller, with narrowing of the intercostal spaces and curvature of the spine. The res-

piratory movements are lessened; the mediastinum and its organs are dislocated, leading to a variety of symptoms, such as malposition of the apex-beat, visible pulsa-

work. Laennec referred to emaciation, and Aufrecht agrees that this has some influence. Marchand believes that a previous pneumonia which has not entirely disappeared or has left behind pleural adhesions with sub-pleural thickening is responsible for most cases, and it is a fact that most cases, but not all, show pleural adhesion. Such adhesions increase the flow of blood to the parts and, at the same time, by lessening respiratory movements favor the organization of the exudate. Kahl-den agrees with this, and notes that in cases of this sort the alveoli seem to contain a larger amount of fibrin than is ordinarily present.

CASE 11.—J. J., colored, was seen Feb. 20, 1899. His family and personal history were good. He had had no previous pneumonia. About two weeks before he had had a severe chill, followed by fever, with cough and shortness of breath; nausea, vomiting and anorexia.

Examination showed a well-developed and intelligent negro, with left chest normal; heart negative. Right chest.—From the third dorsal spine to the fifth rib in the nipple line was an area of more intense dullness. There was no vocal fremitus over this area, but there was very distinct bronchial breathing. Pulse was 120; temperature 103; respiration 44. The dullness and resistance over the right chest were so marked that in spite of the distinct bronchial breathing and the voice sounds, the exploring needle was used, but without result. The course of the temperature, pulse and respiration are shown by the curve. The physical signs in the chest did not change, but after three weeks stinking sputum appeared, and after lasting a few days disappeared. About this time it became apparent that the right side of the chest was decreasing in size, and this became more and more marked until at the time of discharge there was a very manifest difference.

This case presents the ordinary clinical history of an induration, continuation of the fever, persistence of the signs of consolidation, and later, retraction of the affected side. The intense dullness and resistance in the early stages suggest that there were here the scars of an old pleurisy, and that this case supports the idea of Marchand and Kahl-den that such a pleurisy favors the organization of a pneumonic exudate.

Abscess of the lung is an infrequent happening. Aufrecht found 3 in 253 autopsies, i. e., 1.2 per cent. Sello found 11 in 750 cases, i. e., 1.5 per cent. The abscess may be single or multiple, and is usually small. They are more common in the upper than in the lower lobe, and more often left than right. All debilitating conditions, malnutrition, alcoholism and senility, are said to favor the formation of such abscesses. It seems probable that in all cases the abscess formation is due not to the pneumococcus, but to a coincident infection with the common pyogenic organisms.

The cases are characterized clinically by the continuation of the fever, which presents the characteristics of a pus temperature, or there may be a period of apyrexia lasting a week or two, and ending with chill, followed by fever. Resolution is delayed. These are often the only clinical manifestations, and since there is nothing here which more than suggests an abscess, the diagnosis is often impossible. The diagnosis can be made only on the appearance of the characteristic sputum. The sputum gradually changes from pneumonic to mucopurulent or to pure pus. In some instances the change takes place suddenly, with a sudden expectoration of considerable amount of pus. Sello, in his 11 cases found 2 in which the sputum remained pneumonic. Both of these died and the diagnosis was made in the dead-house. In 4 the fluid was mucopurulent, and in 5 pure pus. Only once did he find the green sputum described by Traube. The sputum from an abscess contains pus corpuscles, shreds of pulmonary tissue and elastic fibers, with crystals of cholesterolin and hematoidin and bacteria, and has the odor of pus. Diagnosis of the site of the abscess is

Case 11.—Pneumococcus ending with induration.

tion of the pulmonary artery, and closure of the pulmonary valve.

Induration is not a common outcome, and probably the figure of Sello, who places it at 2.1 per cent., is too high. The causes for its occurrence are not definitely known, but it has been referred to senility, alcoholism, general debility, and other indefinite causes. Fraenkel thinks that there may be some bacterial influence at

usually impossible, but if cavity signs appear in such a case, the diagnosis of the site can be made. Rupture into the pleural cavity occurs frequently, causing an empyema or a pyopneumothorax. If death does not result, the course of the abscess is prolonged; recovery may occur.

Gangrene occurs even less often than the abscess. Grisolle found no instance of it in 305 cases of pneumonia, and in 70 cases of pulmonary gangrene only 5 were referred to pneumonia. Sello found 3 examples in 750 cases, i. e., 0.4 per cent.; Aufrecht none in 1501. The course of the pneumonia is not modified in any characteristic way by the development of the gangrene, and here, as with the abscess, the diagnosis rests upon the change in the character of the sputum. The sputum becomes thinner and gradually changes through the browns to the color of prune juice, and at the same time takes on the terribly stinking odor of gangrenous parts. It contains shreds of tissue, elastic fibers, cells, crystals and bacteria.

Other sequelae, such as neuritis, tetany, chorea, and psychoses, occur, but so infrequently as to need nothing more than mere mention.

DISCUSSION ON PNEUMONIA.*

DR. J. H. MUSSER of Philadelphia—I do not feel qualified to open this important and serious subject, which has been thoroughly discussed by the readers of the various papers, without more reflection, but in the absence of those to whom it has been assigned I can not shirk the duty. Pneumonia has been taken out of the category of lung diseases and is now considered an infection. I suppose we shall have to continue the use of the term pneumonia, but as we near the time of im-

proved pathology it would be better to associate pneumonia with the term "pneumococcus infection." For certainly it is an infection; long before bacteriology came to our assistance we were satisfied that pneumonia was not a local but a systemic disease, from the clinical course. The chill, fever, possibly vomiting, rapid pulse, alteration in the respiration rate, and the leucocytosis—the occurrence of all these symptoms, before physical signs can be made out, indicate that an intense general process is present. Because of the few physical signs it was called pneumonia. Although we often could not make out the physical signs during life, at autopsy we may find small portions of the lung the seat of the consolidation. Pneumococcus infection it should be called.

It is not necessary for me to refer again either to the course of the disease, its clinical history or to the manifestations of this infection. I shall refer to one or two points: 1. To the form of pneumococcus infection beginning with abdominal symptoms; there are many cases of this character. Chill, fever, vomiting and abdominal pain are present, the pain localized, probably, over the upper half of the abdomen, and often again localized in the portion of the abdomen where the appendix lies. Indeed, in one instance the patient was supposed to be suffering from appendicitis. In a large majority of cases, however, the tenderness and great pain in the upper half of the abdomen are very misleading. One must not be misled by the severity of this infectious process.

Again, too much stress can not be laid on the occurrence of pericarditis during the course of the pneumonia; it is often overlooked because of the insidious development of the complication. Without pain, but with only an increase in the pulse-rate, we are feebly warned of the development of this associated process. As has well been stated, the physical signs alone enable us to distinguish pericardial infection. I wish, however, to lay stress on the importance of watching the pericardium, noting the physical signs there, for in the large majority of instances, it is too late when we first learn of this complication by symptoms of great effusion when operative measures must be resorted to.

There are a few other complications that have not been referred to. Meningitis has been considered, and also the intoxication symptoms. One word further in regard to pleural effusion or empyema. Dr. Preble called attention to the localized areas in the pleura; such areas may be confusing, and we can not determine whether small empyemas may be present. I rely on the locality of the physical signs which indicate fluid in the pleural cavity. If I have physical signs, even if small, along the margins of the lobes, absent fremitus and breathing signs, and with these a continuation of the fever, I look out for the occurrence of infection. This may be between the lobes of the lungs, pointing toward the surface.

In regard to the treatment of pneumonia I shall say but little. I approach no subject with any greater embarrassment than this one of the treatment of pneumonia. I can not tell you how to treat it. Dr. Hare[†] has pointed out that we can not have any "cut and dried rules" regarding it. I feel that all of us should formulate to ourselves what to do in cases of pneumococcus infection. Notwithstanding the fact that this disease should be taken out of the category of lung diseases and included among the infections, still I am convinced that cupping is of great value; cup freely and continuously. I cup in the morning, in the evening, and again during the next day. I repeat the cupping around the areas I believe to be the seat of the consolidation. Following this I am satisfied of the value of cold compresses applied during the course of the disease as insisted on by Baruch. I need not tell you why. These compresses are wrung out of ice-water and applied during the course of the fever. This is especially of value where the temperature is above 102 degrees, and where there is general infection and marked evidence of toxemia; otherwise the compresses are not indicated. Bear in mind, I do not apply these compresses because of their effect on the lung alone, but because of their effect on the heart, the general circulation and nervous system. I am satisfied that the toxic symptoms are controlled by the local applications of cold and it is better to apply these in bed rather than by means of the cold bath out of bed. Cold sponging may be used in addition. In regard to the remedial remedies I know of no specific. I have never given aconite or veratrum viride, nor have I found it necessary to use cardiac sedatives. I look toward establishing proper eliminations as well as possible by the use of marked laxatives and mild diuretics and diaphoretics. I use large quantities of water internally. I do not fear systemic intoxication in typhoid fever or any infectious disease if I keep the kidneys freely acting; as long as the kidneys are acting and there is passed 50, 60 or 80

* The other papers of the Symposium on Pneumonia appeared in the JOURNAL August 19.

[†] Dr. Hare's paper having been published elsewhere, an abstract appeared in the JOURNAL, July 29, p. 274, '28.

ounces a day, I then feel satisfied that the heart is acting all right, the tongue will not become dry, and the so-called typhoid state will not develop. The action of the kidneys is encouraged by simple measures. Of the drugs, we use strychnin and nitroglycerin during the course of the pneumonia, especially during the later stages. With digitalis I have had but little experience. I am doubtful as to its efficaciousness.

Dr. CHARLES G. STOCKTON, Buffalo.—I have had a case that confirms the position taken by Dr. Stengel, that leucocytosis does not mean that the case will result fatally in pneumonia. In my case there were not more than 6000 leucocytes to the cubic millimeter, and the case recovered; this seemed to be quite extraordinary in view of the fact that this was a case of relapsing pneumonia, the only one I have ever seen. It was lobar pneumonia and the child had three relapses. The late Dr. Flint said that this disease had no relapses; it is very extraordinary.

There is another point about the general question that is very interesting: I have stated to my classes that the patient may die of lobar pneumonia without having inflammation of the lungs. I have never seen such a case, but I have seen two cases approaching death where no pneumonia could be discovered. One case died of lobar pneumonia and showed no evidences of any pneumonia until the sixth day, and he died on the seventh day. That was a case of toxemia; that man was like one bitten by a serpent. There was vasomotor paresis and evidence of the most serious processes in operation, but death occurred in the beginning of the inflammation. I think that toxemia is the question that concerns us in the treatment of pneumonia, and wish again to emphasize the fact that lobar pneumonia is a toxic disease, and the treatment should oppose the toxic condition. Why is Dr. Hare careful in the use of stimulants at certain times? He warns us against whipping up the heart too early in the disease. This brings us to a state of timidity when the stimulants are needed. If we have to deal with a patient whose blood is loaded with poisons we would try to eliminate these poisons; a proper amount would be withdrawn and a saline solution introduced. Why not give calomel? I believe that calomel in large doses is of more importance at certain junctures than any one remedy. It should be used to stimulate the liver and to rid the organism of pathogenic bacteria, as Fütterer has taught us, as well as their toxalbumins.

Cardiac failure and edema of the lungs, which mean toxemia, constitute the real danger in this disease. Therefore, we should use strychnin. Strychnin should be used in 1/15-1/20, if needed, in 1/10 grain doses hypodermically, and it should be given until there is no longer vasomotor paresis. There is no doubt that patients will be rescued when any other means would have been futile. If the patient show much excitement from the large doses of strychnin, the use of small amounts of opium will control the irritability.

Dr. GEORGE DOCK, Ann Arbor, Mich.—So many valuable papers have been read, and so much has already been brought out in the discussion, that I can hardly do more than reiterate or criticize some of the statements already made. In no other disease is a knowledge of the natural course of the untreated disease more instructive, and I agree with the advice of Dr. Hare in regard to the duty of the physician as a watchman in dealing with pneumonia. I wish to add my voice to the value of strychnin in the later stages of pneumonia, given judiciously, and also to the value of calomel. I often find the latter useful toward the end of the acute stage. I wish especially to speak of the use of ice-bags in the treatment of frank, croupous pneumonia. I see many such cases in country people of good habits and constitution, and in previously healthy students. Formerly I treated these cases with the cold bath, but this is more difficult to carry out in pneumonia than it is in typhoid fever, and so I was especially glad to find the results with the ice-bag quite as good. A few patients were seen early, and in many the temperature ran high, with breathing rapid, with a good deal of pain, etc. For the latter I formerly used hypodermic injections of morphin. Now the application of the ice-bags quickly relieves the pain, the respiration soon becomes slower and the patient feels greatly improved. The ice-bag is usually applied over the consolidations, and the ice may be mixed with bran if the patient be a weak child or woman. In many parts of the country patients are still treated by hot plinches or the cotton jacket. The heat does not relieve the patient so quickly as cold in most cases. In speaking of the treatment of pneumonia, there is another point that is not borne in mind as it should be, viz., watching the condition of the pleura. In all cases of pneumonia careful examination of the chest should be made for areas of dullness and absent fremitus; and, in doubt, the aspirating needle should be used freely but with proper care. Dr. Preble pointed out the importance of this matter, and I wish to reiterate what he has said. A fairly

good-sized needle should be used. It is also important to make a bacteriologic examination of the fluid for the purpose of finding out the character of the germs present, whether diplococcus, streptococcus, etc., since this assists us in prognosis and in deciding whether a radical operation is necessary or not.

Dr. A. M. HOLMES of Denver, Colo.—I might say a word or two in reference to altitude. For several years I have had the good fortune to live in Denver. At an altitude of about one mile above us and 100 miles from us we have the celebrated Cripple Creek district. At this point there is a great increase in population, it being a new settlement, and there is a great deal of exposure and pneumonia. The mortality rate at this point is exceedingly high. It is customary to send patients to a lower altitude as soon as the diagnosis of pneumonia can be made.

Dr. J. M. ANDERS, Philadelphia.—The subject which now engages the attention of this Section is one of paramount importance, and every aspect seems to have been touched on. It has been shown recently, by Drs. Wells and Folsom, that while the death-rate from typhoid fever, diphtheria, tuberculosis, and other infectious diseases has been decreasing, that of pneumonia has been rather rapidly increasing in recent years. In a disease that prevails so extensively as does lobar pneumonia, this fact corroborates the view expressed by Dr. Wells as to the extreme importance of the subject.

It is now the generally accepted view that lobar pneumonia is due to various cocci, but that the pneumococcus is found in about 90 per cent. of the cases, and it is the only organism present in about 75 per cent. of the cases. Now the special etiology is known to decidedly influence the course of the disease, and to have a bearing on the prognosis. For these reasons it is of the utmost importance that more accurate methods of diagnosis than are now in vogue should be applied to this affection. In short, a bacteriologic diagnosis should be made whenever practicable, for prognostic and therapeutic reasons. Thus the course is apt to be more prolonged, and the prognosis more unfavorable in a streptococcal lobar pneumonia than in a diplococcal pneumonia. The streptococcal variety is more commonly met with in persons previously debilitated by chronic disease than the diplococcal variety, according to my experience.

Again, if it is ever hoped to employ the antipneumococcal serum in a rational way in the treatment of lobar pneumonia, a bacteriologic diagnosis is imperatively demanded. Antipneumococcal serum can not be expected to give good results in a streptococcal pneumonia, nor yet in cases of mixed infection. For the obvious reasons that I have adduced, a plea for the general adoption of an accurate bacteriologic examination for all cases of pneumonia is both timely and important.

The aspect of the question considered by Dr. Stengel is an interesting one. According to my observation and experience, moderate leucocytosis is the rule; only rarely does the count rise to 50,000 white cells to the cubic millimeter. I have always found it to persist during the pseudo-crisis that is so apt to occur on the fifth day, but it also rarely persists for hours, or even a whole day, after the true crisis. This is especially apt to occur in cases in which the resolution is delayed, and those due to the streptococcus alone, or a mixed infection with the streptococcus.

The cases of relapsing pneumonia, a subject to which Dr. Stockton referred, are of lively interest, although rare. During the past winter I attended a male, aged 23, suffering from double lobar pneumonia complicating influenza; he had nearly recovered when he developed a relapse, which, however, affected only one side. Full recovery ensued after a prolonged illness. In this case Prof. Martin examined the sputum, and failed to find the pneumococcus or any other recognized pathogenic organism. It is probable that the relapsing cases are due to some other, as yet unknown, organism than the pneumococcus.

Since lobar pneumonia has been regarded as an acute infectious disease, its real nature and dangers have come to be better appreciated. The true element of danger is the toxemia and septicemia. But the fact should not be lost sight of that there is, in pneumonia, oftentimes a mechanical hindrance to respiration and circulation. This is particularly true of the function of respiration and circulation. This is particularly true of the function of respiration after the heart begins to fail, and after collateral edema and congestion appear in the lungs.

The treatment of pneumonia has been ably discussed. There is no treatment for pneumonia, but there is for the individual case. I heartily approve of the division of the cases into sthenic and asthenic groups, since the treatment of the former should be different from that of the latter. Sthenic cases are commonly met with in the country, while, according to my ex-

perience, they are comparatively rare in cities, particularly in our large general hospitals. In dynamic, or sthenic cases, it is sound practice to resort to blood-letting in the stage of engorgement. This lowers arterial tension, allays the nervous excitement, greatly relieves the pain, and, finally, directly removes a portion of the burden from the heart, without robbing it of much of its power. Cardiac sedatives, as veratrum viride, fulfil the same indications as blood-letting, but they do so at the expense of cardiac power, and the same is not true, to the same extent, at least, of venesection. In the asthenic type of pneumonia, during the stage of congestion, morphin is to be used; this guards the heart, relieves the pain, and at the same time gives comfort and rest to the patient. Leeching, or local blood-letting, withdrawing from six to eight ounces of blood from the side, are measures that may be combined with the use of morphin. It is hard to explain, on physiologic premises, the effect of the local abstraction of blood, but it does diminish arterial tension and nervous excitement, and gives relief from pain. Asthenic cases do well under blood-letting and the application of cold compresses to the chest.

During the second stage of pneumonia the treatment should be sustentative and supportive. In cases of dynamic pneumonia, alcohol must be given sooner or later; the condition of the pulmonary second sound of the heart, the blood-pressure, and the pulse should be our guide in the administration of alcohol. Strychnin should be always employed when alcohol fails, and where there is threatened collapse; it should be administered hypodermically, and not be withdrawn, but continued in smaller dosage until convalescence is reached. Turpentin should be tried in cases of delayed resolution. I can not tell you how it acts in these cases, but it sometimes exerts a good effect.

Dr. H. B. FAVILL, Chicago—My experience in the past affords me abundant proof that Dr. Billings, the chairman, has never an intention to be unkind to me. My position on this program, however, and the fact that I consented to be put on the program, suggests to me the experience of the country boy with the yoke of steers. Those of you who have encountered the mysteries of a log chain and a yoke of steers, know what is meant by a "toggle." The boy, whose chain had impudently broken, slipped one link through another, and used his finger for a "toggle." The lack of correspondence between his judgment and his zeal is eloquently set forth in his comment. "I seen my mistake the minute the steers straightened." When I saw from one glance at the program, that my enthusiasm had caused me to be made to follow such a list of masters in medicine, I felt for that boy. The gentlemen who have preceded me have all admitted that everything has been said, and that nothing more is to be said, with which I agree, and, like them, I shall probably take my full allotment of time.

The fact that impresses me more strongly the longer I think about it, is the correctness of the conception of our predecessors of pneumonia as "lung fever." For several years now we have abandoned the latter idea of "inflammation of the lungs," and have regarded the process, the symptoms, the dangers as those of toxemia, and have held the local considerations as subordinate thereto. A still broader grasp of the facts as we reach them, involves the conception of pneumonia as a septicaemia of pneumococcus origin. To what extent it is always so general is, for the present, doubtful. That very often it is distinctly so, admits of no question. The place to study pneumococcus infection is in the child. There it manifests its variety and versatility in great intensity, often with the minimum of local developments.

I call your attention to the protean aspects of an infection in which the developments in throat, ear, lung and brain present a shifting picture of confused and inseparable symptoms, which must utterly dismiss the anatomic diagnosis. The tardiness of development of local evidence, the rapidity of evolution, the marked tendency to shift, the masking of crisis by "lapped" developments, but, characterizing all its phases, the tendency to *crisis*, mark a most significant septic process, whose local accidents have many names. Unfortunately, these names are to the practitioner a stumbling-block and a hindrance. When shall we escape? What happens in the adult is less picturesque and less frequent, but frequent enough to greatly enlarge our ideas as to the septic possibilities of pneumonia.

When one considers the confusion resulting from the coincidence of streptococcus infection, and the impossibility of diagnosing with our present knowledge the relative value in a septic case, one must long for the day of rational classification.

I am very much of the opinion expressed by Dr. Stockton as to the value of strychnia in treatment. To regard its use as an extreme measure of stimulation is, I am sure, to overlook its well-demonstrated supportive and steadying power. To use it to the extent of putting the nervous system on a "wire

edge," is to use it injudiciously in the early stages. Its management is much broader than that.

Time will furnish the experience necessary to determine the best use of cold water baths in pneumonia. On this point I am not clear, but I am quite convinced that they have a great value and present no contraindication from the mere element of cold or wet. Just how best to utilize the sedative, tonic, and eliminative qualities may not be established, but the future will give hydrotherapy a prominent place in treatment.

Dr. EDWARD F. WELLS, Chicago—In the twenty minutes allowed me in the reading of my paper, I endeavored to present as clearly and concisely as possible those features of pneumonia, which, in my opinion, are of the greatest present interest and importance. Necessarily, in such a brief period only a little of the results of history, observation, analysis and speculation, as they concern the subject of pneumonia, has been told, and the discussion has brought out the fact, and it is one of the first importance, that I failed to sufficiently emphasize the point that primarily pneumonia is a local affection—the facts at hand lead irresistibly to this conclusion. Pneumonia is not a general disease with a local manifestation. At the expense of partial repetition, allow me to restate, a little more fully, this proposition: Pneumonia is an acute infectious disease of bacterial origin; the essential cause of the malady is the pneumococcus; this micro-organism incites the pulmonary inflammation; and the general symptoms depend, for the most part, on a toxemia due to the introduction into the general circulation of pneumococcal toxins. Primarily the affection is a local one, but many of its principal features and dangers depend on the general toxemia.

I had hoped that the subject of prophylaxis would receive elaborate treatment in the discussion, but apparently we are not quite ready to formulate opinions on this question. It is clearly the most important problem which confronts us today.

Dr. H. A. HARE, Philadelphia—One of the pleasant things about a discussion of this character is that it enables us to use the complimentary terms just applied by Dr. Stockton to what I have said. I was not, however, sufficiently heard to make him understand what I meant, viz., that I believe strychnin was much abused, that it often caused, when given continuously, a rapid, thready pulse, but that in an emergency to overcome a crisis it was one of the best, if not the best, drugs to be employed, and that it ought to be given freely and hourly, but not for days at a time as a stimulant. It does not act as a supportant, but as a "whip."

AFTER-TREATMENT OF ABDOMINAL SECTIONS.*

BY C. L. BONFIELD, M.D.
CINCINNATI, OHIO.

The fate of the vast majority of patients subjected to abdominal section is sealed when the incision is closed. Many will recover without any especial skill being required in their subsequent treatment, others are doomed to die in spite of the most judicious care that can be given them; but in some cases the result is determined by the after-treatment. The days and nights immediately following operation are, for the patient, ones of extreme discomfort. It is not unusual to hear her say: "Had I known what I must suffer, I should never have had it done." A subject that concerns the lives of some and the comfort of many of our patients seems to me to be worthy of more consideration at the hands of operators than it has received in recent years.

The indications for treatment after abdominal section are to secure reaction from shock; to arrest secondary hemorrhage should it occur; to combat sepsis, if need be; to administer proper nourishment, and to make the patient as comfortable as possible without interfering with her recovery. Ordinarily reaction from shock occurs without much assistance, wrapping the patient in warm blankets and surrounding her with hot water bags is all that is required. There can, however,

* Presented to the Section on Obstetrics and Diseases of Women, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

be no objection to giving 1/30 gr. of strychnin hypodermically. If the shock be more severe, normal salt solution is the best weapon with which to combat it, given per rectum, subcutaneously, or intravenously, as the urgency of the case may demand. Sulphate of spartein is of decided value as an immediate stimulant to the heart, while digitalin may be used for a more lasting effect. The physiologic action of alcohol is so nearly identical with that of ether and chloroform, that its utility is to be doubted when the system is saturated with one of these agents.

There are few surgeons of large experience, who have not one or more times found, after the patient has been put to bed, that their hemostasis is incomplete, and that it is necessary to reopen the abdomen and secure the bleeding vessel. Some one competent to do this should be within call for at least twelve hours after operation. No other treatment is to be thought of.

It is now generally recognized that the best means we have of averting or combating sepsis is free purgation. To produce this, probably most operators are in the habit of employing magnesium sulphate, or some other saline, doubtless because they have the property of abstracting water from the blood, thus causing absorption of free fluid from the peritoneal cavity—"draining the peritoneal cavity through the bowels," as it is often described. This effect is not so essential, in these days of painstaking work, when raw surfaces are covered and great care is taken to stop all bleeding, as it was formerly. But if it is desirable, it is better to first secure a movement of the bowels with some other agent, and administer salines afterward. The objections to the use of salines are that they act almost entirely by increasing secretion, stimulating peristalsis but slightly; that if they are not effective in a few hours, they will not act at all; that they can not act when the system is very deficient in fluids; that they produce dilatation of the intestines, and that their unpleasant taste frequently produces nausea from vomiting. The indication is for a purgative that acts chiefly by increasing peristalsis, thus urging flatus onward and preventing dilatation. I have experimented with numerous purgatives and combinations of purgatives, and have concluded that calomel is the most generally satisfactory. I usually give 5 grains, by itself, or with sugar of milk, dropped dry on the tongue about twenty hours after the operation. Four hours later, if there is no indication of peristalsis having been excited, the dose is repeated. This is a better way than to give it in divided doses, which, while they are not so apt to nauseate, are not so effective as a purgative, and are more apt to produce salivation. Two hours after the second dose of calomel, the administration of the solution of citrate of magnesium is begun, 2 or 3 ounces being given every hour until the bowels move or the stomach rejects it.

If there has not been much nausea, instead of the second dose of calomel a capsule of 5 grains of compound extract of colocynth is frequently given. This very efficient preparation was one of the purgatives with which I experimented most persistently. When it was retained its action was ideal, but unfortunately I found that the stomach rejected it in about 50 per cent. of the cases. Where the colocynth is given instead of the calomel, the magnesium is seldom required. The colocynth may be repeated as often as is necessary. An enema of soap-suds is usually given when the patient feels that her bowels are about to move.

If there is vomiting and distension of the abdomen, calomel is the only purgative given. If a dose of it is

vomited, it is immediately followed by another. The stomach is kept absolutely empty of everything else. Persistent efforts are made to move the bowels with rectal injections every four to six hours. I have always found the Davidson more satisfactory for this purpose than the fountain syringe. I have seldom been able to pass the rectal tube above the sigmoid flexure, and when my assistants have thought they have done so, I have usually been able, with my finger in the vagina, to demonstrate that it is coiled on itself in the lower bowel.

Little benefit is to be derived from leaving a tube in the rectum for the escape of gas. It is not the splanter that retains the gas; on the contrary, it is so high up that the tube seldom reaches it. Where relief from it is apparent, it is because peristalsis has already been started, and the relief would come a little later when the bowels move, without its assistance. Were this not true the escape of gas would be only from one loop of intestine, as it is when the bowel is punctured for the escape of gas in operating for obstruction. The tube renders the rectum intolerant, and prevents the retention of the large injections, which are the last means we have of securing a movement. When the purgatives have failed to act in forty-eight hours, and the rectum has become intolerant, the patient's condition is truly alarming. Under these circumstances every operator must have wished for a purgative that would act when injected subcutaneously, with the same certainty that apomorphin acts as an emetic when used in this way. But the pharmacologists have not yet supplied us with such an agent. The physiologic action of physostigmin, causing contraction of involuntary muscular fibers, especially contracting the intestines and causing increased secretion of various glands, would suggest its use for this purpose. And the fact that it is employed with so much success by the veterinarian in horse colic, where overdistension of the bowels is the alarming symptom, would lead us to hope for results from it. I have employed it in a few cases, but not in a sufficient number to arrive at any conclusions as to its usefulness or the proper dosage. One to two grains is the ordinary dose given a horse, so it would probably require 1/20 to 1/10 gr. for a human being, though text-books place it variously from 1/12 to 1/200 gr., some stating that the maximum dose is 1/60 gr. In experimenting with it I have been very cautious, and I believe I have not used a sufficiently large dose.

If the bowels have not moved within forty-eight hours after the commencement of the administration of purgatives, it is best to desist from all efforts to secure this result, and to devote one's energies to sustaining the patient. Oftentimes we will find that stimulants will accomplish what purgatives have failed to do. This would seem to indicate that the overdistension and paralysis of the bowels is caused by some toxic agent occurring in sepsis acting on the nervous centers in the spinal cord.

Keith and others recommended quinin by the rectum as a stimulant to the nervous system under these conditions, but in my experience full doses of strychnin hypodermically are much more efficient. The rectum should be reserved for nutrient enemata. Champagne may be tried by the mouth. If it is retained for even a very short time, enough is absorbed to produce some stimulation. When the evidences of peritonitis are unmistakable, the advisability of reopening the abdomen and flushing the peritoneal cavity with salt water is always to be considered. But usually when one can be sure that he has peritonitis to deal with, it is too late

for even this to save the patient's life, enough poison having already been absorbed to prove fatal. The immediate, though usually short-lived improvement, following its use, is, nevertheless, sufficient to justify one in resorting to it in all desperate cases. It should be done without an anesthetic, or if one is used the stomach should first be washed out. By neglecting this precaution I one time had a patient drowned in the fluid her stomach contained.

Unless the patient is unusually weak, and in need of it, all nourishment should be withheld until the bowels have moved. If any is given it should be as hot as can be swallowed. It is more stimulating, more readily absorbed, less apt to produce gaseous distension. It should be left to the patient as to whether it shall be milk and lime-water or some meat broth. Food that is distasteful is much more apt to be rejected by an irritable stomach. For a day or two after the first movement of the bowels only liquid food in small quantities can be allowed, but the quantity and variety may be rapidly increased, and at the end of the first week her diet may usually be quite generous.

The pain suffered by patients after celiotomy varies from slight discomfort to that which is excruciating and unbearable. It is most severe in those cases of salpingo-oophorectomy where, on account of interstitial salpingitis, the stumps ligated are thick and hard to strangulate. Hysterectomies and ovariectomies for large cysts are followed by much less pain. It was formerly the custom to relieve this pain with morphin, but when the necessity for early and free purgation was recognized it was seen that the use of this drug was contraindicated. Morphin not only constipates the bowels and checks elimination in every way, but also nearly always produces more or less nausea, rendering the administration of purgatives more difficult.

I formerly adopted the usual practice of ordering that all morphin be withheld, gave my patient the not very comforting assurance that after twenty-four hours her suffering would be much less, and made my visits as few and short as possible, that I might not yield to her entreaties for relief. When at the end of twenty-four hours I observed how haggard and worn those patients were who had suffered severely, I always felt sure that had I been able to relieve their pain without producing nausea and checking elimination, they would have been in far better condition to battle against sepsis. To meet this indication I adopted the use of codein phosphate and chloral hydrate by the rectum. At both hospitals at which I work it has been a standing order for three years that if the patient suffers she shall be given such an enema; 3 grains of the codein and 30 of the chloral is a full dose for a robust woman. It may be repeated every four or six hours, if necessary. A second dose is not infrequently given, but rarely a third. The rectum absorbs fluid so readily after celiotomy that relief is surprisingly prompt. Lauder Brunton has pointed out the fact that ovarian pain may cause constipation, which is relieved by small doses of opium, and it seems probable that relieving the pain by these drugs, which are not markedly constipating in their action, may facilitate rather than retard peristalsis. At any rate my experience proves that the constipating effect, if there be any, is so slight that it may be practically disregarded.

If it is especially desirable for any reason to prevent vomiting, the enema may be given before the patient entirely recovers from the anesthetic; otherwise I have thought it advisable to wait an hour or two to give the

stomach a chance to empty itself of the secretions which have been pouring into it during anesthesia.

Next to pain, the symptom that patients complain most of is thirst. If there be any fluid in the peritoneal cavity, to be absorbed, it is advised not to relieve it. It is a question whether the good to be obtained by this treatment is not counterbalanced by the general depression caused by lack of circulating fluid, and the consequent inactivity of the kidneys. I am satisfied that the withholding of fluids may be overdone. It seems rational to believe that the benefits derived from the postural drainage of Clark are more from the stimulating effect of the salt water used, than from the carrying of the infectious material to a new and healthy part of the peritoneal cavity for absorption, for Nature, in her efforts to fight infection, pursues exactly the opposite course, limiting it to as small an area as possible, by every means at her command. The best way to supply the system with the required fluid is by rectal injection of normal salt solution, a half pint being given every two to six hours. A half ounce of very hot water by the mouth may be allowed every hour after the first four. It has a tendency to settle the stomach, and it pleases the patient to get something. The nurse should frequently wipe out the mouth with a moist cloth, but the patient can not be trusted to rinse it out for herself.

In conclusion, any surgeon who does a capital operation owes it to his patient, his profession, and himself, to see that everything possible is done to secure recovery. For this reason, only when it is absolutely unavoidable, should an abdominal section be done in the country and the after-treatment left to a practitioner inexperienced in this work.

THE STUDY AND TEACHING OF OBSTETRICS.*

BY ELIZA H. ROOT, M.D.

Professor of Obstetrics, Northwestern University, Woman's Medical School; Senior Obstetrician to Wesley Hospital.
CHICAGO.

Child-bearing, though a physiologic function, is not without danger to both mother and child. Danger arises from two distinct sources. The first is external to the mother, and depends on her environment, in which her safety is menaced by infections that may occur during gestation, during labor, and during the period of lying-in. The second source of danger is internal in nature. It belongs within the woman herself, growing out of conditions that make the passage of the passenger unsafe or impossible. It finds expression in faulty physical development for which our modern methods of living are largely responsible; in faulty development of the parts concerned in parturition, and in accidents of mechanism.

The treatment of the first source of danger must be prophylactic and remedial, while that of the second must be mechanical, and includes a wide range of surgery. If a perfect prophylaxis is observed, remedial measures will fall into disuse, while a thorough knowledge of, and training in, methods for the second will contribute greatly to the safety of child-bearing. To make obstetrics a stepping-stone to some other branch of surgery is fatal to skillful obstetrics.

In the last ten or fifteen years obstetrics, in our country, has had a marked uplifting. Our best schools of medicine are giving the subject more attention than ever

*Presented to the Section on Obstetrics and Diseases of Women, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

before. Students are asking for more thorough work and increased facilities for practical training. In schools requiring a four years' course the subject may be profitably graded, to consist of a junior and a senior course in obstetrics. For the junior course only normal obstetrics should be taught. This insures a reasonable amount of time for drill in the fundamental principles of the subject, and lays the foundation for careful conscientious practice.

Before entering further on methods, a few words regarding qualifications essential in the teacher may not be out of place. First, the teacher must be thoroughly in love with his chosen subject and with the work of teaching. He must be a student himself, coming in close and sympathetic touch with his pupils; he must always be the interested, enthusiastic student-teacher, carrying his students with him as willing followers. In his practice of obstetrics, each case, though he may have seen hundreds of similar ones, must be studied with as undivided and careful attention as his cases in early practice. Each phase and feature, carefully observed, keeps freshly filled the store-house of experience from which he is to draw daily supplies for his pupils, and from which he must draw with a generous, unselfish mind and heart. Time is saved to teacher and student by the use of a good text-book. To instill life and interest into the recitations, the teacher amplifies the lesson out of his own experience and by demonstrations on material from the working museum.

In the first semester the student should become familiar with the obstetric pelvis, static and dynamic. Its axes and diameters, together with the diameters of the fetal head, and its conformations should be as familiar to him as the alphabet, for this knowledge forms the foundation on which he must build all future knowledge of obstetrics. The diameters of the pelvis, and its inclinations are best taught by comparisons made by means of the pelvimeter. The student should make the measurements, first on the dry pelvis, and then on the pelvis of the living subject. He learns to use the pelvimeter, of its advantages and its disadvantages, and obtains a comprehensive idea of differences in the pelvis compatible and also incompatible with safe and normal labor. He should systematically learn the steps taken in abdominal palpation, and should be firmly impressed with the importance of this means of reaching a diagnosis, making the vaginal route a secondary step, not in importance but in order. Before entering on the study of obstetrics, work in embryology prepares the student to readily distinguish the clinical features, diagnostic of the age of gestation at which the embryo and fetus was expelled or perished *in utero*, and he reaches this end by means of his text-book and demonstrations made on preserved and fresh specimens. The subject of diagnosis should enter into the course as early as possible, and be made a marked feature throughout the entire two years of instruction.

At the end of the first semester he is, or should be, ready to begin the work of the second, which includes the normal mechanism, the management and physiologic phenomena of normal labor, together with the management of the lying-in period, and the care of the newborn. He also learns the prophylactic treatment of dangers arising external to the patient, which includes, as a chief feature, the technic of surgical asepsis and antiseptics in its every detail. At this time, drill on the manikin prepares the student to take charge of normal cases, always under the personal supervision of an able and painstaking clinical demonstrator. At the bedside

he now learns to apply and verify what he has learned from his text-book, and his teacher in the classroom and the clinic.

The drill on the manikin with the normal fetus, or with the dummy, is of supreme importance to the student. He sees and understands for himself the wonder-inspiring process of accommodation of the fetal diameters to the pelvic dimensions. He begins to accept as demonstrable truth what before seemed only half truth, and he is willing to again and again repeat his assigned task, for he is beginning to love the work, and to desire its mastery.

After the student has thoroughly mastered the normal mechanism of first position vertex, he may begin to study departures from this first and normal standard: the second position in head with its anterior and posterior positions, to be followed by other varieties of head presentations in which delivery can be spontaneous. Breech presentations are then studied in detail. During these different exercises on the manikin he should be taught the judicious use of the hands in aiding spontaneous delivery; such as aiding flexion when extension prevents progress; watching and aiding rotation forward in the second posterior position; aiding the delivery of the shoulders, and the different manual methods of delivering the after-coming head. While manual interference properly belongs to abnormal obstetrics, it impresses the details of mechanism on the student mind, and teaches the use of his hands. The student must not be passed too rapidly over the exercises on the manikin, or he becomes confused, and fails to divine important steps one from another. Mastering each step as he advances, he becomes more and more interested in the work, and studies his subject for itself, and not for the forthcoming examination, which he should pass with credit at the end of the year.

The second or senior year should be devoted to pathologic obstetrics. In order to place the student on an independent footing, for which he has been prepared in the junior year, it seems best to drop the use of any particular text-book, and to assign his work by topics. Having his topic, he is free to consult any text-book or books available. He not only by this means gains a comprehensive idea of his subject, but he learns how to use his text-books. I have found it a profitable exercise to assign a particular topic for the whole class, both in the junior and senior courses, for investigation, requiring each student to write an essay on the subject assigned, giving the literature consulted. It is surprising the amount of research an enthusiastic, intelligent student will accomplish by adopting this method.

The surgery of the puerperium, the pathology of pregnancy and of the puerperium must receive due attention. While operative obstetrics is made a prominent feature of this year's work, especial attention should be given to the obstetric forceps. No student should be allowed to leave his school without a safe knowledge of this instrument, which he will gain only by the study of it as a mechanical appliance, and by thorough drill in its use on the manikin. The teacher should carefully guard the student against forming bad and careless habits in the execution of a forceps operation. How and when to make traction should be strongly emphasized and proper movements insisted on. Whenever an error is committed, the student should be required to correct it then and there, and be made to see his error, and to understand its correction. Beginning with the low operation he learns coolness, deliberation and the methods of making proper traction. From the low, he is advanced to the

medium, then to the high operation, learning in each case the meaning of "axis traction." It is unfortunate for the student's comprehension that the "axis traction" is so universally used to mean high operations or inlet operations. All traction made by forceps must be axis traction, whether their application be made at the pelvic brim, the pelvic cavity or at the pelvic outlet. Hasty, jerky and impulsive movements made by the student when using the forceps should bring from his teacher words of correction. A lack of knowledge of, and experience in, the important matter of applying the forceps, characterizes the work of the young, and sometimes the older practitioner as clumsy and dangerous.

Practical work in obstetrics should be required of each student before graduation, and to enable him to apply what he has learned from his text-book and his teacher he should be required to keep a systematic record of each case attended. In this way he can learn what can not be taught so well in the classroom; the characteristics of true and effective labor pains and of anomalous and inefficient pains; the indications for the application of forceps and the contraindications for their application. The record sheet should make a part of the year's course, and of the final examination, as an evidence of his fitness to practice obstetrics. The requirement of record keeping impresses the student with the importance of supervising each case that may come to him for care. It helps him to form systematic habits of thinking and of making observations that must contribute to a successful practice, and to the science of obstetrics. In the pathologic laboratory, room should be made for the study of disease and unhealthy conditions so frequently met with in pregnant and lying-in woman. In order to make his work useful and with a given purpose, clinical reports of cases, including pathologic studies made in the laboratory, may be required of the student.

Thus equipped at graduation, he is in a condition to make a post-graduate course in some good maternity, of value to him for further preparation for the practice of obstetrics.

EARLY OVARIOTOMY: ITS PRACTICAL NECESSITY.*

BY MARCUS ROSENWASSER, M.D.
CLEVELAND, OHIO.

The time has long gone by when the growth of ovarian tumors was watched until they attained enormous proportions and were finally tapped to prolong the life of the doomed victim. Such tumors are almost extinct. We very rarely see them. The time has also passed, when ovariotomy was delayed until every other means, including repeated tapplings, had exhausted the patient's strength and the operation was then performed as a last resort. The comparative safety of the operation, the inevitable growth of the tumor if left alone, and the possible later complications are facts so well known to physician and layman, that consent is readily obtained for early removal.

As is but too frequently the case with uterine carcinoma and with unruptured tubal pregnancy, the early stage of ovarian cystoma may likewise pass without subjective symptoms; the physician is not consulted until the patient herself notices some enlargement, or until it is discovered by accident. The rapidity of growth of such tumors can only be estimated. We are obliged to date them from the time of observation. At this time, un-

less malignant, they are considered harmless; the advice is accordingly given to put off their removal until they interfere with health and comfort. The family physician who gives such counsel hardly realizes what mischief his advice may ultimately cause. This lack of up-to-date information is not surprising when we recall the proportionately small number of cases that pass through the hands of any one individual. My motive in writing this paper is to bring more prominently before the profession the many accidents and complications that happen with small, as well as with recent growths of this kind. Note that neither the size, nor the age of a tumor is a criterion of the possible immediate or remote dangers from its presence.

A few typical cases have been selected to exemplify the various complications that may arise even in the early stage of ovarian cystoma, or that may result from delay. A number of these cases have heretofore been published in detail, and many others have from time to time been reported and the specimens exhibited to the local society. Only a brief synopsis will therefore be presented at this time to emphasize the special points to which attention is called.

It would prolong this paper beyond its scope to dwell on the subject of malignant cystoma, because if recognized early, we are all agreed that they should be removed at once.

Papillomatous tumors are classified as semi-malignant. Whether malignant or benign, removal before rupture, or before penetration of the cyst wall is likely to be curative. On the other hand, recurrence is the rule when the contents have escaped and have become disseminated. Both visceral and parietal peritoneum become secondarily infected and patients survive but a limited period. Absorption of the papillary excrescences and consequent complete recovery are the exceptions. A differential diagnosis between benign cysts and unruptured papillomatous cysts can not be made. The latter are liable to burst at any time and thus to contaminate the abdominal cavity. The only safe course lies in the removal of the tumor.

CASE 1.—Referred by Dr. A. F. Meyer. Mrs. S., aged 28, mother of three children, first noticed enlargement two weeks after birth of the last child, nine months ago, when she was larger than at term. She has been tapped three times since, is anemic and much emaciated. The diagnosis was ovarian cystoma, probably malignant. At the operation, Dec. 12, 1890, the broad ligament and peritoneum were fused by inflammatory adhesions. Papillary outcrop had penetrated the cyst wall and proliferated freely on the surface of the peritoneum; tumor removed; warty tufts not removable. Recovery followed with gain of twenty-five pounds in weight, but death from recurrence two years later.

CASE 2.—Referred by Dr. J. R. Smith. Mrs. S., aged 31, mother of two children, noticed a rapid increase in size of the abdomen the past four months, and was tapped three weeks ago. She is anemic and emaciated. The abdomen was filled with free fluid, in which a large nodular tumor was felt floating. The diagnosis was papillomatous cystoma. Operation, June 30, 1891, revealed a large quantity of ascitic fluid; multilocular tumor with extensive omental and sigmoid adhesions; peritoneum and pelvic floor studded with papillomatous growths. The tumors were removed; growths remained. Recovery followed, but death from recurrence ten months after operation.

CASE 3.—Referred by Dr. M. Abl. Mrs. C., aged 31,

* Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

¹ Cleveland Med. Gaz., September, 1890.

mother of one child 12 years old, has been sick with pain in the left inguinal region during the past three months. A tumor was found by the attendant three weeks ago. One week ago she was taken with severe pain in the lower abdomen; in bed since; temperature ranging from 100 to 101 degrees; "flowing" past two weeks; mass in left pelvis, size of orange; rectovaginal pouch bulged downward; cervix compressed against symphysis. A diagnosis of suspected ruptured tubal pregnancy was made and operation, Aug. 26, 1895, showed general intestinal adhesions; peritoneum deeply injected; large quantity of serum in the pelvis. In the midst of the adherent intestinal coils was an irregular, nodular, resilient tumor from the upper part of which cropped out papillary growths which spread over the surface of the intestines. Evidently the cyst had recently ruptured and caused the acute peritonitis. The cyst was removed; weight eight ounces. Recovery followed and the patient is still living, but with recurrence; abdomen enlarged, filled with nodular masses.

CASE 4.—Referred by Dr. A. F. Spurney, Mrs. T., aged 32, mother of three children, has had gradual growth of the abdomen the past year, with rapid increase the past three months. It is now the size of pregnancy at term. A diagnosis of ovarian cystoma was made. Operation was done Oct. 5, 1897, and the tumor found fixed above by dense, spiderweb adhesions, below was an immovable intraligamentous, papillomatous cyst; both appendages diseased; cyst dips deep down into base of the broad ligament, where there are papillomatous patches; impossible to form pedicle. Removal of both tumors and uterus by suprapubic hysterectomy was followed by recovery, but recurrence within six months, the patient still living.

CASE 5.—Referred by Dr. N. S. Everhard, Wadsworth, Ohio. Mrs. W., aged 52, passing through menopause, has had three children. She first noticed a movable bunch in the left side fifteen months ago, with rapid increase the past two or three months. Temperature ranges from 99.5 to 100 degrees; abdomen tender. The diagnosis was ovarian cystoma, and at operation, Oct. 23, 1897, the peritoneum and tumor walls were deeply injected; free, dirty fluid in the abdomen; numerous, recent intestinal adhesions; their separation causing copious oozing, the control of which required clamping of both ovarians. The contents of the tumor was the same as the fluid in the cavity; cyst papillomatous. One clamp was left on the broad ligament to ensure safety from hemorrhage. Recovery followed with recurrence within nine months. She is still living, but failing.

In the following two cases the cysts were intact when operation took place; there has been no recurrence to the present time.

CASE 6.—Referred by Dr. A. Steiner. Mrs. M., aged 57 years, was never pregnant. Her menopause was seventeen years ago. She first noticed enlargement six months ago; no pain, only discomfort. She was tapped three months ago for ascites, a second tapping three weeks ago, when a movable solid tumor, the size of a fetal head, was discovered in the right side above the pelvic brim. She was much emaciated. The diagnosis was malignant ovarian tumor. At the operation, Dec. 13, 1894, ascitic fluid was evacuated. The tumor consisted of papillary growth so soft in texture that it broke in a number of places, allowing the contents to ooze back into the pelvis. Below the pedicle in the broad ligament were five or six indurated nodules which were not re-

moved. The patient has remained well the past four years, doing her own work.

CASE 7.—Mrs. H., aged 34, has had two abortions. She was curetted Oct. 20, 1896, for metrorrhagia; right ovary prolapsed, hard, not tender, size of walnut. Hemorrhage recurred in January, 1897, and after unsuccessful medical treatment she returned to be again curetted April 6, 1897; right ovary slightly increased in size. Early in July metrorrhagia recurred with rapid growth of the right ovary. By the middle of July the tumor reached midway between the pubes and umbilicus; distinct fluctuation. Diagnosis of ovarian cystoma was made, and operation, July 19, 1897, showed some free fluid in the abdomen; cyst the size of a child's head; contents bloody, flesh water-like fluid and papillomatous growth; thin two-inch pedicle. One year after the operation she had her first living child, now five months old.

These cases suffice to demonstrate the lesson I wish to draw. The tumors begin slowly, but after a time take on rapid growth and are liable to rupture, or the papillomata penetrate the cyst wall, and in either event the cyst contents infect the peritoneum. Not only does this lead to the formation of inflammatory adhesion, but it lays the foundation for an early recurrence. It is often impossible to differentiate between the character of cysts before operation. It is equally impossible to estimate the resisting power of the cyst wall. A cyst no larger than the fist is just as liable to burst as is one that fills the abdomen.

Even cysts that are not papillomatous may rupture before attaining a very large size, and lead to peritonitis unless the fluid contained within is sterile serum. In the latter event, whether the cyst ruptured or be tapped, patients may exceptionally recover and be cured without operation.

CASE 8.—I have no notes on this case. The facts in brief are these: I was asked by my friend, Dr. Cotton, to see Mrs. B., an elderly woman, who was known to have an abdominal tumor reaching a little above the umbilicus. At the time of the consultation she had been suffering from peritonitis for about a week. She was feverish, had marked abdominal tenderness; there was free fluid in the abdomen; the tumor itself could not be distinctly outlined. I advised awaiting the subsidence of the inflammation, and subsequent removal of the cyst. I did not see the patient again, but was informed by the Doctor that with the abatement of the acute symptoms the enlargement diminished until the tumor entirely disappeared.

CASE 9.—Mrs. V., aged 20, mother of one child, five months old, after confinement noticed she was much larger than other women under similar circumstances. She continued to grow until she was nearly as large as at term. The tumor was movable and gave distinct fluctuation. On Aug. 17, 1875, I tapped the tumor midway between the pubes and umbilicus, and removed about one gallon of thin, reddish fluid. The abdomen never refilled. The patient had a number of children afterward, and remained in good health. I would not dare treat a like tumor in like manner today.

CASE 10.—Referred by Dr. J. Goldfinger. Miss K., aged 20, after suffering "cramps" in the lower abdomen for two days, called at the doctor's office for relief, but refused examination. She was ordered to go to bed, but knew better, and was up and down for two weeks, when she finally allowed herself to be persuaded to enter the hospital. During the prevalence of peritonitis, together with a tender mass in the right iliac fossa, she was treated for appendicitis. After subsidence of the acute

symptoms, the diagnosis of ruptured ovarian cyst was made. The cyst reached to the umbilicus. Operation, Sept. 29, 1898, revealed right ovarian cyst; more or less recent adhesions in the right iliac fossa, fused with an ugly exudate on the cyst wall resembling a phagedenic ulcer of the size of a silver dollar. This proved to be the remnant of a small secondary cyst which had ruptured and was the original cause of the peritonitis; cyst contents, three pints of clear, viscid fluid. Recovery followed. Had the patient been aware of the existence of a growth, its removal before rupture would have been a very simple thing.

Even without rupture or trauma, cysts may become adherent or infected by intercurrent disease, especially of the tubes or of the appendix.

CASE 11.—Referred by Dr. E. M. Davidson. Mrs. A., aged 25, was never pregnant; six months ago Dr. D. found a tumor in the pelvis. The tumor caused no trouble until recently. The diagnosis was parovarian cyst. Operation, March 16, 1893, revealed right unilocular cyst with clear fluid contents; a knuckle of intestine so firmly adherent that the gut was opened while liberating the adhesion; immediate closure of intestinal laceration; left pus-tube burst during enucleation; intestinal adhesions to tube. Despite difficulties and complications, the patient made good recovery.

CASE 12.—Referred by Dr. T. A. Weed. Mrs. W., aged 20, mother of one child, had symptoms resembling tubal pregnancy. Under anesthesia, before curetting, a mass the size of an orange was found in the right pelvis; no improvement after curetting. Laparotomy one week later, July 13, 1894, proved the mass to be a small ovarian cyst attached to the right pus tube; omental adhesions; left tube also contains pus. Recovery followed.

Cysts that have formed adhesions to contiguous viscera not only offer greater difficulties in their removal, but are more readily infected—on account of the diminished resistance of the partition wall to the passage of disease germs. This may lead to infection of the cyst contents, and suppuration. The removal of suppurating cysts is likely to be a difficult procedure, very often followed by serious complications, or resulting in death.

CASE 13.—Referred by Dr. F. S. Pomeroy of Chardon, Ohio. Miss E., aged 23, had been sick about four months, in bed six weeks, having chills and fever, with temperature varying from 100 to 103 degrees. Three weeks ago Dr. P. outlined a fluctuating tumor on the left, reaching to the umbilicus and dipping down into the pelvis. When seen, Aug. 31, 1894, she was a very sick woman: Pulse rapid and weak; temperature 102 degrees; no distinct tumor wall, but fluctuation could be felt over the entire abdomen. Diagnosis of sepsis from suppurating cyst, or ruptured cyst, was made. Operation September 1, revealed the cyst wall acutely inflamed; contents offensive and grumous; intestinal adhesions; patient in shock. She died fifteen hours after operation, from post-operative hemorrhage.

CASE 14.—Miss J., aged 20, five years ago had abdominal enlargement, with much pain. The enlargement gradually disappeared. After this she always had pain in the left hypogastrium, on exertion, or sudden jar. July 11, 1895, she was taken with severe pain in the left side, with pulse 116, and temperature 103 degrees. Rectal examination showed a globular, resilient tumor filling the left pelvis. Peritonitis lasted two weeks; August 3, sudden pain and collapse; reaction with chills, fever and sweats. A diagnosis of probable suppurating cyst was made. Explorative operation, August 17, re-

vealed universal adhesion of the omentum and intestines. Careful separation opened into the pus cavity. Continuation of exploration was not warranted; drain. Discharge of pus continued for three weeks, temperature ranging from 99 to 103 degrees; streptococci in pus. Operation was made for removal of tumor, September 6, the incision from the fistula; small intestine injured during separation of interminable adhesions. On enucleation the tumor proved to be an ovarian cyst the size of a small cocoon, leaking pus. She recovered from the second operation, but succumbed in a later attempt to close the fistula resulting from lacerated intestine.

In several of the above cases the tumors were undoubtedly present during pregnancy, though not discovered until after delivery. The danger of this complication is so well appreciated that removal of the tumor during pregnancy at any period is the established rule. Tapping may temporarily accomplish the same result, though it is very unsafe practice.

CASE 15.²—Referred by Dr. A. Peskind. Mrs. K., aged 21, had one child. When she was four months pregnant, Dr. P. found a tumor occupying the right side of the pelvis. Later she had spells of localized peritonitis. At eight months her attendant tapped to relieve distension, evacuating a gallon of turbid fluid. Two days later premature labor occurred, the child living but a few hours. The tumor refilled. Diagnosis of intraligamentary cyst was made and operation Jan. 5, 1890, six weeks after labor, showed monocyst of right broad ligament, containing puriform fluid. Recovery followed.

CASE 16.—Mrs. C., aged 28, pregnant two months, had felt a small hard movable body above the pubes seven months before, and has felt it occasionally since. Six days ago she was taken suddenly with violent vomiting, which still continues. A hard, irregular, nodular, movable tumor present in the anterior portion of the left pelvis; enlarged uterus to the right. Diagnosis: torsion of pedicle of solid ovarian tumor, with probable pregnancy. Operation, Jan. 12, 1898; fibroid tumor, size of large apple twisted two and one-half times about its thin, flat pedicle, growing from broad ligament just above the enlarged cystic ovary. The tumor removed, recovery followed and pregnancy continued to term, the mother and child doing well.

Torsion of the pedicle may convert an innocent growth into one of very serious import, even though pregnancy does not exist.

CASE 17.³—Referred by Dr. N. Weidental. Mrs. S., aged 39, mother of four children, was known to have a smooth, pear-shaped, freely movable tumor in the hypogastrium, reaching to the umbilicus. Three months ago she was seized with a sharp, lancing as well as labor-like pain from the left lumbar region to the groin. This pain has never ceased; it has returned at intervals of three to eight days. On September 26 she was seen in consultation and had been in bed for two days; pains more constant and severe; tumor outlined and movable. On September 28 she went into collapse; intense pain, vomiting, abdomen distended, tender; tumor indistinct; bowels obstructed. Diagnosis: Peritonitis due to ruptured cyst, or a twisted pedicle. At operation, Sept. 29, 1892, an intensely congested, black tumor presented. It was twisted three times about its short, thin pedicle; hematoma of tube and cyst wall. Circulation had been completely cut off; peritoneum deeply injected, but as yet no serum or lymph formed; tumor removed. Recovery followed.

² Ibid. ³ Ibid. November, 1892.

Dermoid cysts are especially prone to infection, owing to the heterogeneous character of their contents. The adhesions formed between these cysts and the hollow viscera, as the bladder or intestines, may not only cause suppurative of the cyst, but a perforation of the adhesion may lead to chronic septicemia. An interchange of contents takes place; feces, urine and products of decomposition enter the cyst, and bones, teeth, hair and other tissues belonging to the dermoid, pass into the viscera by process of ulceration, frequently leading to exhaustion and death. The dermoids I have met have fortunately been removed before infection, hence have caused no trouble.

It seems to me unwise to further multiply instances lest my time and your patience be exhausted. Sufficient facts have been cited from my own limited experience to call attention to the frequent accidents, misfortunes and complications occurring during the development of ovarian growths. The experience of others, much larger and more varied, only serves to corroborate the conclusions to be drawn.

1. Uncomplicated ovariectomy, in proper hands, is a simple operation with scarcely any risk.

2. Malignancy, trauma, torsion of pedicle, infection, suppuration, adhesions to viscera, and pregnancy materially increase the difficulties and risks of the operation.

3. To avoid complications liable to occur at any time, the removal of ovarian growth should follow the diagnosis without unnecessary delay.

Let the terse axiom, formulated by Dr. Howard Kelly, henceforth be the recognized rule of procedure: "*From a practical standpoint all ovarian tumors must be considered as malignant until removed and proved otherwise.*"

THE NEUROTIC'S DIET.*

BY HENRY C. EYMAN, M.D.
CLEVELAND, OHIO.

Before entering the special domain of the neurotic and discussing his proper diet, it will be necessary to devote a few minutes to the general subject of diet and the value of foods. The value of foods may be considered as three-fold: 1, the production of energy; 2, the repair of tissue; 3, the increase of adipose tissue to serve as a protection and covering in the body.

There are at least thirteen chemical elements which enter into the composition of the body, but only four which are found so abundantly as to indicate that they are indispensable to life, viz., carbon, oxygen, nitrogen and hydrogen. Now, foods which contain these elements are necessary for the three-fold use above mentioned. We are taught that nutrition of the body involves several distinct processes:

1, the secretion of digestive fluids and their action upon food in the alimentary canal; 2, the absorption of the ingredients of the food, when digested, into the blood and lymphatic vessels; 3, the assimilation of the absorbed nutritious products by the tissues; 4, the elimination of waste material.

There may be an abundance of nutritious food, and yet with any of these processes in deranged working order, malnutrition will at best be all that can be accomplished.

Baron von Leibig was the first to suggest a scientific division of foods. He grouped all foods into two classes—nitrogenous and non-nitrogenous. The former he

claimed to be "tissue-builders" and the latter "force-producers." Under the former he classed fish, flesh, fowl, milk and eggs; under the latter, vegetables, fruits, cereals, starches, sugars, gums, fats and oils. This division had many vulnerable points, but it served its purpose and is still used in speaking of foods in a general way.

Some vegetables contain nitrogen, and animal food is not strictly nitrogenous, as it contains fat and glycogen, therefore it is not practical to confine ourselves to either an absolutely nitrogenous diet or to a non-nitrogenous one, but for general purposes this classification answers very well. There are other divisions and classifications, notably that of Prout, who groups foods as aqueous, saccharine, oleaginous and albuminous. But much can be found to criticize in this division, because it fails to provide for salines, starches and gelatinous substances. Thompson, in his work on practical dietetics, classifies foods as follows: 1, water; 2, salts; 3, proteins—chiefly albumin and allied gelatin; 4, starches; 5, sugars; 6, fats and oils. And, indeed, to be exact one should not stop here, because we have oxygen, hydrogen and other elements which can be used as foods entirely independent of either of the groups above mentioned.

It will sufficiently answer the purpose of this paper to accept the most simple classification, as we desire to discuss foods from the standpoint of value. First, then, are the energy-producers. Here is a call for foods which will store up energy in a latent form and subsequently allow liberation in the form of heat and motion. "Force is the manifestation of energy," therefore that which stores up energy must be subsequently manifested as force. The foods which produce this in the greatest degree are sugar and starch. There are numerous tables given, showing the comparative values of the different articles of food, and the relative amount of the nitrogenous and non-nitrogenous matters. These can be found in almost any text-book. Sugars may be defined as crystallizable carbohydrates in which oxygen and hydrogen exist in proportions to form water. There are many varieties of which those commonly contained in food or used as an adjunct to diet are cane sugar, saccharose, grape sugar or glucose and sugar of milk or lactose. Then we have beet sugar, maple sugar and sugar from other vegetable growths. In addition to these all starches must be converted into sugar before they can be assimilated.

By some it is claimed that sugars are merely force-producers, and by others that they are fattening as well. It is probable that their action in the production of adipose is merely because they spare the consumption of albumin and fat, as stated by Bauer, which are then converted into tissue fat. It is, therefore, pretty well established that the production of energy depends entirely upon the sugars and the starches, yet if the repair of the tissues be not looked after, this energy would soon consume the body. It is not our purpose to go into a study of the various kinds of energy-producers, nor whence they are obtained, as that would be manifestly impossible in a short paper. The second of these three-fold values—the repair of the tissues—will be found in the nitrogenous foods, chief among which are the various kinds of meats, milk and eggs. Meats have been used as foods for neuropathic individuals for many hundreds of years, and are still regarded as the *sine qua non* in certain forms of nervous diseases, and in persons suffering from neurasthenia. It is obvious, if a patient is exhausted and his tissues improperly functioning from

*Presented to the Section on Physiology and Dietetics, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

a lack of proper nourishment, that the tissue-repairers are indicated. In these cases a meat diet often works wonders. And I wish to emphasize the fact that this exhaustion and subnormal vitality is not always accompanied by any great reduction in adipose tissue. In fact, the patients often look to be in good bodily health, but as a matter of fact the muscles are atonic and the whole system is incapable of prolonged resistance. On the other hand there are cases of mental alienation in which the meat diet aggravates the psychosis.

Clouston claims that a large proportion of cases of adolescent insanity are found to have been flesh-eaters. They have a craving for such foods, and have eaten but little else. He says it is such boys who form the habit of masturbation, which when acquired, produces such a fascination and a craving that it may ruin the bodily and mental powers. Such patients should be given a diet of milk, fish and farinaceous foods. The greatest reliance is to be placed in milk. Alcohol should be prohibited in such cases. All patients who can assimilate it should have cod-liver oil. Hypophosphites and pepsin are excellent remedies, and in connection with the oil, serve as foods. Many patients take on fat rapidly under this treatment, and oftentimes lose in weight promptly should the diet be discontinued. A patient suffering from adolescent insanity should gain in weight if steady improvement is desired. Dr. Rutter, superintendent of the Hospital for Epileptics at Gallipolis, says that he can throw half his patients into fits in twenty-four hours by improperly administering a meat diet.

In speaking of the diet for young persons suffering from mania, Dr. Clouston says: "It should consist largely of milk and farinaceous diet for the young." "I lately saw a very excitable boy of 6 years, very thin, restless, not sleeping much, and of course very bright and quick for his age. I found he was getting animal food three times a day, and his guardians deplored the fact that he could not take milk. My advice was to starve him into taking it, to make him walk much, and keep him out, and give him when he came in, only bread and milk. Of course, it was disagreeable at first, but the boy soon acquired an appetite for such food, his bodily conformation largely changed, and he got fatter, less active, less nervous and slept far more." Children with this disposition are nearly always flesh-eaters, and I have sometimes found them fed on beefsteaks and port wine with strong beef-tea between meals.

There are some forms of neuroses in which an almost exclusive meat diet is absolutely essential. When the skin is dry and parched, and the nerves are desiccated, burned out, producing an irritability and motor restlessness not found in any other condition, then we should regard the meat diet and hot water as peculiarly indicated. I say hot water because cold water would surely derange the digestion and the system is so evidently in need of fluids. Therefore it is as necessary for the physician to diet his patients as individuals and not classes as it is to individualize in the administration of any drug.

Probably the most important manifestation of mental trouble is melancholia, because, as has been aptly said, "melancholia is the sanest kind of insanity," and because it is the most frequent manifestation and the one with which the general practitioner most often comes in contact; therefore we will consider the proper diet for melancholic patients. All those who have had the opportunity of observing the melancholic are cognizant of the fact that the patient is suffering from dyspepsia. He

refuses food; the breath is foul, the tongue is coated, and the bowels are constipated. It is probable, however, that all these symptoms of dyspepsia are the result and not the cause of the depressed nervous condition. Because of the disease of the nerve-centers, the tongue is coated with old dead epithelium, which for the same reason, is not thrown off; this causes the fetid breath and the dislike for food, and consequent starved condition of mind and body; and because of the general lowered tone the bowels become constipated. We should not attempt to relieve these conditions by treating symptoms only, but should direct our energies toward the relief of the general neurosis. We might be able to relieve the dyspepsia temporarily by the administration of drugs, but the relief would not be lasting; the condition which contributed to the primary dyspepsia would undoubtedly be a potent factor in its recurrence, therefore we must reach the seat of the disorder. A proper diet is our most powerful agent, and for these cases the following should be prescribed: Before getting out of bed a cup of hot water with a dash of brandy; breakfast, meat and eggs; lunch at eleven and two, consisting of beef-tea or cocoa, crackers, milk and fowl dinner at six, consisting of broiled fish, roast beef, green peas, asparagus and toast; at bed hour a light repast with a small quantity of malt liquor. I have known many patients to improve rapidly upon this, or a similar diet, and their dyspeptic symptoms disappeared with the improvement in the general tone. Your melancholy patient is always illy nourished, and nothing so retards improvement as lack of proper diet. How dependent these melancholic patients are upon food has often been proved. Some who have convalesced steadily and who are apparently almost recovered if they for some reason miss a meal, or even have it considerably postponed, have felt at once a return of the depression and delusions, which vanished again after the reception of foods.

Those connected with our large hospitals for the insane will bear witness that nearly all suicides occur about twilight in the morning.

As nearly all melancholics suffer from brain anemia the natural conclusion would be that the brain would be clearer at this hour than any other, and consequently there would be less inclination to suicide, therefore there must be some other reason for this almost universal exacerbation of depression. Because of the general malnutrition we have thought this great depression might be due to lack of food, and if a light lunch be served after midnight to these sleepless melancholics the period of exacerbation might be bridged. Acting upon this thought it has been our custom to administer milk or eggnog to the restless after midnight, and so far with gratifying results. The patient becomes quiet, restful and nearly always falls into a refreshing slumber, awakening in the morning in a more nearly normal state of mind. We have not given the thought sufficient experimentation however, to advocate it unreservedly, though we do believe there is a field of useful research in this direction. When a patient habitually awakens after three or four hours and can not go to sleep again, we always try a glass of milk and a few crackers, and nearly always secure for the patient from two to four hours of undisturbed rest. Clouston says: "If I were as sure of everything else in therapeutics as this, that fresh air and fattening diet are good for melancholic people, I should have saved myself many medical questionings."

Melancholic patients can not have too much fresh air, though they may have too much exercise. Pure oxygen

is as necessary to them as pure food, though the mistake should not be made of exhausting your patient by too much walking or other exercise. Should the weather be fine, the patient should be in the open air nearly all the time. Nothing else is so conducive to sleep as fresh air, or equals it as a hunger producer. Every possible care of the patient may count for naught if pure air can not be supplied. It is not considered possible to fatten a patient too soon or too rapidly, though great care will have to be taken not to overload the stomach and thus produce gastric and intestinal troubles.

Fatty foods, milk, ham and cod-liver oil, maltine, eggs, farinaeous foods, easily digested animal food, such as beefsteak fish and fowl, can all be used to advantage in feeding melancholics. I suppose milk is more universally recommended than any other one article of diet, and by some authors regarded as a sheet anchor. Clouston speaks of having given as high as sixteen tumbler a day with surprising benefit. We should, however, constantly keep in view the fact that neurotic people are usually lean people, and that fat and nervousness are antagonists, particularly when the nervousness is manifested by melancholia. Therefore, whenever one has succeeded in increasing the adipose in a patient an amelioration of the melancholic symptoms can almost always be expected. "Laugh and grow fat" is an old saw, but from a medical standpoint it might be better said by "grow fat and laugh." Mrs. Carlyle, after an attack of "nervousness," wrote: "Oh! thank God for the precious layer of impassivity which that stone weight of flesh has put on my nerves."

As I have previously said, there are times when stimulants are useful. Ale and porter work wonders on lean, anorexic melancholics, by their fattening and appetizing qualities. A favorite prescription is a half glass of Burgundy and the whites of two eggs every three hours. The stronger stimulants are seldom used, except in cases of extreme exhaustion. The writer has had excellent results, however, with whisky and hot water, in cases of insomnia, though some authors claim to have equally as good results from the hot water alone taken at bedtime. As soon as the patient has notably gained in body weight all stimulants should be discontinued.

To take up seriatim the different forms of insanity is manifestly impossible in our time limit. We must therefore content ourselves with a few general statements. Some medical men of acknowledged ability advocate a purely vegetarian diet, and others of equal ability advocate a meat diet, to the exclusion of all vegetables and fruits. It is probable that there is a golden mean to be found along the lines indicated in this paper. Take the two extreme schools and add them together and you get a plentiful dietary; subtract the one from the other, they reduce themselves to a simple and unsatisfied emptiness. Exclusive systems of diet result from the application of observation on disease to the regulation of the body in health. It is only necessary to change the disease to get an entirely new set of requirements. There is no doubt of the efficacy of raw meat, dry bread and hot water, exclusively in the very common acid dyspeptic states, while plethoric individuals with irritated kidneys and the neuralgic twinges of the uric acid condition, will just as surely obtain relief by the use of farinaeous food and nuts.

In addition to the above-mentioned schools, we have the Ralston club, whose advocates claim to have solved the mystery of arteriosclerosis. Their logic is simple. The arteries calcify; the lime salts cause calcification. All food except fruits, and all natural waters, contain

lime salts, *ergo*, eat nothing but fruit, drink nothing but distilled water and avoid this most common disorder of the aged. Students in natural history tell us that monkeys eat nothing but fruit and live to a great age. Their intellect, however, is not remarkable. On the other hand the raven eats nothing but carrion and lives to a greater age than the monkey, therefore we are forced to the conclusion that the study of our remote ancestors or their contemporaries will not aid us materially in solving this vital question which resolves itself into one of temperance and moderation. Burton says: "Food improperly taken not only produces original disease, but affords those that are already engendered both matter and sustenance; so that, let the father of disease be what it may, intemperance is certainly its mother." And now in conclusion let me say to you in the words of Quarles: "If thou wouldst preserve a sound body use fasting and walking; if a healthful soul, fasting and praying, walking exercises the body, praying exercises the soul, fasting cleanses both."

INHIBITORY ACTION OF THE CEREBRUM.*

BY J. F. PEAVY, M.D.

ASHVILLE, N. C.

Irritability and contractility are primary properties of protoplasm. In their earliest forms they express the simple play of elementary chemical and physical forces. In undifferentiated protoplasm, they exist as general diffused properties of reacting to incident forces indifferently in all directions. The progressive differentiation of form and function expressive of organic progress implies the development of specific irritability or susceptibility to specific excitants, along with the capacity to react in definite ways to these excitants. It implies further the development of a nervous mechanism by which this special irritability is manifested, and through which the reactionary impulses are transmitted to be developed into organic activities. The special senses are special developments of this irritability, and the varied motor activities of animals are derivatives of this primary contractility manifested by protoplasm.

All organic reactions involve a reflex element or factor in that they are in a sense responses to stimuli received through sensation. A strong tendency is manifested by the modern physiologic psychology to treat all nervous action as reflex, even to our highest acts of cerebration. This view I cannot accept unless we regard the reactions when they occur as due to a summation of sensory stimulations. In an act properly reflex the sensory incitement should be the equivalent of the reactionary discharge. As manifestations of energy there is, in fact, no correlation between the two processes, even in acts that are usually considered typically reflex. What the sensory stimulation really does is to discharge an accumulated tension. The properties or qualities of an organism may be defined as its store of accumulated potentials, built up by the operation of experience upon inherited capacities, and existing with reference to ends in the environment. Sensation discloses relations between organism and environment. When reactions follow sensory excitement the real impulse arises within the nerve-centers of the organism, the sensation serving to unlock a stored potential. Reactions occurring without conscious cerebration intervening between sensation and act may properly be described as automatic rather than reflex. Even here, as well as in the

*Presented to the Section on Physiology and Dietetics, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

case of voluntary action, measured in dynamic terms, the motor efflux may vastly exceed the sensory influx, the merest suggestion serving sometimes to put the nerve-centers in energetic action.

Sensory stimulations may not, however, be immediately discharged in motor impulses, but may be themselves stored as part of the accumulated tensions. Herein lies a power the antagonist of reflex action. It is this capacity to stay action, to dominate reflex impulses, inseparably associated with organic progress and especially with the higher phases of human action and development, that I wish to emphasize in this paper.

In every action there is a primary impulsion taking its rise in some way from the needs, desires, inclinations or aspirations of the organism. This primary initiative contributes in part only to the shaping of our voluntary acts. In the sphere of automatic activity, it is entirely the determining factor. Inhibition has doubtless played an important part in shaping even our automatic activities, directing action and development along definite lines. Doubtless there are automatic inhibitions operating subconsciously as part of our self-acting physiologic mechanism. The action of arrest exerted by the pneumogastric on the heart is a familiar illustration of automatic inhibition. The action of the vasodilator nerves and the physiologic dilation of the sphincters are other examples of this mode of action. Doubtless the normal rhythm of glandular actions is dependent largely upon inhibitory nerve influences. Abolition of secretory action, arrest of peristalsis, and cardiac and vasomotor disturbances frequently illustrate pathologic inhibition.

Inhibition as a cerebral function, as a factor in voluntary conduct, is of more especial interest to us in this paper. Even the organic inhibitions which we have instanced, at least those which are physiologic, if not cerebral functions, are closely related to cerebral states. The vasomotor disturbances, flushing and paling of the face, as well as the disturbances of cardiac rate and rhythm produced by strong mental excitement or emotion are due to disturbances of the normal influence of the cerebrum over cardiac and vasomotor control. The normal dilatation of the sphincters of the bladder and rectum which precede the evacuation of those organs are inhibitory acts which lie just within the limits of voluntary control, and involve, of course, the participation of the cerebrum. Like all actions which lie near the boundaries between voluntary and automatic action, they are easily lost control of, and sometimes take place automatically under strong cerebral excitement. In infancy, where all action is, in the main, reflex or automatic, and voluntary control only incipient, these functions are performed without the intervention of conscious volition. Instances are on record of persons able to exert a voluntary inhibition of the heart's action, slowing it at will, and even causing it to stop beating for a time. Such are instances of function ordinarily automatic placed in these cases within the reach of voluntary influence. This action would imply an organic deviation involving a closer connection of the consciously acting cerebral centers with the origin of the cardiac fibers of the pneumogastric.

The cerebrospinal axis, with its connections, sensory and motor, with all parts of the body, constitutes the nervous mechanism for directing the motor activities of animal life. Its progressive development has been a condition of the progressive specialization of actions in the higher orders of animal life. The later stages of this development in the higher animals and in man has been chiefly cerebral, going on *pari passu* with the de-

velopment of intelligent direction and control of actions. This cerebral development has marked man's progress as an intelligent and moral being.

The spinal nerve-centers preside over actions which are reflexly excited and automatically performed, and which relate in general to the avoidance of pain or injury, the protection and preservation of the body. These centers, however, are not entirely independent, but subject to more or less control from the consciously acting cerebral centers. This control is effected by the exercise of inhibitory or depressomotor influence over them.

The highly evolved and complex conditions under which the civilized man lives, make it necessary at times to postpone the present to the future, to endure present discomfort or suffering for the sake of future good. Reflex action prompts to avoid the present pain or grasp the present pleasure, regardless of future consequences. Advanced mental organization, which means high cerebral development, is the antagonist of reflex or impulsive action.

The advance of the race in intellectual and social development and organization has produced new relations, and imposed new obligations. The cerebrum is the special organ for apprehending these new relations and obligations which grow out of the social state. The reasoned purposes upon which the enlightened and moral man acts mean a higher and broader adjustment to the conditions of life. Man reaches and maintains himself upon this rational and moral plane by inhibiting the lower impulses of his nature. These lower instincts, by continued control, lose something of their fierce power, the energy being diverted into higher channels, and developing into higher forms of activity. Inhibition is as much a factor in mental as in moral activity. The power of attention, of application, of mental concentration, is secondary to a power to inhibit impulses to distracting excitations.

The cerebrum is a sort of storehouse for excitomotor impressions. These impressions, instead of being reflected directly in acts, tend to build up mental attitudes or tensions. They may serve to discharge accumulated tensions. Any mental position is incipiently motor. It is this capacity of the cerebrum to store impressions, to stay action, to accumulate energy of position, which distinguishes it radically from the lower centers in its mode of action. This is thinking, as opposed to reflex action. Conscious thinking takes place in the interval between sensation and adjusted action.

The field of conscious action has expanded proportionately with the growing complexity of the conditions of civilized life and the difficulty of automatic adjustment. With each step in development the cerebrum has more and more assumed control of the activities of the organism. The lower centers, however, have not been abolished, but retained in subordinate places in the hierarchy of nervous organization.

The demonstration, by Cajal, of direct fibers connecting the nerve-roots in the posterior sensory horns of the spinal cord with the anterior motor cells, shows that the mechanism of reflex action in the spinal cord has been retained, as the possession of the function itself would necessarily imply. The existence, however, of nerve-routes from these sensory roots to the consciously acting cerebral centers is doubtless an important part of the mechanism for regulating spinal reflex action. Many so-called inhibitions are, perhaps, passive, and consist simply of the sensory stimulation flowing on through an open channel into a higher center without awakening the reflex center at all.

FRACTURES OF THE FEMORAL NECK.

THEIR ANATOMIC TREATMENT.

BY C. E. RUTH, M.D.

Professor of Descriptive and Surgical Anatomy in the Keokuk Medical College; and Clinical Surgery at St. Joseph's Hospital.

KEOKUK, IOWA.

Can the notoriously bad results following fractures of the femoral neck be improved? We feel like answering unhesitatingly that they certainly can, and therefore should be. Explanations are numerous and plausible for the frequent occurrence of this accident in the old, especially women. The causes given for non-union are much less satisfactory. We may instance the following defects supposed to exist: Nature's provisions for repair by limited vascularity, inefficient immobilization, insufficient extension force.

It is not my purpose to review extensively the literature of this subject, but to indicate more especially some of the reasons I consider most important factors in obtaining the unsatisfactory results thus far. In 1890 my attention was first called to what I have come to consider the correct anatomical treatment of these lesions, by Prof. T. J. Maxwell. The method was, I believe, original with him. He has used it for twenty-five years.

The first indication in the treatment of all fractures is correct adjustment of position; the second, immobilization, the third, overcoming muscular action which would tend to disturb the relations by extension, splints, etc. It is very easy and natural to blame nature with defects in our own work, but we should first look carefully to our own responsibilities and see that our own errors are eliminated.

In these cases there is no muscular effort or influence operating on the upper fragment, and the results as to the position of the lower portion will depend on the position of the patient, the kind of retaining force, and his own muscularity, for muscular action is of more importance in determining results of fracture here than anywhere else in the body.

This is due to the great number of powerful muscles passing over the fracture line to be inserted somewhere beyond, and which must exert a powerful displacing force.

The position at least for a time that must be taken by these cases is upon the back, and the displacement is known to be upward, backward and outward rotation, with all the internal displacement of the lower fragment which the muscular tissue will permit.

The pronounced tendency to eversion and external rotation is increased greatly by the external rotary power of the psoas and iliacus, which was neutral or else an internal rotator now must be a pronounced external rotator, because the insertion into the back and internal portion of the upper end of the femoral shaft and lesser trochanter throws the line of action internal to the point of resistance, whereas it was formerly external.

The result is that we have the following muscles acting to produce the following results:

Those pulling nearly directly upward and tending to shorten the limb by over-riding the fragments: Rectus, sartorius, gracilis, semi-tendinosus, semi-membranosus, long head of the biceps, vertical portion of the abductor magnus.

Those pulling very strongly inward as well as upward: Adductor magnus, except vertical portion; adductor longus, adductor brevis, pectineus, gluteus maximus, gluteus medius, and gluteus minimus.

Those which pull almost directly inward and rotate outward: Piriformis, obturator internus, gemellus superior and inferior, obturator externus, quadratus femoris, lower half of gluteus maximus.

Those which pull inward, upward, and rotate inward: Tensor vaginæ femoris, and the anterior portions of the gluteus medius and minimus.

Those formerly internal rotators exerting a strong upward pull are now external rotators, often drawn

directly between the fragments and absolutely preventing approximation of the bony parts: psoas and iliacus.

It will thus be seen that the external rotary force greatly predominates over the internal because of the conversion of internal rotary force of the psoas and the iliacus to external, besides the power of the limb's weight to accomplish the same ends. Lastly, we have the important displacing force, weight, tending to carry the upper end of the lower fragment behind the line

it should occupy because its old attachment support is gone. Posterior displacement and external rotation are only limited by the Y ligament.

Adjustment of the fragments is best accomplished by flexing the thigh upon the abdomen to relax the psoas and the iliacus, bringing them above the fracture line, thereby preventing them from being permanently caught between the fragments.

This position also relaxes nearly all the external rotators; then make vertical traction on the shaft of the femur, which now stands at right angles to the trunk, while moderate eversion is being maintained; next abduct to normal line and make extension in the long axis of the trunk while an assistant makes traction one-half to two-thirds as strong outward, slightly upward and forward from the upper end of the femoral shaft. These manipulations should be made by firm, steady traction, not by jerks, which is to be made continuous by Buck's

1 Psoas and iliacus above line of fracture, when thigh is flexed at right angles to the trunk before making extension.

extension with a weight of from ten to twenty pounds, according to the muscularity of the patient, with elevation of the foot of the bed enough to counteract the tendency of the patient to slide down to the foot. This means an elevation of from six to fifteen inches. A binder's board, or other splint material, should now be moulded to the upper inner aspect of the thigh, over which a band of muslin four to six inches wide should pass outward, slightly upward and sufficiently forward that the weight over the pulley shall overcome the internal pull of all of the rotators and adductors and at the same time raise the lower fragment to its normal level.

The weight on this lateral pulley will be from five to fifteen pounds, according to requirements. The side of the bed corresponding to the injured side of the patient must be raised enough to prevent the individual from being drawn out of position toward the lateral pulley. Patients so treated will have absolutely no pain whatever after spasmodic muscular action is entirely overcome. As to results I herewith report a few cases treated as above.

CASE 1.—Mrs. G., aged 52 years, had intracapsular fracture of the femur Jan. 14, 1871. She lived twenty-five years there-

after, being able to perform the duties devolving upon the average farmer's wife without any disability in any manner traceable to the injury. No shortening. Physician, T. J. Maxwell.

CASE 2.—Mr. R. P., aged 72 years, sustained an intracapsular fracture of the femur Jan. 29, 1881. Result, union without shortening. Physician, T. J. Maxwell.

CASE 3.—Mrs. Courtney, aged 64 years, sustained fracture of the femoral neck in January, 1883. There was union with no shortening, discoverable on examination and careful measurements four years later, by Drs. Kinnaman and Maxwell. Physician, T. J. Maxwell.

CASE 4.—Mr. P. F., aged 25 years, in 1883 fell thirty feet sustaining an intracapsular fracture of the femur. The result was a union with one-half inch shortening. Physician, George F. Jenkins.

CASE 5.—Mr. —, aged 50 years, who was a bridge carpenter, and heavy and large, fell twenty feet, sustaining fracture of the neck of the femur, one through the upper third of the femoral shaft. Result was a union with one-half to three-fourths inch shortening. Physician, T. J. Maxwell.

Showing through the artificial muscles the tendency of the psoas and iliacus to fall between the fragments.

CASE 6.—Mr. C., aged 86 years, fractured femoral neck by fall on the ice. Result was a union in four weeks, but death resulted in seven weeks from exhaustion resulting from his enfeebled condition, bedsores, etc. Physician, T. J. Maxwell.

CASE 7.—Mrs. T., aged 71 years, fractured the neck of the femur in June, 1891. Result, union with three-fourths inch shortening. She uses the limb without apparent inconvenience. She was very poor, had indifferent care, and the weights were not always on. Physician, C. E. Ruth.

CASE 8.—Mrs. W., aged 70 years, in July, 1891, fractured the femoral neck. Result, union with one inch shortening, and use of the limb seems but slightly impaired. Physician, C. E. Ruth.

CASE 9.—Mrs. P., aged 86 years, sustained fracture of the femoral neck in August, 1891. This patient was so completely demented that she would not tolerate any restraint; would not allow dressing to remain on more than a few hours. Treatment was abandoned after the third day. The result was a flail-like limb and no union. Physician, C. E. Ruth.

CASE 10.—Mr. Myers, aged 70 years, fractured femoral neck in 1892. Union with one-half inch shortening. Physician, R. H. Fegers.

CASE 11.—Mrs. Fox, aged 82 years, sustained fracture of the femoral neck in December, 1894. Result, union with one-half inch shortening. Physician, H. A. Kinnaman.

CASE 12.—Daniel F., aged 35 years, sustained fracture of neck of femur by team of horses running away. Patient was a subject of well-advanced pulmonary tuberculosis. A good union was secured, although somewhat slow on account of the

pulmonary condition. The limb was about an inch shorter than normal. Physician, J. H. Coulter.

CASE 13.—John McK., aged 80 years, fractured femoral neck by falling backward on a stone sidewalk. The case was under treatment of another physician a week before it came into the hands of Dr. Coulter, and the joint was found to be very much swollen and painful. The dressings were put on at 4 p.m., but on return next morning found them removed, and the patient absolutely refused to have them replaced. The case was then abandoned. The patient has since been seen frequently, but the limb dangles like a flail. Physician, J. H. Coulter.

CASE 14.—Mrs. D., aged 78 years, fractured the femoral neck by falling in a furrow on the frozen ground. Treatment of the case was uneventful, except that the union was somewhat tardy, perhaps on account of the advanced age of the patient. A good union was secured with only one-half inch shortening. Physician, J. H. Coulter.

CASE 15.—Mrs. Clara K., aged 40 years, sustained fracture of the femoral neck by jumping from second-story window on a brick pile. She was at first under the care of Dr. Coulter of Summitville, Iowa. Dr. Coulter frequently found the weights hung up and patient quite unruly. She would not keep quiet, and was removed at the end of one week to St. Joseph's Hospital, a distance of six miles, and operated upon at my clinic for hemorrhoids and perineal laceration three weeks later. She was quite tractable in the hospital. Result was a union with no shortening whatever. Physician, C. E. Ruth.

CASE 16.—Mrs. Dr. Nellie M.U., aged 30 years, sustained fracture of the neck of the femur in a runaway in June, 1896. A good union was the result, with no shortening discoverable after repeated measurements. Physician, C. E. Ruth.

CASE 17.—Mrs. M. J. B., aged 60 years, very feeble, fractured femoral neck Sept. 7, 1898. Union in six weeks with no shortening. The condition of this patient was very precarious for several weeks, so much so that but little hope was entertained of saving her life. Physician, C. E. Ruth.

We do not come to you with a single case in the hands of a man of slight experience, but with seventeen cases of unquestioned fracture of the femoral neck in the hands of men of large experience. In fifteen of these cases union was obtained with useful limbs in persons ranging in age from 25 years to almost the extreme limits of old age, and yet the shortening was no more than one inch in any, and after the most careful measurements no shortening whatever was discoverable in five of the cases.

In one of the cases reported with one-half inch shortening the physician in charge informed me that he could find no shortening, and that the patient walked without a particle of halt or limp, but one-half inch shortening was claimed in the prosecution of a suit brought against

his employers for damages. This man fell thirty feet when the fracture was produced. In some of my own cases I am certain that I did not use heavy enough weights, and in others the treatment was interrupted occasionally by having the weight removed to satisfy some meddlesome attendant, nurse or patient.

The only failures to secure union were in two cases that absolutely refused to have the treatment carried out. I might cite you many cases of flail-like limbs from this cause, as can be done by most physicians of any considerable practice. I have had no opportunity to examine the condition of the bones post-mortem. I have no doubt whatever that in these fifteen cases bony union was obtained. Where little or no shortening took place, and the limb was functionally perfect, there can be no doubt that the union was bony.

Whatever may be the opinions in regard to repair in this bone, results that are almost perfect, and make the patient comfortable while repair is taking place, are certainly worthy of our attention, endorsement, and most earnest efforts to establish. The usefulness of this plan of treatment is not alone limited to fractures of the femoral neck, but is equally applicable to the treatment of hip-joint disease with or without operation.

In some of these cases treatment was not begun until several days after the injury, and in some the treatment was interrupted occasionally for a short time. In no case was pain complained of after the first day if weights were enough to prevent muscular spasmodic disturbance of the fragments.

By this plan of treatment the patient can be raised, if needs be, to the sitting or semi-sitting posture for the purpose of cleansing. Some of these cases had bed-sores, and were lying in their own excrement and suffering severely when the treatment was begun. These were raised daily to the sitting posture, cleansed, and the sores healed during the use of the extension treatment. The patient can be easily handled in the use of the bed-pan. The method is easy of application, and only fulfills the indications we require for all other solutions in continuity of bone, viz., securing coaptation of fragments without the possible intervention of the soft parts overcomes all displacing tendencies of powerful muscular action instead of ignoring the action of more than one-half the muscles and displacing power of the limb's weight.

The results prove that it is not necessary to allow most of the fractures of the femoral neck in the aged to produce cripples for the rest of their lives, or that they should suffer, except from the confinement, and that could be scarcely less by the plan of treatment proposed than to give the patient every possible liberty during the time required for procuring union. It also proves that the influence of the *synovia* is *nil* as a preventive of union. I do not wish to be considered as claiming that perfect results can be confidently expected in all of these, or in fact any, fractures, and thereby invite prosecution for malpractice in every case of failure. What I do want, however, is to see the day when we will be able to lay aside prejudice and custom if need be, and use the method that will give the best results.

THE STUDY of the mosquito in its relation to malaria is being prosecuted with great vigor at Johns Hopkins Hospital. The crow is found a good subject for receiving the infection from the insect.

accurately tested at this date. Note change in cutaneous sensibility four days later, as shown by charts appended.

Reflexes.—Organic. No defects of deglutition, defecation or micturition. Tendon: Elbow-jerks present and equal; wrist-jerks present, active and equal. Knee-jerks present, exaggerated and equal; rectus and ankle-clonus present and equal on both sides. Cutaneous: Not observed. Vasomotor system: Patient sweating freely. Trophic: No muscular atrophy observable to ordinary examination. No trophic ulcerations.

Urine.—Reaction acid, barely; sp. g. 1030; phosphates in excess; albumin and sugar absent.

Blood-count shows a moderate leucocytosis (16,500.) This was probably due to the intercurrent tonsillitis.

July 10.—A tuberculin test, with m. xv of a 1-250 solution was followed in two hours by headache, and chill and sweating in twenty-six hours. Two days after admission the acute tonsillar inflammation subsided, the temperature dropped to normal, and for the next four weeks fluctuated between 98 (a. m.) and 100 (p. m.), only once during this time rising 2 degrees above the 100 mark. After the two weeks following this period, the temperature varied between 98.4 (morning) and 99.4 (evening). (See chart appended.)

Re-examination four and five days after admission. (See chart No. 1.)

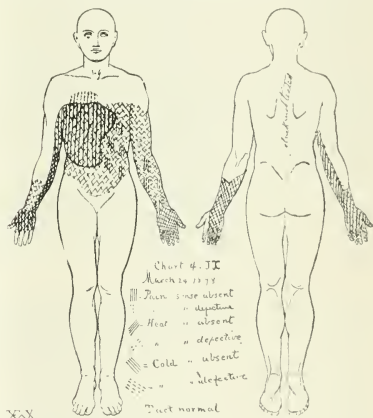

2.) Tests were made in the ordinary manner with test-tubes of decided warm and cold water for temperature, cotton and pin for tact and pain. A week later (see Chart 3) these sensory defects were increased by addition of an area of *analgesia* over the thorax anteriorly. At this date power in legs has apparently increased, so that he can move both feet and legs with considerable freedom as he lies in bed.

Reflexes.—Pupils are moderately dilated when at rest, respond well to accommodation and contract to light, but do not dilate farther when light is excluded. Organic: Has to be catheterized for a day or two. Vasomotor: Well marked "tache" over thorax and abdomen. Trophic: No "bedsores" or other ulceration.

March 17.—Electrical tests now and later showed partial R. D. in muscles of hypothenar group of right hand, as evidenced by very sluggish contraction to galvanism and nearly equal responses to both poles, though K. C. is slightly greater than A. C.

Muscles elsewhere react normally to galvanic and faradic currents. There is slight improvement in power of legs and arms.

Twelve days later the motor symptoms were practically unchanged, the defects of heat and cold sense were somewhat diminished in area, but persisted on thorax and a longitudinal strip along the inner surface of the

Motion.—Quadruplegia, of waxy, rigid type is still present. The pectorals, deltoids, supinators, small thenar muscles, and short extensors of toes seem absolutely powerless on both sides. Elsewhere the muscular power is barely sufficient to flex and extend joints, extension seeming rather stronger than flexion at the elbows.

The tongue protrudes in the median line, is longitudinally fissured, and a general fibrillary tremor of the entire organ is present.

Sensory defects of a "dissociation type" have appeared as per Chart No. 2. These consist practically of diminution and loss of appreciation of heat and—to a less degree—of cold, with preservation of tact and pain over thorax, abdomen and upper arm anteriorly, and on forearm and hands anteriorly and posteriorly. (See Chart

right arm, forearm and hand; also over left forearm and hand posteriorly. (See Chart 4.)

March 29.—About this time I asked my colleague, Dr. Freiberg, orthopedic surgeon to the hospital, to see the patient, and it was decided by his advice to make extension on the entire vertebral column in the hope of relieving the pressure which was presumed to exist on the upper cervical cord. The effect of the extension and counterextension on the sensory symptoms was startling. Twenty-four hours after application of the apparatus, it was difficult to detect any sensory loss over thorax or abdomen, and when found it was in such irregularly scattered patches as to make its accurate charting impracticable. By April 10—twelve days after application of extension—the only remaining defects were a loss of temperature—heat and cold—sense over right

hand, palmar and dorsal surfaces; and over the left hand, dorsal surface only. The case was now transferred to the care of Dr. Freiberg, who furnishes the following:

SURGICAL HISTORY.

On March 28 I examined the patient whose condition has been accurately described by Dr. Langdon. I found present, exclusive of the nerve symptoms already described, a considerable, firm, diffuse swelling immediately below the occiput and extending downward to the fourth cervical spine. Without any distinct boss it was sufficient to render indistinct to the touch the vertebral spine. There was considerable tenderness on pressure complained of in the whole swollen area.

There was no torticollis whatever, but the patient was unable to rotate the head with freedom. Likewise it was impossible for him to bend the cervical spine backward to the normal extent. There was some interference with

of by Dr. Langdon as startling; this is by no means an exaggeration. The improvement was, however, steadily progressive from this time forward.

June 4.—The appetite is good; no fever; no pain; less rigidity. He can move his neck with considerable freedom; also all joints of extremities. Grasp: dynamometer R. 50, L. 46; knee-jerks exaggerated; R. and L. ankle-clonus present R. and L.

The patient was kept in bed with the same weight attached until Aug. 4, 1898. At this time an examination showed an apparently complete return to the normal in every regard save one—the power to rotate the head laterally. The extension was therefore removed and a Sayre jury mast applied. On August 22 the patient expressed a desire to leave the hospital and was permitted to do so, wearing no apparatus, and he walked out of the hospital without assistance. About six weeks ago I had an opportunity of examining the patient, and his con-

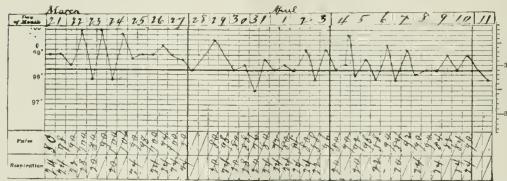

Chart 6, J.X. Pachymeningitis Spinalis Externa.

the power of approximating the head toward either shoulder. The nodding motion was not interfered with. Examination of the pharynx failed to show anything abnormal.

The diagnosis of tubercular disease of the upper cervical spine was made with some reserve, especially with regard to its exact localization. The treatment consisted in the application of weight and pulley extension to the head, the weight of the body serving as counter-extension. The weights were increased gradually from three to twelve pounds.

The change in the patient's condition has been spoken

condition remains the same. A very slight interference with rotation of the head and the induration about the upper spinous process, which has never disappeared entirely, are all that remained of the conditions found upon the first physical examination of the neck. The patient asserted that his muscular power had returned in full degree.

ADDITIONAL COMMENT AND SUMMARY.

Since leaving the hospital the patient has been under our separate and joint observation at intervals of a few weeks. His health remains good and he attends regularly to his duties as salesman and clerk in a store.

Neurologic examination May 19, 1899, by Dr. Langdon: Height, 5 ft. 8 inches; weight, 138 pounds; general nutrition good.

Temperature, 99.3, after dinner and active exercise; pulse 72, regular. A slight fullness is apparent about the fourth or fifth cervical spines. Head movements are free as regards rotation and extension; somewhat limited as to flexion forward—can not touch manubrium sterni with chin. There is no muscular atrophy; no defect of gait or station. Power is good in all extremities. Grasp: dynamometer R. 105, L. 98—normal average about 80. The same dynamometer was used as in former tests.

Sensation.—No subjective sensory symptoms; no defect of tact, pain, temperature or muscle sense.

Reflexes.—Organic: No bladder or rectal defect, no dysphagia. Myotatic: Elbow and wrist-jerks present; right rather more active than left; knee-jerks somewhat hyperactive and equal. Rectus-clonus and ankle-clonus absent. Cutaneous: Palmar absent; epigastric, hypochondriac, abdominal and cremasteric present; normal. Plantar present, giving marked "flexor" responses in both feet.

Diagnosis: Having in view the quadruplegic type of paralysis, the possibilities to be considered were: 1, cerebral diplegia; 2, poliomyelitis anterior; 3, multiple neuritis; 4, cervical myelitis; 5, spinal tumor; 6, hematomyelia; 7, hematorrhachis, external or internal; 8, leptomeningitis spinalis; 9, pachymeningitis spinalis interna; 10, pachymeningitis spinalis externa.—primary, *a*, rheumatic; *b*, gonorrhoeal; secondary *c*, tubercular (vertebral caries.)

Cerebral diplegia was readily ruled out by the history, the gradual onset, and absence of mental, aphasic, or cranial nerve symptoms. Poliomyelitis is excluded by the rigid type of paralysis and the presence of marked sensory defects. Multiple neuritis was not indicated by the history, and was further eliminated by the absence of pain, tenderness and muscular atrophy. Cervical transverse myelitis would have presented sphincter defects and trophic lesions, which were absent. Spinal tumor is conspicuous for the presence of root pains, which were absent. Gumma was excluded by lack of evidence of syphilis; and as already stated, syphilis is absolutely excluded in the case by recent developments of a most convincing nature.

Hematomyelia and hematorrhachis have a sudden onset with rapid improvement if the patient lives. Leptomeningitis was contraindicated by slow onset, the absence of pain or hyperesthesia on movement of the spine, the evident localized character of the lesion, with little tendency to spread. Pachymeningitis interna was excluded by absence of adequate causes, as syphilis, alcoholism and trauma; also by absence of marked pain, and irritative root symptoms, as well as absence of the later muscular atrophy. Thus, by a process of exclusion a tentative diagnosis of pachymeningitis externa was reached, but whether this was primary, i. e., rheumatic or gonorrhoeal, as the history might suggest, or secondary to vertebral caries, as the heredity and part of the symptomatology would indicate, is perhaps an open question.

As Dr. Freiberg has stated, the diagnosis of tubercular disease of the vertebra was made with some reserve by both of us. Gowers⁴ states on this point: "When clear indications of caries precede the paralysis the nature of the case can hardly be mistaken. . . . When the two develop together mistakes are often made, but are

usually due to the want of repeated examination of the spinal column. . . . It is when the root or cord symptoms precede distinct evidence of bone disease and when the latter is so slight as to be equivocal that the chief real difficulty in diagnosis occurs." It will be seen that the case here recorded comes under the third condition described above.

To sum up: The symptoms indicated an increasing pressure of exudate with its incidence at the first and second cervical segments of the cord anteriorly, thus compressing the ascending anterolateral tract of Gowers—temperature sense symptoms—and the pyramidal tracts before their complete passage into the lateral columns. In no other situation is it possible to conceive an external lesion causing the motor symptoms here presented, viz.: quadruplegia with waxy rigidity and without muscular atrophy of the arms. The slight electric changes noticed in the hypothetic group of right hand were doubtless due to a nerve-root involvement lower down; as was the absence of pupillary dilatation on removal of light.

Against the presence of primary vertebral disease are the supposed "rheumatic" constitution, the preceding gonorrhoeal infection, the absence of trauma. In favor of primary vertebral disease of tubercular origin are the hereditary factor, the tenderness on pressure, with thickening over cervical spine; the reaction to the tuberculin test, which, however, was much delayed; and finally the doctrine of probabilities, as well as the favorable outcome.

Treatment.—In addition to the surgical treatment proper, of extension and counterextension, potassium iodid was given in twenty-grain doses for about one month following his admission to the hospital. Cod-liver oil and hypophosphites were also administered, and the patient was kept in the open air whenever practicable.

MEDICINE.

ITS PROGRESS, PROBLEMS, AND PROSPECTS.*

BY J. BRUYERE, M.S., M.D.
SURGEON TO MERCER HOSPITAL,
TRENTON, N.J.

(Continued from p. 446).

Many of the forty odd specific infectious diseases are now known to be due to micro-organisms. For a long period germs had not been isolated, and no cultures or inoculations had been made; hence, the only proof of their action in disease was the constancy of their presence in infectious diseases. This led many to believe that organisms might be the result, rather than the cause of disease. Some thought that organisms were present in healthy tissues, and could not be the cause of disease. Koch, in 1881, and subsequently, by his careful scientific methods, did much to establish the foundation of bacteriology. He demonstrated the distinct varieties of infection, the possibility of isolating their germs, of making cultures, and inoculating animals by the same. He first used for bacteriologic purposes, the Abbe system of substage condensing apparatus, the aniline dyes, the cultivation of bacteria on solid media, etc., and furnished many original and important suggestions. Such in brief, is the history of bacteriology, which has such a marked influence in revolutionizing etiology, pathology, and the principles and practice of medicine. The modern germ theory of disease now fully explains spontaneous generation, fermentation, putrefaction, infection, etc.

* Read before the Mercer County (N. J.) Medical Society, at its Fiftieth Anniversary, May 23, 1898, and subsequently revised.

³ See Collier, "Brain," 1899.

⁴ Manual of Diseases of Nervous System, vol. i, p. 251.

Their discovery of minute organisms and the study of their life history, their culture and growth, their likes and dislikes, their secretions and chemical character, is teaching us the origin of the infective maladies and the laws of their development.

The study of microscopy and bacteriology has established a new era in the practice of medicine by giving to etiology and pathology a new impulse and many scientific truths. Twenty-five or thirty years ago the uses of the microscope were limited. There was no section cutting, no staining process, no oil immersion or apochromatic lens. But little was known of etiology or pathology. An ocular description of morbid changes was given, with but little knowledge of how or why these changes took place. This constituted morbid anatomy, which was afterward changed to the science of pathology by the advance in bacteriology and microscopy. The "cell theory," and the "germ theory" established modern pathology. In pathology system followed system, but these have all perished and been replaced by cellular pathology, which is the accepted theory of to-day. Hooke discovered plant-cells and later animal cells were discovered by Schwann and cell-nuclei by Robert Brown. Hooke, in 1667, introduced the term "cell," and Malpighi and Grew did much to establish the "cell doctrine." Merbel, in 1806, and Johannes Müller, in 1835, more elaborately described cells, but it remained for Schwann, in 1839, to establish the "cell theory." Schleiden, Baumgärtner and Schwann, proved the cellular origin of the various vegetable and animal tissues, and their investigations became the foundation of all modern histology and led to Virchow's "cellular pathology," and the development of microscopic botany, etc. In 1858 Virchow formulated his doctrine of "modern vitalism," which is the cell-theory of the present day. He showed that every organism is composed of an aggregation of cells, and that every cell has an individual existence, a unity and purpose of its own. He expressed a strong belief in the continuity of living matter. This belief he recently reaffirmed in a most impressive manner. At the twelfth International Medical Congress, lately held at Moscow, he reiterated with great earnestness his view of cellular life. "Life," he said, "has no other origin than from life itself. Life is in the cell. He who speaks of serum as a vital force apart from cells is wrong. The grand truth of cellular succession may be assailed in the future, as it has been in the past, but it will never be thrown to earth." In 1856 Virchow introduced microscopic anatomy, and in 1866 published his great work on "Tumors." He demonstrated the fact that the blood is not the prime cause of dyscrasia, as Andrel supposed, but only the medium through which dyscrasia is produced. He also showed that pyemia accompanies thrombic processes and is not due to the absorption of pus. Accepting the "cell" and the "germ theories," and by the use of the microscope and scientific methods, he, more than any other, established the modern science of pathology.

The first pathology written in the English language was by Gross, in 1839, but still in 1848 pathology was almost an unknown science. The first pathologic society was founded in Dublin in 1839. The New York Pathological Society was founded in 1844, the London in 1846, and the Philadelphia in 1857. The rapid advance in bacteriology and pathology has taught us much about the processes and causation of disease, and has greatly modified the principles and practice of medicine. Not only did bacteriology revolutionize pathology and etiology, but it gave rise to hygiene, preventive medicine,

sanitation, boards of health, the knowledge of infection, serumtherapy, immunization, antiseptics, aseptics, etc. We can only briefly allude to these. When Jenner discovered the principles of vaccination, little did he think that his virus would become the forerunner of the antitoxins, and be suggestive of serotherapy, immunity, or preventive medicine. Scientific investigation into the nature and cause of disease has led to natural methods of cure—to organotherapy, serumtherapy, antiseptics, etc. Organotherapy aims to supply to an organism the chemical or vital elements which it requires. These elements are the animal extracts, which are secured from the glands and tissues of the body—such as thyroid, thymus, and lymphatic gland; the brain, heart, stomach, kidneys, spleen, pancreas, testes, ovary, uterus, blood, bone-marrow, suprarenal capsule, etc. When there is loss of function of these glands or tissues the extract from a corresponding healthy organ or tissue is given to supply the deficiency, and must be continued regularly, just as food to relieve hunger. Whatever the function of the thyroid—whether to change or destroy injurious substances in the blood or to secrete substances to aid in the development of bones, muscles and nerves—its secretion passes directly into the blood, where it has a physiologic action. When the thyroid gland is removed, or its functions impaired by disease, as in myxedema, cretinism, and exophthalmic goiter, it has been ascertained that the pathologic conditions engendered are removed or greatly improved by the administration of thyroid juice, extract or powder. Thyroid secretion or extract has been used to great advantage in anemic obesity, struma, uterine fibroids, uterine hemorrhage, at menopause, epileptic psychosis, acromegaly, rachitis, Basedow's disease, mild cases of diabetes, psoriasis, lupus, ichthyosis, eczema, pityriasis rubra, alopecia and various kinds of insanity. Iodothyren—the active principle from the thyroid gland—seems to be less objectionable and just as useful. The pituitary body may be of use in acromegaly, and bone-marrow in anemia. If the suprarenal capsules are removed, emaciation, feebleness and death follow, but if injections of the fresh extracts of the organ are given death is at least retarded, if not averted. Suprarenal extract is used in eye diseases, etc. It is a powerful astringent, and is sometimes injected into the eye, and upper air-passages, with good results in congestive conditions. It is also a heart tonic, and may increase the red corpuscles, and act as a vasoconstrictor, etc. Brown-Séquard's testicular juice is no longer regarded as an elixir of life, although it accomplished considerable through auto-suggestion. Babes and Paul have made the glycerin extract from the brain, which may remedy some of the defects of nature, by increasing cerebral activity. Other glandular extracts are given with varying results, and the time may not be far distant when organotherapy has a well-defined field of usefulness. Nevertheless, animal therapeutics remain yet to be developed, for physiologic chemistry, experimental physiology, and clinical observation have yet to determine the definite uses of the animal extracts.

Serumtherapy, though still in its infancy, promises brilliant results. Richet, in 1889, claims to have given the first serotherapeutic injection, and Bouchard, in 1890, published the first contribution on serotherapeutics. Behring and Kitasato, in 1890, showed the nature and effects of antitoxic serum on the fixed tissue-cells, and in 1892 Behring showed the splendid results of serumtherapy on diphtheria. Diphtheria antitoxin not only has immunizing qualities, but is also a veritable remedy—having reduced the mortality from 47 to 8 per

cent. The serum treatment for bubonic plague has been demonstrated to be of great value. The serum treatment of pneumonia is also said to be very successful in Italy. De Renzi, Ughetti, Cantieri, Messolongo, and others declare that "it is more efficacious than any other agent." Wasserman lately reports excellent results. Haffkine's vaccinations for cholera are said to afford considerable protection against this disease, vaccinated persons being twenty times safer from attack, and eighteen times securer from death than the unvaccinated. Out of over two hundred coolies inoculated by Dr. Hare under Haffkine's direction, only 2.55 per cent. died, while among the inoculated 19 per cent. died. Sanarelli has prepared a serum that has reduced the mortality in yellow fever from 50 to 27 per cent. Bird serum, according to Behring, is superior to horse serum and other animal serum, in tuberculosis, still antituberculous serum is not very favorable in its results. The antistreptococci, antisymphilitic, antityphoid, antitetanic, antisnakebite, and many other serums have been used with varying results, but space will not permit their further enumeration. Lately the mixed toxins have been used with good results in the treatment of disease. It is claimed that the mixed toxins of the streptococcus of erysipelas, and the bacillus prodigiosus, have been used in the treatment of sarcoma, with marked results.

The knowledge of the infectious diseases that bacteriology gave us led us, as we have previously stated, to a better knowledge of vaccination, and developed the idea of serumtherapy for its curative and immunizing properties. It also developed and gave a new meaning and impulse to hygiene, sanitation, boards of health, or preventive medicine, and finally led to Listerism, antiseptics, and asepsis. The origin of the infectious diseases being known, their prevention became apparent. Dirt no longer possessed the odor of sanctity, but became the symbol of death. That "cleanliness is next to godliness" is also the teaching of bacteriology. The Mosaic laws enjoined cleanliness, isolation of the sick, and wholesome food and drink, hence the Jews enjoy a remarkable immunity from epidemic diseases. A greater knowledge of hygiene has led to greatly decreased mortality. Two centuries ago, the mortality in London was 80 per 1000; it is now 18 per 1000. A century ago scurvy was to be found on nearly all ships, and jails and hospitals were the hotbeds of disease. Thirty years ago the English troops at home died at the rate of 20 per 1000, now the death-rate is less than half this amount. In the fourteenth century the plague or black death is said by Wingate to have destroyed "13,000,000 people in China, 24,000,000 in Oriental countries and not less than 25,000,000 people in Europe." Cholera, yellow-fever and smallpox have also been epidemic for hundreds of years, and cost millions of lives. In Jessora, India, in 1817 more than 10,000 people died of cholera in two weeks, and in Benares in 1818, 15,000 died in two months. In 1878 there were 15,934 deaths from yellow fever in Louisiana, Tennessee, Alabama and Mississippi. Smallpox exterminated whole tribes and almost wiped out whole nations. In Mexico it attacked "3,500,000 of the population, leaving no one to bury them." Dr. Crighton estimated that in Russia "every seventh child died annually of smallpox," and Colon tells us that in France the annual number of deaths from smallpox was from 60,000 to 72,000. When bacteriology revealed to us the cause of these deadly infectious diseases, boards of health were appointed as guardians of the public health. In 1865 Louisiana appointed the first state board of

health to cope with yellow fever; but this had such limited powers and was so brief in its existence that the Massachusetts State Board appointed in 1869 should be regarded as the first actual state board in the Union. Now nearly every state and town has its board of health. France, Germany and England have their national boards of health, or departments of health; but the United States is still lacking in this.

Increased knowledge as to the cause of many diseases has led to the adoption of preventive means. The adoption of public health acts by sanitary authorities has increased the general health, especially among the poor. The mortality from smallpox, says Parker of London, has diminished 96 per cent.; deaths from fevers have declined 82 per cent.; deaths from typhus 95 per cent.; deaths from enteric fever 60 per cent.; deaths from scarlet fever 81 per cent.; and deaths from phthisis 46 per cent., and diphtheria about 59 per cent. The decrease in the deaths from malaria and many other zymotic diseases has been very great. Parker says that, "the general effect of improvement in sanitation is that 600,000 persons reached the age of twenty-one, who sixty years ago would have died." Skillful operations and appropriate medicines have saved many, but preventive medicine has saved far more. Through preventive medicine, which is now being established on a scientific foundation, infectious diseases will soon become unknown in civilized countries. To this end individuals and communities must act in accordance with well-established hygienic laws. Increased diagnostic skill has done much for preventive medicine. Diagnosis is now arrived at by a process of reasoning, not by intuition as formerly. An elaborate description of symptoms no longer takes the place of accurate diagnosis. We no longer base diagnosis and treatment on the theories of disease. Diagnosis is now the result of scientific precision in methods of thought and observation, together with a skillful use of instruments of precision. By such methods, we now quickly and definitely recognize many diseases that were formerly recognized only after long periods of observation and many autopsies. Time is thus gained by an early and precise diagnosis, and the community, by being forewarned, is largely forearmed, so far as epidemics are concerned. Modern diagnosis, therapeutics, and operations all aim at prevention. And yet we are told by Gould, that more money is devoted to astronomy than to the prevention of disease. Men seem to be more interested in the stars and constellations than in their bodies or physiologic life. Nevertheless, the progress of the age in which we live is characterized by preventive medicine, and private and public hygiene. This fact is a monument to the honor and glory of medical men, rather than to the laity, who have done more for astronomy than for preventive medicine.

Prevention is far better than cure. This is the medical idea, object and aim of the future. We now have a proper respect for Hygeia—the goddess of health. We no longer respect ascetics, dyspeptics and pale melancholics. Those pale, devitalized, saintly people, filled with negative goodness and amiable tameness are insipid, and incapable of those positive, robust, aggressive virtues, so much in demand at the present day. Good digestion and assimilation—or good health—the prevention of disease—is the sub-stratum of happiness, of usefulness and of morality. The great object and aim of medicine is to secure and maintain health, or to prevent disease. If this is so, should not doctors strongly and unitedly protest against the violation of the laws of

heredity, which produce so much disease. Why should not syphilis, consumption, scrofula, epilepsy, inebriety, insanity, criminal tendencies, etc., be a restriction to marriage? The increase of degeneracy is largely due to the violation of the laws of heredity, and to unregulated marriages. The altruism that is a product of civilization protects the degenerates and fosters abnormalities. This is an age of charities, of asylums, hospitals, reformatories, prisons, sanatoriums, and eleemosynary institutions of every kind, and the demand still increases. Christian civilization, by reversing the Darwinian law, makes the survival of the unfittest a possibility. Our social and political institutions and the general welfare of the race require that the wholesale production of abnormalities cease. Is there any just reason why the insane, epileptic, syphilitic, consumptive, and other degenerates, should marry and bring into the world those who are a burden to themselves and to the society? Is it altruistic to permit the propagation of hereditary disease and crime? Do we not owe something to humanity? To entail disease, evil tendencies, degeneracy, on a child—is this not cruel and unkind? Is not marriage under such circumstances based on sentiment, rather than upon reason and justice?

Degeneracy has become such an enormous burden to society, such a blight on human happiness and well-being, that the laws of heredity must be considered, and marriage must be regulated by the law of conscience, if not by the law of the land. The future altruist will consider the methods of preventing degeneracy, rather than methods of cure. We now have sanitary laws, and we will then have hereditary laws to protect posterity. A parent is not allowed to give material poison to the offspring, so as to produce weakness, disease and death, but he is allowed to transmit congenital and moral poison to his offspring, and thus consign it to a fate worse than death. A better civilization will remedy this. We now have laws to protect the bodies from external disease; we will then have laws to protect the child from inherited disease. Prevention is the watchword of the future, for individuals and nations alike. Herein lies the hope of the physician, of the individual, and of the nation. Preventive medicine will teach people how to live and will be the index of a higher civilization. We need a higher moral education based upon the study of medicine. The grandest study for mankind is man. Seven thousand murders take place annually in the United States, and about 122 legal executions, and 131 lynchings. There are about 100,000 orphans, and, according to J. S. Billings' statistics for 1890, there were 106,252 insane; 95,571 imbeciles and idiots; 50,411 blind; 41,283 deaf-mutes; 73,095 paupers, and 86,000 prisoners. It is said that from 65 to 75 per cent. of crime, imbecility, and insanity is due to heredity, and yet only about one-tenth of the criminal offenses are detected and punished. During the past ten years crime has increased 60 per cent. When we consider the great increase among the delinquent, defective and dependent classes, who are filling to overflowing our prisons, asylums, and reformatories, and when we consider the enormous burden they are to society, should we not as physicians do all in our power to prevent this great increase in degeneracy? With this general consideration of preventive medicine, we will pass on to the consideration of the prevention of infection by means of antiseptics, which was originated by Lister.

In 1867 he first published his experiments on the antiseptic treatment of wounds. His theories were received

with distrust and contempt, and it was said that "the man who would claim to heal wounds without suppuration was a visionary." Not until about twenty years after this publication was antiseptic surgery fully accepted and developed. Gross, "the Nestor of American surgery," in his "System of Surgery" (1882 edition), says that although various observers "have established the existence of myriads of low forms of organisms in our breathing atmosphere, the demonstration of living, disease-producing germs is wanting." He thought that putrefaction, suppuration, blood-poisoning, etc., were induced by "epithelial, and pus-cells, and other particles of organic matter" held in suspension in "the atmosphere of ill-ventilated and long-occupied hospitals." The true causes of abscess, septicemia, hospital gangrene, erysipelas and tetanus, were at this time still *sub judice*. Lister, at first, supposed that micro-organisms existed principally in the air; hence, ligatures, instruments, dressings, sponges, etc., were only cleansed. He soon ascertained that spraying the air was not sufficient, as everything that came in contact with wounds might contain germs. Following this idea, the skin of the patient, the hands of the operator, and all bandages, ligatures, etc., were made free of germs by antiseptic solutions. Germicidal agents now came rapidly in vogue, and Lister not only filled the operating-room with the vapor of carbolic acid, but antisepticized all tissues and surgical appliances. Observation soon demonstrated that the air did not contain so many deadly germs as supposed, and that such persistent and strong irrigation was not only not essential, but irritated the tissues, and was injurious. Dressings that had been sterilized by dry heat, live steam, or boiling water, were found effective; hence, it became apparent that antiseptic solutions were to be used to irrigate tissues only when some septic material was to be washed away.

Thus the antiseptic gave way to the aseptic, and the old adage, "prevention is better than cure," was again confirmed. The germicidal powers of the vital tissues later became known, and the necessity of strong antiseptic fluids, which irritated and impaired the power of these tissues, was found to be limited. From these observations it was found that the aseptic, and dry method, is a great improvement over the antiseptic method. Before Lister's great discovery of antiseptics, our hospitals were hotbeds of contagion. Fevers, blood-poisoning, erysipelas, suppuration and hospital gangrene were very common. When pain was abolished by anesthesia, operations increased in number, and as nothing was known of antiseptics, there was unfortunately a corresponding increase in hospital diseases. Forty years ago the operating-room was said to have been the dirtiest room in the hospital. Sawdust was strewn over the floor to catch the blood, and the surgeon wore his dirtiest garments, which were sometimes "stiff with blood and animal filth." "He was as proud of this blood-stained rag as a peer of ancient lineage may be of his faded ceremonial robes, and he would step into the operating-room, like a great matador into the ring," and proceed with the operation, which was followed by horrible moans and shrieks, entreaties and curses. During these horrible times it was regarded as "indecent, unwomanly, and revolting," for a nurse to enter the hospital. Anesthesia and antiseptics civilized hospitals, and made nursing a profession of refinement and honor. Cleanliness is now regarded as next to godliness. Hospital diseases have become almost a thing of the past, and mortality records have been greatly lowered. During the Civil War, in

the Massachusetts General Hospital, which had a world-wide reputation for neatness, cleanliness and efficiency, hospital gangrene became epidemic and surgical operations had to be abandoned. There were epidemics of hospital gangrene in many of the prisons and military and municipal hospitals, and infectious diseases were common, and caused more deaths on the battlefields than were due to wounds. In fact, during our late rebellion, there were 2642 cases of hospital gangrene reported, with 1142 deaths. Had we possessed a knowledge of antiseptics, at this time, thousands of lives would have been saved. We no longer have such wide-spread epidemics of erysipelas, dysentery, gangrene, and other infectious diseases. Antisepsis has made "laudable pus, both unlaudable and reprehensible." Formerly the surgeon would go from ward to ward, handling the various cases, with unwashed hands, and spreading the contagion impartially. The risks of surgery, at such a time, were very great. In the large hospitals of Great Britain the deaths from amputation of a limb were at least one to three. Simpson collected a series of 2089 cases, and ascertained that the mortality was as high as one in two and four-tenths. In the Paris hospital the mortality after amputations was nearly one in two, and in 1861 it was three in five, and a few years later it was estimated at 58 per cent. Writing from Paris in September, 1861, Sims says, "In hospital practice almost all cases of amputation die," and attributes it to their methods of dressing wounds. In Germany and Austria, the mortality varied from 43 to 46 per cent. The mortality for amputations of the thigh, in 1840, was 63 per cent.; in 1890, 21 per cent.; but Estes, in 1894, in 77 cases, had a mortality of only 10.4 per cent. Before anesthesia and antisepsis the development of a skillful technic in the handling of surgical instruments and the dexterity and rapidity of operation were the chief essentials. Now the glass-top tables, iron bedsteads, tiled floors and walls, and the great improvement in hospital methods, in heating, ventilating, general sanitation, cleanliness and aseptic methods bespeak another age. Modern surgery owes everything to anesthesia and antiseptics.

We will next briefly consider the progress that has been made in surgery and other branches of medicine during the last fifty years. The scientific progress in surgery has been so great that no surgical genius who thirty or forty years ago went to the land of shadows could return and teach or practice modern surgery. He would not understand the surgical vocabulary, and would be more than astonished at our modern operations on the brain, chest, abdomen, and pelvis. In 1579 Ambroise Paré says of surgery, that antiquity has "nothing wherein it may exceed us, beside the glory of invention, nor posteriorly anything left but a certain small hope to add something." Every generation seems to think that it is the crowning glory of all the ages, and has reached the "*sumum bonum*" of all knowledge. Scarcely twenty years ago Sir John Erichsen declared that, "operative surgery had nearly reached its furthest possible limits of development," and that there were certain regions of the body, such as the brain, the heart, and the lungs, that "must ever remain inaccessible to the surgeon's knife." Goltz, Broca, Hitzig, Fritsch, Ferrier, Horsley and Macewen, during the last fifteen years, have solved many neurologic problems in cerebral surgery, and have recently created a new department in surgery. Under antiseptic precautions and a better knowledge of localized centers, the brain substance is dealt with as freely as any other structure. The motor, special sense, and cortical centers

are now well known, and were thus able to classify and localize brain lesions. We now operate for fractures of the skull, intracranial hemorrhage, abscess, epilepsy, tumors, insanity, imbecility, hydrocephalus, trifacial neuralgia, and sometimes even remove the Gasserian ganglion. We also evacuate pleural effusions, invade the lungs, and suture the pericardium, and even the heart itself. Tumors are removed from the liver, the spleen is extirpated, the great veins are sutured and tied, and the appendix—thanks to Parker and Fitz—is now successfully removed. The stomach is now opened and sutured, and the pylorus is dilated and partially or entirely removed. In August, 1897, Schlatter of Zurich successfully removed the entire stomach, which was extensively involved by cancer. Eight months later the patient had gained thirteen pounds, and was doing nicely until a metastasis of the original disease involving the mesenteric and other glands caused her death on Oct. 29, 1898, about fourteen months after the operation. This was the first case of the entire removal of the stomach with the survival of the patient. On Feb. 24, 1898, Dr. Charles B. Brigham of San Francisco successfully removed the entire stomach in a woman 66 years of age, for carcinoma. Seven weeks after the operation the patient was reported to be gaining in weight, and the condition "satisfactory in every respect." In May, 1898, Dr. George C. MacDonald of San Francisco removed the entire stomach from Jean Patriti, for cancerous involvement. Patriti has since regained his weight and health, and is said to be able to digest the ordinary articles of diet, without any discomfort or inconvenience. Cholecystectomy was first performed by Langenbuch in 1880. Pancreatic cysts are now removed, and Simons, in 1870, demonstrated the fact that the kidney is an accessible organ. A floating kidney is secured, cysts and abscesses are evacuated, calculi are removed, and sometimes even the kidney itself.

(To be continued.)

Correspondence.

Hamburg from the Medical Side.

HAMBURG, Aug. 15, 1899.

To the Editor.—Few Americans stop in Hamburg to study medicine. They rush off to Berlin or Vienna and then have the rare chance of finally finding what they want, or they work around until they are tired out or come across a real teacher. As for myself, with the advice of experienced friends, Hamburg was my first stopping place, and here I stayed for two weeks and never missed a day when I did not have a most valuable surgical clinic of from two to six hours.

Hamburg, without its suburbs, is the second city in Germany. From a clinical standpoint it is of the greatest importance and interest because it has the cosmopolitan population of a great commercial city doing a business with other cities in every part of the world, and its hospitals therefore contain examples of disease from every zone.

It is within eight days and within \$50 to \$100 of New York. Living in the city costs about one-half as much as in New York or Chicago. It is delightful for summer residence, rarely hot. During my visit in July the street lamps were not lighted until 10 p.m., and a newspaper can be read on the street until 10:30. The city is clean. Like Venice, much of the communication within the city is by means of canals. The medical student does not lack for opportunity for recreation.

The neglect and even ignorance of Hamburg as a place for medical study is apparently due to the fact that there is no university here. Until the Franco-Prussian War, Hamburg

was a Free City, and it still is less intimately attached to the Empire than most other territory. The city can not yet afford to undertake a medical school or university itself and the Imperial Government has enough universities on its hands already. Nevertheless, there are courses given in the various branches of medicine twice a year, at the Neues Allgemeines Krankenhaus at Eppendorf. These courses are based on the enormous clinic of the hospital. The next course begins Sept. 25, 1899, and continues three weeks. Each course costs \$3 to \$5. A student can get tickets for as many courses as he can attend to for \$20 or \$25, and he can live at a good hotel in the city for \$2 a day.

The new general hospital is beautifully situated in what was once a suburb of Hamburg, and a village called Eppendorf. It is one of the best examples of the detached pavilion plan of hospital building, so popular twenty years ago when this hospital was built (1884). It accommodates 2500 patients at a time and had during the past year about 3000 surgical operations. The surgical department of the hospital is in charge of Dr. Kimmell, who is to be remembered as the author of early works on the antiseptics of the hands, and a long series of valuable surgical contributions. The hospital is reached by street cars from the center of the city, in twenty minutes, 4-cent fare, and by boat and a short walk in forty-five minutes, for 2½ cents.

Prof. Kimmell gave me an opportunity to see him operate for the removal of a gall-stone in the common bile-duct on a man who served in the Federal army during the Civil War. The incision was slightly oblique from the beginning of the costal cartilages downward and outward, and directly through the rectus muscle. The gall-bladder was opened, emptied and closed; the adherent omentum and intestines gradually and carefully separated from the cystic duct, the border of the liver and the common duct. This seemed to open a small abscess, the border of which was a mass of gangrenous omentum. This infected surface was scraped and at last cut away, and then the denuded surfaces were brought together carefully and closed in by about two rows of catgut sutures. The common duct was then exposed by drawing up the ribs and the liver and pressing away the intestines and omentum with the hands. The duct was well exposed. No defect in it was demonstrated. The edematous and greatly thickened common duct was then opened with the scalpel directly over the impacted stone, which stone seemed to me to be in the middle or upper third of the choledochus. The duct was carefully emptied and sponged out. Into the open duct was inserted a long rubber drainage-tube about 1 cm. in diameter, and held fast there by catgut sutures, which were quickly inserted. The duct was closed tightly about the tube, also with catgut sutures. The tube outside the common duct was then surrounded with a bismuth iodized gauze and the injured omentum brought in contact with this tampon. The lower and upper corners of the laparotomy wound were then closed with a single story of silk sutures and the retracted gall-bladder was fastened into the middle of the wound by the side of the protruding drainage-tube and tampon by a number of catgut sutures. The temporary sutures, used in closing the gall-bladder after emptying it, were now removed and another long drainage-tube was passed into the gall-bladder and down into the cystic duct. This tube was carefully sewed to the protruding opening in the gall-bladder with catgut sutures, and the gall-bladder itself was tightly closed around the tube with the same material. The whole region was then covered with a large dressing. The operation was done in a most direct, quiet and masterful manner. The assistants were alert and sympathetic. One male and one female nurse, two direct assistants and two anesthetizers were the only persons present except five observers. Prof. Kimmell reached his own instruments, grasped his own sponges and threaded his own needles. Live steam was used in a small instrument steri-

lizer during the operation. Chloroform was the anesthetic, and it was well given.

As soon as this operation was over, the room was washed out with a hose. A young woman was brought in with a diagnosis of pyosalpinx. Dr. J. Schutz, one of the resident assistants, operated. The patient was put in the Trendelenburg position. The operation was neatly and skillfully done. A small ovarian tumor was removed from the right side and a thickened, distended and tortuous tube from the opposite side. It was a bloodless operation. Catgut ligatures were used. There was one assistant, two anesthetizers and the same nurses as before. The anesthetic was chloroform, given on the mask. The incision was long, four or five inches, and it was closed completely.

On a subsequent occasion I saw Prof. Kimmell operate on a man for the removal of stones in the cystic duct. He is accustomed, when he can remove all the stones, to perform the so-called ideal operation, which he has successfully carried out twenty-five or more times. In no case has there been any accident or necessity of opening the wound. In these cases, after the complete removal of the stones, the opening in the gall-bladder has been perfectly closed with catgut and the abdomen closed over it.

Prof. Kimmell is accustomed to use the Murphy button in intestinal anastomosis, and has had many cases where it made operating safe and easy.

In the wards of the hospital I saw two patients that had been operated on successfully for echinococcus of the liver. In one of these the diagnosis was quite obscure. The determining factor, however, before operation, was the statement of the patient that he was from Mecklenburg. This peculiarity seems to furnish all the cases of hydatid. In another ward I saw a case of echinococcus of the hip-joint cured by operation. This patient also came from Mecklenburg. Three cases of lupus of the face and nose, almost completely cured by the use of the X-rays, interested me very much. Two of these patients seemed completely cured. Prof. Kimmell informed me that he had treated twenty such cases successfully with no other therapeutic measure. The exposures are made at a distance of nine or ten inches, once or twice a day for fifteen to twenty minutes at each exposure. This treatment is kept up four to six months. The earlier patients suffered a few slight burns, but otherwise the treatment has been without accident. When we consider the unsatisfactory treatment of lupus in all medical and surgical experience, this seems to indicate a great advance in therapeutics. (v. Kimmell *Holländische Heilschrift* *behandlung des Lupus*, *München Medicinische Wochenschrift* 1897, No. 51.) At the Altona Hospital the X-rays have been used with equal success, both alone and combined with conservative surgical treatment. It seems to be reliable. At the old general hospital, the use of the X-rays on lupus has not been so successful.

Another case that is worthy of more than a passing notice was resection of three inches of the femoral artery for sarcoma. The operation had been performed fourteen days previous to my visit. The foot and leg were warm and comfortable. In the course of this operation it was found necessary to remove a portion of the artery. Rubber-protected intestinal clamps were put on the artery, which had been exposed for a considerable distance above and below the tumor. The tumor and the surrounded artery were then removed. The distal end of the artery was then closed with sutures, and the proximal end was drawn down and implanted in a slit in the side of the distal portion in the manner suggested by Dr. Weller Van Hook for the ureters. (*Surgery of the Ureter*, *JOURNAL*, vol. xvv., Nov. 16, 1895, p. 842.) As soon as the clamps were removed the leg, which had become cold and blue, instantly became pink and warm. Sufficient length of artery was obtained by slow gentle pulling and by flexing the leg. This seemed to me a

most brilliant surgical victory. It is the first case treated by that method by Kümmell, and added only twenty minutes to the duration of the operation. In a similar case the crural vein was treated in the same way with equal success. Prof. Kümmell has made several side-to-side anastomoses of large blood-vessels, but he considers this method preferable.

In all his operating, in his treatment of assistants, nurses and patients, Prof. Kümmell is ideal. He is a kind, gentle but strong and masterful man. When he came into the children's ward they gave him a shout as salutation, and a number of the children held on to him as to their fathers. This is not according to our ideas of the German physician, but he seemed to have the entire confidence and sympathy of his assistants and nurses, and in all he was most unassuming.

At the Altona Krankenhaus, which takes care of the 120,000 laborers of Altona, when they are sick, and is truly a city hospital, it was my privilege to see Prof. Fedor Krause in company with Prof. Keen of Philadelphia. This hospital has about 3000 patients, and 1400 surgical operations are performed each year. It is admirably located in a beautiful garden, and is compactly built. It is thoroughly equipped with every adjunct to medical and surgical treatment. Prof. Krause will be remembered as the author of a monograph on the extirpation of the Gasserian ganglion for a facial neuralgia, and of the volume of "Deutsche Chirurgie on Tubercular Diseases of the Bones and Joints," the second and greatly enlarged edition of which has just appeared. He is a genial and attractive man of about 40, with a quick eye and ready hand. His technic is said by those who have seen much of his work to be direct and expeditious.

One of the most remarkable cases in the hospital at the time of my visit was a 14-year-old boy on whom Prof. Krause had four days before extirpated the urinary bladder for sarcoma, and implanted the ureters into the colon. The diagnosis was made by the cystoscope and suprapubic cystotomy. The bladder was removed by blunt dissection down to the ureters. These were ligated and the prostatic portion and urethra cut away. The seminal vesicles and ducts were left intact. This part of the operation was done without opening the peritoneal cavity, except for one or two minute tears which were immediately closed. The ureters could not be brought down to the rectum, so a coil of the sigmoid flexure of the colon was drawn forward and both ureters implanted in it. The cavity from which the bladder had been removed was then packed with gauze to stop the oozing from the prostatic and urethral portion. During the first day the urine was slightly bloody, but after that it was clear and contained only a trace of albumin; 1400 c.c. were collected each day, in a urinal between the boys' legs, by means of a rectal tube passed up to the sigmoid. It was a very impressive sight to see this large quantity of perfectly clear urine coming out of the rectum. The small trace of mucus was easily filtered out and then there was no albumin. The operation lasted four hours. Chloroform was used. The patient was in perfect condition when I first saw him. When the bladder was first removed it was carefully washed and the hole in the fundus completely closed. The interior of the bladder was then filled with formalin solution and stuffed and the distended specimen put in the same solution, to harden. It was a most perfect dissection. Both ureters could be easily seen and the nodular tumor covering and infiltrating over one-half of the bladder wall. When the boy was dressed the first time, ten days after the operation, the wound was clean, and was healing. The boy passed his urine at that time voluntarily by the rectum once every two hours. He was in splendid condition.

Both at Altona Krankenhaus and at the Neues Algemeines Krankenhaus in Hamburg there are separate pavilions for therapeutic gymnastics. At the latter a new pavilion for this purpose is now in process of construction and will be fitted up

about April, 1900, costing about \$50,000. This is a method of therapeutics which in America and England is much neglected. It is possible that the close connection between the Laborer's Insurance Bureau, referred to before, and the hospital has made this treatment necessary. The Imperial Government is bound to take care of the laborer until he is ready and fit for work again, therefore, the broken bone, for example, must not only be united but the muscles, tendons and joints must be in working order before the patient is discharged cured.

The construction of the gymnasium in use now is of a rather primitive kind. The fittings are those which may be found in all the club, college and Y. M. C. A. "gyms" in the United States, and a lot of special machines designed by the Swedish and German orthopedists.

Each machine is adapted to special purposes and can also be made to measure the progress of the cure. Each is adapted to active and to passive motion. The hand, for example, which has been stiffened by injury or infection, is strapped into the machine. The arm is immovable. The pendulum of the machine is made to swing a few degrees, as far as the patient can stand without much pain. This is recorded. For twenty minutes, or other interval, the regular motion of the pendulum is kept up. Then a little advance is made or the patient is required to use another machine or use the same machine in another manner. For office use there is a so-called universal machine. The separate machines are evidently better, as being simpler and adapted to the use of many patients at the same time. The use of these instruments is very satisfactory to the patients. The rhythmic motion of the pendulum, and the gradual manner in which the breaking up of the adhesions and the restoration of circulation and nutrition in the part is accomplished and the recognition of the progress of the repair secures the co-operation of the patient.

At the Eppendorff Hospital I saw some, to me, novel machines. One was a bottomless hopper in the middle of a box of moist sand. The hopper was about as high as a wagon-box. This is used to secure and demonstrate the ability to shovel. Another peculiar "machine" was a flight of steps and a row of sandbags of graduated weight, from fifty to two hundred pounds. These were used to prepare the patient for labor of that kind.

I was told by the editor of a labor paper that the laboring classes are turning against the regularly educated medical profession everywhere in Germany, and resorting to the water and massage methods of treatment. This man was himself educated in medicine, and yet he was not able to explain the phenomenon. One of the books that seems to be most popular and influential, published by a Dr. F. E. Belz, was shown me. It contains 1900 pages, poorly and cheaply illustrated, and is sold at 10 marks—\$2.50. It advertises a sort of sanitarium at Radelbein near Dresden. The book itself resembled any one of a dozen so-called "Family Medical Advisers," which flood our own country. In my subsequent bicycle tours throughout Germany and Austria the popularity of this so-called *naturheil kunde* has been impressed on me. I often stopped in small villages over night and became acquainted with many people. It seems to be a strong movement, and perhaps began with Father Kneip.

BAYARD HOLMES, M.D.

PROPOSED UNIVERSITY OF LONDON.—The proposed University of London, which will have a large medical, and probably also post-graduate school, has at last secured a home in the fine buildings of the Imperial Institute. The Institute lies just north of the famous Natural History Museum at South Kensington, and is in much the same style and an even larger building. This not only provides an appropriate nucleus for a great school, but is also easy of access from all parts of London, and near to the art, architectural and science museums and schools which have made Kensington a household word.

- 1. Phantom Tumor.—After discussing the literature briefly and their supposed causes and nature, Fitz shows that in recent literature reports of phantom tumors are rarely to be found, while a large number of cases have been published closely simulating this condition, in which the tumor is supposed to be permanent enlargement of the colon. The object of his paper is mainly to show that an increase of the size of the colon occurs at times without any organic or mechanical cause other than fecal accumulation, and that this may be sufficient to

produce discomfort, demography, and even death. These idiopathic dilatations of the colon have been described in a recent article by Treves, who thinks that they are due to actual mechanical obstructions in the terminal part of the bowels. Nevertheless, some recent examinations have not found such stricture, and Fitz thinks it would be more in accordance with the facts to recognize two types, one due to a defective development producing its disturbances from birth, and the other presumably those in which defective expulsive power is the prime factor. Those that have been observed in adults are connected with the same general conditions as in this last variety of infantile dilatation. Fitz reports a case which seems to him to support his view that chronic phantom tumor is rather due to dilatation by gas or feces, and in which relief was only obtained by laparotomy and excision of the dilated sigmoid flexure. In this operation he followed the example of Treves, who had similarly relieved a patient from the effect of congenital malformation of the lower bowel.

2. Typhoid Cholecystitis.—Da Costa notices the seriousness of the complication of inflammation of the gall-bladder in typhoid and thinks that recovery may occur more frequently than has been generally supposed to be the case, our conclusions having been derived only from the severer cases. He reports three cases in which recovery occurred, two in soldiers and one in a child 8 years old, in whom the symptoms were quite severe. He had never seen the pain so marked as in this last case, and vomiting was incessant and jaundice pronounced. He was just on the point of calling in a colleague to perform an operation when improvement began and the child recovered. The treatment in the cases given consisted for the most part in the administration of fractional doses of calomel frequently repeated to combat the nausea, and the local use of ice and poultices. Counter-irritation with turpentine stupes and iodine may be used. Morphine hypodermically may be necessary for the pain, and, as in his recent case, the circulation may have to be supported by hypodermics of strychnin and digitalis.

3. Influence of Diet on Urinary Inflammation.—The experiments of Taylor were performed on himself, and eight separate diets were tried, each a period of six successive days: 1. A mixed normal diet with the avoidance of sweet-breads, liver and brains. 2. Diet of sweet-breads, no other animal proteins being taken, but bread and non-proteid vegetables as usual. In this there was considerable systemic disturbance, diarrhea, etc., subsiding, however, toward the close of the period. 3. A heavily proteid diet. 4. Purely vegetable diet without milk or eggs or any animal fats in cooking. He incidentally remarks that it is these latter that are the salvation of so-called vegetarians; without them the diet is bulky and revolting. Naturally a large amount of proteids in vegetable form will be required. 5. A milk diet. 6. A nitrogenous free diet, consisting of sago, sugar and butter. In this there was loss of weight, constipation and distinct loss of strength. After a long period of rest, Diet 7 was tried, a normal one with the addition of three cups of coffee and two bottles of beer, and 8, the same with a little more coffee and no alcoholics. In all experiments except the sixth, the total urinary elimination of nitrogen corresponded with the intake. This nitrogen represented the common proteid metabolism of the body, and had no constant relation with the nucleic metabolism, which is a lower specialized process, causing a small output of uric acid and purin bases. The common nitrogenous metabolism is a process of high specialization and produces a larger output of nitrogen in the form of urea and ammonia. Keeping these distinctions in mind, and that they may be decreased or increased independently, the worthlessness of the ratios based on the comparison of their results, like the urea-uric acid ratio is obvious. The urea, during the first experiment, averaged 90.8 per cent.; it fell to 82.3 per cent. on the abnormal sweet-bread diet; on the heavily proteid diet it was 90.1 per cent.; on the vegetable, 92 per cent.; 94.3 on the milk diet; 82.4 on the carbonous diet, and on the two last diets it was respectively 89.6 and 91.3 per cent. The average of the physiologic diets was therefore 91.3 per cent. of the total nitrogen, which is about 5 per cent. above the ordinary figures. He attributes this, however, to an individual peculiarity. The uric acid was lowest on the milk diet, 0.284 g. per diem; very little less on the carbonous diet, 0.273; on the normal, 0.364, on the heavily proteid diet, 0.456, and on the purely vegetable

diet, 0.462 g. The average, for the three days without the diarrhea, of the sweet-bread diet, 1.260 g., he thinks, represents the output most accurately, the excess being due to the large amount of nucleins in sweet-breads. When coffee and beer were added to the normal diet the uric acid rose to 0.721 g., just double the amount without these. He attributes this mostly to the coffee. The failure of the heavy meat diet to increase the uric acid is contrary to the English theories, but muscular tissue is not rich in nucleins, and it is only from nucleins and purin compounds that uric acid is derived dietetically. The large amount in vegetable diet is a heretical performance, but easily accounted for by the peas and beans which must form so large a part of a vegetable diet. The average of purin bases eliminated in the normal diet (Experiment 1) was 0.0249. During the sweet-bread diet there was but little change. Apparently all the nucleins in this diet passed into uric acid. In the heavily proteid diet there was a slight reduction; in the vegetable diet a still greater one. The first decided change was seen in the milk diet, 0.0112 g., and on the carbonous diet of the next period (6), the bases fell to 0.0066 g. As soon as coffee and beer were added, as in 7, they rose to 0.0544 g. a day, and in Experiment 8, without beer, even a little higher. Obviously caffeine has been eliminated as a purin base. These figures confirm Krueger and Salomon's findings, who in a study of the purin bases obtained from the human urine found that less than one-third came from metabolism, while the other two-thirds belonged to the homologous series and were derived from xanthins ingested with the diet. Taylor's notes on the ratios between the uric acid and the bases are interesting, but not specially valuable. The ratios of the total nitrogen to the purin nitrogen are subject to about the same considerations as those of the urea uric acid ratio. They depend on distinct sets of conditions. He wishes to emphasize the distinctions between the common nitrogenous and the nucleic metabolisms by these facts. The experiments are to be considered physiologic, and have no special bearing on the physiology of gout in his opinion.

4. **Pyocyanus Bacillæmia.**—Brill and Libman report a case of septicaemia confirmed by blood culture in which the staphylococcus invasion was followed during life by a pyocyanus invasion, also determined by the blood. They review the cases in literature and find that this is the second on record in which the pyocyanus bacillus was found in the blood during life in such a way as to exclude all doubt, and the first case in which it was found in an adult.

6. **Gastric Ulcer.**—The statistics of gastric ulcer in the Massachusetts General Hospital are carefully analyzed by Greenough and Joslin, with the following general conclusions based on the study of 187 cases of gastric ulcer occurring in the Massachusetts General Hospital, 1888-1889. 1. Gastric ulcer is more frequent in Boston than in Chicago, Baltimore, Denver or San Francisco. 2. It is five times as common in women as in men. 3. The average age in men is 37 years; in women 27. 4. Hemorrhage was present in 81 per cent. of the cases. It caused the death of 17 per cent. of the male patients, but only 1.27 per cent. of the females. No woman under 30 died of hemorrhage of gastric ulcer during this period. 5. The blood was that of a chlorotic type of anemia. 6. Perforation occurred in 3.2 per cent. of the cases, and none of these patients left the hospital alive. 7. Of 114 patients 80 per cent. were discharged cured or relieved, but at the end of an average period of five years only 40 per cent. remained well. The mortality at the same time—due to gastric disease—was 20 per cent. Among the males it was 30 per cent., with the females 9 per cent. 8. The excessive mortality of ulcer among men, its occurrence in life a decade later than in women, and the absence of fatal cases of hemorrhage in females, point to a difference of the ulcer in the two sexes. 9. The mortality of 8 per cent., and the failure of medical treatment to effect a lasting cure in 60 per cent. of the patients indicates the need of surgical intervention in other than emergency cases of this disease.

11. **The Varying Type of Paresis and Ataxia.**—In an article last year, Mendel called attention to the changes in the characteristic features of paresis as distinguished from the classic descriptions of early writers and those generally observed two or three decades ago. He notices a marked increase in the demented type, a greater frequency of remissions and an apparent arrest of symptoms, its greater frequency in the fe-

male sex and its appearance in the young. Nowadays, he says, we make a diagnosis by the pupillary immobility, altered knee signs, analgesia of the legs, changes in disposition, speech and writing. Hughes says that these changes in the type of paresis are beyond question, and asks how we are to account for them. He believes that it is by the precocity and more general diffusion among all classes of people of business ambitions and schemes, excess and overstrain, the spread of intemperance and the constantly increasing rush of modern life.

12. **Legal Disabilities of Natural Children.**—Spitzka, in a curious article with a large number of interesting historic notes, maintains that the legal disabilities of bastards are actually justified, notwithstanding their apparent hardships, by social and historic conditions. His article gives a large number of instances where illegitimacy has been an evil to mankind as well as to the unfortunates themselves.

16. **The Pauper Inebriate.**—Certain statistics of inebriety and crime are discussed by Dr. Mason, and after general consideration of the social and legal status of the habitual drunkard he takes up the special points as to the care and treatment of inebriates: 1. Pauper inebriates, he holds, should be recognized as the wards of the state, and their care and maintenance should be provided for. 2. They should be isolated as a distinct class as the insane and criminal are isolated. Neither the asylum nor the prison is the proper place for them. They should be sequestered by law for a long term, at least two or three years, and the directors of the institution should have the privilege of giving tickets of leave or parole, as in the insane asylums. The asylum or place of restraint should be a strictly remedial and reformatory institution, with large tracts of land and means for educating the inmates in various manual trades and occupations. The clerk or bookkeeper who has become an inebriate will find, as a rule, serious difficulty in regaining work, but if he has learned a trade comparatively few questions will be asked. The inmates should be graded and classed. Dr. Mason thinks that well-established state institutions for the care of such inebriates would greatly decrease the number of insane annually treated in the state institutions.

17.—See abstract in JOURNAL, June 10, p. 1322.

19. **Pathology of Alcoholism.**—Grosvenor, after discussing in detail the known facts in regard to alcohol and its effects on the body, concludes as follows: Scarcely any disease, perhaps none, exerts so extensive a pathologic influence as alcoholism on the organs, tissues and fluids of the body. The paralyzing effects of alcoholism extend throughout the nervous system from its periphery. This paralytic effect is seen not only in the body but, in the intellect and moral sense. The principal degenerations in alcoholism are fatty, fibroid and atrophic. Fat is substituted for normal tissues; alcohol withdraws water from the tissues, and thus they become dry and hardened, and at length assume a fibroid character; through lack of proper nutrition the cells become shrunken and atrophied. By these degenerations the anatomic integrity of the organs is destroyed, partially or wholly, and their functional activity is impaired. Thus the whole system suffers and in time becomes a wreck. Alcohol has been aptly termed "the genius of degeneration." So profound and widely disastrous are the pathologic results of alcoholism on the individual and the race, and believing the disease may be placed properly in the list of preventable diseases, it is his firm conviction that it is the bounden duty of the medical profession, sanitarians, and the boards of health to use their utmost efforts for its complete eradication.

23. **Pott's Disease and Its Modern Treatment.**—After presenting the various methods of the treatment of Pott's disease, McCurdy outlines the following rules:

1. For the mechanical support of Pott's disease below the seventh dorsal vertebra, the plaster-of-paris jacket of Sayre is the best support now known.

2. It should be worn day and night, from the earliest incipency, until all active symptoms have subsided and convalescence is well advanced.

3. During convalescence the Taylor brace is to be preferred.

4. For cervical diseases, the brace shown makes ample support.

5. For upper dorsal disease the plaster-of-paris jacket, with anterior chin shelf, is to be preferred.

6. Finally, when cases are placed upon proper treatment

early, and such treatment is continued throughout the entire course of molecular disintegration, absorption and reproduction, cases should recover without deformity, in all variety of disease, except in upper seventh dorsal vertebra, and in this region with a minimum of deformity.

24. Cerebellar Abscess.—Crombie reports a case in a girl aged 11 years, who had acute inflammation of the middle ear with symptoms indicating brain trouble. As long as she lay on her right side she felt no pain nor distress and had a good appetite, but turning on her back or left side, or sitting up caused intense dizziness and vomiting. Her temperature was normal, pulse 78, pupillary reactions correct, visual field normal and no ocular paresis. There was slight edema about the right eye and the urine was strongly albuminous. Later the edema became more marked about the eye and the right side of the face, so that the eye could not be widely opened on account of it, and was thought to be more protruded than the left. She finally died of respiratory failure after having had several convulsions, apparently hysterical. The post-mortem showed edema of the scalp, an excess of fluid in the cerebral cavity, an abscess containing about one-half ounce of greenish pus in the anterior part of the base of the cerebellum, terminating at the point of adhesion of the temporal bone. On the inner side of this abscess, communicating with it, was another about half as large. In the posterior inferior lobe was a third abscess the size of a walnut and a fourth and smaller abscess lay mesial to the third. These latter did not communicate with each other nor with the first. Remarkable on the diagnosis, the Doctor remarks that if they had ventured to operate they would have opened the mastoid and found it healthy. They might have punctured the sinus with a like result, and explored the attic and tympanum without finding lesions, and then operated on the cerebellum at the usual site to evacuate one abscess and leave three.

25. Treatment of Appendicitis.—Gibbon's paper is a strong plea for operative treatment of appendicitis. As regards the operation, he prefers Dr. McBurney's incision as being surgical as well as anatomic in every sense.

26. Stricture of Rectum.—The newer methods, according to Beach, have made the rectum no longer an unknown region. Its stricture requires early recognition and the normal anatomy must be understood, but more especially the rectal valves demonstrated by Dr. Martin of Cleveland. Many so-called strictures of the rectum are hypertrophied valves and can be treated in a radical manner. He believes that the use of the proctoscope for complete inspection of the rectum should become the routine practice as it is most important in the diagnosis and location of stricture of the abdominal rectum. The rectal valve must be considered in the pathology of semilunar, annular and tubular strictures, and obstipation is the result of semilunar stricture, and can be cured by valvotomy.

27. Cleaning the Hands.—Forbes recommends a contrivance which he called a Job, consisting of three ounces of curled horse hair rolled up into a flat oval mass. He claims that this thoroughly cleanses the skin by rubbing, and is easily cleansed with boiling water before and after each surgical operation. Kept in alcohol, it is ready for use in the hospital or elsewhere. He called it a Job for, like Job of old, having passed through all the tests, its vitality and integrity remain unimpaired.

28. Atypical Features in Common Nervous Diseases.—Diller briefly calls attention to two or three leading symptoms of apoplexy, tabes and paresis. In the former disease, cases unattended by hemiplegia are not so rare, and the text-books that seem to imply that this symptom is constant present an incomplete picture of the disease. Sudden unconsciousness in persons over 50 years of age, with flushed countenances, is probably due to apoplexy and should be looked into. Probably many of the slighter apoplectic attacks are mistaken for fainting spells, and the reasonable prophylactic measures are neglected. The symptom of staggering, so characteristic of tabes, is really much less conspicuous or absent in many cases. Diller believes that failure to recognize tabes is more often due to the absence of ataxia than to any other one symptom, and it would be a safe rule to take tabes into consideration in any patient complaining of pains in the legs, arms and epigastric region in which the cause is not apparent, and the Argyll-Robertson pupil and epigastric pains in combination are very characteristic of

this disease. Staggering has frequently led to the diagnosis of tabes where it did not exist. Delusions of grandeur suggest paralytic dementia, but it is a great mistake to depend on this symptom. They are probably absent in the majority of cases at certain stages of the disease, and are less common now than in years gone by.

29. Slight Ailments of the Eye.—The chief point of Allyn's article is the fact that the eye is never out of danger until perfectly well. The slightest injury is not a trifling matter.

30. Normal Movement of Eye Muscles.—The object of Willett's paper is to advocate the necessity of correcting not only the errors of refraction but all lack of ocular muscular balance in neurasthenic individuals. Individual cases are not to be judged by the appearance of the deviation, as a thorough diagnosis can not be reached until we determine which of the many complex functions of the neuromuscular apparatus is deranged. It is an important fact that while the defective actions of other organs are readily apparent, often the ocular defects are not, the patients themselves having no knowledge of their existence. The constant unconscious excitation of the muscle nuclei to overcome this masked, untreated defect, affords a leak or consumes the necessarily small amount of nerve force generated, and the treatment instituted is generally deflected unless these errors are corrected.

32. Instruction in Pediatrics.—After noticing the importance of pediatrics as a study for medical students, Nothrup maintains that didactic lecturing is important and can not be superseded. Clinical instruction necessarily requires no argument as to its value. He advises section teaching by competent assistants in special departments or wards of children's hospitals, and as apparatus he believes in the use of the stereopticon. In conclusion he speaks of another requisite, that of recitation.

33. Pulmonary Hemorrhage Following Chest Puncture.—Koplik considers that the introduction of the exploring needle should not be considered as an entirely harmless procedure, though he has in the past so considered it. He reports several cases in which puncture was made and no fluid found. Where the needle enters directly into the substance of the lung, and causes a wound of a blood-vessel, hemorrhage results, and while in a child the puncture is not sufficient to overwhelm the air-passages, it is a sufficiently alarming symptom. He never punctures more than once at a sitting, after making certain of the exact place where fluid is likely to be found. It should be made with caution on the left side, either behind or in front, in the vicinity of the heart and great vessels.

35. Separation of Bacilli from Milk.—Freeman finds that with the rising of cream in milk, 99 per cent. of the bacilli are found in the cream, and sterilization of the cream, removed from the milk, the same being afterward restored, makes a comparatively germ-free milk.

38. See abstract in JOURNAL, May 27, p. 1172.

40. Ibid.

43. Physician, Priest and Patient.—This article gives the views of a Roman Catholic priest on ethical questions of medicine and the relations of the physician to the clergy. The physician can aid the priest by performing baptism in emergencies or giving notification of danger so that the priest may be called in, etc. He also dwells on the iniquity of abortion and means to prevent conception.

44. Contagious Skin Diseases.—Carrier notes some of the more common skin diseases that may be due to contagion, not merely those caused by hygienous germs, such as trichophyton, microsporion, and achorion, and the animal parasites, but also various pustular affections such as syphilis, eczema, sycoosis, acne, impetigo, etc. As regards eczema, it has not generally been considered contagious, but Unna's theory of a germ infection has been adopted by many dermatologists, especially for the seborrhoeic forms, and the author favors this idea and accepts it to the full extent claimed by Unna. Acne has been claimed by late investigators to be caused by a germ, but he holds this still unproved. He says in conclusion: 1. There are many known contagious skin diseases in which a proper prophylaxis is not exercised to prevent invasion of healthy persons. 2. There are many diseases of the skin that from their mode of onset and behavior are so similar to known contagious

affections, that the same means should be used to prevent their spread. 3. Pustular lesions, no matter in what disease they occur, must be regarded not only as antioinculcable, but as capable of developing similar lesions when transferred to healthy individuals.

45. **Some Gynecologic Deductions.**—Martin's paper consists of certain practical deductions from his experience in gynecologic work. He adds his testimony in favor of the use of warm saline solution after or during operation, when shock is feared, both by injection into the veins and tissues, and also by enema. A quart of this solution left within the abdomen has a very valuable effect in reviving the patient and stimulating the kidneys. He has had but 1 per cent. of postoperative hernias after abdominal operations, and he attributes this to the precautions taken the first month after operation, and the advice given patients. Patients are not allowed to sit up for three or four weeks, and the adhesive strips and outer bandages are worn for two weeks longer, and after that the patient is not allowed to do any heavy lifting, jumping, etc., for a year or more, and must wear a well-fitting abdominal supporter. He thinks that many retrodisplacements of the uterus are due to allowing the patient to lie, on the back too much after labor, and suggests advice as to changing position in these cases. Another cause of trouble is the lack of care after abortion, which should be as great as after labor at term. Still another cause of uterine disease is the lack of aseptic precaution in the use of aseptic uterine stems. He notes the special connection between neglected perineal laceration and irritable bladder, and insists on the importance of early perineorrhaphies. Other subjects noted in this article are: malignant disease of the ovaries, which is more frequent than was formerly held to be the case, and the necessity of operation; uterine fibroids, and cancer, the latter of which he attributes largely to cervical laceration and erosion; and deficient menstruation occurring in apparently healthy young women of sedentary habits.

47. See abstract in *JOURNAL*, May 6, p. 995.

48. *Ibid.*, April 8, p. 761.

50. **Sutural Closing of Visceral Wounds.**—Walker describes the purse-string suture recommended by Dawbarn for the closure of bullet wounds of the stomach and intestines, consisting in encircling the wound with a series of continuous sutures, each of which transfixes the serous and muscular coats, but not the mucous coats, the encircled tissue being then inverted and the knot completed. This is especially adapted to wounds of not over one-half inch diameter, and preferably in thin-walled viscera. Another method is the Czerny-Lembert suture, which has no superior for the closing of large visceral wounds, the continuous suture being speedier than the interrupted, but it is advisable, to avoid distortion, to employ both. In making an anastomosis of a hollow viscus, at least four separate threads should be used. Supposing an entero-anastomosis is to be made, let four Lembert sutures be formed by four separate threads, one inserted into both portions of the gut at the mesenteric junction, a second into the wall opposite the mesentery, and the other two into the lateral wall at points equidistant from the first two. Let the knots be so tied as to leave a long and a shorter end on each thread. The quadrants thus formed may then be approximated, one after the other, by continuous sutures, using for this purpose the long ends of the thread, which are finally tied to the shorter ends respectively next adjacent. A wound of this character, thus encircled by two tiers of Lembert sutures of sterile catgut introduced by small smooth needles will be found to be accurately closed and, barring complications, will afford a favorable prognosis.

51. **Gloves in Surgery.**—The advantages and disadvantages of cotton and rubber gloves are discussed by Graves, who rather favors the more general use of the latter. As to the general question as to the value of gloves, he has no doubt. They have come to stay, and, as a step in surgery, rank with the use of sterilized instruments and dressings.

53.—See title 154.

54. See title 87.

57. **Skin Clinic.**—Gans considers dermatitis venenata, paresthesia and urticaria.

59. **New Treatment of Tetanus.**—After going over the literature of cases of tetanus treated with antitoxins, both in the ordinary way and by intracerebral injection, Lanphear

concludes that: 1. In wounds of such character that the onset of tetanus is feared, preventive injection of tetanic antitoxin is advisable. 2. When symptoms of acute tetanus arise, hypodermic injections of 10 c.c. or more of serum should be given every six to twelve hours. 3. As early as possible a competent surgeon should be called to trephine, under strictest aseptic conditions, and inject 6 c.c. of concentrated serum into the brain. 4. In tetanus neonatorum appropriate doses should be given subcutaneously, and into the brain substance through the fontanelles. 5. Combined with the serum treatment should be the free use of those sedative agents which have been found of benefit prior to the introduction of serotherapy.

61. **Radical Treatment of Congenital Hernia.**—Roach insists on the importance of early treatment of congenital hernia, and advocates the Bassini operation as the most suitable for this purpose. He expresses his surprise that so many people go on through life wearing a truss with the continual possibility of a strangulation occurring, instead of permitting an operation to give them relief and comfort for the rest of their days.

62. **Sarcoma Treated by Toxins.**—Nicholson briefly reports four cases of sarcoma where the diagnosis was confirmed by skilled pathologists, and where operation was impracticable on account of the extent of the growth, in which he has used the erysipelas and prodigious toxins. In three of the cases the results were good. In one there was some reaction after injection, but no change in the growth.

63. **Endometritis.**—Murphy's article treats of the management of endometritis, and advocates as a general practice Munde's method of cervical dilatation, curetting and packing, with subsequent treatment with nitrate of silver or iodized phenol, and with hot vaginal douches throughout the treatment.

64. **Distortion of the Skiagraphs.**—Remarking on the occurrence of distortion by position and normal distortion of the image of the X-ray, Roberts insists on the importance of the use of Dennis' fluorometer for their correction. It consists of right-angle devices impervious to X-rays, together with wooden supports and an adjustable table, and it provides: 1, a perfect shadow when thrown on a screen or sensitive plate; 2, elimination of the distortion resulting from radiant energy known as the X-rays; 3, the normal distortion and distortion by position having been eliminated, the fluorometer provides an accurate cross-section of the body and supplies an absolutely correct right-angle at the intersection of the lines of which the foreign object will be found in the body. He adds, as a final conclusion, that without the evidence of a fluorometer having been used, clearly shown by its own shadows in the radiograph, no X-ray picture should be admitted in court.

68. **Exercise Cure in Neurasthenia.**—Holden reports a case of neurasthenia, with a possible traumatic element, treated by regulated exercise and nutrition, which resulted in a complete cure. He points out that the rest cure in such a case as this would have been decidedly bad treatment.

70. **Spread of Tuberculosis.**—Goldie has repeated some of the experiments of Flugge as to the dissemination of bacteria by coughing. Using a room where tests showed the bacillus prodigious was lacking, he washed his mouth with a culture and gave twelve coughs. Prepared plates were exposed in different parts of the room, at the end of five, ten and fifteen minutes for five minutes each, and all the plates showed varying numbers of colonies, thus demonstrating that a single act of coughing might so infect a room in every part that cultures could be produced from the air. In concluding his paper he calls attention to the risk of surgeons infecting wounds, especially in case they have any disorder in the mouth.

81. See abstract in *JOURNAL*, May 27, p. 1175.

87. See title 54.

89. **Lecture.**—Patton here considers hydrothorax, hemothorax, chylothorax and tumors of the pleura.

95. **Cancer of the Stomach.**—Graham concludes, after an analysis of the best established physiologic and chemical views in regard to the diagnosis of cancer of the stomach by chemical means, that careful investigation has brought us no pathognomonic symptoms, that we must consider carefully all the circumstances of the case in order to make a proper diagnosis, and that experience in the handling of cases has not yet been superseded by ready-made tests that make a diagnosis for us.

104. **Early Diagnosis of Pulmonary Tuberculosis.**—Gordon calls attention to the importance of early diagnosis, if possible, in pulmonary tuberculosis, and remarks on the difficulty, noting that the microscopic methods were utilized over thirty-six years ago when the elastic trabeculae were considered diagnostic by Clarke and others. The fact that the disease is curable if taken early makes this a matter of great importance, and though early symptoms may not be of very much use, he alludes to those that may serve to some extent as guides. An inherited tendency should put the physician on his guard. Pain may often be complained of before any other sign. A slight rise of temperature, especially in the afternoon, may exist early and be very important. A cough without expectoration and any general failure of strength, or loss of weight or appetite should at once lead to a careful physical examination. Bronchophony is also one of the early signs. Hemoptysis will generally be preceded by some of these other signs, and he alludes to the use of the X-ray as promising in this regard. The general treatment seems to be resolved into the use of fresh air and the most favorable hygienic surroundings. He speaks well of the use of creosote, however, in his own practice. As regards the location of the health resort for consumptives, he gives figures from the *Practitioner* of June, 1898, which seem to show that high altitudes give the best results. He favors compulsory notification as of great importance, enabling health officers to locate cases and to disseminate information as to precautions, disinfection, etc., admitting, however, that it may produce hardships in individual cases.

106. **Nephritis Without Albuminuria.**—Jennings reports two cases of nephritis accompanied with an abundant discharge of casts, but without albuminuria, and discusses the literature of the subject. From the writings of these authorities he finds it shown: 1. That very rarely chronic parenchymatous nephritis has been observed in which albumin and casts have been absent from the urine for certain periods of time. 2. That chronic interstitial nephritis is characterized by a urine in which albumin and casts appear in smaller quantity, and that frequently both disappear for short or long periods of time. 3. That the appearance and disappearance of casts and albumin in nephritis are synchronous—in other words, that the pathologic changes that cause albuminuria and cylindruria are identical. Simon is particularly emphatic on this point.

110. See abstract in *JOURNAL*, June 10, p. 1320.

112. See abstract in *JOURNAL*, July 8, p. 101.

114. **Urethritis.**—Patton gives his ideas as to the treatment of urethritis, which in most cases may be considered as specific. He thinks that local remedies combined with ordinary systemic tonics are most effective, and the so-called specifics have little real curative value. He remarks on the unreliability of the subjects of this disease as regards their statements or their co-operation in the treatment. A prescription which he has used largely for hospital and private practice as an injection is: Aque picis liquide, 16 oz., and zinc oxid, q. s., triturated together in a mortar until the solution is neutral to test-paper, and then filtered. He has used before, in many cases, a solution of 4 grains of permanganate of zinc in a quart of hot water. If this does not succeed after seven days he uses the tar prescription. As regards chordee, a drink of a pint of any warm demulcent tea containing 30 grains of nitrate of potash will almost invariably prevent its occurrence. A well-fitting suspensory bandage is a very important element in the treatment, especially in the prevention of epididymitis.

115. **Malaria in Children.**—Remarking that the subject is not less important from a social than a medical point of view, since malaria not only increases mortality but produces mental and physical deterioration in the growing children, Moncorvo gives some of the results of his experience in Rio Janeiro, in a total of 5000 cases of malaria in children of various ages. He selects the 513 cases occurring during the years 1891 and 1892, and finds that it is most frequent during the first year of life. His experience in this respect does not vary greatly from that of other observers. He upholds the view that it may exist in the prenatal condition, and reports several cases in which children were born with enlarged spleens and symptoms of paludic intoxication. He also finds that in his cases the majority were boys, and more than half came from the working class quarters, where the sanitary conditions were least favorable.

The greatest number of cases occurred during the first three months of the year, which, it must be remembered, is midsummer in that hemisphere. The paper is to be continued.

117. **Night Terrors.**—Morgenstein reports a case of a child who suffered greatly from night terrors, and he found that threats of the devil coming to take him away were the basis of these disturbances. The moral is that mothers should not frighten their children when they misbehave. There is generally in these cases some gastro-intestinal derangement co-existent with the attacks and tonics and aperients, with light wholesome diet, will generally suffice for medical treatment.

120. See abstract in *JOURNAL*, June 3, p. 1254.

122. **Repair of Perineum.**—Baker describes an operation claimed as devised by himself for repairing perineum rupture. He passes the tenaculum through the mucosa of the ruptured vaginal wall, in the median line, about 1½ to 2 inches above the posterior commissure. Then with a scalpel he makes an incision from the tenaculum downward and outward on both sides to a point where the parts are normally approximated. Next he makes an incision connecting these two points, thus describing a triangle, then denudes the enclosed space. Then, using silver sutures, he passes the first from either side of the denuded surface near the apex, bringing it out on the opposite side not too close to the margin, passing downward to the base with as many sutures as are necessary, being careful to allow a sufficient margin for a firm hold, and a flat surface for twisting the sutures. All the sutures are wholly within the vagina. The ends are left long enough to pass through a rubber tube to prevent laceration of other parts. Two or three superficial silk sutures are taken in the median line, which is the base of the triangle, the parts cleansed, dried and dressed antiseptically and bandages applied. He claims perfect success in the operation.

123. **Injections in Diarrhea and Dysentery.**—Lofton recommends the use of high injections of 1 to 6 per cent. solution of permanganate of potash in the treatment of diarrhea and dysentery. He gives these injections in the dorsal or Sims' position, with the pelvis elevated, the amount varying according to the patient's condition and the irritability of the gut. Injection is given very gently with a fountain syringe, and followed by gentle massage of the abdominal viscera over a dry heated flannel or woolen garment. Then the injection is removed and after fifteen or twenty minutes repeated with a milder solution, which the patient is instructed to retain as long as convenient. He cautions against the use of permanganate in cold water, as it will create intolerable tenesmus. The water should be as hot as can be easily borne. He reports two cases which he thinks illustrate the value of this method.

126.—See title 143.

127. **Mental Element in Treating Headache.**—Dr. Zener's paper is one presented in the symposium on Headache, before the Section of Neurology and Medical Jurisprudence at the recent meeting of the Association. He points out that the great influence of the mind in the cure of disease is becoming more and more recognized in the medical profession: "That knowledge is the key to understanding how sacred shrines and relics, new 'systems,' and vaunted remedies have effected and still effect, apparently marvelous cures, and succeed in imposing to such a degree on a credulous public. We are learning in the same manner, and this is of greater consequence to us, that many of the drugs, and other therapeutic agencies applied to the treatment of disease, often act chiefly through mental impressions. This influence of the mind is not limited to any one class of diseases. It is often observed, sometimes even marked, in organic disease, especially in the amelioration of some of its manifestations. Yet its greatest display of power is naturally to be expected in functional, and above all in nervous, diseases." He reports two cases of brain tumor in detail. The other papers of the symposium will appear in an early issue of the *JOURNAL*.

128. **Bacillus Icteroides in Yellow Fever.**—Sternberg replies, in his article, to Sanarelli's recent communication. He calls attention to some misunderstandings which he thinks Sanarelli has shown of his own statements and gives his reasons for not admitting the specific rôle of the latter's bacillus. He considers it a pathogenic saprophyte occasionally present in the blood and tissues of yellow fever pa-

tients, but its etiologic relation has not yet been established. He is open to conviction if his views prove erroneous.

129. See abstract in *JOURNAL*, May 6, p. 997.

131. **Calomel.**—Funch calls attention to calomel, which he considers a veritable king and giant among remedies, unique in its own peculiar action, irreplaceable by any other as a sedative eliminative, but brought almost into disrepute, limited to the treatment of syphilis, an occasional purgative, and an emipic use as an anti-emetic in children, without any explanation in the books as to its *methodus medendi*. He thinks that the faulty application of physiologic experiments to therapeutics in this case has wrought incalculable harm in limiting and discrediting the use of calomel as a therapeutic agent.

132. **Liquid Air.**—Pearce reports observations of the use of liquid air by Dr. A. Campbell White, in Lusk's dermatologic clinic. He believes it to be a specific in almost all forms of neuralgias. In sciatica the relief from pain is instant. He gives pictures of cases of erythematous lupus, epithelioma, cancrizing nevus, treated with liquid air.

133.—Abstract will appear in next issue.

134. **Pulse in Diagnosis and Prognosis.**—In this article Jackson calls attention to the value of the indications shown by the pulse in various disorders, especially typhoid fever and meningitis. In the former disease he has come to the conclusion that the pulse of 120 is a danger signal, and in meningitis when the vagus is stimulated the slow pulse is often of diagnostic importance. It is only seen in the early stages, as after the vagus has been paralyzed by pressure or by disease we have an exceedingly rapid pulse. The value of the pulse in prognosis in typhoid fever is very great. A sudden rise suggests hemorrhage, if accompanied by a fall in temperature. In perforation it is of the greatest value. It may be rapid in complications, such as otitis media and phlebitis, without rendering the prognosis unfavorable, but with acute inflammation of the parotid, prognosis is grave, more so, indeed, he thinks, than when pleurisy or pneumonia complicates the disorder. In convalescence the pulse is often rapid without any very serious import. He, in conclusion, calls attention to a symptom which has not been much noticed, viz., a discrepancy between the rate of the heart-beat and the pulse as felt at the wrist. This condition may be said to represent the acme of cardiac weakness, and it may be responsible for some of the cases in which a slow pulse is reported in fatty degeneration of the heart, or similar discrepancy and great dilatation of the heart in acute degeneration of the heart in infectious diseases, as in typhoid fever and diphtheria. He gives brief statements of two cases illustrating these facts.

136. **Improvements in Army Medical Service.**—Experience in the late war has suggested marked improvements in army medical service, which are summed up by Devine in the following paragraphs:

1. Physical examination of recruits; at first voluntary and now made mandatory.
2. Ration to be used at camp. Something after the pattern of army ration, but modified for adaptation to State service.
3. School for medical officers. One session annually.
4. Company bearers; four privates in each company specially trained in emergency and first-aid work.
5. System of red tape patterned after regular army, but modified for state service.

The following is a brief résumé of the suggestions offered to improve the efficiency of the army medical service. Some of them have been practically adopted by the Massachusetts Volunteer Militia, and it is hoped will be adopted by the entire National Guard:

1. That professorships of military medicine be established in every reputable medical college.
2. That until such time as professorships are established, the State provide a course on required subjects.
3. That physical examination of officers and men be made mandatory.
4. That troops at State encampments conform as nearly as possible to duties required in service on the field.
5. That every medical officer receive commission. (This pertains to contract surgeons.)
6. That one or more men in every company be detailed for regular instructions in ambulance corps, to prevent possibil-

ity in the future of the country losing the service of men especially trained for this service.

7. That one medical officer be selected in each regiment or brigade for his surgical ability.

8. That a corps of trained female nurses be organized in every state.

9. That divisional hospitals, in the broad sense, be abolished, and that small brigade and divisional hospitals be established for special cases, such as surgical and contagious.

10. That the volunteers follow, as closely as practicable, the regular army, so that when called into service together the two branches may work in harmony.

11. In addition to the present instruction in "first aid," a course in prevention of contagious diseases, etc., be given.

12. That a reserve staff of medical officers be formed in each state; said staff to be composed of ex-members of the medical department of the National Guard.

138. **Localized Tuberculosis of the Intestine.**—Mayo's paper calls attention to the subject of intestinal tuberculosis, and he reports seven cases operated on for this disorder. He also calls attention to the tolerance of operation in these cases and its benefits.

139. **Retroversion of Uterus and Functional Neurosis.**—Gardner concludes, after consideration of the subject, that uterine retroversion, while it may aggravate existing conditions, is not the primary cause of the functional neuroses sometimes attributed to it, and concludes her paper with the quotation from Dercum that: "There is no necessary relation between neurasthenia and pelvic disease. There is no relation between pelvic disease and hysteria even where the two affections coexist in the same case."

140. **Cerebrospinal Meningitis.**—Hirsh reports three cases of epidemic cerebrospinal meningitis, all diagnosed by a lumbar puncture, and he thinks that in one case the operation had decided therapeutic effects, while in the other two there was temporary relief. By relieving abnormal pressure and possibly getting rid of some of the toxins its beneficial effect can be readily conceived.

141. **Abdominal Injuries Due to Blunt Force.**—Three cases are reported by Fowler: One of rupture of ileac mesentery, with recovery, and another of rupture of the intestine treated by a resection and a Murphy button applied, with death. He reviews the symptoms in this class of injuries, calling attention to the special importance of temperature, pulse and vomiting. The latter is constant, but its significance depends on its persistency. As regards temperature, the diagnosis of grave intra-abdominal injury is made sure by a steady rise of temperature from the beginning, and in all cases by rise of the pulse-rate. If the initial symptoms of vomiting, temperature, etc., persist, especially the acceleration of the pulse, the diagnosis is fairly positive, and if in addition there is added marked increasing distension and steady increase of temperature the diagnosis is absolute. Operation must be early.

143.—See title 126.

145. **A Type of Tropical Fever.**—Von Wedekind's communication is in regard to a common type of tropical fever usually known under the name of calentura, which he noticed in all the ports he has visited during the dry season. Its onset is sudden, without prodromal symptoms, except perhaps a slight sensation of chilliness quickly followed by a high temperature, gradually increased until 104 or 105 degrees are reached. There are general myalgic pains, headache, loss of appetite, weakness with gastric disturbance. Without treatment the case will convalesce in about seven days. It occurs mostly in dry seasons; quinin is without effect, but aconite relieves the discomfort better than any other remedy. The exposure to the sun appears to be its cause, and avoidance of this will in almost all cases prevent the fever.

146. **Osteoplastic Surgery.**—Remarking at first on the greater demand of conservative surgery at the present time, Manley notices the methods of restoring symmetry in compound and complicated fractures. After some statements as to the necessity of paying attention to the individual condition and the danger of too early interference in way of premature rough handling, he advises the first effort to be in securing complete and permanent hemostasis, cleansing and covering the parts and placing them in comfortable position. Then he ad-

vises a delay of forty-eight hours before determining the future treatment, as the patient is then better able to bear with success what is needed to be done. It is impossible in many cases to operate so as to make an effective and complete replacement in primary manipulations. Frequently the desired result can only be obtained by secondary osteoplastic measures after union has taken place. He combats the rather established opinion that it is unsafe and inadvisable to make compound out of simple fractures; it is a mistake to assume that all compound fractures are slower in uniting than are simple ones. Under modern methods this is by no means always the case, and he says that free incision is justifiable for the purpose of treatment, but not for diagnosis, excepting in skull fractures. Secondary osteoplasty is one of the best achievements of modern surgery, and in medicolegal cases in the future involving serious fractures where the working value of a limb is to be estimated, the question whether all the resources of osteoplasty have been exhausted must be answered before any definite estimate of the extent of permanent injury is made. In conclusion he talks of the advantages of osteoclasis in acute angular deformity of the thigh, with shortening of the limb.

147. Angioneurotic Edema.—After a discussion of some of the literature of the subject, Baruch describes four cases of this disorder, two of which were distinctly traceable to intestinal autointoxication.

148. Malarial Hemoglobinuria.—Steggall reports three cases of malarial hemoglobinuria, and concludes from his experience that: 1. Quinin causes irritability of the kidneys and may cause hemoglobinuria. 2. Malarial attacks in chronic cases with malarial cachexia may cause hemoglobinuria. 3. In these cases quinin has lost much of its specific effect, and large doses must be exhibited. Should there be a periodicity, we must give the quinin before the time of attack. 4. The action of quinin must be assisted by such drugs as iron and arsenic, and, more important even than quinin, the liver must be acted on well and the effect kept up. He has never been able to cure an attack of hemoglobinuria without getting the liver active. The bilious vomiting in these cases sufficiently indicates the necessity of this.

149. Concealed Menstruation.—Brothers reports cases in which the menses disappeared at the age of 39, but the symptoms recurred at regular intervals and in very severe form. On examination a cystic tumor was found in Douglas' cul-de-sac, which was punctured through the vagina and a large amount of dark unclotted blood escaped. A second tumor also existed and laparotomy was performed; both specimens consisted of ovarian sacs communicating with the corresponding Fallopian tube. The openings at the fimbriated ends were completely obliterated. He was first inclined to think that, in accordance with Tait's theory, tubal menstruation existed shut off from the uterine and peritoneal cavities, and had discharged itself into the substance of the ovaries, but lack of typical hematosalpinx led him to believe that he was dealing with a case of primary menstruation into the ovaries.

150. Cutaneous Electrolysis.—Leviser describes his methods of electrolysis in the treatment of hirsuties, angioma, etc., and dwells especially on the importance of using the negative pole in operation. He emphasizes the fact that this is not simply cauterization, but may be better compared to a more accurate and equally distributed injection of a caustic solution.

151. Facial Eruptions Due to Intra-nasal Disease.—The point of Seiler's paper is that the swelling of erectile tissues of the lower or middle turbinated bones pressing on the capillary tissues of the septic mucous membrane produces disturbance in the circulation of the skin of the face, causing various eruptions. His observation is that since the introduction of cocaine as a local anesthetic into nasal surgery, and its unfortunate application by the laity for the temporary relief of nasal obstruction, it has largely increased the frequency of these eruptions.

154.—See title 53.

156. Conservative Gynecology.—Gorden's paper discusses, at some length, the so-called conservative and radical measures resorted to by surgeon-gynecologists. Conservative gynecology, it is pointed out, demands saving health rather than diseased or useless organs. The writer concludes that in all

operable cases, in women past the child-bearing period when uterine fibroid exists, hysterectomy is by far more conservative than myomectomy. Only in comparatively young women are we justified in doing a myomectomy when it is found necessary to make an abdominal section. Again, it is pointed out that fibroids are seldom single, and after myomectomy the development of an unsuspected fibroid is sometimes rapid, demanding a second operation. Myomectomy is attended by as high a mortality as hysterectomy; this conclusion is based on ninety cases of myomectomy with four deaths.

157. Complete Monocular Blindness, Recovery.—Posey's patient, while romping with another child, received a severe blow over the left eye; after thirty-six hours a severe pain developed back of the left eye, the sight gradually and progressively became dim, and resulted at the end of the fifth day in total loss of vision in that eye. The treatment followed was that of depletion; rest, leeches, salines, and a course of mercurial inunctions were resorted to; after three days improvement was observed; further treatment resulted in a complete restoration of sight within a few weeks. The lesion in this case was considered either a retrolabular hemorrhage or extravasation, sufficiently extensive to interfere the function of the fibers of the optic nerve. The writer considers it probable that as a result of the transmitted force attending the blow over the eye, the sphenoid bone was fractured, the roof of the sphenoidal cells being especially involved in the injury. This supposition is supported by the fact that the loss of sight began in the upper part of the field, which would indicate that the inferior portion of the nerve was first involved, the complete blindness which followed would indicate a gradual involvement of the entire nerve trunk.

158. Typhoid, Death One Week After Onset.—The onset of the symptoms was abrupt, delirium developed rapidly; cyanosis, clammy perspiration, rapid and difficult respiration, hyperpyrexia, cough and the physical findings at the base of one lung led to the diagnosis of lobar pneumonia. The patient was placed on a supportive treatment. The following day, some typhoid symptoms were observed. Under the suspicion that the diagnosis was incorrect, the Widal test was resorted to and the positive clump-reaction obtained. Subsequently the patient died; bacteriologic examination of the cultures taken at the time of autopsy showed typhoid bacilli in the spleen and mesenteric glands. Cultures made from the material in the bronchial tubes and lungs showed the presence of staphylococci. The anatomic diagnosis was typhoid fever and bronchopneumonia. The unusual extent of the involvement of the solitary and agminated follicles in the intestines is to be noted; the ileum, the colon even as low as the sigmoid flexure, was thickly studded with enlarged lymphoid nodules. The extensive distribution explains the violent short course of the disease. All intestinal lesions were in the first stage of swelling and infiltration; no ulcers were found. The spleen was greatly enlarged, and, together with the liver, had been displaced upward by the enormously distended intestines. The diagnostic value of the Widal test was well demonstrated in this case.

159. Acute Diabetes.—Three rapidly fatal cases of this rare disease are reported by Elsner. The first occurred suddenly, in a child of 5 years, a few weeks after receiving an injury to the head. There was great thirst, polyuria, and the urine, heavily loaded with sugar, had a specific gravity of 1042; within ten days the child died in a comatose state. The second case, also occurring in a child, but without any suggestion of head-injury, suddenly developed great thirst, voracious appetite, and glycosuria. The child died before the ninth day, comatose, with symptoms of acetoneuria. The third case occurred in a man of 45 years, who had enjoyed usual health. Within a few hours after exposure to cold and wet weather, he complained of dysuria, which was soon relieved by a continuous dribbling of the urine, hiccough, with mental hebetude. The bladder was enormously distended, and when withdrawn, the urine had a specific gravity of from 1015-1025, as much as five gallons of a 3 per cent diabetic urine being withdrawn in twenty-four hours. The disease terminated fatally within one week. There was no evidence to show that this patient had any pancreatic or other associated diseases, nor was there any hereditary tendency.

British Medical Journal, August 5.

Recent Advances in Practical Medicine. RICHARD DOUGLAS POWELL.—In his address in medicine, Dr. Powell notices the recent advances that have been made in instruments of precision and methods of diagnosis, modern studies in bacteriology, serumtherapy, preventive inoculation, the prevention of tuberculosis and the relation of soil to disease. The paper ends with a tabulated statement of the action of the different serums with reference to bactericidal, antitoxic, and prophylactic qualities. Among those decidedly antitoxic and prophylactic he includes the antistreptococcus serum and snake poison, and as of special prophylactic value, though not antitoxic, the protective serums of plague, cholera, anthrax and yellow fever. Tetanus is still somewhat in question, and the antitoxic action of the diphtheria antitoxin is, of course, understood.

Address in State Medicine. GEORGE WILSON.—The address of Dr. Wilson in the Section on State Medicine, before the British Medical Association, is notable for its antivivisection ideas, even going so far as to doubt the value of the diphtheria antitoxin. He claims that bacteriology has led us in false lines in assuming that the pathogenic microbe of any disease is the primary cause.

Etiology of Malarial Fever. GEORGE THIN.—The address of Dr. Thin gives one of the most thorough and complete statements of the insect theory of the origin of malaria, from the earliest speculations on the subject by Nott, King and others down to the completed investigations by Ross, Biggiani, Grassi and Bastianelli. In the concluding part of his paper he shows up the advantage of the military medical school at Netley for the study of tropical diseases, and expresses a hope that it may be opened to civilians in the near future.

Lancet, August 5.

Some Structural Varieties of Enlarged Prostate Relative to Its Treatment. REGINALD HARRISON.—Remarkable first on the different results from the various operations for enlarged prostate, Harrison states that there are at least three varieties of this disorder that are not uncommon, and yet widely different. In the first we have enlargement proceeding from blood engorgement, more or less chronic in its nature, so that the organ is somewhat assimilated with the erectile structure. In the second form there is a fibrous degeneration, and the symptoms are those of local irritation, such as in the case of vesical calculi. In the third form the enlargement of the prostate may be said to be self-contained, and consists of an almost isolated mass of tissue resembling an adenoma, which, like the kernel of a nut, easily shells out and can be enucleated. He asks what surgical or pathologic analogy there can be between these conditions, other than their location, and what good is likely to follow a uniform operation in all three cases? For the first form he thinks that vasectomy is indicated, while in those of the second and third, prostatectomy has been successfully practiced in many cases. Vasectomy, which is a comparatively harmless operation, has been found to greatly relieve vesical irritability and prevent the recourse to the use of the catheter.

Origin of Antitoxin: Is It Present in the Blood of Some Normal Animals? L. COBBETT.—In Cobbett's article, he is inclined to accept the "Seitenkette" theory of Ehrlich, that is, that there is in the cells a certain portion of protoplasm which has the power of entering into chemical combination with a given toxin. As regards the question whether antitoxin is formed out of its corresponding toxin, or is an independent product, it is as yet an undecided question, with the probability in favor of the latter. Cobbett reviews the experiments as to the existence of antitoxin in the blood of normal animals, and finds that in certain cases, especially in horses, there is in the normal serum a power of neutralizing the toxins of diphtheria. Whether this is due to the presence of a diphtheria antitoxin or not, it does not follow that it is a normal constituent of the blood. The fact that it is absent in many cases is against such a supposition. He asks whether it might not be of advantage to study the suitability of an animal for the production of the antitoxin, as we know that at present there is a vast difference in this regard between them. Whether the presence of antitoxin in the blood has any relation to this matter or not, he can not positively say, but he is working at the subject and hopes to make a further communication in regard to it.

Bulletin de l'Académie de Médecine (Paris), July 18 and 25.

Relations Between Dermatoses and Gastric Affections. A. ROBIN AND LEREDE.—This important communication is based on a study of 129 cases of cutaneous affections occurring among 422 dyspeptics. The fact is established that in all these cases there was a gastric fermentation with the formation of lactic or butyric acid. The excretions of these acids through the skin irritates the nerve-fibers in the skin and causes pruritus, prurigo, eczema, acne, etc. The acidity of the sweat is twice and three-fold the normal acidity, and constant, after jabardani has been administered. Thirty cases studied more closely showed that the metabolism was diminished, the elimination of nitrogenous matters imperfect and that there was less phosphoric acid, with a higher coefficient of mineralization. The therapeutics indicated by this conception of the autotoxidemic origin of dermatoses have proved wonderfully successful. One case, a man of 50, with diffuse prurigo and eczema which had resisted all treatment for twenty years, was entirely cured in two months, "very much to his surprise." The first step is to determine the character of the dyspepsia and treat it even when there are no clinical evidences of gastric disturbance. The next step is to note the general disturbances in nutrition and the special disturbances, if any exist, and treat them also: ammonium fluorid, if the gastric fermentation is due to lactic acid, and biniodid of bismuth and cinchonidin (erythrol), if to butyric acid. A strict sterilized milk diet may be required in certain old cases: local treatment as usual.

Transient Acute Aortitis of Malarial Origin. POTAIN.—It was objected to Lancereaux' communication in regard to malarial aortitis (see abstract in JOURNAL, p. 345), that the malarial infection was probably a mere coincidence in his observations. A convincing argument in his favor is the case now described by Potain, in which a young soldier in Algiers contracted malarial infection and for nine months had intermittent fever and diarrhea. Returning to France the fever recurred every second day. The heart sounds were distinct and clear, with no abnormal sounds. The area of total dulness covered ninety square centimeters. The portion corresponding to the aorta extended 2 cm. beyond the sternum. The fever yielded to quinin and the aorta gradually receded until it ceased to encroach beyond the sternum by the tenth day. This transient enlargement could not have been due to increased blood-pressure as this had been, and is usually, exceptionally low in intermittent fever, later returning to normal. The distension of the artery could only have been due to diminished resistance in its walls, and this diminished resistance to the malarial infection. Repeated or protracted infection is therefore liable to in time lead to specific alterations in the walls corresponding to the extent of the functional modification.

Ganglionic Pseudolymphadenic Tuberculosis (Tuberculous Lymphoma). P. BERGER.—"Histologic investigation is the only certain means of differentiating lymphadenoma from ganglionic tuberculosis, confirmed by inoculation and extirpation is the only certain treatment, although arsenical treatment and especially a course of Bourboule waters, may be tried if patients have leisure and means for it." The extirpation is generally easy, and free from much danger, as the engorged ganglia are encapsulated, circumscribed, and without adhesions to the cellular tissue and neighboring organs. It is only necessary to remove the ganglion or ganglia constituting the chief mass of the tumor, as the secondary engorgements frequently subside after extirpation of the rest.

Human Coccidiosis. CORNIL.—Three observations of tumors in the subcutaneous cellular tissue or scrofulous bursa are described, the tumors formed of a multitude of pockets filled with a yellow-brownish, creamy or viscous and mucous puriform fluid, containing yellow calcareous grains, fragments of capsules of coccidia or complete egg-shaped capsules or several egg-shaped bodies contained in a single capsule. The existence of coccidiosis in man is thus established. The cavities were lined with inflammatory tissue with a border of large giant cells. Cornil has previously noted the significance of giant cells as an indication of the struggle of the organism against foreign bodies, and particularly against small parasites.

Frequency of Herpetic Manifestations in Influenza-Grippe. VIDAL.—The frequent appearance of herpes, zona and herpetic manifestations on the mucous membrane of the mouth,

ears, etc., in the course of la grippe, in his experience, leads Vidal to enquire whether others have noted this coincidence and whether some of the la grippe symptoms may not possibly be due to a localization of herpes on the brain or internal organs.

Journal de Médecine de Paris, July 23 and 30.

Protracted or Recurring Diphtheria. H. BARBIER.—In the case reported, slight septic complications and evidences of bulbar intoxication recurred several times after apparent recovery; sometimes accompanied by the formation of pseudomembranes, and again not. Each recurrence yielded to serum treatment, which finally dispelled the infection. One of the most frequent and reliable indications of this diphtheritic bacillosis is tachycardia with weak and arrhythmic heart action. Barbier urges the necessity of serum treatment in these cases, even in the absence of all pseudomembranous neoformation.

Symphysiotomy Without Consecutive Immobilization. G. FIEUX.—The extremely successful results attained in a case in which symphysiotomy was performed when the fetus was in jeopardy, the heart beat 100, dull and irregular, induce Fieux to recommend the method followed, which was simply to carefully suture the coaptated parts and paint the wound with a little steresol—gum laquer dissolved in alcohol. No application of any kind was used, and the next day the patient could raise the buttocks and move her limbs without pain or effort, like her neighbors in the ward, and got up the fifteenth day. After the seventeenth day, she could go up and down stairs as nimbly as before the operation. The non-interference with the post-partum care is a special advantage of this simple method.

Nord Medicale (Lille), July 15.

Pernicious Malarial Infection, Failure of Quinin, etc., Cured With Hydrotherapy. G. LEMOINE.—The observation reported is noticeable on account of the absolute failure of all therapeutic measures and the prompt and permanent recovery after the application of the cold douche at 10 C., for six seconds to one minute, avoiding douching the region of the liver and the spleen. The patient, a man of 31, was robust until after a month at Beyrouth and an attack of influenza on his return to France, followed by the indications of pernicious paludism.

Presse Médicale (Paris), July 20.

Hysterectomy in Acute Puerperal Infection. T. TURFIER.—In acute postpartum septicemia without peritoneal or annex localization, Tuffier advocates hysterectomy as justifiable and no more difficult than any hysterectomy when the facts of the extreme friability of the uterine tissues and of the vessels are borne in mind. The rock to be avoided is cutting through the tissues with the forceps, which should be applied in stages. He has collected thirty-five observations, including three personal, of such cases thus treated, and the results have been that thirteen were saved although in an apparently hopeless condition. A number of the rest were probably beyond all aid, as any innovation of the kind is always first restricted to absolutely desperate cases. He considers the uterine muscular tissue the seat of infection and starting point for the toxic-infectious accidents in these cases without tympanism, pelvic sensitiveness, much vomiting or visceral infectious localization and no supuration found at the autopsy. In one of his own observations the temperature persisted at 41.5 C., even after curetting, irrigating and disinfecting the uterus, etc. It fell to 37 degrees in less than twenty-four hours after the uterus was removed by the vagina, and staphylococci and streptococci were found in scrapings of its inner surface. Prompt and rapid recovery followed.

Revue Générale d'Ophthalmologie (Paris), July 31.

Acute Optic Neuritis from Uricemia. ANGELUCCI.—A number of cases of uricemic optic neuritis are on record, but they have been classed with the manifestations of rheumatism. The symptoms of the retrobulbar form are the same in each. The reasons for assuming an uricemic origin are that the optic neuritis appeared in subjects with pronounced uricemia and progressed in spite of all the usual local remedies, but yielded promptly to salicylic treatment. In a few cases the uricemic manifestations coincided with the aggravations of the ocular affection. In each case the visual disturbance appeared abruptly, and the sight improved with appropriate treatment notwithstanding aggravation of the oph-

thalmologic signs. Another point is that in seven out of fifteen cases there was central scotoma.

Revue Hebdomadaire de Laryngologie, etc. (Bordeaux), July 22 and 29.

Chancriform Uleeromembranous Amygdalitic. RAOULET AND THIRY.—Study of several observations of this affection, which deceptively simulates both chancre and diphtheria, has demonstrated that it is an affection analogous to uleeromembranous stomatitis, and may possibly be only an unusual localization of it; that the amygdalitis is caused by a necrosis of the tonsil tissue extending inward; and that it is due to the presence of the spirillum and spindle-shaped bacillus described by Vincent. The three personal observations happened to be all medical students; two had a recurrence. In two cases of uleeromembranous stomatitis without tonsillar lesions, the same flora was found, also in a case of ulcerated gingivitis. The spirilla were found in a syphilitic chancre, but not the bacilli, which are always associated in the affection described. The bacilli are larger than the Loeffler bacillus, will not grow on serum, do not take the Gram stain and are often found end to end, with vacuoles. The usual methods of inoculation and cultures have failed, but mixed anaerobic cultures have recently been successfully grown.

Adenoid Vegetations in the Adult. JANKELEVITCH.—This puzzling case of adenoiditis with acute "pushes," accompanied by hemorrhages, and dry laryngitis, was diagnosed tuberculosis, until the vegetations were discovered and removed, when the hemorrhages and cough ceased, although some months were required before the laryngitis was completely cured. The patient was a butcher aged 29 years.

Berliner Klinische Wochenschrift, July 17.

Case of Tetanus Puerperalis Treated With Dural Infusion. E. V. LEYDEN.—The tetanus antitoxin was introduced directly into the spinal canal, and also injected subcutaneously, in a case of very severe tetanus consecutive to a traumatic three months' abortion. Improvement was evident at once, suggesting the greater effectiveness of the antitoxin when introduced into the nervous system direct.

Cerebral Tumor. JOLLY.—This observation demonstrates the benefits to be derived from simple trephining in case of inoperable tumor. An unusually large glioma of the right central convolution had grown through the skull. The patient was very much relieved and improved by trephining, and the improvement lasted a year. Excision was impossible on account of the depth of the growth.

Infectious Character of Chorea and Its Connection With Acute Articular Rheumatism. WESTPHAL, WASSERMANN AND MALKOFF.—Westphal reports observations of three girls with severe chorea, producing hallucinatory mental disturbances; in each case the chorea was consecutive to acute articular rheumatism, and acute endocarditis in one. Albuminuria and herpes labialis were also present. One patient, 19 years old, first had the acute articular rheumatism; a month later the chorea and herpes labialis appeared and death followed an extremely violent delirious state with high fever and collapse. The autopsy disclosed endocarditic deposits on the mitrals and fresh parenchymatous nephritis. Cultures were derived from the blood, brain and mitrals, which produced severe joint affections in rabbits, introduced into the circulation, as proved in eighty animals, and the same diplococcus, a kind of streptococcus, was found in the joint effusions. The incubation period was three to ten days.

Deutsche Medicinische Wochenschrift (Berlin), August 3.

Vascular Changes During and After Artificially Induced Anemia. A. BIER.—The hyperemia which follows release of an Eschscholtz tourniquet is usually attributed to a paralysis of the vasomotor nerves by the constriction, which causes relaxation and dilation of the arteries. Bier denounces this assumption and describes numerous experiments which demonstrate that any diminution in the arterial current in any part of the body, causing this part to be insufficiently supplied with fresh blood, materially reduces the resistance to the arterial current in this part. This decreased resistance is most conspicuous when the blood-stream is totally arrested for a while and then allowed free course again, and the result is extreme hyperemia. This diminished resistance is not a paralysis of the vessels in the usual sense, as it does not occur in the venous circulation. Instead of paralyzing, it stimulates

the arteries and capillaries to contract, and thus drives the blood out of them into the veins. It is this property of the vessels which produces collateral circulation until the arterial collateral routes are sufficiently enlarged, and it is a peculiarly useful and necessary vital process.

Improved Needle Holder for Curved Needles. V. SCHULTZ.—The jaws of an ordinary rack needle holder are hollowed out lengthwise inside, the concavity tapering to the point, which is sloped off obliquely. The edges of the lengthwise concavity and of the oblique ends are provided with fine teeth. The needle thus fits into the space and is held by two pairs of firm supports while the middle portion is untouched.

Muenchen Medicinische Wochenschrift, August 1.
Gonococcus Toxin and Its Action on the Nervous System. M. J. MOLTSCHANOFF.—White mice, rabbits and guinea-pigs injected with toxins derived from an unfiltered 20 to 25 days' culture on bouillon and hydrocele, heated to 70 C. for 15 minutes, to kill the cocci still alive, showed most distinct and pronounced alterations in the nervous system as the result of the action of the toxin. In cases of acute intoxication these alterations are most evident in the cells of the anterior cornua of the spinal cord, next in the cells of the intervertebral ganglia and least in the cells of the nuclei in the medulla and cerebral cortex. In cases of chronic intoxication the most prominent manifestations are symptoms of a degenerative neuritis, with occasionally degeneration of the posterior roots and posterior columns of the spinal cord. The toxins were injected into the abdominal cavity or a vein.

Capacity of the Urethra and Syringes. H. LOEB.—Investigation of fifty patients with subacute or chronic gonorrhoea and others resulted in the discovery that the capacity of the anterior urethra varies from 6 to 20 c.c. in different persons, healthy or diseased, although there are no external means of gauging its size; age, physique, appearance, are frequently deceptive. As it is necessary to adapt the injection to the capacity of the cavity, Loeb advocates determining this capacity for each individual case by measuring with a graduated syringe or irrigator, and then ordering a syringe for future injections of the exact size required. He uses a syringe holding 20 grams of a warm solution of potassium permanganate the piston rod graduated for centimeters. The filling urethra and increasing resistance indicate the moment when the anterior portion is fully distended.

St. Petersburg Medicinische Wochenschrift, July 8 and 15.
Pemphigus of Upper Air-Passages. R. OTTO.—In connection with a detailed observation of a case of chronic pemphigus of the upper air-passages, and of the conjunctiva, Otto asserts that the difference is not pathologic nor anatomic, but merely a difference in degree, between the bullous-exfoliating form of pemphigus and the adherent-fibrinous form. The favorite location for the former is the nose, soft palate, throat and larynx, with a tendency to extend to the conjunctiva of the lids. The second variety appears on the cheeks and tongue, extending later to the throat and larynx and leaving the nose and conjunctiva untouched. The terminal phases of the first variety are a thickening, shriveling and growing together of the membrane, while these processes have not been noted in the few observations of the latter variety on record. The bullous form affects weakly, and the other robust, persons. The one point in common with both is the chronic and obstinate character of the process. The etiology is still obscure.

Wiener Klinische Rundschau, July 2, 9, 16 and 23.

Sexual Perversion Among Insane. P. NAECKE.—The practical conclusion of this careful study of the hundreds of inmates of the Hubertusburg asylum in Saxony are that imbeciles and idiots should have separate institutions, as they far outnumber all the other cases of sexual perversion, and incite others to imitate or join in their practices, or more readily fall victims. Habitual criminals also should not be allowed to mingle freely with the other inmates, particularly the females, as they introduce new practices. Naecke considers it unproved that onanism can produce a mental disturbance per se. The disposition to extreme onanism is the first symptom of the encroaching psychosis. Sexual perversion is very rare among the cases of paralysis, and was only noted in a few instances of male onanism and exhibitionism, and female masturbation after excitement. Cases of homosexual perversion

were remarkably rare. He was unable to distinguish any markedly unfavorable influence of the onanism on the course of the mental affection in any case, "although the prognosis with excessive onanism is bad, as such an abuse can only occur in extreme degeneration, congenital or acquired. It may eventually render the mental affections worse, but this rarely happens." Prospect of improvement of the mental affection by breaking up the habit is only possible in fresh cases with incessant onanism, but all should be examined for phimosis, a too short frenulum, or inflammation of the genitalia, which may be the cause. Little can be accomplished with any except prophylactic measures; close supervision of the water-closets, no dark corners, no beds placed together, etc. Naecke thinks that much might be learned by comparison of such records from various institutions, with especial study of the dreams, etc.

Recurrence of Syphilitic Affections of the Eyes, and Means to Prevent It. GALEZOWSKI.—Twenty years of observations and tests have demonstrated that syphilitic affections of the iris and conjunctiva are cured as the syphilis yields to specific treatment, but that affections of the choroidea persist and recur as the last lingering manifestations of the infection. The only effective treatment is local friction kept up daily for two years, with a pause of four days after ten, but never over three weeks' suspension. His experience has been that the best preparation is of mercurial lanolin salve, from .5 to 2 grams, rubbed into a different spot each day. Potassium iodid is not only ineffectual, but is directly injurious, as it induces conjunctivitis, although it may occasionally be indicated to neutralize the effects of excessive specific treatment.

Wiener Klinische Wochenschrift, July 20 and 27.

Thread Formation in Serum. R. KRAUS.—The serum reaction noticed and called thread formation by Pfaunder (see *JOURNAL*, xxxii, p. 935), is a phenomenon which occurs with certain micro-organisms under the influence of an agglutinating serum, as confirmed by Kraus. But he asserts that agglutination invariably precedes it, and is of more constant occurrence. It is governed by the same laws as agglutination in general except in respect to the bacillus coli; a non-specific serum can produce both phenomena with this bacillus.

Uterine Myomata and Pregnancy. R. CHROBAK.—Myomata were found in 862 cases out of the last 30,000 patients at Chrobak's gynecologic clinic, or 2.8 per cent of the total. Of these, 284 were sterile; 148 had only one child. It is his opinion that myomata are not frequently the cause of sterility, but he considers statistics almost valueless in this respect, as we have "no even half-way reliable statistics for comparison, in regard to the fertility and sterility of marriages, as it is so uncertain whether conception is prevented or not." He has frequently witnessed the hypertrophy and retrogression of a myoma parallel with the development and involution of the pregnant uterus; in one instance a myoma the size of a nut increased to the size of an apple and then returned to its former size, four times in succession. But usually it does not subside. A case is described in detail in which the pressure of a subserous myoma, growing from the upper posterior surface of the uterus, had twisted the gravid organ on its axis. As the uterus had developed the tumor had been pressed down into the small pelvis. As term approached it was manually reduced and pushed up into the abdominal cavity, but symptoms of peritoneal irritation appearing, the child was safely delivered by abdominal Cesarean section and the myomatous uterus extirpated. Smooth recovery followed.

Abnormal Sweating. J. MAIRSCHLEER.—A peculiar case of neurosis is described in this communication, distinguished by abnormal functioning of the sweat center and nervous depression. The sweat drops form profusely in all weathers, but, strange to say, the maximum is in the coldest, the minimum during the hottest months. This hyperidrosis is limited to the trunk, face and upper extremities. Study of the metabolism showed retention of Cl, but this is probably only apparent, and the Cl is eliminated in the perspiration. The subject, a young Jew, is otherwise normal but feels too weak to work. The affection is of several years' standing.

Acute Lymphemia. F. PINELLES.—Examination of the blood of a woman of 73, presenting the clinical picture of

acute leucemia—death the nineteenth day—showed a proportion of 1 to 6½ for the whites and reds; 96 per cent. of the leucocytes were lymphocytes; 3.7 per cent. polynuclear neutrophils and 0.1 per cent. polynuclear eosinophiles. No nucleated red corpuscles were found. The lymph glands and spleen were much enlarged and the liver once and a half normal size. The composition of the blood, the hyperplasia of the lymph-forming organs, the proliferation of the lymphocytes and the severe lymphoid degeneration of the bone marrow, entitle this to be designated a case of acute lymphemia, corresponding with the cases that have been observed of chronic lymphatic leucemia."

Revista Medica (Mexico), July 1.

Explanation of Sleep by the Slowing of the Protoplasmic Currents. A. L. HERRERA.—Sleep, according to this author, is caused by a retarding of the protoplasmic or neuroplasmic currents—in which life consists—by a lack of nutritive fluids, by congestion, by anemia or by cold, and is the same in the infusorium as in man. The currents persist but they are slow and languid, and the process of slowing up and becoming active again is extremely gradual. His summary for all living things is: Nutritive currents with the maximum velocity: Active life. Nutritive currents (sap, blood, protoplasmic currents), periodically retarded by the lack of reserves which are expended during the day: Sleep. The same, less active during the day, from inactivity, nervous excitement or other cause: Insomnia. Currents retarded by the action of cold: Hibernation. Currents retarded by a lack of moisture or completely obstructed: Latent life. General co-ordinated currents definitely arrested by coagulation, intoxication, hemorrhages, asphyxia, etc.: Death. Herrera considers all the movements of protoplasm from the amebism of the rhizopods to the amebism in our brains, caused by an absorption of oxygen and a liberation of carbonic acid. He has succeeded in reproducing these supposed "vital processes" with a drop of printer's ink mixed with sodium bicarbonate and spread on a cover-glass moistened with tartaric acid, as he has previously announced.

Gazzetta degli Ospedali e delle Cliniche (Milan), July 9, 22 and 30.

Antagonistic Influence of Syphilis on Tuberculosis. I. MONTEVERDI.—The influence of one disease on another has long been recognized, but few if any instances are on record of tuberculosis absolutely cured by a fresh syphilitic infection, as in the observation here reported. The night sweats, high fever, cough and Koch bacilli in the sputa, were banished by a mild syphilis which readily yielded to treatment. Six years have since elapsed, with no recurrence of the tuberculous symptoms in the now robust young man.

Location of the Parathyroids in Man. C. GANFINI.—The upper parathyroids, corresponding to the inner ones in animals, are situated at the junction of the upper third with the two lower thirds of the posterior surface of the lateral lobes of the thyroid body, as Ganfini has established by inspection of forty cadavers. The two lower parathyroids in half of the cadavers, were situated on the posterior surface, near the lower edge of the lateral lobes of the thyroid. In the rest they were below this lower edge, and from a few millimeters to 2 to 3 cm. from it, and thus located on the lateral surface of the trachea, surrounded by the retrosternal adipose tissue. In six of these latter cases the inferior parathyroid was connected with the cranial portion of the thymus, either right or left. He considers that these six cases prove not only the origin of the inferior parathyroids from the thymus, but also that the thymus in its descent carries them down with it, and, as it atrophies, they remain closed in its residuum, the retrosternal fat.

Osmotic Tension in Exudations and Transudations. ASCOLI.—Comparative cryoscopic study of the organic fluids has established the value of the variations in the freezing point of the exudations and transudations as a means of differentiating certain affections.

Tubercular Intoxication. S. MIRCOLI.—The peculiar luster of the eyes, and the tendency to mydriasis in tuberculous subjects, indicate a toxic origin, to which Mircoli also attributes the psychic disturbances and impulsive actions. In one case he has observed mydriasis and paralysis of accommodation on the side opposite the pulmonary lesion. He mentions an observation of a young man with a slight local lesion, and extreme

cachexia, but no pulmonary symptoms, who reacted to a dose of .5 c.c. tuberculin more intensely than most persons to a dose of 50 c.c.

New Form of Anemia from Toxic Sera. ZENONL.—The serum of certain animals treated by injections of blood from animals of other species, became toxic for the animals from which the blood was derived. A few c.c. of this serum, injected into rabbits, produced a most acute form of fatal anemia, which fact may throw some light on the pathogenesis of primary anemia and of hematology.

Pathogenesis of Gout. CARBONE.—The assumption that gout is caused by a local hyperproduction of uric acid was practically tested by injecting urates into the spinal marrow, but without results. Injection of neutral urates or solutions of sodium biurates into the articulations also failed to produce inflammation or necrosis. But these phenomena were most intensely produced when adenin hydrochlorate was injected into the articulations. This aloxur base is produced from the nuclein in the bone marrow, in large quantities, and combines with uric acid to form a compound that is remarkably insoluble under certain conditions. Considering these two facts, in connection with Minkowski's recent assertions that he had produced uric infarcts in dogs by administering adenin per os. Carbone concludes that adenin must play a conspicuous part in the pathogenesis of gout. It produces necrotic and inflammatory processes in the tissues and binds uric acid in the form of adenin urate, which later becomes transformed into sodium urate.

Action of Venesection on Arterial Pressure. TREVES.—The arterial pressure and frequency of the pulse in twenty-seven subjects were studied with the sphygmograph before, during and after venesection and cupping. It was found that neither are capable of diminishing the arterial pressure; that the force with which the organism maintains it constant requires such an extreme degree of these mechanical means to conquer it, that it transcends the limits of therapeutics. Consequently, the explanation of the undoubtedly favorable results obtained by cupping and venesection must be sought in some other direction than in the diminution of the blood-pressure.

Cystocolostomy for Exstrophy of Bladder. BOARI.—The idea of utilizing the anus for a sphincter and transplanting the vesical flap in the lower portion of the intestine has been carried into execution twenty-one times. The result has demonstrated that a healthy intestinal mucosa does not suffer from contact with the urine in most cases, although a few instances of rectitis and colitis have been observed. Continence was perfect during the day in all, but relaxed at night in four. Pyelitis from ascending infection was only noted in two cases, and in each there had been previous renal disturbances. The bladder flap retains its vitality. Boari ascribes the success more to the distance of the cicatrix from the vesico-ureteral sphincter to avoid cicatricial constrictions, than to the retention of the sphincter. Experience has shown that ascending infection can be avoided and that uretero-enteric anastomosis is not incompatible with life.

Operative Cure of Prolapsus of Female Genital Organs. G. OBSINI.—The successful results in twenty-four cases treated by scraping the uterus, anterior colporrhaphy, Hegar's colpo-perineoplastica and shortening the round ligaments, induce Orsini to recommend this procedure in high terms. Half of the number were treated over three years ago, and most lead particularly laborious lives. Only five had passed the menopause. The subjective results were not perfect in a few ultraneurotic patients, and the surgeon must be guarded in his promises before an operation of any kind on this class.

Thyroid Treatment for Bone Regeneration. FERRIA.—Two more cases are reported in which tardy regeneration after a fracture was hastened by the administration of thyroid extract. The thyroid gland was normal in each.

For Increasing Sound of Voice.—Complete removal of the larynx usually leaves the voice a faint whisper. Mikulicz has obviated this by a contrivance, described in the *Berliner Tageblatt*, on the principle of a whistle, which the subject can put to his mouth as desired and magnify the sound to a natural tone. It has proved very successful on the patient for whom it was devised, a man of 47.

Societies.

Jasper County Medical Society.—At the last meeting of this society, held at Newton, Iowa, the following officers were elected: President, L. C. S. Turner, Colfax; vice-president, W. H. Shaw, Monroe; secretary and treasurer, Harry P. Engle, Newton.

Kankakee Valley District Medical Society.—Physicians from the counties of Cass, Pulaski and Jasper met with the Starke County, Ind., Medical Society at Bass Lake, Ind., and formed a temporary organization by electing Dr. L. D. Glazebrook, president, and E. P. Mitchell, secretary. On motion the society was named "The Kankakee Valley District Medical Society." Drs. Washburn of Rensselaer, Thomas of Logansport, and W. H. Thompson of Winamac were selected a committee on constitution and by-laws. The society meets in North Judson, Ind., September 12. The Starke County Medical Society will meet in the forenoon and the district society in the afternoon to complete the organization. All physicians of Lake, Porter, Starke, La Porte, Fulton, Pulaski, Cass, Carroll, White, Jasper and Newton counties are invited to be present and aid in the organization. The organization will include ten to fourteen counties in northwestern Indiana.

British Medical Association.

(Continued from p. 481.)

RECENT ADVANCES IN PHYSIOLOGY.

J. J. CHARLES, M.D., F.R.S.E., gave an address on this subject before the Section of Anatomy and Physiology (see *JOURNAL*, August 12, p. 419), and said, in part:

Physiology is held by Max Verworn to have as its task, "the investigation of life;" but the nature of life is to us, as yet, a mystery. No doubt, we are acquainted with many of the phenomena which accompany it; but it has been truly said that "everywhere, to whatever branches of physiology we may turn, wherever the gross activities of the body are traced to the activity of the individual cells, we always come upon an unsolved problem." Thus, we can not explain, nor can we discover, how nervous impulses originate in the retina, and give rise in us, through the agency of the cerebrum, to the idea of the image; why the salivary glands secrete ptyalin, and the glands of the stomach pepsin; or why some cells of the mesoblast develop into muscle and others into cartilage.

The minute structure of living cell protoplasm is a question still open to discussion. According to W. B. Hardy, the four views at present held on this subject are: 1, that protoplasm is made up of a reticulum and a homogeneous fluid substance; 2, that it consists of a more or less solid material containing vacuoles, in which there is a fluid; 3, that it is a homogeneous jelly, with granules; and, 4, that it is entirely homogeneous. As a result of his observations on colloids, such as white of egg, and on the living cell substance of the pancreas and other glands, Hardy has come to the conclusion that the reticulum which may be demonstrated in fresh or fixed cell protoplasm is largely due to the physical and chemical alterations which occur in it at death, and to the action of fixing reagents on it which induce coagulation. Hardy has succeeded in making preparations with egg albumin, showing a reticulum very closely resembling that of protoplasm. One of these, a film fixed by steam, while flowing between two cover-glasses (Fig. 1), is very interesting, as exhibiting the abrupt transition from the network to the homogeneous substance similar to that demonstrated years ago by Schäfer, in the white corpuscle when fixed in the same way by heat.

The microscopic characters of striped muscle have not ceased to be a debatable subject among histologists. The interpretation given by Rutherford has met with much acceptance, and is undoubtedly supported by the examination of specimens of crab's muscle which have been prepared according to his method; but the recent researches of Hardy would lead us to look with suspicion on the appearances presented by this tissue after it has been subjected to the action of chemicals.

The contraction of muscle is believed by McDougall to depend on the elimination of lactic acid, causing the passage of the fluid sarcoplasm into the sarcostyles. Unstriated muscle has been found by Tripel in all the cerebral veins, but the muscle

cells, he says, are isolated and mixed with white fibrous tissue.

By the use of osmic acid and uranium nitrate, with various dyes, Kolossov has demonstrated between the cells of the liver, testis, ovary, pancreas, and thyroid body, processes of connection which may serve for the conduction of impulses and the transference of nutrient materials.

The axis cylinders of nerve-fibers have been shown by St. Apathy, in invertebrate animals, to be made up of fibrils which terminate, in the case of the sensory cell, in a single basket around the periphery, and in the motor cell in one basket around the periphery, and a second around the nucleus. This view, in some respects, resembles that which Arnold advanced, years ago, as the mode of origin of nerve-fibers from nerve-cells.

It is now agreed that the amount of hemoglobin in the blood is not greater in the inhabitants of high altitudes than in those living at lower levels.

Gangee has drawn attention to the absorption band in the extreme violet end of the spectrum of blood, which he has named "the band of Soret," after its discoverer. He has pointed out that not only is it more distinctive than the bands seen in the spectrum when examined in the ordinary way, but that it is absolutely characteristic of hemoglobin and its compounds; so that by this means they can at once be distinguished from bilirubin and urobilin as well as from carmin and all other coloring matters yet examined. This is a matter of practical importance, because this method may yet come to be employed in medicolegal investigations. Gangee has indicated that the best and easiest way of demonstrating this spectrum is by means of an electric arc, a fluorescent screen, and a Bunsen's spectroscope.

R. Jarry has investigated the influence of reduced pressure and increased temperature in causing the compounds of silver chlorid with ammonia to dissociate somewhat like oxyhemoglobin. Perhaps the further study of such "loose" compounds may lead to an increase of our knowledge with reference to the properties of hemoglobin.

Fig. 1.—Film of white of egg fixed by steam while flowing between two cover glasses, showing the abrupt transition *a a* from network to the homogeneous substance (Hardy).

Haldane has discovered a quick and ready plan of liberating the oxygen of the blood by the use of potassium ferricyanid; but to insure success, the blood should be fresh, else bacteria will interfere with the result. Nicloux, employing Gantier's test for carbonic acid—namely, that this gas has the power of decomposing iodic anhydrid and forming carbon dioxide, while iodine is liberated and absorbed by copper—has endeavored to prove its presence normally in blood; and Louis St. Martin has estimated the quantity in the blood of animals living in towns to be 1.5 c.c. per liter. But as it is possible that during the application of this test, while the blood is being boiled with acetic acid, carbonic acid may be formed by combustion, in the absence of oxygen; and as several hydrocarbons at 60 degrees can reduce iodic anhydrid, and as other gases besides carbonic acid might respond to the test in a similar way, the results of Nicloux and St. Martin can only be provisionally accepted.

A fully satisfactory theory as to the coagulation of the blood has yet to be discovered. Probably, we shall not find it till we are better acquainted with the chemical constitution of the proteids of the blood. The view, however, which meets with most favor, and is open to fewest objections, is that there are three agents or factors concerned in the formation of fibrin, viz.: 1, fibrinogen, which is present in the plasma; 2, nucleoprotein derived in part from blood platelets, but chiefly from the shedding out, or perhaps from the disintegration of the white corpuscles; and 3, lime salts, in solution in the plasma. The nucleoprotein, by the action of the lime, is changed into fibrin ferment, and this ferment reacting with fibrinogen transfers its lime to the chief constituent of fibrinogen—thrombosin—

and thus give rise to fibrin. Pechelhaar is of opinion that fibrin is a *compound* of fibrinogen and lime, but it has been proved conclusively that fibrin contains no more lime than the fibrinogen from which it is derived. It is admitted that a lime salt is essential in some way in the coagulation of the blood, but the exact parts it plays is still undetermined.

Delezenne has succeeded in isolating an anticoagulant substance, of the nature of Lilienfeld's histon, from peptone plasma. He believes it is derived from the destruction of white corpuscles, but others hold that these corpuscles only leave the blood-vessels, and are not destroyed. The fact that a second dose of peptone injected into the veins of an animal shortly after the action of the first has disappeared, produces no anticoagulant effect, Delezenne explains by supposing that an antitoxin has been formed which protects the white corpuscles against their destruction by peptone. In favor of this view is the fact that the blood or serum of a peptonized or immunized dog when injected into the veins of another animal confers on it immunity from the action of peptone, snake poison, or extract of crab's muscle.

The formation of lymph is still a fruitful source of controversy. Some, as Heidenhain, regard it as in the main a secretion by the walls of the capillaries from the blood, while others maintain that it is the product of filtration and osmosis from that fluid. Asher and Barbèra have recently advanced the view that lymph is produced by the tissues and organs generally, such as the liver, the muscles, and glands; but the evidence in favor of it can scarcely be considered adequate.

Langley has caused the vagus and the sympathetic nerve in the neck of a cat to join together; and on applying stimuli, before and after the injection of nicotine, he has been able to prove that the nerve-fibers of the vagus make functional connection with the cells of the superior cervical ganglion of the sympathetic, and give rise to the same results on stimulation as the sympathetic did before the section.

There has been considerable discussion of late years concerning the causes of the entrance of oxygen into the blood in the lungs. Most physiologists, following Pflüger, and believing that the tension of oxygen in the blood is less than in the air of the alveoli, regarded diffusion alone as sufficient to explain the passage of the gas. But the results obtained, first by Bohr and recently by Haldane and Lorrain Smith, have induced many physiologists to consider this view untenable. Attention has accordingly been directed to the chemical affinity of the hemoglobin in the blood for oxygen. It is not likely that this affinity acts at a distance on the alveolar air; but undoubtedly the hemoglobin in the red corpuscles, by absorbing oxygen, is constantly lowering the tension of the oxygen in the plasma around them, as Foster has pointed out, and so indirectly causing more oxygen to enter the blood from the air cells by diffusion. The chemical affinity of hemoglobin is, therefore, an important factor, though it acts more as an aid to diffusion than as an agent or force by itself. Another hypothesis—that the cause depends on the secretion of oxygen by the endothelial cells of the alveoli, and perhaps by the capillary walls—has of late come into prominence. In favor of it we have the fact that in the secretion of urine, and possibly in the transudation of lymph, the endothelium containing living protoplasm discharges a somewhat analogous function. Again, there are some grounds for believing that epithelial cells may be the active agents in causing the passage of oxygen from the maternal to the fetal blood in the placenta. But the most important evidence in support of this view is found in the case of the swimming bladder of fishes, in which oxygen, nitrogen, and likely argon, are at one time secreted and at another absorbed under the influence of the nervous system.

Opinions are likewise much divided as to the causes of the exit of carbon dioxide from the blood in the lungs. Some physiologists endeavor to explain all the phenomena by diffusion; but we can not regard this process by itself as sufficient, if we accept Bohr's statement that the tension of this gas in the trachea is usually greater than its tension in the blood. But Werigo, while accepting this statement, has tried to prove that the diffusion hypothesis is correct. He alleges that the *actual* tension of the carbon dioxide in the blood in the capillaries of the air cells may be higher than the tension as made out by the aërotonometer, because oxygen on its entrance into the blood

breaks up the compound of carbon dioxide and hemoglobin—a very doubtful compound—sets carbon dioxide free, and thereupon raises its tension in those blood-vessels. But these grounds are insufficient to establish Werigo's supposition.

With regard, then, to the exchange of oxygen and carbon dioxide in the blood at the lungs, I think it must be admitted that though diffusion plays an important part, it is by no means "master of the situation," but is supplemented and largely modified by chemical affinity and possibly by the vital or secretory activity of the endothelial cells.

Lorrain Smith infers from a series of experiments on birds and other animals, that while oxygen at the tension of the atmosphere excites the cells of the alveoli to absorption, at a higher tension (say 180 per cent. of an atmosphere) it gives rise in twenty-four hours to inflammation of the lungs, and at a still higher tension (say 300 per cent. of an atmosphere) leads, as first pointed out by Paul Bert, to convulsions like those of tetanus, owing to its toxic effects on the nervous system.

G. N. Stewart, by what is known as the electric method, and also by the injection of methylene blue, has determined in the dog the duration of the circulation as a whole, and he concludes that in man the pulmonary circulation would take fifteen seconds and the entire circulation one minute. This is a longer period than that hitherto accepted. The mean velocity of the blood in the larger arteries of the dog has been found to be about 100 mm. per second—a rate less than formerly believed. He has also by the electric method made investigations in the dog as to the output of the heart, and infers that the output in man would not be much more than three ounces of blood for each beat.

The old view—that a man may increase in weight without the use of food—has been revived. Bouchard has ascertained that the increase may amount to one ounce in an hour, and he attributes it to the absorption of oxygen, or to its retention in the body, along with the production of glycogen, and the imperfect oxidation of fat; but Berthelot believes it is due to the formation of new substances, and the imperfect oxidation of albuminoids.

Pembrey and Nicol, with a flat bulb mercurial thermometer, have made a large number of observations on the temperature of different parts of the body, and have arrived at the conclusion that the temperature of the rectum is 0.26 degrees higher than that of the urine, and 0.65 degrees higher than that of the mouth; and that the mouth is not as trustworthy as the rectum for clinical observations. Pembrey thinks that the mouth, by increasing the loss of heat, takes part in the regulation of the temperature of the body during exercise.

The extract of the suprarenal capsule was injected by Langlois into the veins of the rabbits and dogs, but its presence could not be detected in the arterial blood a few minutes afterward. There is reason to believe that it is destroyed principally at the liver.

Information has been obtained regarding the movements of the stomach by observations made on animals immediately after death, and by means of the Roentgen rays alone, or after the administration of bismuth subnitrate with the food, during life. It has been noticed that shortly after the entrance of food the stomach becomes almost completely divided by a transverse band of contraction, about three inches from the pylorus, into the fundus and antrum pylori. The fundus is for the most part at rest, retaining the food as a reservoir for digestion, but at intervals pressing it through the constriction into the antrum. The peristaltic contractions of the antrum—about six per minute in the cat—always proceed toward the pyloric valve, and drive its fluid contents into the duodenum; but any solid masses present which may be too large to pass, are forced back by the antiperistaltic wave into the fundus, to be further acted on by the gastric juice.

Bayliss and Starling, by means of a "rubber capsule" and by "enterographs" have studied the intestinal movements in the dog. They have observed two kinds of movements in the small intestine—the "pendulum movements" and the true peristaltic contractions. The former, slight swaying movements, are caused by rhythmic contractions of the circular and longitudinal muscular fibers acting *simultaneously*, ten times per minute, and traveling with a velocity of 2 to 5 cm. per second. The

latter—the peristaltic contractions—travel as a wave, always from above down, and are, they say, “true co-ordinated reflexes, started by mechanical stimulation of the intestine and carried out by the local nervous mechanism (Auerbach’s plexus).” A local irritation of the intestine causes excitation above the spot stimulated and inhibition below it. Stimulation of the splanchnics leads to inhibition of the longitudinal and circular fibers; stimulation of the vagus nerves first produces a short inhibition and then augmentation. The splanchnics exercise a tonic action on the intestine, but the vagus nerves do not.

In connection with the peristaltic action of the intestine, it is interesting to note that Grützner has observed that liquids and particles, such as lycopodium spores, may, if placed in the human rectum, make their way to the stomach.

The entire stomach has been removed in man by different surgeons; the small intestine, nearly its whole length, has been cut out in the dog by Fillipi; and the large intestine, the greater part of it, has been excised in the dog by Vaughan Harley. In all these cases, when successful, digestion appears to have gone on as usual, except that after excision of the small intestine, fat was imperfectly absorbed, and after removal of the large intestine, proteids and water were only partially absorbed. Indeed, Mr. Treves, the eminent surgeon, states, as the result of his experience, that we “might possibly dispense with our present type of stomach;” and the removal of considerable portions of the intestine “has done no more than add to the comfort of those individuals who have recovered from the operation.” It is probable that after these operations, the remaining parts of the alimentary canal took on vicarious or abnormal action, and thus adapted themselves to the changed conditions. It is also, no doubt, true that care was taken to administer food easy of digestion. We can not, therefore, attach much importance to the results of such operations and experiments as guides to the use of individual parts of the alimentary canal. It might as well be contended that because a portion of the cerebral cortex of a dog can be removed without inhibiting the performance of most of its ordinary functions, the portion so removed was unnecessary.

Vaughan Harley recently isolated a loop of the large intestine of a dog, and after some months, he found that the contents consisted of fat, cholesterin, proteid and salts—which, he thinks, form the normal excretion of the large intestine—in fact, its contribution to the feces. Another observer, Moraczewski, described the excretion in a loop after the lapse of a year as made up principally of sodium carbonate. Voit, by a similar plan, ascertained the secretion of the small intestine to be fat, cholesterin, proteid, salts, with coloring matter. But in these cases the intestine can scarcely be said to have been in a normal condition. At any rate, the results obtained are discrepant, so that it is difficult to know what inference should be drawn from these.

Carbon dioxide is a constant constituent of the gases in the intestines. It is the product of fermentation, and of the neutralization of the sodium carbonate of the secretions. Moreover, it is derived from the blood by diffusion, as well as given off in the small intestine by the bile, which, as I showed in 1881, contains in the case of the rabbit a larger percentage of this gas than any other animal liquid.

Waymouth Reid’s experiments on the absorption of serum, peptone, and glucose from the intestines of animals by means of two loops of intestine—the experimental and the control loop—have led him to infer that the epithelial cells are essential agents, because absorption continues when filtration and osmosis have been excluded; and because it diminishes or ceases altogether after these cells have been injured or removed, as, for instance, when they have been poisoned with sodic fluoride, or when their blood-supply has been cut off. An attempt, however, has been made to explain results of this kind by the chemico-physical method. Thus, if we place a solution of gelatin in the inner cylinder of a dialyzer, and a solution of common salt in the outer vessel, the gelatin will not diffuse through the membrane, but owing to its affinity or “elective” action for the salt, will draw the salt to itself by what has been termed “adsorption.” Similarly, it is alleged that the protoplasmic contents of the intestinal epithelial cell do not diffuse, but being complex in chemical composition may contain imbibing substances of various kinds. These substances are supposed to

exercise an affinity for certain food stuffs, which they draw from the contents of the alimentary canal into themselves, and form “loose” chemical compounds with them, while they leave behind, untouched, other substances, for which they show no such affinity. Further, as cells differ in chemical composition, it is said, they will accordingly vary in their affinities; and it is alleged that it is no more extraordinary that epithelial cells should take up fat and not pigment, than that phosphorus should unite with oxygen and not with platinum. But that the cell contents have an affinity for such a substance as fat, and afterward form a compound with it, seems to be a mere conjecture; consequently this explanation, ingenious though it is, can not be accepted—if accepted at all—as having more than a limited application.

A few years ago it was authoritatively stated that bacteria are not only useful in digestion, but that death would ensue if the air and food used were sterilized. But the experiments of Nuttall and Thierfelder have shown this statement to be erroneous.

Aldehoff and Mering believe that they have proved by their experiments that the central nervous system exercises only an inhibitory influence on the stomach. They excised the vagus near the diaphragm, and observed that the movements of the stomach were unaffected; that the quantity of the secretion and the amount of hydrochloric acid in it were at first diminished, but afterward became normal; and that absorption was not interfered with. Riegel has experimented on the stomachs of animals after Pawloff’s method, and has noticed that atropin diminishes the amount of hydrochloric acid and of gastric juice secreted, but pilocarpin, especially if there was no food present, increases it five times.

Bunch, by using a plethysmograph for the intestines, has demonstrated the existence of vasoconstrictor and vasodilator nerve-fibers in the splanchnic nerves supplied to it, the vasoconstrictors being the more numerous. He has observed that nicotine, conin, and piperidin cause great constriction of the vessels, followed by slight dilation; that stimulation of the central end of the vagus produces either constriction or dilatation of the vessels of the small intestine, while stimulation of the central end has no vasomotor effect on these vessels.

The process of internal secretion is carried on by many of the organs of the body. The action of the kidney in this respect is not yet fully understood, but the remarkable results of Bradford indicate that it has an important influence in the nitrogenous metabolism of the tissues of the body. Bradford has removed two-thirds of the total kidney weight, and has observed that the urine is much increased, but the urea only slightly so. However, if three-fourths be excised, there is an increase in both the urea and the urine excreted, with an increase of the nitrogenous extractives in the blood and in the muscles, to a rapid breaking down of their substance. W. H. Thompson has ascertained that normal salt solution causes a marked increase in the urine and in the amount of urea in it, but he does not offer any explanation of the fact.

Many are now disposed, with Heape, to believe that menstruation in monkeys is virtually the same process as menstruation in women; that, in both, “ovulation does not occur during each menstrual period, and that it does not necessarily occur during any menstrual period,” and therefore may take place independently of it.

Vitzou has found that the blindness following entire removal of the occipital lobes in young monkeys may be recovered from in the course of two years. The recovery he attributes to the growth of new nerve-cells and nerve-fibers; but this supposition is very doubtful, as regeneration of nerve-cells is unknown in the higher animals.

Mott and Hill, after ligating all the cerebral arteries in cats, dogs, and monkeys, observed five to twenty-four hours afterward that the sensori-motor area of the cerebral cortex was in a very irritable condition, so that the application of a weak induced current gave rise to movements of the limbs, and sometimes even to fits. The cells of the cortex—their nuclei and processes—were all swollen, the granules of Nissl were altered, and the edges of the cells irregular. The interest in these results lies chiefly in the fact that corresponding changes have been noticed in the brains of persons who have died after prolonged epileptic convulsions.

Hodge and others, some years ago, described changes in the shape and size of the ganglion cells and of their nuclei as the result of fatigue. Recently, Lugano of Florence, by injecting Cox's solution—chiefly corrosive sublimate—into the carotid artery of a dog, killed it instantaneously, and at the same time fixed the nerve-cells of its cerebral cortex in the functional state they were in before death (Fig. 2). His results lead him to agree with Ramon y Cajal that nerve-cells and their larger branches are incapable of amoeboid movements, such as we find in the white corpuscle, but to believe that the small processes of the dendrites—the gemmules—exhibit forward and backward movements sufficient to make and break contact.

Fig. 2.—Cerebral cortex, showing nerve-cells with their dendrites and gemmules (Lugano).

Lugano thinks that the nerve-cell in a state of functional activity has few connections, lest the entrance of other impulses should interfere with the impulse which at the moment is being elaborated in its interior, and consequently the most of its gemmules are retracted (Fig. 3); but when it is ready to receive new impulses, the gemmules resume their expanded condition and approach others in their neighborhood (Fig. 4). In sleep as well as in the narcosis produced by chloroform, ether or chloral, the gemmules are usually all expanded and in a torpid state, their capacity for contraction being exhausted until sleep is nearly over. It is too soon to criticize the results of Lugano's experimental investigations and the ingenious theory he has based on them. But I may mention that Ramon y Cajal has not found any histologic change in the dendrites during activity; and that Alex Hill has adduced some reasons to show that Golgi's method is inadequate to prove a want of connection between the dendrites and unstained filaments in deed, Hill holds that the gemmules serve rather as a mode of connection between the dendrites and unstained filaments in the intercellular material. Then, if we keep in mind the possibility of some of the dendrites and gemmules being produced by the action of chemicals on the nervous tissue, as structure in

protoplasm has been shown to be by Hardy, there are undoubtedly good grounds for withholding our assent to any histologic theory of brain activity till these questions have been settled.

Horsley and Lowenthal have found that the removal of the cerebrum in certain animals is followed by tonic contraction of the extensor muscles, and that in such animals the stimulation of the superior vermis of the cerebellum, at its junction with the lateral hemisphere, leads to the relaxation of the extensor muscles, and at the same time to contraction of their antagonists, the flexors.

Fig. 3.—Dendrites of molecular layer of cerebral cortex of dog, representing state of functional activity. Gemmules retracted (Lugano).

It is now generally acknowledged that there is not sufficient evidence for belief in specific trophic nerve-fibers. The Gasserian ganglion and the part of the fifth nerve proximal to it have been excised, and no truly trophic effect has resulted.

Fig. 4.—Dendrites of molecular layer of cerebral cortex of dog in chloroform narcosis. Gemmules expanded (Lugano).

A rare opportunity for studying the characters and the secretion of the cerebrospinal fluid has lately occurred to Drs. St. Clair Thomson and Halliburton in the case of a patient who is described as having had a "continuous dripping from the nose." The liquid on examination proved to be cerebrospinal, and amounted to half a liter in twenty-four hours. The flow was observed to be increased by the horizontal posture, by compression of the abdomen, and by forced expiration—all of which usually cause in the capillaries of the brain a rise of blood-pressure. According to Cavazzani, the cerebrospinal fluid varies somewhat in composition at different periods of the day—that collected in the morning being more alkaline, and containing more solids than that in the evening, the difference, it is conjectured, being due to the activity of the nervous system.

Our views of the functions of the spinal cord have been considerably altered of late years, owing to the remarkable results which have been found to attend operations made on it. Goltz and Ewald, after destroying the lumbar and sacral regions of the cord in dogs, have observed that these animals in the course of time regained the power of retaining and spontaneously evacuating the contents of the bladder and rectum, while digestion as well as parturition took place in them as in normal animals.

There is still doubt whether, and if so, to what extent, the afferent fibers decussate in the spinal cord. Some maintain that in man they decussate almost completely; others that they do so only partially.

Schäfer has recently made hemisections of the spinal cord in the monkey, and as the result of his investigations has come to the conclusion that Clarke's column atrophies almost entirely in two or three months, on the same side, below the lesion, and that the fibers of the pyramidal tract do not terminate in the anterior cornu, but in the base of the posterior cornu and in Clarke's column. If this be the case, efferent impulses descending from the cerebrum by the pyramidal fibers would influence the motor cells in the anterior cornu of the cord indirectly, though the afferent arm of the reflex arc, and not directly, as hitherto believed. This view as to the termination of the fibers of the pyramidal tract is, however, so contrary to the results of all past observers, that it should not be accepted until it has been confirmed by further investigations. Besides, it has yet to be shown how these fibers terminate in the lower portion of the cord where Clarke's column is absent, and also that they are not diffused fibers belonging to some other descending tract. In addition, he has traced, he believes, the fibers of the descending anterolateral tract to the anterior cornu, where they end for the most part in arborization among its cells.

(To be continued.)

ORLEANS PARISH MEDICAL SOCIETY.

Meeting Held in New Orleans, La., July 22, 1899.

DIABETES MELLITUS AND COMPLICATIONS.

DR. P. L. CUSACHS related the case of a young white man suffering with a complication of diabetes mellitus, sclerosis of the liver and incipient pulmonary consolidation. Observations on the daily quantity of urine—up to 10½ pints—and on the contained sugar were read in detail. The treatment had consisted in the administration, successively, of pancreatic essence, guaiacal, aromatic sulphuric acid, arsenauero, etc. No treatment had had any beneficial effect, the patient growing gradually weaker. Dr. Cusachs suggested that the hepatic disease might be an etiologic factor in the case, interfering with the glycogenic function of that organ.

DR. H. B. GESSNER told of a case of diabetes mellitus in a stout colored woman of 60 years. The cure appeared to have been effected by the use of antipyrin, codein sulphate and arsenic, the latter in the form of Fowler's solution. The usual dietetic instructions had been given. Fluid extract of eugenia jambolana, endorsed by H. A. Hare in the treatment of diabetes mellitus had been administered at one time, but had been ill-borne by the patient's stomach. At the time when the patient was last seen, some three months ago, no sugar was found in the urine; there was complete relief from symptoms. Treatment had lasted two years.

DR. A. NELKIN thought it was jumping at conclusions to have a diagnosis of diabetes mellitus or polyuria associated with glycosuria. Likely these are the common symptoms of several diseases affecting the nervous system, the liver or the pancreas, and differing from each other as widely as cancer and tuberculosis, both of which cause wasting. He referred to glycosuria of alimentary and of alcoholic origin respectively, probably neither of them a true diabetic condition.

DR. F. A. LARNEY thought it unwise to depend on polyuria and polydipsia as symptoms. Of three persons at present under his care for diabetes mellitus, not one has polydipsia, while but one has polyuria. As to the specific gravity of the urine, in his experience this had proved misleading, as he had found sugar in urine of as low a specific gravity as 1602.

ANCHYLOSTOMIASIS.

DR. C. HAMILTON TEBAULT, JR., presented a case convalescing from anchylostomiasis or tropical anemia. After quoting Patrick Manson on the disease, he detailed the case as follows: G. H., aged 15 years, of German extraction, was born in New Orleans, where he has always resided. His father died of cardiac disease; there is no family history bearing on his trouble. About 1½ years ago he began suffering with epigastric discomfort, loss of appetite and weakness, with paroxysmal diarrhæa. He was treated in the Out-Clinics of the Charity Hospital for pernicious and for malarial anemia. When admitted to Dr. Tebault's service, the boy's anemia was marked; the lips, tongue, and conjunctivæ were very pale; there was edema of the hands, feet and lungs. The temperature ranged up to 101 F.; there was a hemic bruit at the base of the heart; the urine, of 1008 specific gravity, had no albumin in it. There was capricious appetite, with headache, vertigo and spots before the eyes. Diarrhæa alternated with constipation. There was no emaciation.

Examination of the blood showed plasmodia; red blood-corpuses, 2,500,000 to the c. mm. Examination of the feces revealed the presence of the ova of the anchylostoma duodenale. The patient then weighed 79 lbs.

Thymol was given in 10-grain doses three times daily on an empty stomach for two days; meantime alcohol was prohibited on account of the danger of its dissolving the thymol and thus producing toxic effects. At the end of the second day castor-oil was given; at the end of the fourth day, 3i of male fern was given, followed by dose of castor-oil. Numerous anchylostomata were expelled. The lad was then put on arsenauero and compound syrup of the hypophosphites. His appetite improved, his headaches troubled him less. The red blood-corpuses increased in number. The male fern was administered a second time. The result of the treatment has been that the weight rose to 85 lbs., the number of red blood-corpuses to 5,540,000 per c. mm.; the mucous membranes regained their normal color, the temperature fell to normal, and the edema and cardiac symptoms disappeared.

"CALENTURA."

Dr. Tebault also discussed "Calentura," a fever observed in Cuba during his service there as an acting assistant-surgeon, U. S. A. This word, which appears to have a general meaning of "feverishness," is applied to a febrile attack of one paroxysm, beginning with a chill in the early morning or late at night. Sometimes there is only a sensation of chilliness. The temperature rises to 103 or 104 degrees, falling on the fourth or fifth day, in mild cases as early as the second day. The pulse is relatively slow. Jaundice is unusual. Headache, capillary stasis and pain in the calf of the leg are present, as in yellow fever. The liver is large, the spleen large and tender. Gastric symptoms are frequently absent altogether, and when present, are of but short duration. Instead of the acute prostration of yellow fever there is a debility which lasts for weeks, and which, in foreigners, may not disappear until some time has been spent away from Cuba, in a more healthful country. Albuminuria is absent.

In the rare cases of death, for the mortality is practically nil, the appearance of the organs is such as would be expected in death from congestive chill.

There seems to be no connection between yellow fever and calentura; neither protects against the other; the latter is a recurring disease, usually attacking Cubans at least once a year, and sometimes as often as three or four times a year. Blood examination in the cases seen by the Doctor revealed the presence of plasmodia; but these are present in all cases of disease in Santiago.

The treatment consisted in the administration of quinin and strychnin, with liquid diet; turpentin enemata were used to keep the bowels open.

DR. T. S. DABNEY called attention to the fact that anchylostomiasis is not confined to tropical countries, having been observed in Switzerland. As for calentura, he had come in contact with a disease of that name in South America; this had proved to be simply intermittent malarial fever, yielding promptly to quinin.

DR. W. M. PERKINS, who had also observed calentura in Cuba, during the late war, was of the opinion that it is a malarial disease; the natives treat it with quinin.

PURE FOOD.

DRS. J. A. STORCK and L. KOHNKE discussed pure food, the former from a chemical, the latter from a legislative standpoint; attention was called both to the deliberate adulteration of food products with noxious substances, and to the use of such chemicals for purposes of preservation.

THE
Journal of the American Medical Association

PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:

Per Annum, in Advance	\$5.00
Foreign Postage	2.00
Single Copies	10 Cents

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

These new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 26, 1899.

UNSOLVED PROBLEMS AND FUTURE WORK IN
TUBERCULOSIS.

Great as is the progress of the last ten to fifteen years, in the study of tuberculosis, there yet remain many and weighty problems to be solved before we can hope for more decided results in our efforts at staying the ravages of this widespread disease. In a recent lecture¹ Dr. E. L. Trudeau of Saranac Lake, N. Y., presents the aspect of some of these questions relating to tuberculosis in a manner which surely is helpful to all who are directly or even indirectly interested in this matter.

He points out that more knowledge of the conditions which lead to variations in the manifestations of the disease is necessary. We are in the habit of explaining these differences as due to variations in virulence of the germ and in the resisting power of the tissues. But upon what factors does variation in virulence depend? And wherein lies predisposition, be it individual or racial, inherited or acquired? Among the various channels of access to the body more attention should be given to adenoid growths in the nasal fosse, as this part of the respiratory tract is probably a more frequent channel of invasion than is suspected.

Among the problems in pathology, Trudeau emphasizes the need of thorough study of the chemical changes which occur in tuberculosis in the digestive secretions, and of the anemia in this disease. The secret of the nature of the changes which result in cure in peritoneal tuberculosis after laparotomy has not been solved. Perhaps much light could be thrown on some of the issues connected with acquired immunity if we could learn

the mechanism whereby the bacilli are made innocuous. What is the exact significance of the appearance of bacilli in the milk, urine or semen? Are they excreted or is there always active tuberculosis in the organs when bacilli are found in the products? The botanic position and the possible occurrence of the tubercle germ in nature are also among the problems suggested by Trudeau when he discusses the nature of this microphyte and asks, is it a bacillus at all? The relation of the germ of tuberculosis to the ray fungi, the grass and dung bacilli of Moeller and the acid-proof bacilli described in butter is now one of the questions that invite investigation.

In respect to prophylaxis, some way of determining to what extent there is danger in the spraying of bacilli in fine particles of mucus and saliva by the act of coughing and talking, as demonstrated by Flügge's recent work, would be of great value to preventive medicine. It has been shown at Saranac Lake that the hands of patients using handkerchiefs may, in the majority of cases, be the carriers of unsuspected bacilli. "Practical suggestions as to the education of the masses in regard to the sources of infection, and studies which will give us more light on the best and most practical methods to guard against them would be of inestimable value." The value as a prophylactic measure of state and municipal sanatoria and special hospitals in educating patients and removing from crowded communities individuals who are a constant source of danger, needs but to be mentioned in order to be appreciated. Hence, all facts in regard to the management and construction of such institutions are greatly desirable.

And then come the problems of bacteriology and physiologic chemistry relating to methods of exaltation and attenuation of virulence, of obtaining toxin of fixed strength, and to the study of the various chemical substances elaborated by the germs of tuberculosis. The probable value for future research of the collodion sac method of cultivating microbes, previously mentioned editorially in the JOURNAL, is pointed out. Collodion sacs partly filled with fluid media and inoculated with germs are inserted into the abdominal cavity of animals. The walls of the sac allow a slow interchange between the fluid in their interior and the fluids of the animal incubator, the bacteria are protected against the cells, toxic substances are slowly disseminated into the body of the animal, but the germs are not disseminated. The influence on the germs of cultivation under such circumstances opens an interesting field of study, as also the effects of freshly and continuously elaborated toxins on the animal organism; new methods of producing immunity and obtaining antitoxic substances suggest themselves. Already Nocard has succeeded in making the human tubercle germ pathogenic for fowls, by cultivation in collodion sacs inserted into the peritoneal cavity of chickens, and Vincent, in transforming saprophytic bacteria into virulent, by repeated passages through animals, in collodion sacs.

¹ Bull. Johns Hopkins Hospital, 1899, No. 10, p. 121; JOURNAL, August 12, p. 470, * 7.

The necessity of bringing to light the true facts as to the exact value, the limitations and possible objections to the use of the tuberculin reaction in diagnosis is brought out forcibly. It is pointed out that there is no evidence of this test being dangerous or tending to aggravate the disease. Virehow's statement that tuberculin-treated patients revealed many new tuberculous foci at a distance from the old lesions contains no proof that the bacilli are scattered through the system as the result of the injections. Broden's study of experimental, peritoneal tuberculosis of dogs treated by tuberculin injections shows the rapid development in larger numbers of nodules containing much fewer and more degenerated bacilli than in the control animals.

Trudeau also lays stress upon the use of X-rays in the diagnosis of incipient tuberculosis; the height of the excursion of the diaphragm and the presence of a light shadow over the suspected area in the lung may help greatly toward reaching a correct conclusion even before unmistakable symptoms are present.

Finally the problems connected with the treatment and especially with the production of an efficient antitoxic serum are considered. In opposition to the conservative view which sees no hope that artificial immunity against tuberculosis can ever be produced especially because the natural history of tuberculosis shows that recovery from a tuberculous process does not afford protection against future attacks, Trudeau finds considerable evidence in his own work as well as in the result of others in favor of the claim that the resistance of the body to virulent tuberculosis can be greatly increased by preventive inoculation. Failing to obtain appreciable results by inoculation of cultural products and of dead bacilli, he, like de Schweinitz, has of late used living germs attenuated by various methods. Cultures of mammalian bacilli attenuated by prolonged growth on artificial media have been found by both de Schweinitz and Trudeau to protect guinea-pigs in a marked degree. By this method of attenuation the biologic characteristics of the germs are least altered, the organisms merely losing those attributes which are not called into use, in this case the specific pathogenic powers. In 36 control animals, the average life was 57.2 days, in 66 vaccinated animals it was 154.3 days. As yet, however, complete recovery has not been secured, although vaccinated pigs have lived for three years in good condition, ultimately dying of chronic tuberculosis. This may mean that the disease is not auto-inoculable and that an animal with a very chronic experimental tuberculosis is not susceptible to reinoculation with a more virulent material.

Here then have been indicated problems enough of great practical and scientific importance, inviting the efforts of the enthusiastic investigator and the patient student, efforts which merit the support of the state and private munificence.

It is reported that anterior poliomyelitis prevails in epidemic form in Poughkeepsie, N. Y.

WEIGHT AND NUMBER OF THE FUNCTIONATING CORTICAL CELLS.

In 1872 Meynert estimated the number of nerve-cells of the cortex of the convex surface of the cerebral hemispheres in round numbers at 612,000,000. In 1895 Donaldson, taking Meynert's calculation as a starting-point, estimated the total of cortical cells at 1,200,000,000 and in the whole nervous system at 3,000,000,000. In 1895 also, Hammarberg published a very minute and careful study of the size and arrangement of the nerve-cells in the human cortex, which has been already noticed in the *JOURNAL*. He did not, however, apparently carry out his calculations to the estimation of the total number of cells in the cortex of the brain, and it remained for a woman, Miss Helen Bradford Thompson, to take up the subject and apply Hammarberg's methods to solving the question. Her paper appeared in the June issue of the *Journal of Comparative Neurology*, and by adopting the data as to dimensions and arrangement of nerve-cells given by the Swedish investigator, supplying as far as possible their omissions and applying them in detail to all the separate cortical regions, she comes to the conclusion that they indicate the total number of cells in the cortex to be the astonishing figure of 9,200,000,000, or nearly eight times the estimate of Donaldson.

Using the same methods of measurements of cells for estimating their proportion of the volume of the cortex, Miss Thompson concludes that the grand total of all these 9,200,000,000 cells amounts to only 1.37 per cent. of the substance of the peripheral gray matter of the hemispheres, a conclusion hardly less remarkable than the other. Inasmuch, however, as Hammarberg's method—alcohol hardening followed by methylene blue—did not bring out the dendritic processes, this estimate is possibly too low, and Donaldson, in his comments on Miss Thompson's work, allows 0.63 per cent. for these, making a total of 2 per cent. in round figures, including in this also the terminals of the axones ending about the dendrons. The figure is small enough with the addition and is, in a manner, still a shock to the average preconceptions on this point. The article still gives another calculation that is perhaps still more directly suggestive in relation to the function of these cells. Using the same data to compute the number of giant cells, usually considered as distinctly motor and located in the accepted motor regions of the cortex, she finds them to number 159,690. Bloq and Ozanoff had already determined the number of pyramidal fibers of one side of the body to be 79,111. Doubling this we have 158,222, a number very nearly corresponding to the number of giant cells, according to Miss Thompson's calculation. The most of these are found in the upper and mesial portions of the anterior central gyrus containing the centers for the trunk and limbs. The significance of the figures is obvious. The cellular origin of the motor fibers for the head and neck, she suggests, not being provided for in these calculations, must be looked for elsewhere than in

the giant cells, probably in the large pyramidal cells of the fifth layer in the lower portions of the motor region, where are situated the head and neck centers.

Immediately following Miss Thompson's paper is one by Prof. H. H. Donaldson, where he discusses the significance of this small total volume of the nerve-cell bodies in the cerebral cortex. Hammarberg has shown that a comparatively slight deviation from the normal development of these cell bodies suffices to impair the intellectual faculties to the extent of producing imbecility. Donaldson's estimate of the average weight of the cortex is 658 grams, which seems certainly liberal enough, and 2 per cent. of this would give for the cell bodies and their dendrons only a total weight of a little over 13 grams, which leaves only a very small margin for changes of brain weight dependent on alteration or deficiencies of these bodies. The real differences, nevertheless, are considerable, amounting to as much as 134 grams between the average brain weight of eminent men and that of the ordinary individual (1360 grams), and 142 grams between the average male and female brains. The mean difference between the brain weight of the prime of life and that of old age, 55 grams, is more than four times that of the total of cortical brain cells. Admitting the possibility of a certain range of variation in the number and complexity of the neurons in different individuals, the excessive variation will still have to be accounted for. Donaldson finds the most probable explanation in an increase in the axone portion of the neurons and, therefore, practically insignificant for any physiologic complexity of the cortex. Whether this last inference is entirely justifiable may be questioned, perhaps, as the abundance and development of commissural connections has no unimportant part; it is probable that in cerebration, any greater bulk and weight of the axone mass may be taken as possibly pointing directly to such a development, which in turn could hardly fail to increase the functional complexity of the receiving and transmitting cortical mechanisms—in other words, their physiologic complexity. This fact is undoubtedly recognized by Professor Donaldson, though he fails to make it prominent.

There are some other points noted in his paper, such as the fact that the weight of the child's brain is nearly as great at 6 or 7 years as at maturity, which Donaldson is also inclined to account for by an increase of medullary substance, and the lack of difference between the hemispheres, notwithstanding the functional predominance of one over the other. In the case of the child, we will have to assume a provision made for future development, as the physiologic complexity at that age can not be assumed to be as complete as at maturity. There must be a potential complexity there, so to speak, and this may be provided for to some extent anatomically. As to the hemispheres it is easy enough to assume that the actual anatomic differences corresponding to the functional ones need not be so great as to materially affect brain weight.

The two articles, while giving new data as to the anatomy of the cerebrum, are especially suggestive in many ways and deserve more attention than they have apparently as yet received from the medical press.

THE DEPARTMENT OF PUBLIC HEALTH.

"There is to-day in the United States a striking need for a legislative committee so constituted that by virtue of its representative character it can speak for and in the name of the great medical profession." This vigorous statement by Dr. Charles A. L. Reed, in his London letter published in the *JOURNAL*, August 19, is deserving of especial attention from the members of the ASSOCIATION at the present time. The remark was made apropos of Dr. Reed's observation of the powerful influence wielded by the Council of the British Medical Association, on English legislation and state medicine. For years all the thoughtful men in our American profession have seen and said that, until it is thoroughly organized, the profession can not adequately exert that power for good which is inherent in its possession of knowledge, that can and must be applied for the general welfare of the nation. The machinery for the formation of a powerful representative committee was set in motion at the Columbus meeting of the ASSOCIATION, by the unanimous adoption of the resolutions offered by Dr. L. B. Tuckerman from the Ohio State Medical Society, which provide for the appointment by the ASSOCIATION of a special committee on national legislation, of three members, one of whom is to be the member of the Board of Trustees resident in the District of Columbia, and the others resident in Philadelphia and Baltimore. The resolutions further authorize this committee to invite, in the name of the ASSOCIATION, the army, navy and marine-hospital medical services, and each state medical society, to send one delegate each to a conference to be held at Washington, D. C., at such time as the committee may determine. It is further provided that this conference shall consider medical and sanitary legislation now pending. Also at the Columbus meeting the Committee on Public Health, of which Dr. U. O. B. Wingate is chairman, was ordered to continue its work in furthering the passage of the bill to create a department of public health. These actions of the ASSOCIATION received, previous to their unanimous adoption, the recommendation of both the business committee and the Board of Trustees, and funds were appropriated for carrying them into effect.

These committees are fully prepared to carry out the will of the ASSOCIATION and they must have the undivided moral support of the members. It is not too soon now to consider the campaign which is to be waged in Congress this winter for the passage of the Spooner bill, establishing a department of public health. The conference of representatives of the state societies, to be called by the ASSOCIATION'S Committee on National Legislation, will no doubt be held during the session of Congress, and by its presence and action will exert a

great influence on that body. But, as Dr. Wingate pointed out in his report, the chief obstacle so far met in the attempt to secure the passage of this law has been the lack of information on the part of members of Congress concerning the importance to the nation of the proposed legislation. During the three autumn months now intervening before Congress assembles will occur the most favorable opportunity for the profession to individually and collectively educate the members on these points. Many members of this Congress are new and know little or nothing of previous efforts of the profession, or of the arguments it has advanced. Physicians everywhere should see and write to their nearest senators and representatives strongly urging on them the facts and reasons that imperatively demand the institution of a department of public health, with a cabinet officer at its head. The new problems now arising in connection with tropical diseases, as well as many old ones, plainly show that such a department as the ASSOCIATION asks would now be of inestimable value to the other departments and to a still greater degree to the general public. Literature urging these facts should now be sent to congressmen through the personal medium of their constituents, thus effectively preparing the way for the great contest to be waged this winter. Let every member of the ASSOCIATION, and indeed every physician, now get to work, for there must be no question of the profession's success in its efforts at the coming Congress.

ASSOCIATED POLIOENCEPHALITIS AND POLIOMYELITIS.

Probably no influence is more potent in the domain of the etiology of disease than the various toxic processes. Closely related with these, and of scarcely less importance are the infectious processes. The latter are necessarily of extrinsic origin; the former may be also intrinsic. Infectious processes arise necessarily from the activity of micro-organisms, and these are invariably derived from without. Poisonous substances, however, not only may be derived from like sources, but they may also be generated within the body—for instance, on the one hand, alcohol, lead, mercury, opium, strychnin, etc., and on the other hand the toxic substances responsible for the manifestations of uremia, of diabetic coma, etc. Intoxication may further result through the activity of substances generated by infecting bacteria; from failure in the activity of certain glandular organs, as of the thyroid in myxedema, of the adrenals in Addison's disease, of the pituitary in acromegaly, of the pancreas in diabetes; and of excessive glandular activity, as of the thyroid in exophthalmic goiter. Many of the poisonous substances under consideration, while capable of widespread injury, appear to possess better or less defined affinities for certain special structures or organs, and of all of these the nervous system seems to be the most susceptible. Apart from traumatism, neoplasm, aneurysm, vascular occlusion and hemorrhage, hyperplastic processes and other mechanical conditions, almost all diseases of the nervous system may be attributed to in-

toxication or infection. Recent additions to our knowledge of the finer histologic structure of the nervous system have done much to establish the connection between pathologic processes and clinical manifestations, and to confirm certain analogies between the brain and the spinal cord, each of which is endowed with certain independent functions.

The foregoing considerations help us to understand not only how different parts of the same nervous tract, but also how various disconnected and even widely separated portions of the nervous system may suffer simultaneously in consequence of the activity of a single morbid process. Thus we may have, on the one hand, disease of the cells of the anterior horns of the spinal cord or of those of the nuclei in the medulla and also of the related peripheral motor nerves; and on the other hand, the disseminated lesions of insular encephalitis and myelitis, or of insular cerebrospinal sclerosis, or simultaneous inflammation or degeneration of the gray matter of the brain and the spinal cord. An interesting illustration of the last-named association has recently been reported by Williams¹. The patient was a girl, 11 years old, without signs of congenital syphilis, who had been paralyzed for six years. At the age of 5, while in apparently good health and in the absence of any history of any infectious disease, the child, on coming home from school one day complained of severe pain in the head, over the left temporal region. Later, a convulsion took place, and subsequently the face was drawn to the left, while speech was lost and the right upper and lower extremities were paralyzed. The facial palsy gradually improved and the power of speech returned in the course of about fourteen months. The child attended school, but learned slowly and was exceedingly forgetful. The right arm was found spastic, with the elbow more or less flexed, and the fingers flexed or extended and rigid, all movements being slow, incomplete and usually tremulous. The circumference of the right arm was one-fourth inch greater than that of the left, probably in consequence of the constant choreiform movements. The electric reactions were normal. The heart and lungs were healthy. The circumference of the right leg was one inch less than that of the left. Pescaevus existed and for its relief tenotomy had been performed. The electric reaction of the flexors seemed normal, but the peronei yielded reaction of degeneration. The kneejerks were present. The unilateral distribution of the symptoms, the involvement of speech and of the facial muscles, the absence of degenerative electric reaction and the preservation of the reflexes in the affected upper extremity point to a lesion of the cerebral gray matter, while the wasting of the lower extremity with reaction of degeneration indicated a lesion of the spinal gray matter—a polioencephalitis.

DR. A. DUVAL ATKINSON, Baltimore, Md., has been elected lecturer on diseases of children at the Women's Medical College.

¹ *Lancet*, July 1, 1899, p. 22.

THE REACTION OF DEFENSE.

A French professor, M. Soulier of Lyons, explains the Widal reaction in typhoid as a defensive act of the organism, an illustration of the old *vis medicatrix nature*, instead of it being merely an indication of an infective process. It is, according to him, only one example of the action of a defensive power of the system, others of the same general nature being the phenomenon of Pfeiffer, the alkalinity of the serum, leucocytosis assisting phagocytosis, the appearance of bile coloring matters in the stool and urine, the diazo-reaction, etc., all of which point to a special call for some element needed in the organic defense against infection and disease. His ideas as to the vital reaction against disease are not so altogether new, but his suggestion of possible therapeutic indications in these phenomena hitherto reckoned as chiefly or solely of diagnostic value, has, in it, some element of novelty.

REFORM OF THE PRESS.

In the state of Colorado where the great and good Governor Thomas decides questions of medical reform, and where, according to Dr. Rothwell, he is backed in this by an almost united press, there would seem to be need of something above the mere state law to take a hand. According to the *Rocky Mountain Druggist*, editorially quoted in the *Colorado Medical Journal*, the holiday editions of Denver's great dailies are a "sizzling slough of nauseating obscenity," and "the lost manhood" department of a daily paper is its most prolific source of revenue. The "depraved womanhood" department is probably not far behind." The publisher of a daily paper in the wicked city of Chicago conducted his journal apparently on the plan of the Denver dailies, and had, as a result, to retire for a time to the walled city in Joliet to meditate over his misdeeds. It would be well if some public-spirited citizen of Colorado would call the attention of the United States Courts to these "sizzling sloughs." It would be on a line of medical reform that Governor Thomas could not undo.

AN UNREASONABLE HEALTH OFFICIAL.

A health officer of Detroit is reported as having refused to permit the remains of a person who had died of consumption to be taken into church for the funeral. We do not know all the circumstances, but, as reported, it certainly was a case of overdoing on the part of, to all appearances, an inexcusably ignorant official. If instead of a dead consumptive in a coffin, it had been a living coughing one, his procedure would have been more rational, though even then hardly justifiable. In the present general scare about tuberculosis there is very much that is altogether unreasonable, and health officials and physicians should be among the last to unduly encourage it. We are constantly increasing our list of contagious diseases, but the mortality from them will not be appreciably lessened by exaggerating their dangers. Fear is a very appreciable factor in increasing mortality, and serious mischief may be done by its encouragement. As our knowledge of germs increases, we are constantly finding them in places where they were before unsuspected, and thus giving chances for new fears. If the Detroit official's ideas hold sway, we may yet have to

limit church funerals to cases of violent death or those from natural decay of old age.

THE EVOLUTION OF A TESTIMONIAL.

Viewing in perspective the history of the testimonial, there may be observed in its character a regular, logical development. This evolution resembles closely that of Nature, being steadily from the simple to the more complex. Primatively it consisted of a few words from the indulgent physician as to the value of the preparation, sometimes conscientiously given, sometimes without any knowledge, and sometimes perhaps against his judgment. There then came the period of corruption in which the need of the manufacturer and the need of the testimonial writer embraced like long-lost brothers the first wanting praise, the second no less avid of money. The pathologic pathologist and the sick clinician wrote articles which were marvels of unscience, chronicling myriads of miracles in such stupid and hypereulogistic terms that the trick became manifest even to the most unwary, and the second dynasty suddenly ended. We seem to be in the third stage, where the genuinely scientific, well-written article is brought ready-made to the physician, who forwards it to the editor as an original contribution. This poor man is sorely puzzled and full of wonder as to where the physician who sends the article obtained the excellent laboratory experience evident in his work, and where on earth he learned the polished literary technic contradicted by every line of the personal letter he writes. The fourth stage that threatens, who may predict its garb?

REFORM IN THE ENGLISH GENERAL MEDICAL COUNCIL.

Dr. Horsley's—we call him Doctor on general principles—report to the registered practitioners of England and Wales, in the *British Medical Journal*, August 5, is in some respects interesting reading. It states facts that are not specially creditable to the president and some other officials of the General Medical Council, a body which it would seem from this document has been altogether too much interested in the preservation of abuses instead of reforming them. Appreciating the fact that Dr. Horsley would be a disturbing element in this state of affairs, an embargo was laid by the president on him or any other member having access to documents, and this was supported by a misleading opinion of the legal adviser, and the council therefore supported the presiding officer. This prevented him from discovering and thwarting the scandalous prosecution of Dr. Hunter, which he shows was carried out by the penal committee and the lawyers without authorization from the Council as a whole. The result was a judgment which he characterizes as "a farrago of ignorance and rubbish" that has only had the effect of "rendering the use of medical titles and especially of all university degrees by medical practitioners most unsafe." He also shows that he has been able to call to account the Penal Cases Committee and to discover that the legal counsel who had posed as official representatives had really never been so authorized. The body evidently needed the labors of a reformer and it is fortunate in having obtained so able a one. The report is full of suggestive statements that indicate rather than fully state the condition

of affairs that has heretofore existed. Our interest in the matter is only a general one, but we share the satisfaction that every well-wisher of the profession must feel when he sees wrongs being righted and time-honored abuses overthrown.

THE DISEASE OF INEBRIETY.

Of late years the opinion that inebriety is a disease has been so largely put forward that it has, with many, quite obscured the fact that it is also a vice. In common usage the term covers every form and degree of excess in the use of liquor, from periodic dipsomania—which it may be said does not cover every form of occasional spree, as some would have it—to the common besotted habitual drunkard. It, like charity, certainly covers a multitude of sins, and it would be well for us to keep in mind this fact. Only in a small proportion of cases is drunkenness due originally to a disease properly so called. There are very few drunkards who have been irresistibly impelled to their depraved appetites, and there can not be said to be such an overwhelming majority of them who could not reform were they willing to take themselves out of the reach of temptation. They are very largely the victims of vicious self-indulgence, and this fact should not be forgotten or obscured by a theory that they are subjects of disease, which would naturally imply that they were also innocent victims. Many are, it is true, handicapped by heredity or environment, and to that extent they deserve some sympathy, but it should be intelligent sympathy, not the kind that ignores facts and perverts conduct. One of the worst effects of this popular notion that inebriety is a disease is its encouragement to quackery. The numerous "gold" and other cures are the direct results of this notion, and their too often ultimately damaging effects are one of its consequences. It would be well for medical societies that are called on sometimes to endorse the views of the pathologic nature of inebriety to bear in mind these aspects of the question.

JUVENILE SCROFULA AND PHTHISIS.

According to *Pediatrics*, August 1, the opinion that tuberculosis in some form or other is an almost universal affection, is getting to be general. It refers to a recent research of Volland who, on examining 2500 school children, found that between the ages of 7 and 9 no less than 96 per cent. had indolent, multiple, engorged cervical glands, which he holds to be a purely tuberculous manifestation. The percentage decreases each year until in adult life the number of individuals who present the symptom is comparatively small. That is to say, the vast majority of children are infected with tuberculosis and present its lesions in a modified form. It is not surprising, therefore, that some of the weaker ones fail to escape it in later life. This goes further than the observation of Kelsch, who found evidence of "latent" tuberculosis in two-fifths of young persons. Blos of Heidelberg, on the strength of these findings of Volland and others, according to *Pediatrics*, scouts at the idea of the diffusion of tuberculosis by inhaling infected air and drinking infected milk, and returns to the old view that gland scrofula almost always precede tuber-

culosis, and that one who develops consumption is self-infected from his own tissues. The editor of *Pediatrics* judges from the agreement of several distinguished pediatricists at the Berlin Tuberculosis Congress, that the best and most certain mode of arresting the spread of the disease would be the treatment of scrofulous children in seaside sanatoria, that they were inclined toward the same views as Blos and Volland. His suggestion that the profession immediately set to work to confirm or disprove these views is one worthy of attention. Its practical bearing on the whole question of tuberculosis is obvious.

IS THE BIRTH-RATE IN THE UNITED STATES DECREASING?

What may serve as food for proper thought, especially for its bearing on the subject of overpopulation in the United States, is that of the birth-rate throughout the land. Aside from its medical status, this question is one which may engage the sober thoughts of wiser heads who come to deal with political economy as it applies to our country. In proving the subject of the birth-rate we have to fall back on that notorious factor of inaccuracy known as "statistics." In a recent editorial in one of our daily papers, a writer endeavors to prove that the birth-rate in the United States is gradually decreasing. This statement is backed by the statistics as obtained from the records of H. T. Newcomb, a statistician in the agricultural department at Washington. First of all it is believed that the population of the United States—not including colonies—in the year 1900 will be 74,480,860, based on the different state censuses. The increase for the past decade has been 18.94 per cent., which is below that of any previous decade. If the population had increased in the past decade in the same ratio as formerly, the population in 1900 would be 77,680,000, yet it is seen that the population will fall short of this number by 4,200,000. Of this loss it is estimated that 1,622,480 may be allowed for decrease of immigration and to children which might be born to them. However, there remains a loss of from 2,000,000 to 2,500,000 in the population if the increase in population is in the same ratio as in that period from 1880 to 1890. This loss of 2,000,000 to 2,500,000 is believed to be due to a decreased birth-rate, in both the negroes and whites. The writer states that in 1890 there were 1,800,000 less children under the age of 10 years than were expected, judging from the statistics of 1880, and it is believed that this decade will show even greater loss. This decennial loss has gone on for the past 100 years. It is claimed that whereas the native white population a century ago was 35.10 per cent. from 1790 to 1800, from 1890 to 1900 Mr. Newcomb claims that it will probably be only 25 per cent. Statistics show that increase for our total population was 30.08 per cent. from 1870 to 1880; 24 per cent. from 1880 to 1890, while it is believed this decade will only show an increase of 18.94 per cent. It is further pointed out that should this decrease in the birth-rate keep up, within twenty years the increase in this country will be only about that of European countries like England and Germany.

Medical News.

BY THE will of the late John Gillespie of Philadelphia the sum of \$10,000 has been left the Methodist Episcopal Hospital of that city.

DR. WILLIAM PORTER has been elected to the chair of physical diagnosis and diseases of the chest in the Beaumont Medical College, St. Louis.

BY THE recent death of Mr. Zephirin Chapleau, Quebec, Notre Dame Hospital receives \$10,000, the Hotel Dieu \$3,864 and the Sisters of Providence \$6,304.

OWING to the appalling loss of life from the storm in Porto Rico, the sanitary condition of the island is thought to be in a dangerous condition and a serious epidemic of disease is feared.

WHEN President Faure was in St. Petersburg, in 1897, he laid the corner-stone of a French hospital to be erected at the expense of the French Government. It is now practically completed and is to be named after the Countess Montebello, the wife of the present French ambassador, as it in great measure owes its existence to her efforts.

PROFESSOR BANDISSINI of Marburg has received simultaneous calls to Berlin and Bonn. . . . P. Kretschmer has accepted a call to Vienna. . . . B. Kader, privatdocent at Breslau, has been invited to the chair of surgery at Craeow. . . . Dr. E. Bennecke has taken Hildebrand's place at the Charité, Berlin.

AN AMERICAN firm wants the land on which the San Francisco Woman's Hospital at Havana, Cuba, is located, and has offered to build a new model hospital in another part of town and pay \$10,000 in cash in exchange for it. *El Progreso Médico* remarks that it is "high time the poor women of the city had a decent hygienic and comfortable hospital."

L' HÔPITAL International, just opened at Paris, rue de Vaugirard 180, by Bilhaut and others, is a small private and independent policlinic and hospital "fatterned after the small American hospitals," patients isolated or at most three in a room, the remuneration proportional to their means. It is practically the successor of the old Clinique Francaise and Péan's polyclinic.

A CLIPPING states that the increase in the number of women students at German universities during the last few years has been remarkable. In 1896 there were only 177 at the ten leading universities, but at the beginning of the present year the number had risen to 414. Most of the women take courses in philology or philosophy. Only 16 have studied medicine, 6 theology, and 6 law in the last four years.

THE N. Y. State Charities Aid Association has acknowledged its approval of the proposed plan for restricting the appropriation of public funds for the support of private charitable institutions. At present New York City gives over \$3,000,000 annually to 282 of these institutions, and, as referred to before in the JOURNAL, the Association recommends that the amount thus appropriated be gradually reduced, and that no institution receive funds until after investigation by a city official.

THE FRENCH Congress of Internal Medicine, held at Lille the first of August, introduced some noteworthy innovations. The addresses which had been printed and distributed beforehand, were not read, and the *rappor-teurs* did not take the floor until all the objections had been raised, a vast saving of time and patience. There was also a fine stereopticon for general use and a couple of dark chambers for members inclined to photography.

EXPERIMENTS, having in view the adoption of a more scientific system than that at present employed in feeding the insane in the New York State hospitals are now being made in that state by order of the State Commission on Lunacy, under the direction of Prof. H. D. Atwater. Prof. Atwater reports that with a dietary representing the best modern opinion on the subject, there can be not only better results as regards the physical condition of the patients, but very considerable saving in the matter of expense.

ANOTHER victory was scored by the Illinois State Board of Health, August 17, when Joseph Skalla, 571 West Eighteenth Street, Chicago, was fined \$100 and costs for violating the medical practice act. The prosecution charged Skalla with making and selling medicinal remedies and treating the sick in violation of the state law. It also showed that Skalla was not a regularly licensed physician, and on his testimony the justice imposed the regulation fine for the first offense. The case was not appealed.

NUMEROUS severe and puzzling cases of intoxication in Italy, especially among the tourists in hotels and boarding houses, have been traced to the custom of preserving the carcasses of the small birds which are killed in numbers for the feather trade, as they alight during their annual migrations. Those intended for the food market are supposed to be kept separate, but mistakes have evidently occurred, and the necessity of refraining from the toothsome "uccellini," as the cooked birds are called, should be impressed on all starting for Italy.

ACCORDING to the *British Medical Journal* of August 12, the plague continues to spread in Poona, India, to an alarming extent. On July 29 and 30, 360 cases occurred there, and 317 deaths. The plague has also reappeared in epidemic form in Bangalore. In Egypt, during the week ending August 2, six cases of plague appeared in Alexandria. Since the beginning of the outbreak in Egypt 37 cases have proven fatal and 39 have recovered, while four cases are still under treatment. Hongkong shows a decrease, there being but 30 cases and 30 deaths officially reported for last week.

DURING the past two weeks the Chicago coroner has been busily engaged in examining into the demise of several members of the Dowie flock. The first victim was a babe of 9 months, which expired August 16, without medical attendance. The death certificate was given by the coroner as pulmonary and intestinal tuberculosis. Mrs. Augusta Schlater died August 18, after a long illness during which she received treatment at Zion. She was sent to her home when it became apparent that she was unable to recover, and died within twenty-four hours. The third victim was a young woman of 23 years who came to Chicago from Iowa, and who died at Zion three days later.

FROM the *Chicago Times-Herald*, August 21, we learn that Dr. Nicholas Senn, who arrived in San Francisco on his return from the Hawaiian Islands, August 15, while in the Islands met with a slight accident during a hunting trip in the mountains of Molokai. The Doctor placed his gun against a rock and was trying to get his horse alongside, to take his gun, when the animal balked and then rolled completely over. In the tangle Dr. Senn was somewhat bruised and had a thumb mashed. Dr. D. R. Brower, Chicago, who accompanied Dr. Senn, while much interested in watching the skinning of a peacock after the hunt, and not noticing his proximity to the edge of the veranda, lost his balance, fell backward down a

flight of steps, turned three somersaults and had two fingers dislocated besides receiving several bruises.

DAWSON CITY continues to be very good in point of health. A letter last week from Dr. J. N. E. Brown, formerly secretary of the Ontario Medical Association, now private secretary to Governor Ogilvie, states that thus far there has been no outbreak of typhoid. The sanitation of the town has been greatly improved of late, but withal the people are anxiously looking forward to August and September and hope to at least escape with a moderate epidemic this year. Dr. Brown is at present spending his holidays 450 miles up the river, north of Dawson.

AN UNFORTUNATE accident occurred in St. Michael's Hospital, Toronto, a short time ago. This Hospital is presided over by the Sisters of St. Joseph, and by mistake a young lady who had been but recently operated on by one of the leading surgeons, had a solution of carbolic acid administered to her instead of a purgative draught. She died; and now the father of the deceased has instituted two suits, in each case for unstated damages, one against the surgeon for, as the plaintiff alleges, performing an unauthorized operation, and the other against the Sisters of St. Joseph.

THE RECENT tuberculosis congress appropriated \$800 to be awarded as a prize for the best or the two best works on "Tuberculosis as a Folk-Disease, and the Struggle Against it." They must be written in popular style, for general distribution, not be longer than three to five printed sheets, and each have a motto. They are to be sent to Prof. B. Fraenkel, 4 Bellevue-Strasse, Berlin, before Dec. 4, 1899. The work obtaining the prize becomes the property of the central committee. The judges are v. Leyden, several other professors and army officers and the Duke of Ratibor.

THE pure food department of Pennsylvania reports that during the past year there has been sold in the United States 87,000,000 pounds of oleomargarin, over four times as much as was sold in 1888. As a result of the large increase in the manufacture of this product it is also stated that there may be a falling off in cows numbering 4,309,000, worth in the aggregate \$12,927,000. Whether this mixture of lard, tallow and coloring material leads to more harm than pure butter must be solved by future generations. If cows are to be displaced by artificial foods, the question of solving bovine tuberculosis is near at hand.

SWIFT retribution has befallen the assassin of Dr. Bondi (See JOURNAL, July 22, p. 235), as within a month of the crime he was sentenced to thirty days' imprisonment, which is after all somewhat of a nominal sentence, as the man is a consumptive who had been in the hospital and applied for readmission. Dr. Bondi told him he must first obtain the necessary permit from the city authorities, which incensed him to the extent that he waylaid and stabbed the Doctor with a long nail, a couple of days later. The lay press is roused to demand the isolation of tuberculous and other degenerates before they commit crimes, instead of waiting till afterward. One of the nurses in the hospital was killed in 1894 by a tuberculous patient, who it seems was a friend of this assassin.

A GERMAN doctor now residing in Buffalo, Dr. Max Breuer, has recently been decorated with the cross of the Legion of Honor by the French Government, says *Prog. Med.*, August 5. It seems that a young French sailor on an oil ship from Rouen to Philadelphia had his arm crushed and gangrene appeared, with no medical as-

sistance on board. An English ship passed without paying attention to the signal of distress the captain raised, but the *Russia* of the Hamburg line hove to, although forbidden to approach within a certain distance of an oil ship. To the signal for a surgeon, the *Russia's* medical officer, Dr. Breuer, 28 years of age, responded with eight volunteers to man the boat in the heavy sea, amputated the arm and saved the sailor. When offered money for his services he replied: "the danger my men and I are facing at this moment can not be paid with money."

BEFORE the medical section of the National Fraternal Congress, held in Chicago, August 21, papers were read by Drs. J. W. Grosvenor of Buffalo, N. Y.; J. T. Craig, Kansas City, Mo.; C. S. Chase, Waterloo, Iowa; O. Millard, Flint, Mich.; S. T. McDermith, Denver, Colo.; C. A. McCollum, St. Paul, Minn.; and A. L. Craig, Chicago. The medical section is composed of the medical examiners in chief of the various fraternal orders. Dr. J. H. Christian of Baltimore presided and delivered an opening address. The following committees were appointed: On statistics of tuberculosis, to report at the congress of next year, Drs. C. A. McCollum, R. E. Moss and J. W. Grosvenor; on statistics of the height and weight of at least 100,000 applicants for fraternal insurance, Drs. R. E. Moss, T. Millman and C. A. McCollum. The following officers were elected: President, R. E. Moss, Port Huron, Mich.; vice chairman, T. Millman, Toronto; secretary, J. T. Craig, Kansas City.

A NATIONAL PARK IN MINNESOTA.—A proposition is being discussed looking to the reservation of from one to three million acres of land in northern Minnesota, for use as a national park. While the matter had been mentioned before, the Minnesota State Medical Society took the matter up at its meeting a year ago and appointed a committee to take preliminary action. The committee consisted of Drs. J. W. Bell, H. H. Kimball, and W. S. Layton of Minneapolis, and Dr. Parks Pitcher of St. Paul. Committees were also appointed from other bodies, and the matter was finally brought before the state legislature at its last session. This body memorialized Congress to withhold from sale for one year the land that it is contemplating to make into the park. Committees from Duluth, Minneapolis, St. Paul and other places are at work developing the scheme, with considerable prospect of success. If the idea of some of the promulgators is carried out, a national sanatorium for consumptives will be established somewhere in the park.

Therapeutics.

Treatment of Whooping-Cough.

In an article on whooping-cough, published in *The Therapist*, Dr. Edward F. Willoughby says: "The drug on which I have for more than twenty years mainly relied is choral-hydrate, of which the youngest infants are very tolerant. In some cases it may be useful to combine a bromid with the choral, and of late years I have found its action greatly aided by combining it with antipyrin—choral, antipyrin and vin. ipeaca, with syrup being now my favorite formula."

Cheny (Keating's Cyclopedic, vol. v) says, regarding the treatment of pertussis: "The patients, of course, should be isolated and allowed to have plenty of fresh air both by day and night, and should be allowed plenty of good nourishment. The drugs to be employed are: 1. Antiseptic agents, the best of which are the vapors of carbolic acid, cresolin and thymol, and quinin, which can be included in this class. It is very valuable, if the child can retain it, given in doses according to the

age of the patient—3/20 of a grain for each month and 1 1/2 grains for each year of the child's age—three times a day. 2. Antispasmodics, of which the most useful is bromoform, which should not be given in solution, but on sugar in a spoon, in doses of 1 drop every four hours, increasing the dose by one drop each day until an effect is produced. Antipyrin in combination with bromid of sodium is also of much value in the treatment, given in doses of 1/2 grain of the former to 2 grains of the latter, for a child of eight months, 1 to 2 1/2 gr. for a child of fifteen months, and 2 to 3 grains for a child of from 2 1/2 to 4 years of age. Belladonna may be given in small doses, repeated until the physiologic effect is produced."

Salophen.

M. Cresle considers salophen as now definitely settled in the therapeutic domain, says the *N. Y. Medical Journal*. It exerts, he says, an incontestable action upon acute and subacute rheumatism, but its effects are less constant than those of salicylate of sodium. In chronic and hemorrhagic rheumatism it has not shown itself superior to other drugs. Salophen possesses a powerful analgesic action, which is exercised even in those cases where this drug can not be looked for to effect a cure. It has given good results in migraine, in various neuralgias and in sciatica. Salophen employed in a medium dose produces no phenomena of intolerance, nor does it occasion headache, buzzing in the ears, or troubles of vision, but tolerance appears to be rapidly induced. In certain cutaneous affections, salophen appears to have some efficacy, but it is necessary to wait for further experience. The medium dose of salophen is sixty grains daily, more or less, according to the gravity of the complaint.

After Removal of Gall Stones.

We quote from a paper by Dr. Hal C. Wyman in the *Western Clinical Recorder*:

"A prescription which I have often used with great advantage to my patients from whom I have removed biliary calculi by a surgical operation is

- R. Podophyllingr. i
- Leptandringr. v
- Phosphate of sodaʒi

M. Div in twenty powders. Sig. Take one with a full glass of water once in three hours.

Another is:

- R. Tinct. taraxaci
- Tinct. enonymi
- Acidi nitrohydrochlorici dil aaʒii
- Elixir simplicis q. s. adʒiv

M. Sig. Take a teaspoonful with a raw egg in a glassful of cold water before each meal.

Another to relieve the pain and distress which sometimes follow operations.

- R. Extracti piscidie erythrinaeʒiii
- Spiritus etheris comp
- Spiritus vini rect. dil. aaʒi
- Syrupi pruni q. s.ʒiii
- Olei cinnamomigtt. i

M. Sig. Take a teaspoonful in wineglass of hot water once in three hours until pain is relieved.

The Use of Alkalies.

There is a curious paradox running through the medical literature of the past few years concerning the local and systemic result of the administration of alkalies. The writers on physiology and on diseases of the stomach have quite generally maintained that alkalies when they reach the stomach, cause an increased flow of gastric juice, the acid of which they say completely neutralizes the alkalies and there remains in the stomach an excess of acid. On the other hand have stood the advocates of the use of alkalies to diminish the acidity of the urine in gout, cystitis and renal affections. It is fairly clear that if the alkali is entirely neutralized in the stomach it can hardly change the reaction of the urine. As it is certain that the acidity of the urine may be changed by the administration of alkalies, the burden of proof is cast on those

who maintain that these salts increase the flow of acid into the stomach. Late physiologic and pharmacologic studies throw some light on this problem. No recent experimenter has been able to demonstrate that placing an alkaline solution in the stomach has any effect on the flow of the gastric juice. So it would seem that the well-established therapeutic uses of the alkalies in appropriate conditions are well founded, while the theoretic objection, that they produce a corresponding increase of the acidity of the stomach, is not well taken. Indeed the common experience of clinicians, that alkalies frequently disorder gastric digestion, indicates rather clearly that when the acid of the gastric juice is once neutralized, digestion may be interfered with because an acid reaction of the stomach-contents is necessary to the proper function of the organ. For this reason it is the general consensus of experienced opinion that the most effective alkali to administer for the relief of gastric acidity is the weakest—magnesium carbonate,—while for the systemic and urinary effect the dilute alkaline mineral waters are the most useful.

A Nerve Tonic.

- R. Asafetidaʒi
 - Acidi arseniosigr. ss
 - Strychnina sulphatisgr. ss
 - Ext. subulʒiis
 - Ferri subcarbonatisʒii
 - Quinina valerianatisʒi
- M. Make capsules No. xxiv. Sig. One capsule after each meal.

—Brown.

Sciatica.

- R. Chloralisʒiii
 - Sodii bromidiʒiii

 - Ext. escarce fluidi q. s.
- M. Div. in pil No. xii. Sig. One or two pills for a dose.

—Benjamin Ward Richardson.

[Attention should be called to the full dose of morphia and opium respectively in the above prescriptions, and the danger of producing the drug habit if used very long.—Ed. JOURNAL.]

Sulphate of Sodium in Catarrh of Stomach.

According to *La Medicine Moderne*, Simon, of Vienna, uses small doses of sulphate of soda for the treatment of this condition. He usually gives from ten to fifteen grains of it in about six ounces of hot water, and under these circumstances the catarrhal condition of the stomach, with its hyperacidity, passes away, and the sensations of pain and discomfort in the epigastrium with nausea are relieved. This method of treatment is supposed to do good by improving the motor power of the stomach.

Sodium Chlorate in Gastric Affections.

Gastric affections treated with chlorate of sodium in daily doses of from 75 to 120 grains are said to be usually much benefited, says *Merck's Archives*. Soupault reports that every variety of dyspepsia is clearly improved by it, and in cancer the pains, nausea and vomiting decrease or entirely disappear; the patient eats much more and with less disgust, the hematemesis ceases and the general condition improves. In gastric tumor, however, no benefit was obtained. In chronic gastritis, no matter what the cause or anatomical form, the results were also appreciably good. The action of sodium chlorate is particularly excellent in hypersthenic dyspepsia, or hyperchlorhydria and in the conditions resulting—gastroenterocœcia and gastric ulcer—exercising a lasting result. In the paroxysmic attack so frequent in sufferers from hyperchlorhydria and

ulcers, the effects are particularly brilliant. In asthenic dyspepsia, however, the effect is doubtful or altogether insufficient. In the doses named, no ill effects were ever observed, even though the remedy was given for several months.

Gastric Hyperacidity with Constipation.

- R. Magnesie
 Pulveris rhei aa. ʒii
 Sodii bicarbonatis
 Pulveris sacchari aa. ʒiv
 Olei menthe piperrita q. s.
 M. Sig. Half to one teaspoonful in water two hours after each meal.

Intestinal Fermentation with Constipation.

 M. Sig. Take a tablespoonful every two hours.
 —Carson.

Diuretic.

- R. Strychnine sulphatis gr. i
 Caffeine hydrochloratis ʒi
 Pulveris digitalis gr. xxx
 M. Disp. in caps No. lx. Sig. One capsule every three or four hours.

Deaths and Obituaries.

FREDERICK SMITH THOMAS, M.D., died at his home in Council Bluffs, Iowa, August 13. He had been suffering from dysentery for several days, but had recovered sufficiently to be out, when he had a relapse, from which he died. Dr. Thomas was born in Columbia County, New York, in 1845, and was taken to Illinois by his parents three years later. He graduated from what is now known as the College of Physicians and Surgeons of Keokuk, Iowa, in 1870. After practicing in different places in Iowa he went to Council Bluffs, in 1887, where he has since resided.

FREDERICK H. FINCKE, M.D., died in Chicago, August 13, of cardiac disease. His home was in Baltimore, Md., and he had been assigned to duty in the Department of Liberal Arts and Chemical Industries at the Paris Exposition. He was a graduate, Class of 1891, of the University of Maryland School of Medicine, Baltimore.

WILLIAM D. HARTMAN, M.D., University of Pennsylvania, 1830, died at his home in Westchester, Pa., August 16, aged

84 years. He was a conchologist of authority and had written much on his favorite topic, while still in the practice of his profession, which was active for over fifty years.

TENNIS SCHENCK, M.D., College of Physicians and Surgeons, New York, 1865, died at his home in Bath Beach, now of the Borough of Brooklyn, N. Y., August 15, aged 58 years. He was of a well-known family that early settled in that part of Long Island and was a graduate, in the Class of 1859, of Union College, New York State. He early identified himself with the King's County Hospital and continued his relations with it for many years.

Miscellany.

Prophylaxis of Tuberculosis.—The quarrymen of the Rehberg district in Germany, according to *Frankfurter Ztf.*, August 9, have solved the question of the prophylaxis of tuberculosis, which is so frequent and fatal among them, by simply dropping their tools in June and traveling to the coast, where they take service as sailors or herring fishermen for a few months, returning brown and hardy to their quarries in the fall.

Artificial Upper Jaw.—A patient was exhibited at the recent German National Dental Congress, whose entire upper jaw had been removed and replaced with an artificial contrivance, the work of Privatdocent Jessen of Strasburg and the dentist Hahl, with alveolar process and teeth, the two halves connected with springs. It was worn without inconvenience and enabled the patient to speak. Before it was applied articulation was impossible. This Congress, by the way, absolutely refused to receive female dentists as members.

The Pearl a Urinary Calculus.—According to certain naturalists, the pearl is a pathologic product, an attempt to get rid of some foreign body, a grain of sand, fragment of shell or something of the kind, which falls into the genital gland or vicinity, and is thus in fact merely a renal or urinary calculus, and the oyster an unfortunate mollusc victim of nephritic lithiasis. An article in the *Revue des Deux Mondes* describes the efforts that have been made to cultivate pearl development by trephining the shell and introducing a tiny artificial pearl as a nucleus.

Ignorant Midwives in Cheek.—The Illinois State Board of Health has sent the following circular to every midwife in the state, whose address could be found. Good results can already be seen by comparing the advertising columns of the newspapers to-day with those of a month ago:

Madam—Under the provisions of the Act to Regulate the Practice of Medicine in the State of Illinois, approved April 24, 1899; in force July 1, 1899; midwives are forbidden to call or advertise themselves as physicians or doctors, and prohibited from using any drug or medicine and from attending other than cases of labor.

The same law states that any one shall be regarded as practicing medicine, who shall treat, profess to treat, operate on or prescribe for any physical ailment or any physical injury to, or deformity of another.

You are directed, therefore, by this Board, to immediately discontinue all advertisements in the newspapers, in which you are designated as "Doctor," "Mrs. Doctor," "Doctress," or as "Physician," or in which you offer to treat human ailments; and to remove from your office, residence, or place of practice, all signs advertising you as "Doctor," "Mrs. Doctor," "Doctress," or "Physician." You are directed further to confine your practice to midwifery alone, as you are licensed as a midwife and as such are authorized to attend cases of labor only. You have no authority whatever to treat, or profess to treat, diseases of women, or to treat or profess to treat any physical ailment of another.

If you wish to advertise in the newspapers, or otherwise, you must do so as a midwife.

A violation of the above regulations, will subject you to prosecution by this Board, and will be deemed a sufficient cause for revoking your Certificate.

A Plea for the Outcast.—Dr. Denslow Lewis of Chicago, in response to the request of Dr. Isadore Dyer of New Orleans, the representative for the United States to the International Conference for the Prophylaxis of Syphilis, etc., to be held next month in Brussels, has written to the secretary-general and desires the publication of his reply, which is as follows:

Your conference is the most important gathering of medical men the world has ever known. The matters you will discuss are of vital interest to the individual and to society in general. The tendency of your deliberations is altruistic and philanthropic. You will consider the consequences of a God-given instinct improperly and injudiciously applied. You will treat, in no illiberal manner, of practical methods best calculated to preserve the health of our youth and to protect the best interests of society.

In consideration of the prostitute I beg that no inconsistent spirit of assumed superiority prevail. I trust it will be remembered that she is a victim of man's ill-directed obedience to a dominant instinct. She is the creature of our civilization and not a criminal. She is entitled to care and not punishment. She is a citizen who should receive the protection of our laws. She is an outcast from certain grades of society only. She is still a woman and at one time she was a pure and innocent child. She is now what she is not, because of innate depravity, but because our sociologic conditions fail to solve the problem the solution of which would make her existence impossible. She is of special interest to the hygienist and practitioner of medicine in so far as she serves as a disseminator of disease. Her care should consist in restrictive measures against the spread of disease and only to that extent should she be the object of police surveillance. Facilities for diagnosis and treatment of venereal disease should be multiplied. Measures which infringe on the personal liberty of the prostitute are inconsistent with our civilization except so far as they bear on the prophylaxis of disease.

Nature and Cause of Yellow Fever.—The Commission appointed by the U. S. Marine-Hospital Service, to investigate the nature and cause of yellow fever, has made its report. Drs. Wasdin and Geddings claim to have found that the bacillus *icteroides* of Sanarelli is the true parasite of the disease. This conclusion is based on the study of twenty-two cases diagnosed by native physicians as yellow fever, and in fourteen of these the diagnosis was confirmed by the Commission. In thirteen of these the bacillus *icteroides* was isolated by Drs. Wasdin and Geddings, and in the other it was also found by another observer to whom tube cultures made at the autopsy had been given. The Commission also isolated the organism in 83 per cent. of the cultures made at autopsies at New Orleans, from cases occurring in the yellow fever epidemic in 1897, thus identifying the Cuban and the Louisiana bacilli. The blood from a number of patients suffering from other disorders failed to reveal the germs, though taken in the same way, and tested in the same manner. Similar tests were made with thirty-one bodies of patients dead from various diseases, but in none was this bacillus found. The Commission therefore assumes that the organism of Sanarelli is found only in bodies sick with, or dead from yellow fever, conceding at the same time that in many of the sick the blood may not yield the germ. Experiments were also made to ascertain the natural history of the organism, its mode of entering the body, its colonization therein, its toxic possibilities, and its distribution in the organs post-mortem. They found it pathogenic by artificial inoculation to various animals, but the effects were also the same with other germs, the bacillus X, Havelberg's bacillus, bacillus coli, etc. Then placing these animals under condition of natural infection, they found that the bacillus *icteroides* was specific as compared to those mentioned above, and that it should be classed with bacilli cholerae, and bacillus typhosus, as a true infection organism. The Commission also claims to have determined that the route of infection is through the lungs, and that from there it passes to the general circulation. Their conclusions are:

1. That the micro-organism discovered by Prof. Giuseppe Sanarelli, of the University of Bologna, Italy, and by him named "bacillus *icteroides*," is the cause of yellow fever.

2. That yellow fever is naturally infectious to certain animals, the degree varying with the species; that in some rodents local infection is very quickly followed by blood infection; and that, while in dogs and rabbits there is no evidence of this subsequent invasion of the blood, monkeys react to the infection the same as man.

3. That infection takes place by way of the respiratory tract, the primary colonization in this tract giving rise to the earlier manifestations of the disease.

4. That in many cases of the disease, probably a majority, the primary infection, or colonization in the lungs, is followed by a "secondary infection," or a secondary colonization of this organism in the blood of the patient; this secondary infection may be complicated by the coexistent passage of other organisms into the blood, or this complication may arise during the last hours of life.

5. That there is no evidence to support the theory advanced by Prof. Sanarelli that this disease is primarily a septicemia, inasmuch as cases do occur in which the bacillus *icteroides* can not be found in the blood, or organs in which it might be deposited therefrom.

6. That there exists no casual relationship between the bacillus "X" of Sternberg and this highly infectious disease; and that the bacillus "X" is frequently found in the intestinal contents of normal animals and of man, as well as in the urine and the bronchial secretion.

7. That, so far as your Commission is aware, the bacillus *icteroides* has never been found in any body other than one infected with yellow fever; and that whatever may be the cultural similarities between this and other micro-organisms it is characterized by a specificity which is distinctive.

8. That the bacillus *icteroides* is very susceptible to the influences injurious to bacterial life; and that its ready control by the processes of disinfection, chemical and mechanical, is assured.

9. That the bacillus *icteroides* produces *in vitro*, as well as *in vivo*, a toxin of the most marked potency; and that, from our present knowledge, there exists a reasonable possibility of the ultimate production of an anti-serum more potent than that of Prof. Sanarelli.

London.

(From Our Regular Correspondent, August 1).

INFANT FEEDING AND HOT WEATHER.—Owing to the hot weather during the last six weeks, the diarrhea rate among children in the large cities has gone up by leaps and bounds. 98 deaths one week, 204 the next and 466 last week. But our profession has reason to be proud of the results of its work and teaching, for in spite of the unprecedented length and severity of the heat wave, the diarrhea rate has not even yet reached the "normal" for this week of the year. This must be attributed to the more general use of milk and the better preserved and sounder condition of both it and other infant foods, thanks to vigilance and sanitation authorities. But there is room for much improvement in this respect yet, and we Americans may feel honestly proud of the example we are setting to the British brethren. The best of English dairies are not equal to the average of our own in respect to scrupulous cleanliness and skill in handling their product. Scarcely any of them use ice in any form, or cool their milk before it is sent out, and 90 per cent. of all milk and cream is still delivered in small black and battered tin cans with brass mountings, in place of glass jars. A few dairies use bottles, but the usual "Rhine-Wine" shape with small necks and rubber corks, and the suggestion of the use of glass jars is received with horror! "Why, they would be broken in a week!" It is hard to get milk which does not deposit the ancient and familiar black sediment on standing and, as a consequence, most of it will hardly keep for twelve hours, even in a fairly cool place. Our climatic extremes, aided by the more general intelligence of our people, have driven us to a higher plane in these matters.

UNIVERSITY OF LONDON.—Another welcome development in medical education in England has been inaugurated in connection with the proposed University of London. This is a meeting of the teachers of anatomy, physiology and medical chemistry from the various hospital medical colleges of London, for the purpose of trying to arrange either a central teaching institution or a uniform curriculum for the first two years, or scien-

tific portion of the medical course. The conference was a stormy one and ended in something approaching a split, with the appointment of two separate sets of committees, one to devise means by which the improvement could be brought about and the other how it might be prevented. But to get the meeting held at all and the subject on the tapis was a great advance. As it stands at present, the anatomy and physiology teaching of London's few hundreds of junior medical students is divided up among eight or ten complete staffs of teachers, nearly all of whom are so poorly paid that it is hopeless to expect an adequate life income from their work. Consequently they teach in the good old antediluvian fashion until such time as they can get "promotion" to surgical and medical positions, working up a practice meanwhile. As was brought out with painful distinctness in the recent loss of London's only physiologist of international reputation, Prof. Schaefer, to poor, but intelligent little Edinburgh, there is scarcely a chair of anatomy or physiology, or for the matter of that, of any branch of scientific medicine in London, which has a decent salary attached to it. One promising young student after another has started out in original research work, only to sink back into the slough of practice, after eight or ten years of genteel starvation. If the Jenner Institute and the University of London would only establish half a dozen chairs in scientific medicine, between them, with salaries, which are by themselves a guarantee of a responsible life income, such as a man could live on and keep his own self-respect, they would, by giving this class of eager workers some reasonable hope for the future, do an incalculable service to English medicine. There are scores of brilliant young fellows in the English profession, who love their chosen work and would be glad to devote their whole lives to it, if they only had a guarantee of bread and salt in return. It is precisely in giving young men of this sort the mere pittance that they require, and a chance to win by original work, positions of moderate competence in later life, that the secret of Germany's wonderful strides in the march of scientific progress lies, not merely medical but general.

VACCINATION.—An interesting vaccination situation has developed, and is still developing, at Leicester. This town has long been one of the head-centers and banner-bearers of the "antis," as owing to the intensity of popular prejudice against "blood-poisoning" vaccination there has been almost completely suspended for some time. Every member of the Board of Guardians is a rabid antivaccinationist, and as prosecution for non-conformity to the law rests with this body, the statute has been a dead letter for years past. However, they still had a vaccination officer, whose salary was paid under protest, although his occupation was like Othello's. A short time ago he died and some massive intellect on the board conceived the daring gallery-play of refusing to appoint another. This was too good an opportunity of making spectacular idiots of themselves to be missed, and, moreover, it would restore the "anti" propaganda to that place in the popular eye, which it is rapidly slipping out of since the conscience clause was passed. The government remonstrated with them without effect. A writ of mandamus was applied for before the Queen's Bench, and this was resisted by the Guardians who came up to London in a body, attended by brass bands, obsequious local M.P.'s, cheering crowds of fanatics, and all the accessories of martyrs for the cause. The writ was of course issued, ordering them to at once appoint or be imprisoned for contempt of court, whereupon they pranced back to Leicester and are now holding ghost-dances and working themselves up to the sublime pitch of suffering for the faith and going to jail, when the time given in the mandamus expires. Their clap-trap stage-play has succeeded beyond their hopes. They have attracted the widest attention, but not of the kind they desired. On all hands one hears only words of disapproval and disgust, and the episode is going to do yeoman service in the cause of science and com-

mon sense. It is the most convincing demonstration imaginable of what a besotted relic of barbarism and ignorant fanaticism the antivaccination movement is.

EPIDEMICS OF POISONING.—The two "epidemics" of food poisoning are still mysteries. Nothing has been discovered by the analyst, in any of the cherries, milk or other food eaten by the eighty children at Blackheath, (see JOURNAL, August 12, p. 433) nor can any cause be discovered for the poisonings among the guests at the Inns of Court Hotel a few days before. Another of the guests attacked has just died and several are still seriously ill with symptoms of ptomain poisoning. We may, however, breathe easier on this side of the Atlantic, for samples of the "tinned American apricots," which were at once blamed for the entire episode, by the scientists of the daily press, as soon as discovered on the bill of fare, have been tested and found perfectly sound and wholesome. The Blackheath episode has however given the irrepressible idiot who "writes to the papers" one of the chances of his life, and alas he signs himself "An American." He gravely informs the admiring British public that he can explain the mystery, as "no well-informed American would think of eating cherries and milk together, knowing that in combination they form a deadly poison," and President Tyler is alleged to have died in consequence of imbibing this unhallowed mixture, there being, presumably, "no well-informed American" within shouting distance to warn him of the certain consequences. What does our alleged compatriot mean by keeping priceless toxicologic truths like these buried in his bosom until they are too late to be of any use?

WATER FAMINE.—London is threatened with a water famine, as she always will be in summer until she gets some other source of supply than the charming little brooklet, disguised under the name of "Father Thames."

Canada.

(From Our Regular Correspondent.)

TUBERCULOSIS IN CANADA.—The antituberculosis crusade is being placed on a firm footing in Canada. So far, no great national movement has been inaugurated; but the enlightened and public-spirited physician-citizen is again giving evidence of what true philanthropy there is in our own profession. In June last, the Ontario Medical Association took up a whole afternoon on this one topic. The symposium on tuberculosis was opened in an admirable paper on the "Sanitarium Treatment of Pulmonary Tuberculosis," by Dr. Vincent Y. Bowditch, of the Sharon Sanitarium, Boston, which was followed by Dr. N. A. Powell, Toronto, chief consulting physician to the Gravenhurst Sanitarium, in a talk on "The Earliest Diagnosis and Selection of Cases for Sanitarium Treatment." "Home Treatment and Prevention" was the subject of Dr. T. F. MacMahon's (Toronto) paper; while Dr. Charles Sheard, medical health officer, Toronto, spoke on "Care and Prevention." Montreal and the lower provinces have been by no means idle. Dr. H. A. Lafluer has contributed a readable paper on "The Recognition of Incipient Tuberculosis in Man;" while Dr. McEachern, dean of the faculty of comparative anatomy, McGill University, and chief inspector and veterinarian for the Dominion, has ably dealt with the "Prevention of Tuberculosis in Animals, with special reference to prevention in the Dominion." Speaking of his experience with the tuberculin test and its results in animals, he stated that over 10,000 cattle, within the past twelve months, have been tested at government expense, from the Atlantic to the Pacific. In the large number of post-mortems made, there was scarcely a failure to discover the tubercle reported. Before the Montreal Medico-Chirurgical Society, Dr. A. J. Richer read a paper on "Sanatoria—Locality and Cure." He told of the Gravenhurst Sanitarium in Muskoka, situated at a height of somewhat less than 800 feet above sea-level, and emphasized the good and excellent work that institution had been doing the last two years. He thought Kamloops, B. C., at an altitude of 1100 feet, with as dry a climate as Colorado and a mean temperature of 5 degrees above that of Montreal, and more uniform at that, offered

exceptional advantages for a sanatorium. It is the day for the sanatorium and open-air treatment, and Canada promises not to be very far behind in this regard.

THE DISPENSING PHYSICIAN.—Another question rapidly coming to the front, more especially among physicians in cities and towns, is that of the "dispensing physician." From Mr. L. J. Melius, a member of a well-known Halifax drug firm, has emanated an article on this topic, which that gentleman read at the summer meeting of the Pharmaceutical Association of Nova Scotia. Mr. Melius can probably speak with some authority on the subject, as his firm has the reputation of dispensing more physicians' prescriptions than any other single drug firm in the Dominion. Especially in the maritime provinces has this article attracted attention; but elsewhere the profession is gradually becoming alive to the fact that it will be more profitable for the doctor to do his own dispensing; better results in some cases will also accrue. Mr. Melius, however, puts the case strongly for the druggist and puts it well. Flagrant violations of ethical customs between physicians and chemists are all too common on the part of the latter; and the druggist will only have to thank his own covetous propensities for it, when the physicians do all their own dispensing. In Toronto, a pharmaceutical firm has recently been established, whose whole business patronage comes through physicians, and their aim is to supply the dispensing doctor with everything needful. We are glad to see Mr. Melius, however, calling on his fellow wielders of the pestle to discourage "counter prescribing," with all their might. He might go still further and denounce disgraceful substitution, "repeats," the placarding on their walls and store-fronts of ephemeral nostrums and the filling of prescriptions for others than for whom originally intended.

HEALTH OF LEGISLATORS.—The long session of the Dominion House of Commons, just terminated, in its effects on the physical health of members is worthy of both comment and a passing notice. How frequently during the lifetime of this parliament (elected in 1896) have the two leaders on both sides of the house been called on to pronounce an eulogium and give expression to their sorrow, at the departure of some fellow member at the hand of death, is instanced from the fact that fifteen times they have had to perform this duty. The effects of long hours and late sittings, and very often all-night sessions on a house composed of 215 members is truly startling. The assembly hall is notoriously deficient in point of ventilation; and combined with this, the fact that our public men are known to take very little systematic exercise, all seems to militate against them. Public life is not all a bed of roses. Our statesmen should go in for more sport and exercise, abandon these late sittings and all-night sessions, and no doubt reap the reward in a greatly reduced death-rate.

HUMANIZED MILK.—Dr. LaBerge, city medical health officer, Montreal, has lately received an important letter from Dr. D. Gilbert of Brussels, which deals with the system of sterilized milk in vogue in that country, known as "maternized" or "humanized" milk. Parliament and the health authorities in that city have been taking a keen interest in the various branches of the pure milk question. He describes the process for "humanizing" milk, and concludes by showing how infants can be fed on this fluid, until they reach 8 months of age, at a nominal cost. Dr. LaBerge has already interested himself in the formation of a company or association which will supply this "humanized" milk, prepared on the scientific principles on which many countries are now supplying it.

"CHRISTIAN SCIENCE" IN B. C.—British Columbia has so far as known supplied the latest victim to "Christian Science" cussedness. "Evangelist" Eugene Brooks tried to cure a child of Captain McCoskie of Victoria, by the method, with fatal results. The child was taken with a serious illness and Dr. Duncan sent for. This was the only visit of the Doctor, and was made a month prior to the lad's death. Brooks is a disciple of George Armour Fair's sect, Chicago. The father is naturally very much incensed and talks of taking proceedings against the imposter, as it was contrary to his expressed wishes that his son should be treated in any such manner, he himself being away from Victoria on a sea voyage and the imposition being practiced on his invalid wife.

Queries and Minor Notes.

INTERNATIONAL MEDICAL CONGRESS.

CLEARFIELD, PA., August 17, 1899.
To the Editor.—Will you let me know who is chairman of the section of genito-urinary surgery at the next meeting of the International Medical Congress? When and where is it to be held?
 J. A. M.

ANSWER:—Paris, 1900, Prof. Chauffard, General Secretary.

ETHICS AND PREVENTION OF CONCEITON.

WILKESBARRE, PA., August 21, 1899.
To the Editor.—In the JOURNAL of AUGUST 12, I notice among the (Current Medical Literature) articles an article (No. 1) by John C. King. Will you please inform me where I can obtain a copy and price? G. F. L.

ANSWER:—The original paper was published in the *Southern California Practitioner*, Los Angeles, Cal., July. Send ten cents to the publisher, for a copy.

PAROTID EXTRACT.

CHICAGO, ILL., July 19, 1899.
To the Editor.—I note that parotid extract is highly recommended in the JOURNAL of July 12, 1899, as a cure for ovarian troubles. Will you kindly inform me where it can be procured, and the dosage? I have a case which that description fits exactly.
 W. G. H.

ANSWER:—The parotid gland extract used by Malletti, in the cases noted in the article abstracted, was from the Phospho-Albumin Co., Chicago, and was put up in three-grain capsules. In the cases where he mentions the dose given, it was usually 3 grains, three times a day. Parotid extract is also prepared by Armour & Co. and others.

ASCITES IN CHILDREN.

HILLSBORO, N. D., August 4, 1899.
To the Editor.—In *Pediatrics* July 5, 1899, there is an article headed, "Radical Cure of Ascites in Children," referring to the production of "Anastomosis of Vessels of Liver and Abdominal Wall," and some cases of Professor Talma. What did Professor Talma do? Did he operate to join these vessels successfully?
 T. M.

ANSWER:—Talma's patient was operated on by opening the abdomen and fastening the greater omentum and the gall-bladder to the abdominal wound, thus setting up a collateral circulation. In a later operation the spleen was similarly treated. This case is reported in the *Berliner Klin. Woch.*, 1898, pp. 835-836. The case is briefly described in this JOURNAL, May 27, 1899.

TREATMENT OF DEAFNESS IN THE PNEUMATIC CHAMBER.

EVANSVILLE, IND., August 7, 1899.
To the Editor.—In the JOURNAL for June 10, p. 1311, you give a short extract from the *Muenchever Med. Woch.*, of May 16, concerning deafness treated by means of the pneumatic chamber. Will you call this number of the *Muenchever* journal be had, or could you publish the article in full?
 T. W.

ANSWER:—The article referred to can be obtained from the publisher J. F. Lehmann, Henstrasse, 20, Munich, Bavaria (*Muenchever Medicinische Wochenschrift*, xlv. 20, May 16, 1899). It states that the most complete study of the subject is a pamphlet by Dr. J. Hovent of Brussels, published two years ago by Aug. Bernard of Liège, Belgium: "A Treatment of the So-Called Incurably Deaf People." Among his tabulated observations are five women with simple deafness of five to thirty years' duration entirely cured with one to fourteen sittings. Menstrual pseudomembranous agglutination or catarrh had preceded the deafness in three cases. Five other cases, duration five to nineteen years, were cured with one to eleven sittings, although there was more or less discharge from the ear. His record for 1893-1896 included 128 persons who, with five exceptions, had all been declared incurably deaf by specialists in Belgium and France.

FOR SALE TO THE HIGHEST BIDDER.

—ILL., August 10, 1899.
 We can hardly believe that there are men in Chicago, who are willing to sacrifice their professional honor as is indicated in the letter printed below. Evidently there is one, but there certainly can be no others. If there are, then of course it is good business sense on the part of those who have patients to sell, to sell them to the highest bidder. The letter was written to a well-known surgeon of Chicago, and as a similarly worded letter was sent to at least one other surgeon, by the same writer, it is probable that he will get the best terms that can be had.

—ILL., August 10, 1899.
Dear Doctor.—It so happens that I have occasion to refer operation cases to the city for treatment. I have been sending them to a gentleman who has recently treated me in a way I don't like, and I am therefore desirous of making arrangements with some one else for the portion of the fee do you usually give the doctor who brings the case? I am free to say I have always had 50 per cent. This is not too much, because I always know just what the patient can stand, and have never, unless worked up for a good fee beforehand. This is a rich farming country, you know. An early answer will oblige, as I have several cases that ought to be operated on very soon.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including August 17, 1899:

LEWIS S. ANDERSON, lieutenant and asst.-surgeon, 29th Inf. Vols., having tendered his resignation is honorably discharged August 14, 1899.

Fred D. Barney, acting asst.-surgeon, from New York City to San Francisco, Cal., for duty in the Department of California.

William C. Berlin, acting asst.-surgeon, previous orders revoked; he will report for duty at Fort Snelling, Minn.

Rufus D. Boss, acting asst.-surgeon, from Fort Armistead, Md., to temporary duty at Fort Myer, Va.

Robert Boyd, acting asst.-surgeon, leave of absence granted, with subsequent assignment to the Department of California.

Alfred E. Bradley, major and surgeon Vols., from the hospital ship *Relief* at San Francisco, Cal., to his proper station, Fort Yellowstone, Wyoming.

Earl S. Bullock, acting asst.-surgeon, from Fort Collins, Colo., to Fort Bayard, N. M.

Henry J. Combel, acting asst.-surgeon, from Bay St. Louis, Miss., to Fort Sam Houston, Texas, to accompany the 33d Inf. Vols. to Manila, P. I.

Edward T. Comegys, major and surgeon, U. S. A., to close the medical supply depot at Atlanta, Ga., and assume charge of the general hospital and supply depot at Savannah, Ga.

Calvin DeWitt, lieutenant, and deputy surgeon-general U. S. A., now at Fort Monroe, Va., to take charge of the Josiah Simpson General Hospital.

Douglas F. Duval, lieutenant, and asst.-surgeon, U. S. A., former orders revoked; he will report at Brooklyn, N. Y., for duty on the hospital ship, *Mosier*.

Robert M. Embers, Sr., acting asst.-surgeon, from Little Rock, Ark., to Fort Leavenworth, Kansas.

Thomas E. Ervin, acting asst.-surgeon, from New Brighton, N. Y., to temporary duty at Fort Crook, Neb.

Albert P. Fitzsimmons, acting asst.-surgeon, from Tecumseh, Neb., to San Francisco for duty in the Department of California.

Robert J. Galt, major and surgeon, from Angel Island, Cal., to Manila, P. I., for duty with the 8th army corps.

Herman W. Gross, acting asst.-surgeon, from Brookline, Mass., to Plattsburg, Barracks, N. Y., to accompany the 26th Inf. Vols., to Manila, P. I.

Andy Hall, acting asst. surgeon, from Mount Vernon, Ill., to San Francisco for duty in the Department of California.

D. B. Hartinger, acting asst.-surgeon, from New York City, to Middleport, Ohio, for annulment of contract.

Philip F. Harvey, major and surgeon, U. S. A., from Fort Snelling, Minn., to the presidio of San Francisco, Cal.

John Sturgeon Hill, acting asst.-surgeon, from Allegheny City, Pa., to the Department of California.

Deane C. Howard, captain and asst.-surgeon, U. S. A., from Fort Columbus, N. Y., to temporary duty at West Point, N. Y.

D. J. Johnson, acting asst.-surgeon, member of an examining board in session at Fort Terry, Plum Island, N. Y.

Verner Kenerson, acting asst.-surgeon, from Fort Myer, Va., to Buffalo, N. Y., for annulment of contract.

Matthew Leeper, acting asst.-surgeon from Louisville, Ky., to Fort Crook, Neb.

William F. Lippitt, Jr., captain and asst.-surgeon U. S. A., member of a board in Washington, D. C., to examine persons designated for appointment as second lieutenants in the army.

Robert J. McAdory, acting asst.-surgeon, from duty in the Department of California to the hospital ship *Relief*, now at San Francisco, Cal.

J. H. Milrick, acting asst.-surgeon, from Baltimore, Md., to San Francisco, Cal., for duty in the Department of California.

Edward B. Moseley, major and surgeon U. S. A., from the Presidio of San Francisco, Cal., to post duty at Angel Island, Cal.

Edward L. Munson, captain and asst.-surgeon U. S. A., member of a board in Washington, D. C., to examine persons designated for appointment as second lieutenants in the army.

Charles D. Noble, acting asst.-surgeon, to accompany recruits from Columbus Barracks, Ohio, to San Francisco, Cal., thereafter to return to his station.

Harry O. Parley, major and surgeon, U. S. A., from the Army and Navy Hospital, Hot Springs, Ark., to San Francisco, Cal., to take command of the hospital ship, *Relief*.

Junius L. Powell, major and surgeon, U. S. A., from Fort Riley, Kan., to temporary duty in the Department of California.

Gilbert L. Pray, acting asst.-surgeon from Webster City, Iowa, to duty in the Department of California.

John J. Reilly, acting asst.-surgeon from the transport, *Iogon*, to the hospital ship, *Mosier*.

Charles Richard, major and surgeon, U. S. A., from the Josiah Simpson Hospital at Fort Leavenworth, Kansas.

Henry D. Snyder, captain and asst. surgeon, U. S. A., member of a board on clothing at Savannah, Ga.

Dwight B. Taylor, acting asst.-surgeon from the Division of Cuba to Columbus Barracks, Ohio.

George H. Torrey, major and surgeon, U. S. A., from Fort Leavenworth, Kan., to command the Army and Navy General Hospital, Hot Springs, Ark.

Cornelius D. Van Wageningen, acting asst.-surgeon, from the hospital ship *Relief*, now at San Francisco, Cal., to New York City for annulment of contract.

Isaac F. Ware, captain and asst.-surgeon, U. S. A., ordered for examination before an army retiring board in session in San Francisco, Cal.

J. Samuel White, acting asst.-surgeon, from Washington, D. C., to the Department of California.

Robert H. White, major and surgeon, U. S. A., (retired) resignation accepted to take effect August 18, 1899.

A. W. Williams, acting asst.-surgeon, from New York City, to Camp Meade, Pa., to accompany the 27th Inf. Vols., to Manila, P. I.

Compton Wilson, acting asst.-surgeon, from New York City to report to the surgeon-general, Washington, D. C., for instructions.

Charles E. Woodruff, captain and asst.-surgeon, U. S. A., former orders revoked, to proceed from Benicia Barracks, Cal., to Fort Riley, Kan., for duty.

Movements of Navy Medical Officers.—Changes in the medical corps of the U. S. Navy for the week ending August 18, 1899:

Asst.-Surgeon F. B. Bagan, detached from the *Wabash* and ordered to the *Scorpion*.

Asst.-Surgeons G. D. Costigan, M. S. Elliott, F. L. Plensdwell, D. N. Campbell, and J. C. Roy, promoted to the rank of Lieutenants, junior grade, from July 1, 1899.

Surgeon L. B. Baldwin, ordered to be examined by the naval retiring board, Washington, D. C., September 12, and then home and to wait orders.

Surgeon L. W. Atlee, detached from the *Bennington* and ordered to the *Solace*.

P. A. Surgeon H. D. Wilson, detached from the *Castine* and ordered to the *Solace*.

Asst.-Surgeon W. M. Wheeler, detached from the *Baltimore* and ordered to the *Solace*.

Asst.-Surgeon J. C. Thompson, detached from the *Baltimore* and ordered to the *Cataraugus*.

Asst.-Surgeon D. G. Beebe, detached from the *Monadnock* and ordered to the *Bennington*.

Asst.-Surgeon T. M. Lippitt, detached from the *Solace* and ordered to the *Bennington*.

Asst.-Surgeon F. M. Furlong, detached from the *Solace* and ordered to the *Oregon*.

Marine-Hospital Changes.—Official List of Changes of Station, and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended August 10, 1899.

Surgeon S. D. Brooks, to proceed to Augusta, Maine, for special temporary duty.

P. A. Surgeon Rupert Blue, to proceed to Columbia, Washington, for special temporary duty.

Asst.-Surgeon L. D. Fricks, to report to P. A. Surgeon A. C. Smith for duty.

Acting Asst.-Surgeon W. C. Todd, granted leave of absence for seven days.

Hospital Steward S. W. Richardson, to report to Washington, D. C., for assignment to special temporary duty; to proceed to Norfolk, Va., and report to P. A. Surgeon A. C. Smith for temporary duty.

Hospital Steward Frank L. Gibson, relieved from duty at the Delaware Breakwater Quarantine Station and directed to report at Washington, D. C., for temporary duty.

Hospital Steward N. C. Comfort, to proceed to Hampton, Va., and report to Surgeon J. H. White for temporary duty.

PROMOTIONS.
P. A. Surgeon G. M. Kniguder commissioned as surgeon.
P. A. Surgeon J. J. Kinyoun commissioned as surgeon.

APPOINTMENTS.
Charles A. Warhanik of Illinois, to be junior hospital steward.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended August 18, 1899:

SMALLPOX—UNITED STATES.

Florida: Jacksonville, July 29 to August 12, 9 cases.

Kentucky: Louisville, August 3 to 10, 3 cases.

Massachusetts: Everett, July 29 to August 5, 1 case.

New York: New York, August 8 to 12, 1 case.

Ohio: Cleveland, August 5 to 12, 4 cases.

Pennsylvania: Altoona, August 5 to 12, 2 cases.

Washington: Spokane, July 29 to August 5, 1 case; Tacoma, July 29 to August 5, 1 case.

SMALLPOX—FOREIGN.

Arabia: Aden, May 1 to 3, 1 death.

Belgium: Antwerp, July 22 to 29, 3 cases.

Brazil: Rio de Janeiro, June 30 to July 7, 39 cases, 27 deaths.

China: Hongkong, June 24 to July 15, 2 cases, 1 death.

Greece: Athens, July 22 to 29, 11 cases, 3 deaths.

India: Bombay, July 4 to 15, 15 cases.

Mexico: Mexico, July 23 to 30, 9 cases, 7 deaths; Progreso, July 13 to 22, 2 cases, 1 death.

Columbia: Panama, July 21 to August 1, 3 deaths.

Russia: Moscow, July 15 to 22, 7 cases, 4 deaths; Odessa, July 22 to 29, 4 cases, 1 death; Warsaw, July 8 to 29, 3 deaths.

Settlements: Singapore, June 25 to July 1, 2 deaths.

Turkey: Smyrna, July 15 to 23, 1 death.

Uruguay: Montevideo, July 8 to 15, 1 case.

YELLOW FEVER.

Brazil: Bahia, July 16 to 21, 9 cases, 1 death; Rio de Janeiro, June 30 to July 7, 3 deaths.

Columbia: Panama, August 1 to 8, 2 cases, 1 death.

Cuba: Havana, July 27 to August 3, 9 deaths; Santiago, July 22 to 29, 8 cases, 3 deaths.

CHOLERA.

India: Bombay, July 4 to 15, 1 death; Calcutta, July 1 to 8, 4 deaths.

Japan: Yokohama, July 15 to 25, 1 death.

China: Amoy, July 8 to 15, 275 deaths; Hongkong, June 24 to July 15, 306 cases, 305 deaths.

Egypt: Alexandria, July 1 to 16, 17 deaths.

India: Bombay, July 4 to 16, 115 deaths; Calcutta, July 1 to 8, 7 deaths.

CHANGE OF ADDRESS.

Beebe, S. C., from Surprise, Neb., to David City, Neb.

Bird, J. H., from 1407 to 102 So. Ewing Ave., St. Louis, Mo.

Batts, E. L., from Galveston to 602 1/2 Main St., Houston, Texas.

Carl, J. H., from One to Six S. Third St., Clinton, Mo.

Chehran, C. C., from Hamilton to 218 1/2 E. State St., Jacksonville, Ill.

Children, G. A., from Hospital for Insane to Yankton, S. D.

Caldwell, W. S., from Vancouver, B. C. to care Hongkong and Shanghai Bank, Hongkong, Yokohama, Japan.

Guiteras, R., from 23 W. 53d to 63 W. 54th St., New York City.

Kimball, A. L., from Ann Arbor, Mich., to Gen'l Del., Boston, Mass.

Lewis, T. H., from St. Luke's Hospital to 340 Oak Ave., Evanston, Ill.

Madden, J., from Sentinel Bldg to 316 3/4 Goldsmith Bldg., Milwaukee, Wis.

Nickerson, T. S., from 18 Maple St., to 219 Hampden Court B., Chicago.

Noble, R., from 116 to 1715 E. 5th St., Dayton, Ohio.

Norton, C. D., from Greeley, Colo. to Pompano, Cal.

Norton, C. F., from 61 Stouton St., El Paso, Texas, to 1104 Guadalupe St., Dallas, Texas.

Norrick, J. H., from Pensylvania, to Fredricktown, Knox Co., Ohio.

Pickett, W. H., from 6th and M Sts. to 642 Preston St., Louisville, Ky.

Raub, J. F., from 421 B St., N. E., to 225 First St., N. E., Washington, D. C.

Suarez, J. M., from care Mr. Romer, Milberg to 1220 Louisa St., New Orleans, La.

Wright, John B., from Coharie, Sampson Co. to Granite Falls, Caldwell Co., N. C.

Werner, C. A., from Harcourt, Iowa to 249 E. 9th St., St. Paul, Minn.

Original Articles.

MANAGEMENT OF PREGNANCY, COMPLICATED BY ABDOMINAL TUMORS.*

BY RUFUS B. HALL, A.M., M.D.,
CINCINNATI, OHIO.

The subject of abdominal and pelvic tumors, associated with pregnancy, including as it must malignant growths, being so large a subject, I will confine myself entirely to the discussion of the management of ovarian and uterine tumors complicating pregnancy.

One of the gravest problems ever presented to a physician is the satisfactory settlement of this question. We not only have the interests of the mother to conserve, but the interests of one that is wholly unable to protect itself. On the satisfactory settlement of this question much depends, not only to the patient and her friends, but to the good name of the physician in charge and, indirectly, to that of the whole profession. While these cases are not common, they occur frequently enough to make this subject one of exceeding interest to every man engaged in the special work of this Section. I think I voice the sentiments of my hearers when I say that no class of cases coming under observation excites so much interest and anxiety as these. Little has been published in text-books on this subject. What little knowledge is to be gained is found in medical journals and society transactions. The present opinion of the profession on the subject is hard to obtain. I am inclined to the opinion that a large percentage of operators favor operation during pregnancy, in properly selected cases, rather than take the additional risk of complications arising in the tumor during the pregnant state. I am disposed to speak from personal experience, rather than quote the views of others, giving a short history of cases illustrating certain phases of the condition under discussion.

The danger of abortion or premature labor, following the removal of ovarian tumors, has been very much exaggerated. It is impossible before operation to have an intelligent idea whether or not any given patient will abort. Some of the most severe operations coming under my observation, where the greatest amount of trauma has been done in the pelvis and the pregnant uterus was most handled, have not had the least indication of abortion and have gone on to full term of gestation without any inconvenience. In other cases, with very much less injury and less handling and with everything more favorable so far as the patient and operation were concerned, the patients have aborted promptly. These facts should be thoroughly recognized and taken into consideration in every instance before advising an operation. In a large percentage of these cases the tumor is not recognized until several weeks after pregnancy oc-

urs. The rapid increase in the size of the uterus and the increased blood-supply to the tumor favors its rapid growth in all uterine as well as in many ovarian tumors. The first knowledge that the physician has of the presence of the tumor is coincident with the knowledge that the woman is pregnant. He then finds himself in the embarrassing position of deciding the very grave question before us. I am strongly inclined to believe that the danger to the mother is not markedly increased by the fact that she is pregnant so far as the operation relates to the removal of ovarian tumors. Yet we must grant that no one would select the pregnant state as an ideal condition for operation. But if we see the patient, after she has been suffering several days from peritonitis, with a tumor holding a gallon or more of fluid and she is three or four months pregnant, and, at the time of our visit, extremely ill, the responsibility of advising for the patient becomes much greater and the danger of abortion is markedly increased, as illustrated in the following case:

Mrs. H., aged 35, was seen in consultation in January, 1890, with Dr. Fishburn of Cincinnati, Ohio. The patient herself had been conscious of the presence of a tumor for several months. She had been ill four days, from general peritonitis, at the time of my visit. Physical examination revealed the presence of an ovarian cyst and pregnancy at 4½ months. The diagnosis was ovarian cyst with twisted pedicle and general peritonitis. A further consultation was held the same day with Drs. Edwin Ricketts and C. A. L. Reed, and an immediate operation was decided on and made at once, Jan. 20, 1890. The diagnosis was confirmed. The patient did fairly well for thirty-six hours, at which time she aborted and died twenty-four hours later from her pre-existing peritonitis.

The case with which patients recover after the removal of an ovarian cyst in uncomplicated cases is illustrated in the following case: Mrs. H., aged 36, mother of three children, referred by Dr. Burnett of Greenville, Ohio, was operated on Sept. 23, 1893. The tumor had increased rapidly in size for several weeks. She was already suffering from dyspnea, and was greatly alarmed at her condition. She had a thin-walled ovarian cyst holding some two gallons of fluid and was five months pregnant. An immediate operation was advised. In five hours after operation uterine contraction came on. It was necessary to keep her fully under the influence of morphia for four days. Excepting this she made an uninterrupted recovery and was delivered of a healthy child at full term.

We are not always so fortunate as in this instance, as illustrated in the case of Mrs. W., referred to me by Dr. Sylvester of Wellston, Ohio, in June, 1894. She was suffering from a pelvic tumor the size of a cocoanut, which had greatly inconvenienced her for four or five weeks. She had been pregnant twelve weeks. The tumor occupied the true pelvis and the enlarged uterus was above and to the left side. The tumor could not be lifted

*Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

out of the pelvic cavity. I advised an immediate operation because of the thin-walled ovarian tumor occupying the pelvis as it did. The operation was made June 16, 1894. On opening the abdomen I found that the pelvic tumor was an ovarian cyst that had developed from an adherent ovary on the right side. A portion of the cyst wall was adherent in such a manner that the tumor could not be lifted out of the pelvis until these old adhesions were separated. The operation necessitated much manipulation of the pelvis and handling of the uterus. The patient had always been an exceedingly nervous woman and was greatly excited before operation, which she dreaded very much. Within twenty-four hours after the operation she developed acute mania which continued several days, requiring restraint to keep her in bed. This, however, was transitory, and at the end of a week she was perfectly rational and otherwise had a smooth and easy convalescence; 6½ months later she was delivered at full term of a child which is now living. I advised immediate operation in this case because of the fact that the location of the tumor was such that she could not be delivered.

As emphasizing an assertion made earlier in my paper, that some patients abort exceedingly easily after these operations, I will briefly narrate a case coming under my observation recently.

Mrs. C., aged 25 years, was referred by Dr. I. W. Hall of Camargo, Ill.; married four years, one child 2½ years old. For three months she had suffered great pain from periodic obstruction of the ureter caused by a movable kidney. These attacks were becoming more frequent and more severe, necessitating the use of morphia for their relief. She also had a thin-walled ovarian cyst just large enough to block up the pelvic cavity thoroughly. The uterus was enlarged and lifted out of the pelvis above the tumor. The tumor could not be lifted out of the pelvis. The patient was seven weeks pregnant. On account of the frequency of the attacks of pain referred to, I advised an operation for fixation of the kidney and at the same time removing the ovarian cyst. The operation was made May 17. The kidney was anchored by the usual incision in the loin and the ovarian cyst removed by median incision, without difficulty. There was with thin-walled cyst a long pedicle. I placed the ligature fully an inch from the uterus. There was no manipulation of the uterus whatever. The wounds healed without a drop of pus. Her highest temperature was 99 and pulse 90 during her convalescence, yet she aborted at the end of forty-eight hours. The membranes were expelled within three hours after uterine contraction commenced. Otherwise the patient made an easy and perfect convalescence.

The case emphasizes the fact that in spite of all our care and every precaution that is possible, some of these patients will abort after similar operations, and my experience leads me to believe that when they do abort there is great danger of losing the patient. For this reason we should differentiate carefully as to which case should be advised operation. Every case should be law unto itself and be studied individually before any conclusion is reached.

The question of operation for fibroid tumors of the uterus during pregnancy is a much graver subject than that of operation for ovarian tumors. As a rule it must be considered that an operation for the removal of fibroid tumors means hysterectomy and therefore the sacrifice of the child. Fortunate it is for these patients that on account of the presence of the tumor they rarely become pregnant, yet there are instances occasionally

coming before us, of a woman suffering from fibroid tumor of the uterus, who becomes pregnant and within a few months her suffering is greatly intensified and she seeks and demands relief. The question of the advisability of an operation must rest entirely on the conclusions in the individual cases. In a large number of those who do become pregnant the tumor is situated in the upper segment of the uterus, and there is a reasonable hope that the patient can be delivered of a living child in safety. These cases should be watched carefully, examined frequently, and the attempt made to carry them through the pregnant period so as to operate for the removal of the tumor at some more opportune time. We are aware of the fact that there are some cases suitable for enucleation of the tumor, and that if it be a suitable case for that method the child might be saved, yet it must be granted that it is not within the power of man, before opening the abdomen, to say positively that he could carry out such a procedure and he must always be prepared to do a hysterectomy if necessary.

A very interesting case came under my observation through Dr. Halderman of Portsmouth, Ohio, in September, 1897. Mrs. W., aged 32, no children, had been conscious of the existence of a tumor for many months. She was then about five months pregnant and suffered greatly from pressure. I saw her in reference to the advisability of operating at that time. I could then determine that the fibroid tumor occupied the upper segment of the uterus. There was no danger of it obstructing the passage of the child and I advised against operative interference for that reason. By extreme care she went to the full term of gestation and was delivered of a healthy child which is now living.

In contrast to this case I have a vivid recollection of another one: Mrs. J., a colored woman, pregnant with her first child, consulted me in 1891. The woman had a multinodular fibroid in the lower segment of her uterus. She was five months pregnant. An operation was advised and declined. She went to full term. After a protracted labor, lasting many hours, I was asked to see her with her physician. On arriving at the house we found our patient dead from ruptured uterus and internal hemorrhage.

In July, 1898, Mrs. C., of Portsmouth, Ohio, was referred by Dr. Rardin. She had been the subject of fibroid tumor of the uterus for many years. She was then pregnant four months for the first time, although she had been married six years. Since her pregnancy she had suffered greatly from pressure. She was unable to empty her bladder on account of pressure, and it was necessary to catheterize her for relief. The bowels could only be moved after giving her large quantities of physic and liquefying the contents. A portion of the tumor occupied the pelvis so as almost to present at the vulva. The pregnancy occupied the upper half of the uterus. There was no possibility of her being delivered through the natural passage. Her condition was so desperate that it demanded immediate relief. She was subjected to an operation as soon as the necessary preparations could be made. A part of the tumor occupied the left broad ligament. A hysterectomy was made without great difficulty. The patient excreted seven ounces of urine the first twenty-four hours and five ounces the second twenty-four, after which she had complete suppression and died in uremic coma on the fourth day. No autopsy could be secured. This was a case in which no choice was left for the operator other than an operation, unless he deserted his patient without making an effort to relieve her. The conclusions which may be

drawn from the cases reported can be briefly summarized.

The case with which some cases recover, following removal of ovarian tumors, should not mislead us into the belief that there is no danger from abortion and its complications following the operation. Abortion at this time is attended with more risk than at any other and not a few of these patients die afterward, yet this fact should not deter us from advising and making the operation in all those cases where it is deemed advisable to do so after all the facts have been placed before us, even if the case is a desperate one. An operation promises something. We should not refuse to operate on any one where there is the slightest chance for recovery, if there is no chance for recovery without an operation. It is a duty that we owe to our patients to operate and give them the only chance, even if that is but one in a hundred.

I would advise operation for the removal of ovarian cysts in all cases where the tumor is small and fixed in the pelvis below the uterus; where the tumor cannot be lifted out of that cavity.

We should operate in all cases where there are any complications in the tumor itself, such as twisted pedicle, or ruptured cyst. Patients with inflammation in the abdomen, caused by the tumor, should be operated on.

I would hesitate to advise operation during the pregnant state for an ovarian tumor of moderate size that was above the uterus and where the tumor itself was too large to occupy the pelvic cavity, if the woman had not suffered from the tumor and there was no indication of any complication.

In fibroid tumors of the uterus, I would advise operation in all cases where the tumor occupied the lower segment of the uterus and it was in such a position that it would interfere with or prevent delivery at full term. The question as to when the operation should be made, as to the period of gestation, must depend on each individual case.

If the woman has passed four or five months of gestation and it is possible to carry her to or near the full term of pregnancy, the question as to saving the child must be discussed.

If the patient can be placed in good surroundings and operated on just before the full term, or at the time of the commencement of labor we could save both mother and child. But in many of these cases seen at three and one-half to five months of gestation, their condition becomes so intolerable that we are obliged to sacrifice the life of the child to save that of the mother. Their condition will not tolerate deferring the operation even for a few days. The long-continued pressure of a solid tumor in the patient's pelvis, damming back the urine on the kidney by pressure on the ureters, as it must in many of these cases, should have much weight in favor of immediate operation. Even if the patient should go to the full term of gestation and then be subjected to an operation, she would be in great danger of afterward dying from urinary complications. This is more likely to occur if the tumor develops in one of the broad ligaments; but, unfortunately, there is no choice in the matter in many of these cases; we must operate and accept the situation if we are to do anything at all for our patient. A man would be a coward to temporize in the face of such difficulties.

The question of what operations should be made should be left with each individual operator to use his best judgment at the time of the operation. The question of enucleation of fibroid tumors and saving the

uterus is being favorably discussed by many operators, but whether or not that operation would often be selected in the pregnant state remains to be seen.

DISCUSSION.

DR. M. ROSENWASSER, Cleveland, Ohio.—I agree with Dr. Hall as to operation for ovarian tumors complicating pregnancy; the operation should be done just as soon as it is possible. But with fibroids complicating pregnancy that is a difficult question, one in which each individual case must be judged by itself. It is not only the delivery that must be considered, but the tumor above or below, but also the consequences after delivery. A woman that is pregnant is liable to miscarry in the presence of a fibroid tumor; following miscarriage she may have severe hemorrhages and sepsis, conditions which are not the best for immediate operation. The same complications may arise at the end of full term, when again there is liability to severe hemorrhages in the presence of interstitial or intramural fibroids; consequently it is well to consider the advisability of operation while a woman is in good condition and to keep in mind these additional risks, besides the dystocia. Within the past year I had a case in which the fibroid tumor was located above the child. The woman was confined at term; a severe postpartum hemorrhage occurred; within a few days she became septic. She was finally taken to the hospital. I had not seen her in the interval; she had become deeply septic; her condition would not warrant operation. I gave her medical treatment as offering the better chance, and she finally made a good recovery; the tumor has hitherto caused no trouble and she has not been operated on. This is, however, an exceptional case. Many cases die from sepsis. Two years ago I operated and lost a similar case. The point I wish to make is that in considering the proper procedure in fibroids complicating pregnancy, we must not only study the mechanical relation of tumor to delivery, but also the possible serious consequences that may follow a safe delivery and jeopardize the life of the patient.

DR. WILLIAM H. HUMISTON, Cleveland, Ohio.—This is an interesting subject, and, briefly, my position is this, that where we have ovarian tumors complicating pregnancy and they are not of enormous size, and do not encroach on the pelvic cavity, we can treat the case conservatively and allow the woman to go to term, and then remove the tumor or tumors after delivery. When we have multiple myomas, and some of them involve the lower segment of the uterus, and the woman becomes pregnant, the only safe procedure is to operate as early as possible.

DR. EDWIN RICKETTS, Cincinnati, Ohio.—I recall the case of a woman who, a number of years ago, suffered from an ovarian tumor and was delivered of three living children, she refusing to undergo an operation for the removal of the ovaries. The three children were born within five years. My friend, Dr. Hall, asks whether they were triplets. Under the management and treatment of the late Dr. C. Hall, of Marion County, contrary to all expectations, while this tumor was increasing, these three children were delivered and all saved.

As to fibroid, I recently had a woman who had a small fibroid in the upper segment of the uterus; I carried her to full term and delivered her, but came near losing her on account of postpartum hemorrhage. I had everything in readiness to do a hysterectomy in that case. While it is true that in ovarian tumors complicating pregnancy many women can be carried to full term, yet it is a dangerous procedure. I saw a woman not long since in whom at full term an ovarian tumor was present. The child was delivered dead and the ovarian tumor was punctured per rectum. Nine days after that the patient was crying aloud for abdominal section and begging for relief. The abdomen was opened, but no promises were made. What was the result? Two deaths. Dr. Rosenwasser has expressed the matter in a few words, that each case is to be judged by itself, and the physician should be ready to act in connection with the surgeon who may be called in consultation.

DR. G. B. MASSEY, Philadelphia.—An element of danger can be avoided where it is decided not to operate for a fibroid complicating pregnancy, by having a battery at hand. It is impossible for a postpartum hemorrhage to continue if you have a primary faradic current at hand after the birth of the child. You have a contractile uterus; it is not a question of the arrest of hemorrhage as it would be in a hemorrhagic fibroid, but of something to contract, a highly contractile muscular body, quick contraction of which would close the open blood-vessels. A piece of wire and rubber tube can be turned into an electrode, insulated, and thrust into the uterus, and in five minutes you can prepare the instrument. You can put one pole in the uterus, the other on the abdomen, spreading out the external electrode if you had a small ordinary desk by means of a wet towel to increase the efficiency of the contraction by lessening the resistance. While I speak of this in a theoretic way, I ven-

ture to assert that not one case would be lost from hemorrhage.

DR. EDWIN RICKETTS.—The postpartum hemorrhage in this case occurred in three minutes after the birth of the child.

DR. MASSEY.—By previous arrangement the five minutes I spoke of could be dispensed with; a second or two would be enough to stop the hemorrhage by turning on the current suddenly. It is not necessary to give a shock.

DR. J. HENRY CARSTENS, Detroit, Mich.—The question has always been, is a woman who is pregnant in a good condition to be operated on, and will she stand an operation as well as another woman? In my early experience I was a little timid, but in the course of time, with increased experience, I finally came to the conclusion that a pregnant woman can really stand an operation as well, if not better, than a non-pregnant one. I have been fortunate perhaps in my cases; in fact, I have gone so far as to say that a pregnant woman can stand almost anything. One day, however, I was sadly disappointed and had a patient die.

There is one other point to be considered, and that is the mental influence. When a woman knows she is pregnant and has a tumor, it has a very depressing influence on her mind. She is continually thinking and worrying about it, and I am inclined to favor an operation, other things being equal, because we relieve her mind, and her chances for recovery are just as good as when she is not pregnant. We can enucleate fibroids just as well when women are pregnant as when they are not pregnant, and, in my experience, I must say they seldom abort, if we simply handle the tissues carefully and give them what we do when they are not pregnant—morphin after the operation, to quiet the nervous system.

DR. WALTER B. DORSETT, St. Louis, Mo.—This discussion as to the advisability of operating on fibroid tumors complicating pregnancy before term or afterward is an interesting subject from many standpoints. It brings to my mind a case I had while in charge of the St. Louis Female Hospital, several years ago, the woman having been admitted at about term. The tumor was not recognized at the time, although a careful examination had been made. It was not recognized until labor had fairly set in, when it was discovered that there was some obstruction to efforts at delivery with forceps. The traction on the forceps made matters worse, when the woman was placed in the knee-chest position and delivered in that way. It was a case in which a thick-walled cyst got down behind the promontory of the sacrum and obstructed the passage of the child as well as the delivery by means of forceps. The woman was delivered in the knee-chest posture and an ovariectomy was done afterward.

One thing in regard to what Dr. Massey has said deserves some attention. In the presentation of the paper, as well as in the discussion that has followed it, it has been clearly brought out that a uterus with a fibroid tumor is prone to rupture. How does rupture take place? Is it not by the violent contractions of the uterus? If so, and if we apply the faradic current for the purpose of contracting the uterus, are we not much more liable to rupture the organ by electricity than if we were to use other means. Stoppage of hemorrhage is due to contraction of the muscular fibers of the uterus. If we apply electricity, it seems to me the uterus is very much more apt to rupture than otherwise.

DR. CHARLES P. NOBLE, Philadelphia—It seems to me that the question of what to do with an abdominal tumor complicating pregnancy has passed the experimental stage, and that we have had enough experience on the subject to act from knowledge rather than from inference. I agree with what Dr. Carstens has said concerning operations done during pregnancy; we have most excellent results from them. Medical literature is full of cases in which tumors have been removed during pregnancy, and the results have been fully as good, if not on the whole better than the general average of patients that have undergone abdominal operations. The reason is obvious; these patients are not septic. If they had septic trouble they would seldom become pregnant; therefore, they are a class to themselves, and the results of operation are favorable. As to my own experience in dealing with ovarian tumors complicating pregnancy, if promptly removed, all of them have recovered. None of them have aborted. I believe this is the experience in the hands of others. Certainly, up to the eighth month, if I were consulted as to an ovarian tumor complicating pregnancy, I should advise taking it out, and I would most likely take it out if it were the ninth month. My experience in operating in the presence of the pregnant uterus is favorable. In the beginning I have felt it would be difficult to do the operation, but the situation practically settles itself, and the operation is scarcely more difficult than when the pregnant uterus is not present. I recently removed an ovarian tumor complicating pregnancy at the fifth month. This woman has had two ovarian tumors removed during pregnancy. It is very important to

remove dermoid tumors during pregnancy, and others which happen to be adherent in the pelvis, because after labor takes place the tumors become inflamed and gangrenous, and no class of cases is more serious and more difficult to deal with satisfactorily than a gangrenous tumor after labor. If for any reason a small tumor has been overlooked during pregnancy and has been discovered during labor, I feel it is our duty to remove it at the conclusion of labor, because bruising sets up inflammation, if not gangrene, and the only time to deal satisfactorily with such a tumor is immediately after labor has been completed, and before gangrene sets in.

As to fibroids, I feel differently. I think the conditions must be extreme to make it advisable to remove a fibroid tumor during pregnancy. If we have a fibroid tumor of the cervix, it is possible to remove it per vaginam. It is quite possible to remove tumors of the fundus, of the corpus, but it is a question as to whether it is advisable. Dr. Carstens' experience in the matter of operating on fibroids during pregnancy is exceptional. The literature shows that the majority of these cases abort, and on this account, unless the size of the tumor plus the pregnancy interferes seriously with the patient's well-being, I myself believe the patient should be allowed to go into labor. So far as fibroid tumors are concerned, then, the conditions must be exceptional to make it wise to interfere during pregnancy.

DR. W. D. HAGGARD, JR., Nashville, Tenn.—With reference to the remarks of Dr. Noble concerning ovarian tumor complicating pregnancy and the wisdom of removing them after labor has terminated, I wish to speak of the case of a woman in her seventh labor, in whom there was noticed, immediately after labor, a small tumor in the left side about the size of one's fist. It began growing and was attended by elevation of temperature. At the end of six weeks after labor I saw her with a temperature of 104 degrees, and the tumor in the left side, roughly speaking, was about the size of a small Georgia watermelon. A diagnosis of ovarian cystoma was easy, but the complication that caused the elevation of temperature was not so plain. Abdominal section revealed, however, that the cyst contained pus, and there was considerable adhesion evidently at the point of leakage, to the posterior abdominal wall. The patient did nicely, and the case simply goes to accentuate the necessity for the early removal of these tumors. The only point of interest in the case was the remarkably rapid growth of the tumor in six weeks. The point of leakage and adhesion, the infected site, was up on the psoas muscle, so that the ordinary glass drainage was too long, and it was too high up for vaginal drainage. I cleaned out the cavity with peroxid of hydrogen and free irrigation, introducing a strip of gauze down to the point for drainage, and the point I wish to make now is one that we often notice, that gauze drainage does not drain. At the end of twenty-four hours, when pulling out the gauze, at least six or eight ounces of clear serum welled up out of the incision. I instituted gauze-in-gutta-percha drainage and the patient recovered.

DR. C. R. REED, Middleport, Ohio—If the statement made by the gentleman who has just taken his seat, that the majority of pregnant women who have tumors complicating pregnancy abort, is true, it is important to consider the question of instituting abortion or premature labor. This is an important matter for the physician to consider and will always come up where tumors complicate pregnancy. Let us suppose, for instance, that we have a woman who is from two to five months advanced in pregnancy; that her life is endangered by the presence of a tumor. In order to save her life and prevent the fatal results or dire consequences, would it not be well to consider the practicability of inducing premature labor? I do not think that question has been raised in the discussion so far.

DR. RUFUS B. HALL, closing the discussion—I regret not having had time to finish reading my paper, as it would have made clear some points that were apparently not clear to some of those who have discussed it. I am very glad that some of my hearers feel that the time for the experimental stage of operating in these cases has passed. I do not agree with them. One of the speakers said that he never had a case abort; that does not tally with my experience, even in ovarian tumors. In one case narrated the woman aborted within forty-eight hours; there was not a single sponge put inside of the abdomen; no handling of the uterus. There was a non-adherent tumor, firmly imbedded in the pelvis, which was easily removed. She did not die. But if you have a case that has some complication you are called in three or four days after the patient is ill from peritonitis, and there may be some condition in the tumor that causes the peritonitis. Should you operate on such a patient she is very likely to abort; in fact, they almost always abort. These patients are very ill when you operate. If they did not abort they would have a hard fight for existence, and many of them die from the operation alone. If we knew what patients were going to develop some complication we could select the

operation when they are well, and there would be very little danger of aborting. Every one of these women with pre-existing peritonitis, in my experience, some four of five of them, have died. The fact that we cannot differentiate which patient is going to abort makes us cautious about advising operation in cases that can be delivered with the tumor present. I would hesitate in advising an operation on a woman with an ovarian tumor that gave no symptoms of trouble during pregnancy, believing that it would be much safer to wait until after she was delivered. As mentioned in the paper, we are often placed in a position where we have no choice of whether to operate or not, being governed by the conditions present. If the tumor is a fibroid of the uterus, and is situated in the lower segment of that organ and large enough to block up the pelvic cavity, the woman can not be delivered, and if such a woman has been under your observation for some time and is in the fourth or fifth month of pregnancy, you are compelled to operate to relieve her. Now let us reverse this condition: Supposing the tumor to be the size of a coconut, or four times that size, and there is no obstruction in the lower segment of the uterus, no obstruction to the delivery of the child, we do the patient an injustice to do either hysterectomy or myomectomy. We talk about patients not aborting when a myomectomy is done; they are fortunate if they do not. Many of them do, and such should not be operated on if they could be delivered with the tumor. I have seen them abort with a tumor not larger than an orange. Some of the patients abort on the second day and die a few days later.

PROPHYLAXIS OF UTERINE CANCER.*

BY W. W. GRANT, M.D.
DENVER, COLO.

Cancer of the body of the uterus, as a primary condition, and independent of the cervix, is not common.

I assume that there can now be no discussion as to the proper treatment of uterine cancer, when the opportunity for early operation is presented. The field of preventive surgical disease is as interesting a study and imperative a duty as preventive medicine is to the general practitioner and sanitarian. Knowing the cause, we will in time discover and apply the remedy. In this day of perfected surgical technic and brilliant operative achievement, we are prone to overlook and underestimate the great work we can or may do, in preventing disease. In no respect can this interest us more than in reference to those diseases the inevitable tendency of which is to a fatal issue.

A more complete operation for carcinoma is more certain of attainment and more satisfactory, if performed early; hence, the mortality should steadily decrease. It would not be surprising if this generation witnessed a mortality not exceeding 25 per cent.

Cancer of the uterus is rare in virgins. Its common site is the cervix and its common victim the child-bearing woman. Observation and experience justify the belief that, as a lesion is such a common precedent condition to the development of cancer, it deserves to stand in a causative relation. There are few cases, if seen before being obscured by pathologic action, that will not show evidence of traumatism. Neither can it be regarded as inconsistent with the parasitic theory now under investigation. Recognizing that the injury is manifested in contusion and laceration of cervical tissues, we are in position to deduce more rational conclusions. The first is to give to Nature a freer hand in the dilating stage of normal labor, and the use of all possible care and gentleness, to limit traumatism, in operative procedures. Failing in these, the question occurs: Will timely repair of these tissues arrest retrograde metamorphosis and restore normal circulation, innervation and nutrition to the uterus? It certainly will, though

this effect is manifestly influenced, in some degree, by the general condition of the patient.

The significance of such considerations must appeal to the conscience and judgment of every competent gynecologist. To restore the integrity of an organ is the first step in the prevention of more serious disease.

To emphasize the matter of causation and prophylaxis, I will reproduce recent statements of two distinguished authors only—Dührssen and Kelly. The former, strongly recognizing the great mortality in all countries, from cancer of the uterus, and the special danger of the climacteric from this disease, and accepting the belief of German pathologists that cancer develops only in epithelial elements, advises as a preventive measure, entire excision of the uterine mucosa, by a "T" incision through the anterior vaginal vault and body of the uterus, and, in some cases, high amputation of the cervix. These measures of prevention are new and seem needlessly harsh, if not dangerous, to be used for a mere suspicion or fear of malignant disease; and would prove inadequate in most cases of actual disease. Besides, as the aim is to destroy the epithelial tissues beyond regeneration, simple vaginal hysterectomy would seem a more feasible and desirable operation.

The desirability of medical supervision during the climacteric, and even before, must be admitted by all, in order to meet certain diseased conditions promptly. Kelly advises, as a measure of prevention, that every child-bearing woman of 30 should be examined by a competent physician and the performance repeated every few months, for the purpose of treatment if the lips do not appear sound; and that when the lips of a lacerated cervix are thin, uninfiltated and lie together, no treatment is required; but, if the lips are thick and everted, with endocervical catarrh, they should be repaired or amputated; that every woman of 33, or over, who has a tear of the cervix, should be examined once a year for ten years, or longer, if the cervix does not appear perfectly healthy.

The importance of the condition in relation to cancer is unquestionably manifest. I hope it will be considered a fair attestation of my desire for more light, if I question the entire safety and wisdom of the admonition given, as *not* being a full and logical deduction from admitted premises. Is it the best service we can render, to permit a lesion to continue, that requires so much watching, care and attention for so long a time, and whose existence is a constant menace to the health and life of the woman?

My own belief is that the only safe course is to repair every appreciable lesion of the cervix, without waiting and looking for evidence of either benign or malignant disease. It is the only certain way to overcome the just apprehension of the physician, and to anticipate, with reasonable assurance, a constant danger to the lives of many women,—a danger that will not be met by a temporizing or tentative policy.

When will the time come that the general practitioner will see the necessity, or be able to convince women of the necessity, when feeling perfectly well, of submitting to periodic examinations, because of a threatened danger to health or life at some future time? It will be easier to convince both of the significance and importance of a safe operative procedure, both as a precautionary measure and to cure or to prevent a disease that is so frequently fatal.

Regardless of the existence of a cervical lesion, the necessity for unusual vigilance and care, as a preparation for and during the climacteric, must be conceded, and

*Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

the propriety of inculcating it is a duty every physician owes to his patient. But, as an essential to substantial progress, the profession must be convinced as to the facts, before women will have even the opportunity of securing the benefits claimed.

The influence of a persistent, chronic irritant in ultimately causing malignant disease, is well known. Would a thorough surgeon treat the primary condition by the application of means that are chiefly provisional, or would he radically remove the offending agent, and the conditions that so frequently end disastrously? There should be no doubt as to the answer.

I removed the uterus for carcinoma of the cervix by vaginal hysterectomy, on January 13, last, from a patient 68 years old, who had been so well for twenty-two years that she had not consulted a physician for any purpose whatever. She had given birth to two children before the age of 40; and, while the case illustrates the necessity of early examination, yet what would an examination, even at 50 have revealed, beyond a probable unilateral laceration as indicated by the ulcerated condition? The body is small and not diseased.

If the cervix had been infiltrated or thickened with endocervical catarrh, would it not have been manifested in the intervening years? With the laceration repaired, would not the chances for carcinomatous development have been diminished?

Trachelorrhaphy is not a dangerous operation. With all cicatricial and diseased tissue removed, the lips well adjusted and united, the most common pathologic condition antedating cancer of cervix is eliminated. If there is a predisposition to malignant action, cicatricial, which is always unhealthy, tissue, invites it. If there is no such tendency it often excites it. I feel convinced that, with all abnormal tissue removed, and the integrity of the organ restored, the mortality from uterine carcinoma will be still further reduced; and more certainly than by provisional methods, for delay is dangerous, and the trained sentinel is not always on duty.

It may be claimed that, in the young, active, child-bearing period, the operation for laceration, when no apparent disease exists, is not so urgent, but a strong plea for prophylaxis exists, if it is not done before the climacteric begins or is concluded. No one need be deluded because some women with cervical laceration go through life without serious trouble. This gives no immunity to others, and no safe line of discrimination is practicable, if possible; and there is no satisfaction to the physician or surgeon who fails to give the patient, in time, the benefit of every known measure of relief.

JUSTIFIABLE ARTIFICIAL ABORTION AND INDUCED PREMATURE LABOR.*

BY W. C. BOWERS, M.D.

DECATUR, ILL.

After a number of years of observation and study I am led to believe that abortion, both accidental and criminal, is frightfully common in all grades of society. Justifiable artificial abortion is not comparatively common, neither should it be, but seems sometimes required to save the life of a woman. Induced premature labor is as likely to be required in the interest of the child as of the mother, and in some conditions may be done in the interest of both. Neither should be decided on without honest consultation and serious consideration. "If thorough antiseptics be practiced, therapeu-

tic abortion adds little to the risks of the mother if carefully done. Otherwise it is often more fatal than the disease from which it seeks to deliver her."²

In any disease of a woman which is aggravated to so great a degree, because of pregnancy, as to endanger her life, and which can not be remedied so that she may live after labor, induced abortion should be considered in her interest; or, if late enough in pregnancy, in the interest of both mother and child. The possibility of waiting for the viability of the fetus should always be thought of if such a thing is possible without jeopardizing the woman's chances. The reasons for premature emptying of the uterus are many, but fortunately very few of them act with any degree of frequency, and the indications are rarely absolute.

It may be necessary to consider the procedure in a number of diseases and conditions. In nephritis, where eclampsia will probably occur if gestation proceeds or the woman's life be shortened by irreparable damage done, the kidneys as a rule, if albuminuria cannot be lessened and the general condition made better by milk diet, tonics and diuretics, an artificial abortion should be performed³. In advanced tuberculosis, in many cases, a woman's chances of recovery or longer life might be jeopardized by pregnancy, which in selected cases should usually be terminated as soon as discovered⁴. Aneurysm, unless superficially located, is an indication for prompt interference⁵. In the valvular lesions of the heart "success can only be expected if the pregnancy is terminated before the onset of serious symptoms."⁶ L. Demelin²¹ says that all depends on two grand conditions: 1, the anatomic-physiologic state of the myocardium; 2, the anatomic-physiologic state of the large emunctories—liver and kidneys—and that artificial abortion should be done in the gravest cases. In chorea gravidarum there is a marked tendency toward anemia, prostration and insanity⁴. A number of observers have reported favorably and a few unfavorably on the results of artificial termination of pregnancy, and "much after all must be left to the judgment of the individual observer as applied to the requirements of the individual case."²² Peripheral neuritis of pregnancy, which is probably due to autointoxication, occurs as a rule late in pregnancy and may prove fatal. "One must be prepared to induce labor before the disease has advanced too far, for as soon as the uterus is emptied there is naturally a tendency to recovery."⁷

Goiter depending on pregnancy is usually very vascular⁸, and if constantly increasing in volume may cause death from suffocation, by compressing the trachea.⁷

Since treatment of goiter is so unsatisfactory, and intraglandular injection of tincture of iodine, the surest treatment, is so dangerous that it should now be entirely discarded²³, and since some time must elapse before symptoms are relieved, the goiter should not advance too far in size before ligation of the thyroid arteries is performed or the uterus is emptied. Both may be required. Pernicious anemia is a rare disease, but should pregnancy supervene, artificial abortion is justifiable if the anemia deepens in spite of good treatment. This is also true of leucocytosis. Diabetes mellitus in the pregnant is exceedingly rare, but not especially changed in its manifestations. The prognosis is unfavorable to the child and, from this fact and for the reason that many recover after the labor terminates, one should induce labor if the mother's condition prompts it.

*Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

In eclampsia the indications for emptying the uterus are not always plain, as in not half the cases do the convulsions stop after the uterus is empty²³. An old rule followed by many is to deliver immediately under an anesthetic, on the appearance of a fit. Some say that eclampsia depends on a disease of the kidneys peculiar to pregnancy, and for its prevention labor should be induced as soon as any considerable amount of albumin is found in the urine or the case gets progressively worse²⁷, because after the fits have commenced and the urine is solid with albumin the course of the disease is not affected by delivery.²⁴

In cancer of the uterus, which is exceedingly uncommon in pregnancy, termination of pregnancy by artificial means is restricted to the later months of pregnancy⁶, when if a vaginal hysterectomy is determined on an abortion should be done two or three weeks beforehand.

Melancholia, hystero-epilepsy and insanity require close study in each individual case to determine how much the trouble depends on the pregnancy or is aggravated by it before radical measures are adopted. There is a strong tendency in these later days to interfere with the increase of idiots, profound degenerates, and habitual criminals, so much so that castration²⁹ or reaction of the vas deferens²⁰ in males, and ovariectomy or tying³⁰ of the Fallopian tubes in females have been advocated. While interfering with pregnancy in these classes has not been openly advised, yet it has been suggested and is certainly to be thought of in properly selected cases.²⁰

Irreducible displacement of the uterus, particularly if uremic symptoms are manifest⁸, and old adhesions among the viscera above the pelvis⁹, causing retroversion and retention of the uterus in the pelvis, are positive indications for interference.

Anteroposterior contraction of the pelvic inlet to approximately 2.36 inches, and occlusion of the genital tract by tumors, cicatrices, etc., call for interference unless the woman elect Cesarean section.⁸

Unavoidable hemorrhage is a sure occurrence in placenta previa, and abortion is almost without exception necessary, and by means that will control the hemorrhage at the same time¹⁰. In accidental hemorrhage, if the symptoms of loss of blood are considerable and not promptly relieved by rest and opium, pregnancy should be interrupted in the interest of the mother². The membranes should be ruptured and ergot² and strychnia given. Marx¹¹ has lately reported a case in which repeated attacks of profuse epistaxis constituted the indication for the induction of abortion. The bleeding from the nose had occurred every three or four days for ten weeks and the woman was intensely anemic and in collapse. Medicine and plugging the nose had done no good. Accouchement forcé was done and a favorable result obtained.

In missed abortion, dead twin⁶, and vesicular mole¹² the uterus should be emptied as soon as the condition is positively determined. Polydramnios calls for active interference if symptoms of overdistension persist or grave disturbance of the mother's heart supervene³. J. C. Cameron mentions as indications, jaundice with diarrhea, general edema and edema of the vulva, but these would surely be symptoms rather than diseases with rare exceptions. A premature labor might be induced in the interest of the child rather than do a post-mortem Cesarean section where the mother had a fatal malady from which she would be liable to die at any time; also if the children had perished in previous labors because of great size or because of dis-

proportionate size. Probably the most common reason for interrupting pregnancy is hyperemesis gravidarum, which should not be allowed to proceed to "extreme exhaustion, pain beneath the sternum, and coffee-ground vomiting."²⁷ Klein¹³ says that it is especially important that these cases are not allowed to become severe before pregnancy is interrupted. To be pathologic, the "nausea must persist after the patient has arisen or be experienced when the patient is in the recumbent position."²⁷ Bacon¹ says that vomitus gravidarum may be defined as vomiting during pregnancy due to a variety of immediate causes acting on the abnormally irritable nervous system of the pregnant woman. Nausea and vomiting being only symptoms, the physician should not conclude that they are due to the mere condition of pregnancy until able to exclude all other diseases. My cases have been mainly those of hyperemesis, but show interesting features.

Mrs. V., aged 22, American, spare but well proportioned, was neurotic and a bad feeder; general health has been good, but has had "nervous spells" occasionally for years, and at times some dyspnea from no apparent cause; always had dysmenorrhea and constipation. I saw her in one of her nervous spells in May, 1893, when she was pale, very restless, and had dyspnea, and intermittent extreme weakness. Her heart and lungs were normal and no serious disease of any organ was found. Aromatic spirits of ammonia and Hoffman's anodyne relieved her promptly, and it was reasoned that the trouble was a manifestation of hysteria. Following this, sulphate of soda and tonics did her much good. A week after this sickness she menstruated, with pain as usual, but her general condition improved until some time after she missed her monthly, in June, 1893. Constant nausea and vomiting of white or greenish slime, with restlessness, poor sleep, loss of appetite, became a part of her symptoms and steadily increased until signs of exhaustion showed themselves. Chloral and bromid were carefully tried by mouth and rectum, morphia and atropia hypodermatically, bismuth and carbolic acid by the mouth, counterirritation, nitrate of silver to the cervix, and many other remedies. Cocain was given in lemonade, the only thing she could swallow and retain, but as soon as she learned that there was medicine in it, she promptly vomited lemonade. A. S. and B. pills stayed down and induced proper bowel movements. The sight of food or medicine or the smell of either and of perfume would bring on terrific vomiting. The urine was normal and passed properly and there was no pain nor headache, but she ached all over all of the time, and had a slight rise of temperature daily, was in motion day and night, although confined to her bed; and when apparently asleep, which was rarely, she was cognizant of all passing events. July 12, her condition was so alarming that counsel was called in and the cervix moderately dilated with steel branched dilators, carbolic acid applied within the cervix and pure nitrate of silver lightly applied to the vaginal face of the cervix. The vomiting became less for a few days but no other improvement appeared and the vomiting returning as bad as ever by July 20 an antiflexed uterus was dilated and curetted under ether. Plenty of decidua was removed, but no signs of a fetus could be found. Uterine douching followed the curetting, and careful cleaning of the genital tract preceded it. Vomiting and nervousness was relieved for three days, when it started up again as did also some fever. The modest use of the dull curette, removing a few fragments of

decidua, and a rather free intrauterine douche stopped the nausea and moderated the fever. No medicine was given and no food could be taken because of the anorexia. A sip of lemonade taken frequently seemed to be retained, but water, iced, cool, or hot, was vomited the same as anything else. July 28 a relapse of vomiting with severe pain in the abdomen came on with increasing fever. A few small pieces of decidua were again removed with the dull curette and douche, and a rectal suppository of belladonna and opium gave prompt relief, and she sat up some after two days. From the first curettement she had an insatiable desire for iced lemonade and a loathing for every other form of food and drink, but constipation being troublesome and as severe stomatitis showed itself, iced drinks and especially lemonade, were forbidden, and milk and lime-water or animal broths were to be drunk whether vomited or not. Two 5-grain doses of calomel were given two hours apart. A moderately strong solution of chlorate of potash was used to keep the mouth constantly moistened, and a little swallowed every three or four hours. Constant improvement started in, interrupted at times by attacks of acute indigestion, which were always relieved by moderate purging with calomel, placed dry on the tongue, as it in any other form or any other drug was promptly vomited. Carbonized vaginal injections were used daily from the time of the first curettement. She drove out at the end of the third week, when she weighed 72 lbs., her average weight being 115 lbs. She was in fine health four months later and has had easy monthlies ever since. She is yet troubled at times with nervous dyspepsia and hysteria near menstruation time, relieved by correcting indigestion and especially by the free and prolonged use of the tincture of *asafoetida*. She has had two fine children since 1893, with only moderate disturbance, and to-day has excellent general health.

Mrs. F., aged 31, married ten years, never pregnant, sometimes constipated a week at a time, which was often followed by diarrhea, had always slept well, worked hard on a farm, and always had good general health, but for the past year had leucorrhœa, and menorrhagia with clots. On Feb. 25, 1896, she suddenly stopped flowing midway in the monthly, without apparent reason. April 1 she became nauseated, dizzy, and slept only half the night. She was partially relieved by general treatment, but on April 18 nausea, loss of appetite, inability to sleep, and a general decline forcing themselves on the scene, a careful search for local trouble was made. There was no tenderness in the genital tract or pelvis; but in the wall of the uterus, apparently at the junction of the right Fallopian tube, and the uterus was a goose-egg-sized tumor which was sensitive. The uterus was freely movable, somewhat enlarged, and the cervix softened, and some endocervicitis with erosion manifest. My suggestion of pregnancy was laughed at by the woman and her friends. I applied pure carbolic acid to the os, tincture of iodine to the cervix, placed a glycerin tampon and dusted the vagina with boric acid. Bismuth before meals, bromid after meals, laxatives, warm carbolized vaginal injections with the one local treatment relieved her very much for a few days. On April 20 severe nausea and vomiting with bad diarrhea was much relieved by calomel by the mouth and chloral and bromid by the rectum. Following this daily hypodermics of morphia and atropia relieved her some, but not being under any positive control, as she was not in a hospital, and thinking herself not pregnant, she attempted to stay up and about the house, but an error

in diet brought her down again. The morphia and atropia held the vomiting to a moderate amount, but the condition of the patient by May 1 was so serious owing to rapid anemia, debility and slight fever, that a consultant was called who verified my diagnosis of pregnancy and advised therapeutic abortion unless debility ceased to increase. For the next week the wasting of the body and the increasing exhaustion was alarming. On May 9, after thoroughly cleaning the field of operation, I dilated the cervix three-fourths of an inch with a two-bladed steel dilator, and on May 10, morning and evening, to about one inch each time, which was followed by slight pains through the day, while on May 11 there was sharp pain for an hour, followed by a gush of blood and terrific vomiting. In the evening I introduced a sound and found the uterus five inches deep. She slept well most of the night, except for a few spells of vomiting. She took nothing but ice and her vomit was a greenish slime. On May 12 I dilated the cervix one inch, and at noon sharp pains came on for an hour, the patient felt something give way in her side and nearly fainted. The pains ceased, there was no hemorrhage and she rested well until evening, except for two hard vomiting spells. May 13 I found the uterus more rounded and fuller and the tumor gone from the original site. The cervix was dilated to $1\frac{1}{4}$ inches, followed by regular labor pains and at 9 p. m. a live fetus was born by breech presentation. The length was $3\frac{1}{2}$ or 4 inches, the cord 3 inches and not much twisted. The time of pregnancy was about three months. The membranes and placenta were removed by the large dull curette and finger, under chloroform, followed by a copious hot creolin douche. The woman had a ravenous appetite the next day though she vomited once, and recovered slowly but completely with but little flow, no pain and no fever, and to-day is in excellent health.

This must have been a tubo-uterine or an interstitial pregnancy, and had the nausea moderated or vomiting ceased after the tumor changed its place, I should have made a great effort to have saved the conception. This case shows that the treatment of dilating the cervix for pernicious vomiting is not a certain remedy; the reason for the repeated dilatations was that each time they neither stopped the nausea nor caused sufficient irritation to bring on the pains.

I saw the following case Sept. 11, 1898, with Dr. W. P. Davidson of LaPlace, Ill., and obtained the following history and conditions. While an abortion was not induced I have often regretted that I did not commit one as soon as she improved some, and thereby give her the best chance for her life as the ending of the case seemed to show. Mrs. F. G., an American, aged 32, was the mother of four children, who were perfectly well, except the oldest, who is 12 years old and has a bifid lumbar spine with complete paraplegia. The mother had a miscarriage the first year of her marriage and in the spring of 1896. The last miscarriage made her have irregular, painful and profuse monthlies for about a year, when she was curetted with complete relief. In 1897 she had severe subacute rheumatism, which disabled her right hand for six months. With the exception of these troubles she had good health. She always vomited when pregnant, amounting to hyperemesis with the fourth pregnancy only and was relieved by one hypodermic of morphia and atropia followed up with chloral and bromid of potash and by hygienic attention. In May, 1898, she had three days' hemorrhage like a monthly, in June two days, in July one day at

two different dates, and in August a few hours. She commenced being sick by having a severe diarrhea about two days in each week. Some blood was seen in the stools three different times about the first of August. In the last week in August she commenced to feel nausea and vomited almost incessantly day and night, had thirst, but loathed food, and got but little sleep and at night only. September 11 her weight was 120 lbs., having lost 20 lbs. in two months; pulse 100; temperature 99.5; respiration 32. The urine was normal sclerotic yellow. The tongue had a blackish coat. She had unquenchable thirst, retained no food and did not want any, and kept down a little whisky and water and limewater. The uterus was movable, normally situated, and enlarged to two or three months' pregnancy. The vaginal and cervical mucosa was red, soft, eroded and bled easily.

A mixture of iodine and carbolic acid was applied, and a creolin and glycerin tampon was placed against the cervix, and if it had any effect it made the erosion worse. Nitrate of silver, 40 grains to the ounce, was applied several times with no benefit. Alum and carbolic acid injections were used with probably some local benefit; most of the general remedies for such a case had been tried with but little benefit. Therapeutic abortion was talked of, but the danger of sepsis seemed so great in this case and the probability of some serious disease, not determined, complicating the pregnancy, and the family desiring to try other means first, this treatment was postponed. Morphine $\frac{1}{4}$, atropia 1-150, was given hypodermically, and she vomited only five times in the next forty-eight hours. Nutrient enemata were given, as were also saline enemata at irregular intervals, and the morphia and atropia depended on twice a day to give relief from the horrible nausea. After ten days the jaundice was less and the other symptoms had moderated, but ability to take food was not better and the morphia was being constantly, though not rapidly, increased, as is usual when it is given in such cases, and she had in the meantime vomited blood and passed blood in the stools. About October 1, stomach feeding was impossible, anemia was severe, there was pain under the sternum, the pulse increased to 140 and the thermometer showed rise of temperature. She also complained of blindness but the cause could not be determined. Other consultants about this time concurred in the opinion of probable pregnancy and believed it complicated with malignant disease. A post-mortem examination was not obtainable, so the correctness of our conclusions could not be known.

In view of the difficulty of making a certain diagnosis of cancer in any particular case, and from the fact that many pregnant women recover with astonishing rapidity after abortion or labor in what appear to be desperate cases, it is possible that this woman could have recovered had an abortion been induced at the time or her improved condition.

Mrs. A. H. B., an American, aged 39, robust looking, weight 125 lbs., low in stature and neurotic, gave a history of having had headache all her life, diphtheria at 18 years of age, and stomach trouble ever since. Her appetite was usually good, but starchy foods often caused belching and sour stomach, but she was never constipated. She has had painful monthlies since her first child was born, though about normal before then. Three living children have been born to her by slow, hard labors, and she has had no miscarriages. Nausea was quite troublesome with all pregnancies, and especially so with the last one about 1893.

A trachelorrhaphy was done for her in 1889, and benefited her, as her uterus was heavy and prolapsed at that time. In 1892 a moderate prolapse must have been mistaken by some physician for an elongated cervix, for he had cut it off at the utero-vaginal junction and left it to cicatrize without suturing. Her last monthly, before this sickness, occurred the last of September, 1898, and the first nausea about the middle of November. The uterus was retroverted, not freely movable because of its position and its moderate enlargement. No unusual tenderness was felt anywhere and the peculiar round scar with the cervical opening in the center, unlike a normal os, was felt in the upper part of the vagina close to the pubes. The nausea and vomiting of some mucous and greenish fluid was often repeated and awful. An intense pain was felt in the stomach on swallowing anything; and anorexia was complete. Every form of treatment was tried without avail except that chloral and bromid by the rectum gave her some sleep at night, though it did not relieve the nausea and vomiting. The uterus could be replaced without much force, by dragging down the cervix with a tenaculum and pressing up on the fundus through the posterior cul-de-sac, but could not be retained by the meatus tried as it was easily displaced by the force of vomiting. She had pleasant surroundings and good and efficient care, but the consultant and myself decided that in view of the fact that no manner of treatment seemed to benefit her, the difficulty of keeping the uterus from becoming retroverted was so great, and because she was needed in her family, they being wage-earners could ill afford to have her so sick for a long time, a therapeutic abortion was a reasonable procedure. This was done under chloroform, Nov. 25, 1898, by dilating with steel branched dilators and curetting with the sharp curette, removing much decidua, but no part of the fetus was found. Thorough douching was done with hot 2 per cent. creolin solution and an occlusion dressing put on. She got better rapidly but much care in diet and medication was necessary for some time, and chloral and bromid by the rectum was needed several times to relieve severe insomnia. At present she is in good health.

While no operation was done on the following patient, the case is one which illustrates the symptoms, principles of treatment and desperate condition into which these patients sometimes get and yet recover; also from the fact that the hyperemesis occurred late in pregnancy only.

Mrs. J. E. H., an American, aged 42, small, spare built, nervous, active, plucky and not hysteric, as a child suffered considerably with night croup, and later had typhoid fever and was always spoken of as a sickly girl. Her first monthly occurred at the age of 16, was very profuse and accompanied by epistaxis. She had no more monthlies until after marriage, at the age of 19, when a menstruation occurred within the first month, and was painful. She had no more, as she became pregnant. Of late years she has been more nearly normal with her menstruation. She had two children from her first marriage and no severe nausea during these pregnancies; from the second marriage, three children, all these pregnancies showing a considerable nausea. There has also been one molar pregnancy which terminated without unusual disturbance. The last menstruation preceding this sickness occurred April 2, 1898. Nausea and vomiting developed about a month later and kept up until by September it became so severe that a homeopathic physician was called in to prescribe for

her. The vomiting was so terrific and the case looked so desperate that his nerve soon gave out and he was glad to have the patient go to someone else. My colleague, Dr. E. J. Brown, took charge of the case about the last of September and gave her some good rest and sleep by using morphia and atropia by the hypodermic method.

She had not been able to keep food down but for a few minutes at a time for several weeks, but under the influence of hypodermic injections twice a day no vomiting occurred for several hours each time, when butter-milk could be drunk by icing it, although there was a loathing of all forms of food. The ease fell into my hands through the Doctor's courtesy, he being obliged to leave home not long after taking the case. The vomit was greenish, resembling chewed spinach, enormous in quantity, but at times a smaller quantity resembling coffee grounds would be thrown up. There finally appeared a constant pain in the stomach and under the sternum. This pain was for a time relieved by the morphia, as was also the nausea and vomiting, by increasing doses but for shorter and shorter intervals. She had a severe and constant pain in the left arm and some sores on her right hand, which refused to heal completely. Premature labor was talked of, but the woman's condition was so desperate, owing to the extreme reduction of flesh and strength and the almost certainty that either cancer or ulcer of the stomach existed, that the risk of her promptly dying from the operation was considered too great. About November 1 the liquor amnii drained away slowly, but after a week, labor not coming on and in view of the seriousness of her condition, I urged her to have her will made out lest something grave happen depriving her of any chance so to do. On November 7, 1898, two lawyers made out her papers, by giving her plenty of time. Her voice was thin and feeble, her pulse weak and running about 140 to the minute and her features pinched and haggard. Strange to relate, labor set in on the morning of the 8th and was over normally in three hours; vomiting ceased when the os was half dilated, and never returned. The child weighed about 5 lbs., and both mother and child have done very well from that day to this.

Providing no accident had occurred as a result of the operation, an induced premature labor would have yielded a brilliant result. The ending of the case shows that an interruption of the pregnancy had not at any time been necessary, yet almost any one would have considered the case so serious that interference would have been gladly undertaken by all parties concerned could there have been given a promise of the woman's recovery.

In my sixth case the most noticeable and distressing symptom was hyperemesis, but the interesting feature of the case was the pathologic condition of cystic degeneration of the chorionic villi. This condition consists of a hypertrophy of the villi of the chorion and their conversion into cysts. This change is essentially in the endochorion, and is an overproduction of the mucous tissue within the villi.¹⁵ There is no well-established single cause, but it seems a certainty that it never occurs except after impregnation. The manifold causes are given as diseases of the uterine walls or lining, death of the fetus, absence of blood-vessels in the allantois, and stenosis of the umbilical vein. It occurs hardly more than once in two thousand pregnancies and, unless vesicles escape, which is rare, the condition might not be suspected before the third

month, when the rapid enlargement of the uterus, absence of fetal indications, and the history of irregular uterine hemorrhages would indicate hydatidiform mole. Pernicious vomiting may accompany this condition and be as severe and persistent as in natural pregnancies. Relief is finally obtained only through natural expulsion or artificial abortion, and complete emptying of the uterus. Great care is required in using artificial means of removing all cysts and decidua, lest perforation occur through uterine walls made thin²⁸ by vesicles permeating them. If some portion of the blighted ovum remained and seemed hard to detach, probably it were best to leave it to come away, or be removed at some future time when it had loosened or signs of septic danger arose. Well-established rules of asepsis and antiseptics should be rigidly observed in these cases.

Mrs. W.³¹ aged 42 years, robust, stout, belonging to that class of people known as "Pennsylvania Dutch," had a few irregular monthlies in the spring of 1891. She had never aborted, was always regular, and the mother of eight children, the youngest 3 years old; always had easy labors but considerable post-partum hemorrhage after the last confinement, seemingly due to failure of tonic contraction of the uterus, because of too rapid delivery of the fetus. When the case came under my care, about the middle of July, there was a history of absent monthlies from May, with pyalism, morning sickness and other symptoms indicating a probable pregnancy of about two months' duration. For the past two weeks the nausea and vomiting had been increasing so much that apparently no food was now retained, thirst was most distressing, pyalism was troublesome and gushes of blood, dark and watery, from the vagina, were frequent though intermittent and unaccompanied by any marked pain. She had a distressed look continually, loathed food, everything "tasted bitter," bowels were regular, had lost flesh rapidly since hemorrhage and vomiting became severe, and the bladder was irritable, but the urine contained no albumin. She slept fairly well and the nausea was not so bad when lying down, but a sick child kept her up. Calomel was followed by black draught; bismuth and bromid of potash gave considerable temporary relief.

July 29 she took her bed continually, temperature 100, pulse 108, general symptoms severe, and could not urinate except when on her hands and knees; nausea and vomiting horrible. A vaginal examination showed the os a transverse slit and high up behind the pubic bone; the uterus, apparently the size of an average child's head at term, was retroverted and almost pushing out an unusually large ostium vagina, and not felt in the hypogastric region. No evidence of tumor or cancer was noted and the uterus was partially replaced while the patient was in the genupectoral position, and this position ordered to be taken several times a day and the vulva opened to allow entrance of air. Popular remedies were used and rectal alimentation, but with no relief, except that the fundus, in about a week, could be felt in the hypogastrum, and the difficult urination ceased. The family being of the homeopathic faith, would consent to hypodermics only as a last resort. August 4, a hypodermic injection of $\frac{1}{4}$ gr. of morphia and 1-150 gr. atropia was used, giving complete relief for twelve hours. Morphia $\frac{3}{8}$ and atropia 1-100 was given hypodermically from this date for two weeks with suppression of the symptoms and ability to take food. The woman becoming more and more exhausted, and the symptoms returning promptly on attempting to stop the treatment, an abortion was decided to be about

The only promise of relief from the pernicious vomiting. On stopping the hypodermic injections violent vomiting came on in twenty-four hours, the cervix was partially dilated by the fingers, active hemorrhage and pains occurred and an abortion was the consequence. The severe hemorrhage, preceding the abortion, was held in check by fingers and part of the hand in the cervix. The vesicles came away in small masses and felt like blood clots slipping through the hand. There was about a quart of them and blood and clots in a basin, presenting a striking appearance, likened by Dr. Gooch to "white currants floating in red currant juice." Some decidua in the shape of membranes was found, and no embryo. Great care was used in cleansing the uterine cavity, lest a wall made fragile by vesicular penetration be ruptured. A piece of decidua came away the next day. At no time had there been a rapid enlargement of the uterus nor an appearance of vesicles in the discharges, leading me to a diagnosis of the true condition. The woman made an uninterrupted and complete recovery, but hypodermic injections were necessary at 5 a. m. each day for a week, to keep down the nausea and violent vomiting. She has had good health since, and has never been pregnant.

TYPHOID FEVER.

NOTES ON TWO EPIDEMICS IN THE IOWA HOSPITAL FOR INSANE.*

BY GEORGE BOODY, M.D.
INDEPENDENCE, IOWA.

Previous to 1896 there had never been more than two or three cases of typhoid fever in the hospital for insane at Independence. Early in September of that year it made its appearance for the first time as an epidemic, and within three weeks twenty-eight cases, all males, were taken down with the disease. It was not confined to one ward, but after its advent it broke out at intervals of a few days in widely separated wards or in the cottages; sometimes one case a day, and at others

two or three would be stricken with it on the same day and in the same ward. It ran its course within twelve weeks and disappeared, leaving the institution apparently free from the contagion until August 6, 1898, when it was visited by a second epidemic, which spread quite rapidly and in much the same manner as the first, continued over about an equal period of time, and subsided as suddenly as it came. About the time of the beginning of these epidemics there were a number of cases of typhoid fever in the surrounding country within a radius of ten miles.

Source of Infection.—Since the organism is conveyed most frequently through the medium of water, attention was turned at once to the condition of the water-supply. It comes from dry points, thirty feet beneath the surface in a sand-bed, and the city near by receives its supply from the same source. These points are 80 to 150 feet from the river and located in a depression about which there are a number of dwellings, barns and vaults, there being no sewerage system in that part of the city, hence drainage by means of seepage tends toward the drive wells from three directions. There was no typhoid fever in the city, as might be expected if infection came through the water, yet specimens were collected and careful examination made by Professor Beirring of the Iowa State University, with negative results. Then it was thought it might come through the milk, but this was all produced on the farm, and investigation showed that it could not be the source of the contagion, except through one channel of introduction—into the milk first, as will be seen later on. Then it seemed that fruit and other foods which were shipped in from different parts of the country might have become infected by coming in contact with the hands of those who had engaged in preparing them for shipment, and who may have come from homes in which there was at the time, or recently had been, typhoid fever. There was nothing about any of these to indicate infection, and to positively demonstrate its presence or absence seemed a hopeless task and was not attempted. There were a number of cases of fever in the country adjacent to the hospital at the time of the beginning of each epidemic, and this fact revived the old theory that flies carry the organisms upon or within their bodies, or both, and in their migration, deposit them upon the general food supplies, or more likely upon the food after it has been placed upon the tables. They were very numerous, and this led to the belief that they were the carriers of the disease germs, they having first come in direct contact with the sick, or having sipped from that portion of the cup which had been in contact with the patient's lips, or after having walked about upon and eaten some of the dejecta, had flown across the country to the hospital and there deposited their dangerous burden upon food or vessels wherein food was prepared. That the poison was disseminated in this way there seems no reasonable doubt, since it has already been proven that flies walking about upon dejecta or on prepared cultures and then lighting upon a culture-medium inoculate it with the typhoid bacilli; and it is the belief of the writer that both epidemics originated in this manner, yet it was not demonstrated except by partial exclusion.

The prodromal symptoms in each of the twenty-eight cases of the first epidemic were unusually well marked. There was general malaise, severe pains in the head, posterior portion of the neck and back; very marked rigor in nearly all and nausea and vomiting in a number; roseola over the abdomen of all but one, and in one half

*Presented to the Section on Practice of Medicine at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

they extended over the chest and thighs as well. They all had the typical markings of the tongue, the curving fever, with pulse and respiration in corresponding ratio, except when there were lung and heart complications; the bowel disturbances, diarrhea and tympanites and enlarged spleen, delirium in a few and typhoid expression in all; epistaxis in three, and in one of these there was also hemorrhage from all of the mucous surfaces and severe hemorrhages from the bowels of two others; albumin in the urine of sixteen and casts in four. Of the fifteen cases in the second epidemic not a single one had distinct chills, one had the typhoid rash, but it was not nearly so well marked as in the first, except in one patient, whose entire body was so uniformly covered with it that it was impossible to put the tip of the finger upon the skin anywhere without placing it upon a rose spot. They appeared over the abdomen first and gradually spread over the rest of the body. Albumin was present in the urine of all but one, in amounts varying from a mere trace to .5 per cent. in quantity; casts were present in two. With these exceptions the clinical symptoms were the same in both epidemics, and these in the first, together with the diazo reaction, which was found present in a few cases tested, and the isolation of the typhoid bacillus, completed the chain of evidence upon which the diagnosis was based. The writer was not yet familiar with the steps required nor with the technic in making Widal's blood-serum test, or else the last and most perfect test necessary to complete the chain would have been added and the diagnosis still further confirmed. In the last epidemic the diazo test was applied to the urine of every patient and the reaction found to be positive in all but two. Widal's blood-serum test gave a positive result in eight cases within seventy-two hours after the onset of the disease; one was negative until the ninth day, when the result was positive; one until the fifteenth day, when reaction was very positive, four tests in all being made; two negative on the first and also on the fourth days and reaction perfect on the seventh day; a fifth was negative on the first and positive on the seventh day; a sixth negative on the first and positive on the seventh day, and a seventh negative the first and only time the test was made. These confirmatory tests are of exceedingly great value, and without the latter one would always be in doubt as to whether an inverted case of typhoid fever was typhoid or not unless all the clinical symptoms except the fever, pulse and respiration were very well marked. Then, too, one is not justified in relying upon one test unless the reaction is positive, but trials should be made every few days until a reaction is obtained. There is a time in every case of typhoid fever when sufficient toxin has been developed in the blood to cause a clumping of the bacilli.

Of the first twenty-eight cases seven died. One epileptic, 21 years of age, died in status epilepticus after convalescence was well established, and a second, 17 years of age, was taken with tuberculo-pneumonia just as the fever had begun to decline, and perished within a few days. He also had a number of severe epileptic seizures, and the second a typical pneumotubercular lung. A third, a patient 69 years of age, with organic dementia, died at about the tenth day; a fourth, aged 53 years, a case of dementia, and a fifth, 43 years of age, died within ten days, and a sixth and seventh, one 19 and one 30 years of age, both of whom had been unusually strong and healthy, died early in the disease. The findings at the autopsies were typical typhoid

lesions, with a perforation in one of the last two, and in another there was in addition marked brown degeneration of the heart, and a third had softening of one parietal lobe of the brain. Microscopic examinations of sections from the spleen of all the cases examined showed typhoid bacilli. They were stained with aqueous fuchsin, but much difficulty was experienced in staining them. The death-rate was 25 per cent., but it must be remembered that only four of these cases went into the disease with any hope of withstanding its ravages. Of the fifteen cases in the last epidemic not one died, but they were with few exceptions better fortified, and there was no serious physical complication.

The treatment in general was absolute rest in bed, which also included the case of inverted fever to be described later on, careful nursing, dieting, baths, and the administration of medicine with a view of antiseptics as far as possible, and a use of such drugs as seemed best to meet the indications and for tonic effect when needed. During the first epidemic intestinal antiseptics were given all the way through, and the diet consisted chiefly of milk, alternated now and then with beef-tea and broths; water was given when called for. Sponge-baths, tub-baths and ice-packs were given as seemed best suited for the case in hand, the former being used most frequently. In the last fifteen cases little attention was given to drugs as intestinal antiseptics, but instead pure cold water was prescribed in quantities ranging from 100 to 150 c.c. to be given every three hours throughout the twenty-four unless otherwise instructed, a little listerine being added in order to make the patients feel that medicine was being given, and water was also given if the patients called for it in the meantime, the chief aim being to flood the digestive tract with from one to three liters of liquid, including milk and other liquid foods, in twenty-four hours, with the hope of increasing the blood volume, and of thus diluting the toxic elements and hastening their elimination. The diet consisted of milk alternated with Mellin's food and Horlick's malted milk; broths, beef-tea and raw egg were given when a change from the prescribed diet was desired. Tub-baths were given except to patients much emaciated, or where there was unusual weakness, or where it was feared they might be followed by shock and collapse. Some of the patients dreaded very much to be placed in a cold bath, and in order to avoid both mental and physical shock they were immersed in tepid water which was then cooled down to the required degree of coldness. It seems only just and right that heed should be given to the appeals the patients usually manifest in mental or physical shock, if not by verbal request, for more appreciable, and at the same time more humane, methods in the administration of hydrotherapy—the sheet anchor of our hope in the treatment of this dread disease.

The subject of typhoid fever is an old one, and in these days it is next to impossible to express a new idea, one that has not already originated in the minds of physicians everywhere, or to meet with an unusual case, one which has not been observed and carefully studied by every regular practitioner. Hence, when it is said that this paper would not have been thought of had it not been for one case among forty-three reported which differed from the ordinary—and that a case of inverted typhoid fever—each one may be able to call to mind a similar case, yet not many of these cases have been reported. Many authors speak of a low type of fever. Early in winter Goltman gave an excellent report of a case together with

a tracing of the temperature curve; the case was as near like the one here pictured as it is possible for two to be, and nearly the same steps were taken to prove it. It appeared in the *Medical Record*, and was reviewed in the December number of *Medicine*.

This is the first case which it has been my fortune to observe and to study from the onset of the disease to its close. The patient was a male, 57 years of age, and a melancholiac, with marked mental depression and lowered vital functions previous and up to the time he was

taken sick. There was general malaise but no pain, the tongue was coated and the tip and border red but there was no tremor; slight tympanites was noticed, especially in the right iliac fossa, where, upon pressure, faint gurgling could be elicited and also some tenderness. For a time the stools were thin and characteristic in color, and over the abdomen were rose spots, but they were far less numerous than in any of the other cases, yet quite typical. The temperature was 101.2 on the day it was discovered that he was sick, and it rose to 102.8 on the second, then fell below normal, remained there with the exception of a few times, when it reached a point slightly above normal, but remained so only for a short time. The pulse and respiration curves as indicated by Chart 1, which is an exact copy of the temperature, pulse and respiration variations as recorded and accurately traced from the time the patient was taken sick until his recovery, show a very marked relation to the fever curve, being either above or below the normal line and sliding up and down at about the same time. Accurate tracings of the temperature, pulse and respirations in all the other cases, all of which were of the ordinary type of fever, were made, and Chart 2, a copy of one, is typical of all of them. All the clinical symptoms previously mentioned in this special case were very like those in ordinary cases, except they were not so well defined; but when the last three points are taken into consideration there is found to be a vast difference. This difference is better illustrated than told as shown by comparing the two charts. With all these symptoms there was yet much doubt as to whether or not it was a case of typhoid fever, and there yet remained two tests which, if applied at short intervals throughout the course of the disease with negative results, would have classed the case with some low form of fever or toxic condition not typhoid. The first of these—the diazo test—gave a positive reaction during the fourth week, and the second—Widal's blood-serum test—gave a positive result on the third day of his sickness, thus showing that the blood at this early date was sufficiently charged with the toxin to cause agglutination of strong twelve-hour-old cultures of the bacilli within twenty minutes, thus leaving no question as to the diagnosis.

The value of the microscope has been fully demonstrated in these epidemics: 1, in the differentiating between albuminuria so often present in fever and actual structural changes in the kidneys, nephritis; both of which were present in the above cases, the latter in only a few; and in determining the condition of the bladder; 2, in confirming the diagnosis by aiding in demonstrating isolated organisms to be typhoid bacilli and later making it still more positive by proving the presence of the same bacilli in the spleen after death; 3, without it, the most valuable of all the confirmatory tests—Widal's blood-serum reaction—could not be nearly so well made, since the agglutination process must be observed under a high power. The report of this or any case of inverted fever would be of little moment if the diagnosis was based only upon the clinical symptoms, since the latter may be almost entirely wanting, as happened in a case seen in consultation by the author only a few days ago, since this paper was begun, and which was positively demonstrated with those two last named aids to be a case of inverted typhoid fever. Three weeks previous the patient had visited in a district where there was an epidemic of typhoid fever at the time, and the source of infection was contaminated water, of which the patient had also drunk; a second person visiting in the same place was taken with ordinary typhoid

fever shortly afterward. The microscope is one of the most valuable aids the physician has. It enables him to be positive in many cases where there would be much uncertainty without its use; and best of all, the methods and technic in making any and all these examinations are so simple that any physician can easily make them.

Effect on Mental Status.—Of the total number there were two cases of paranoia, two of alcoholic insanity, five of melancholia, four of terminal dementia, six of katatonia, five of organic dementia, five of epileptic insanity, thirteen of dementia precox and one a nurse not insane. Nine of these showed a marked gain in flesh and muscular strength. This change was rapid, and hence nutrition must have been very greatly improved. All the others except the fatal cases regained their former weight and strength but progressed rather slowly.

The changes in the mental status were even less pronounced than the physical, but this is due largely to the fact that the prognosis from the beginning was favorable in only four cases. Two cases of dementia precox became much brighter during the fever, but complete relapse took place immediately after convalescence; one case, delirious during the fever, brightened sufficiently after convalescence to be able to relate the names of his relatives; tell of events that had taken place while he was yet at home; could write a little, but imperfectly; became more interested in his immediate surroundings, kept himself fairly neat, and even took part in and enjoyed in a measure simple sports with the other patients; but in the course of a few weeks he relapsed completely to his former condition. One case of katatonia began to improve very rapidly early in the disease, and at about the time convalescence was fully established, mental recovery was complete, and a second made slight improvement but soon relapsed. Two cases of melancholia improved slightly but soon relapsed, the third continued so well that he was able to return home, where he is now assuming the ordinary duties of life. The only case of acute mania was very much emaciated at the beginning of the fever; there was still great mental exaltation and motor restlessness, a rush of ideas and incoherence, all of which symptoms had continued for a period of three weeks, and because of this he was wholly unprepared to battle with the fever. Within five days he became oriented and being a very intelligent and well-educated man, it was thought best to acquaint him with his physical ailment which had come in as a serious complication. He was told the nature of the disease, that it would be absolutely necessary for him to control himself and remain perfectly quiet in bed or his chance for recovery would be very poor. He seemed to grasp the situation at once, and said, "Doctor, I'll do it." He recovered from the fever, nutrition improved, the gain in weight and muscular strength was remarkable, the recovery from the mental disturbance was complete, and in four months he was taken back into the employ of the government, in the post-office, where he now is.

The conclusions to be drawn are as follows:

1. Cases of inverted typhoid fever are comparatively quite rare, and the subject is deserving of thorough investigation as often and wherever an epidemic occurs, with the object in view of determining the relative frequency of the disease; and in doing this all the methods for confirming the diagnosis should be rigidly applied in each suspected case. In these two epidemics it occurred but once in forty-three cases.

2. Of the patients who recovered 25 per cent. showed marked improvement in nutrition and muscular strength while the remaining 75 per cent. only reached their for-

mer condition in these respects. Compared with previous observations it would seem that insane patients with typhoid fever do not show such a degree of improved nutrition after recovery as do those without the mental complications. The patients who improved mentally showed a corresponding favorable change in nutrition, and those whose mental status returned to normal made the most striking changes in this direction. This may not be true, except for these two epidemics, but in them is beautifully illustrated the profound influence that the mind exercises over the processes of nutrition and assimilation.

3. Of this number 16.6 per cent., all dementias, seemed brighter mentally but relapsed as soon as convalescence was completed, except one case which continued on some little time longer; 2.77 per cent., all melancholias, made partial recovery and one is just fairly able to resume the ordinary duties of life; 5.55 per cent., one a case of katonia and one of acute mania, regained completely their former mental status. The behavior of the cases of dementia would lead one to think the fever had some slight influence upon the mental condition, but it is of no value, since the relapse occurred so soon. Such cases are always beyond the possibility of recovery. The prognosis in melancholia is favorable for some improvement, and it is only fair in this one case to assume that the fever played no important rôle in the partial recovery, since the change was no more than was predicted previous to the fever. The prognosis for recovery in acute mania is generally favorable; and in this case it was regarded as specially hopeful some time before the attack of typhoid. The recovery was rapid and complete and took place at about that period in the course of the mental disturbance at which a change might be expected had he not had the fever, hence one would not be justified in giving to the latter any prominence as a curative factor in connection with the insanity.

TYPHOID FEVER.

A QUARTER OF A CENTURY'S EXPERIENCE THEREWITH,
WITH SPECIAL REFERENCE TO SOME
UNSOLVED PROBLEMS.*

BY JAMES L. TAYLOR, M.D.
WHEELERSBURG, OHIO.

The territory in which I have been located continuously for a quarter of a century is in the Ohio River valley—a region of low hills and valleys, with excellent natural drainage and exceptional freedom from swamps and sloughs, with a permeable soil, an abundant water-supply, furnished mainly by wells and springs, and occupied by a farming population of more than ordinary thrift, intelligence and sobriety. During nearly all of this period I have had more or less cases of typhoid fever to treat, and thus have had opportunities to observe the disease under circumstances quite different from those presented in hospital practice, or surrounding the busy practitioner in large cities.

Speaking generally, I may say that the type of the disease which has prevailed here has been mild, with a tendency to assume endemic conditions. The whole region was formerly intensely malarial, but in conformity with what has been observed in so many other parts of the world, malarial fevers have well-nigh disappeared, and the various forms of typhoid have succeeded. For many years now, I have hardly seen a

case of intermittent fever—ague being one of the rarest diseases that I encounter. Still the germ is not extinct, because only this spring, after the thaw following the unprecedentedly cold weather of -33° in February, I had a few cases of old-fashioned shaking ague of the quotidian type—a fresh reminder of a form of sickness that few were fortunate enough to escape in my boyhood. Now, why has ague disappeared in a region which once seemed to be its congenial home? Men continue to clear land, to turn over the virgin soil—to a less extent than formerly, it is true—but the conditions of heat, moisture, decaying vegetation, and all the alleged circumstances favoring ague still exist. And the plasmodium is still here. But, instead of intermittents we have typhoid—a disease of a very different nature—domiciled now as an endemic. Has Eberth's bacillus run out, so to speak, the plasmodium of malaria? Or by virtue of what bacteriologic law does the one microdeme become diffused, abide and prevail, to the exclusion of another microdeme already in possession of the field, more widely diffused and seemingly more active in its development than the former?

The summer of 1875 in the Ohio valley was an unusually wet season, and was followed, on August 5, by an overflow which destroyed all vegetation on the lowlands. For many days after the flood subsided, the stench from the fields of corn and other vegetation rotting in the August sun was almost intolerable. Added to this was the saturated condition of the surface soil, and every low place filled with standing water evaporating during dog-days in a humid air. Very naturally there was a general apprehension, both among the profession and the laity, of serious sickness to follow such an ideal condition for the generation of a pestilence. Quinin sprang into sudden local demand—to say nothing of whiskey as an assisting antidote. But, strange to say, the following autumn—although somewhat dry—was the most salubrious I have ever known in my practice. I had almost no cases of any kind of fever to treat before cold weather. How many theories concerning the genesis of fevers such experiences completely overthrow! Here the plasmodium of malaria, in one of its aforesaid favorite haunts, with the conditions believed for centuries to be favorable to its activity, reproduced, yet it seems to have lost the energy necessary to its continued propagation, or some physical cause external to the human organism forbids its further multiplication and growth. In our zeal to hunt out, identify and isolate the specific microdeme of each infectious disease, are we not in danger of losing sight of the far greater problem as to what kind of energy it is that determines whether the specific germ shall abide or disappear, remain malignant or grow benign?

In my territory, as I have said, typhoid fever since 1872 has been endemic, and its type in general rather mild, my mortality list rarely attaining to 5 per cent. But it was not always so. While malaria held the field, the incursions of typhoid were epidemic in character and most violent in form. Local tradition has preserved the memory of the first visitation, which occurred in 1823, and which was for many years afterward referred to as the "sickly season." Whole families were then stricken down at the same time, and the population being yet sparse, there were in some cases not enough well ones to minister to the sick, and the records of the neighboring church-yards still attest the unusual mortality of that epidemic. Doctors were then scarce, and medical attention that year difficult to obtain. But, strange to

* Presented to the Section on Practice of Medicine, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

say, the impression lingers yet in that territory, that an unusual fatality everywhere marked the doctor's pathway; which means that the aforesaid treatment of fevers was unsuited and damaging to the type of fever in that epidemic. It was the identical complaint set up in Europe years before, according to Dr. Rutty, who observed regarding the fever epidemics of his day, that "the mortality was great among those who were best attended to, and that the poor—those who were left to God's providence and got nothing but cold water—recovered." Other epidemics have since appeared, as in 1848, but were less widely diffused and not so malignant. Since 1872, when I began to observe and treat the disease professionally, I have seen nothing resembling an epidemic invasion, judging from descriptions of epidemics elsewhere. Take this from Trousseau: "A boy 12 years of age, cowherd to the mayor of Bièves, whose wife and daughters successively had had typhoid fever, contracted it, and brought it with him to his village, Orgeval, distant three kilometers, and where there had been no case of the kind. He there communicated it to a female relation who waited on him and she gave it to another female relative who came from the other end of the village to assist her. From that time typhoid fever spread in the village. Nor was that all; a young man employed as a servant in the house at Orgeval, took the disease, was sent to his home, a distance of six kilometers, whither he carried the disease, which became epidemic in that place." In the sense in which the word is here used, I have certainly never seen an epidemic of typhoid fever. Frequently the disease has infected several members of the same family after one of their number had brought it in, perhaps from some distant locality. Or it has adhered to one side of the street in my village or at one end of it while developing over a limited area. Or it has gradually embraced nearly all the dwellings in some small neighborhood out in the farming districts, with one or more cases in each, and continued for a season, the next year to appear in a different and widely removed locality. But though scarcely a year has passed without more or less cases to treat, many of them so mild that they would not be diagnosed as typhoid, were they not associated with or followed by graver forms of the disease that were unmistakable. In the same or closely related families—yet nothing resembling a wave of epidemic typhoid contagion has yet come under my observation.

Almost every type described in the literature of disease has at one time or another prevailed here, but, as a rule, each year has been characterized by a particular form. Thus, while throughout one year the bronchial form has prevailed, almost every case partaking more or less of this impress, perhaps the next year it would be the cerebrospinal form, and another year the hemorrhagic form, and so on. According to my notes the year 1881 was marked by a tendency to abdominal hemorrhage. This was a dry, hot season in Southern Ohio, there being almost no rain in my neighborhood from April to November, while the thermometer sometimes registered 107 in the shade. We had a touch of the "hot winds," so well known in the Western states, and a consequent failure of crops very unusual in the Ohio valley. That year I had some twenty cases of typhoid fever, the majority of them being hemorrhagic, and one patient dying from the immediate effects of an enormous intestinal hemorrhage. Why the first appearance of a disease in a country should be especially malignant and destructive, and why, after becoming domiciled, it

should gradually become milder, and take on such diverse forms in different seasons—forms so unlike in its mode of invasion and subsequent course that no untrained observer would imagine that the same germ was the common cause of them all—these are questions upon which science has yet shed no light—not even to the extent of offering a plausible theory, but certainly they present features of the most absorbing interest to every observant mind.

Where the disease has prevailed in the country districts over some limited area. I have studied its rise and development with special reference to the water-supply or surface drainage of that territory, and I have long since become convinced that neither the water-supply of individual families, nor the course of drainage of a locality was adequate to explain why the disease should hover over that particular neighborhood for a season and then disappear. The farm houses, as I have said, are supplied with water from their own springs or wells, and it is inconceivable that these sources—widely separated from each other—should become contaminated from some single focus of infection. Nor has the extension of the disease after its first appearance always been in the direction of the surface drainage. On the contrary, I have seen the first case in a new locality appear at the mouth of a hollow, and extend perhaps in an irregular march toward its head, and over the divide, in the most capricious manner possible, omitting some families and visiting others at one side of the direct path, in a way wholly independent of any connection with the surface drainage, or any recognizable focus of infection. My contention is that the disease in its endemic form is propagated, extended and continued according to obscure and indirect methods wholly unlike those employed in its more contagious, aggressive, irruptive character. This aspect of the disease is entirely different from malaria, which clings with tenacity year after year to certain localities. It rather resembles cerebrospinal meningitis in selecting spots apart from each other for its invasion, and then disappearing for a time after prevailing for variable periods.

One great difficulty in tracing the origin of any local development of the disease lies in the fact that a very mild case may be the precursor of other cases of great severity. Frequently my severest cases have come home from a temporary residence in a neighboring city—especially the Ohio River cities, where typhoid is likewise endemic, whether from the use of water from the river, the great sewerage channel of scores of towns and cities in six states, or from some other cause. I know not. But certain it is that the disease is more prevalent in these cities than in the country, and assumes there a form of greater severity. Such cases often come home to the country, and are apt to be troublesome to manage. When properly attended, however, they seldom the starting point of a new infection. Again and again I have seen malignant and fatal cases go through the disease after being brought in, without a single member of the family or other families contracting it. It is the mild cases, where the diagnosis is uncertain, and precautions do not seem to be called for, that are most likely to cause infections, and when once propagated are most difficult to trace to their origin. Now, this explains sufficiently the diffusion of the disease throughout the family after its first introduction. But how shall we explain its gradual extension, sometimes even its almost simultaneous appearance, over a limited area and its restriction, perhaps for that season, to the inhabitants of a single neighborhood?

There are other circumstances connected with the endemic prevalence of typhoid in this region worthy of mention, such as the singular absence of some diseases that are commonly met with almost everywhere. One of these is erysipelas. I do not remember to have met more than three cases of idiopathic erysipelas during my term of practice. Another affection equally rare is puerperal septicemia. Very little of this has appeared in my territory, and I look for twin births, or placenta previa, or postpartum hemorrhage, or hydrocephalic crania, more than I do for puerperal septic infection. Tubercular disease also has greatly diminished in frequency of late years in comparison with its former prevalence. Excluding cases that have contracted the disease elsewhere, tuberculosis has come to be a comparatively rare disease in my territory. Whether all these circumstances are merely coincidences without any etiologic significance or dependence on physical conditions, I am unable to say.

Although typhoid has ceased to exhibit an epidemic tendency here, yet we are not immune to other epidemics by any means. The influenza visitation of 1889 was as general here, as severe, and as fatal, as it was anywhere. And it has shown a disposition to cling to this region, appearing and reappearing with considerable frequency. Typhoid fever for the past few years is much less frequent than it was before, and what is most singular—the type of the disease has undergone a very extraordinary change. I first began to notice this about five or six years ago. Patients would come to me complaining of indefinite ailments—especially loss of appetite, slight headache, chilliness, constipation, coated tongue, and great prostration. I began by labeling it “typhoid ambulans,” usually prescribing some placebo, and assuring them that in a few weeks they would likely be well. But much to my surprise they did not get well, as such cases had been in the habit of doing for so many years past. They called for more treatment, and grew weaker and worse. As I began to study these cases and compare them, I found that they had almost uniformly a slow pulse—sometimes as low as forty—and a sub-normal temperature, ranging from 96 to 98. I left thermometers with the families with instructions to take repeated observations. But at no time during twenty-four hours did it register any fever. These cases went on for months and months, and no sort of treatment availed anything. Some of them were absolutely without pain of any kind, while others complained only of ill-defined aching of the muscles, with cold sensations and numbness. The tendency to sweat, sometimes only over portions of the body, was marked in some cases, even the taking of food being attended with profuse perspiration, though this was not a constant symptom. The most constant phenomenon was the lack of definite symptoms except anorexia and great prostration. I repeatedly interrogated every organ of the body to detect a cause for this condition, with negative results. I plied them with stimulants and tonics to no purpose. I exhausted every resource in the therapeutic calendar without effect. Even generous, well-selected diet often made them feel worse. All the vital forces persisted in remaining below par. Sometimes the patient would be up and down, but oftener in bed. One patient was able to be about the room for two months, then was in bed three months, and after that was five months in convalescing. Emaciation took place slowly—very slowly—but never to the extreme degree of a typical case of fever.

I quickly learned that it was unwise to call these strange seizures by the name of typhoid fever—first,

because they hadn't any fever, and second, because no one, myself included, had ever seen walking typhoid, or any other form of typhoid, act in that way. So I labeled it “nervous prostration.” The patient and family were more easily managed under that caption. I can conceive of no more difficult position for a physician to occupy than to have such indefinite ailments to treat, where there seems to be so little the matter that neither the patient nor his friends can understand why he doesn't get well. As time goes by, the impression is apt to grow that the doctor doesn't understand the case. At first the physician may worry lest the patient should call for a change of doctors. But later on, this feeling subsides and is replaced by the fear that after all, perhaps the patient will not want to change doctors.

I have often racked my brains to conjure up some treatment that would induce a reaction, maybe some fever—a blessed fever—to bring on a crisis of some kind to terminate the suspense. And I have sometimes wondered while treating these interminable cases, notwithstanding our belief in and use of cold packs and antipyretics for the elimination or reduction of fever, whether after all, the dreaded fever, according to the old contention, might not be a great and valuable factor in the unseen armamentarium of the *vis medicatrix naturae*.

It may seem incredible, but my books show that in 1893 I treated one of these cases—a young man at some distance in the country and at no time critically sick—for a period of eleven months. Then he decided to be removed to the city, where he had relatives, in order to be under the more immediate care of a physician. For a time he tried one doctor, and afterward a second one, who told him finally to leave the city and go back to the country where he would likely get well more quickly. It may be of interest to state that he finally did get well, and is now strong and robust again, notwithstanding that his father thought for a long time that the boy looked like “death upon wires.” I have two similar cases in hand at this time, robust men in middle age, who gradually sickened last October, and without having at any time been bedfast, are yet unable to resume their usual vocations.

Now how do I know that this strange form of sickness—never observed here prior to the late epidemic of influenza—is due to Eberth's bacillus? Of course, I do not absolutely know it to be typhoid in character, because I have seen no deaths from it and no post-mortems. I have not punctured the spleen in search of the microdeme. I have submitted blood specimens to Widal's test, but with negative results. Indeed, who would expect the characteristic reaction in cases without antecedent fever, when some undoubted cases with fever fail to respond to it? So that the failure of Widal's test in these cases I regard as inconclusive. But I am inclined to consider it as essentially typhoid, because I fail to see how it can be influenza, since in most cases, there is no history of an initial attack of that disease. Its mode of invasion, too, is so like ambulatory typhoid that at the outset no one would likely give heed to any points of distinction. Besides, these cases have repeatedly developed in dwellings where, at no long time previously, there had been typical typhoid fever. Certain of these cases also have developed in their progress a train of nervous symptoms identical with typhoid, such as insomnia, distressing dreams, intolerance of light and every kind of noise, forgetfulness of much that transpired through the sickness—in one patient insanity requiring temporary restraint in an

asylum—and other nervous symptoms commonly found in the typhoid category. And, finally, some cases have exhibited abdominal tenderness of a persistent character, one case at least being attended with profuse intestinal hemorrhage.

Whether this algid, subnormal type of disease is a simple or a multiple typhoid infection, or indeed, a wholly new form of infection, it is not to be doubted that we now have in this region a very marked change of type in existing diseases. Formerly, as we all know, this question of change of type was a great battleground among physicians, the majority insisting strenuously on this fact which they characterized by the phrase "epidemic constitution," while others of high authority declared that "such changes existed only in the imagination of physicians." But here under my own eyes I think I am witnessing a decisive transition. For five or six years now the old familiar forms of typhoid have been diminishing in frequency until they have almost disappeared, and a new form entirely unlike anything seen before for a quarter of a century holds the field. This sequence of phenomena has the appearance of a demonstration, and one must doubt the clear evidence of his senses not to believe that diseases do undergo marked changes of type. Graves, in his "Clinical Lectures," given in 1835, argued in favor of this doctrine with great force and clearness, showing that certain approved methods of combating a given disease under one form, were simply destructive when applied to the same disease prevailing under a different phase of the so-called epidemic constitution. And in proof, he very felicitously cites the example of Dr. Bateman, who had always opposed blood-letting in his practice, but who was obliged, on account of the inflammatory constitution prevailing in 1810, in opposition to his former views, to prescribe venesection in fevers. Graves also asserts that "in Europe the reign of typhus—the word typhoid at that time not being distinctive—appears to have closed with the influenza of 1804, when a new constitution began, at first more remarkable for the disappearance of nervous, we would say typhoid, fevers and other contagious diseases, than for any peculiar character of its own." For a time what he calls the gastric constitution held sway, but the gastric constitution had scarcely established itself when a new character, viz., the inflammatory, appeared upon the stage, and with its appearance venesection, which had previously fallen into disrepute, became once more a favorite remedy.

Possibly history is repeating itself, because following our own epidemic of influenza, the old familiar type of typhoid has well-nigh disappeared, as nervous fevers did, according to Graves, at the beginning of this century. Of course, I speak only for my own locality, but if I am correct in my observations, and we are now in a transition stage intermediate between types, may we not look for new conditions, new "constitutions," that may possibly modify our nosology and call for wide departures from former methods of treatment? I think I have already seen intimations of the advent of new characters on the stage which may possibly be the precursor of changes as unlooked for and unfamiliar as those described by the physicians of antiquity. For instance, last fall I had a run of laryngeal croup in children—without a single grave case of pharyngeal diphtheria—which carried off more children in the space of ten weeks, than I had lost before with that disease in the course of my practice. Some cases were preceded by a distinct scarlatinous eruption—although scarlatina was not epidemic—while others gave no history of an exanthem. In

nearly all these cases I was called too late in the disease for antitoxin to be of any service, although I injected it in several instances. And these cases developed in widely separated localities, so that there could not have been a focus of contagion. To be sure, this unusual run of bad luck might have been due to a chance coincidence. But why, in the space of ten weeks, I should thus lose so many cases from membranous croup, when neither diphtheria, nor scarlatina, nor any other contagious disease was epidemic, seems unaccountably strange.

Whatever that influence may be which the phrase "epidemic constitution" has been used to describe, to my mind it is a species of morbid energy as powerful and controlling as it is mysterious and ill understood. While the specific germ may determine the kind of disease which its invasion shall produce, the "constitution" stamps that disease with a potency to become mild or severe, sporadic, endemic, epidemic or pandemic, and imposes laws for varying methods of treatment, which even the highest professional skill may not at first distinctly recognize and apply. But if typhoid fever in this country shall follow a course at all similar to its developments elsewhere in the past, under the varying so-called constitutions which from time to time have appeared, I very much doubt whether the semi-expectant plan of treatment which so many of us have successfully employed for nearly a life-time, will then fulfil the requirements of changed conditions and indications.

TYPHOID FEVER.

THERAPEUTIC PRINCIPLES ESTABLISHED IN ITS TREATMENT.*

BY L. F. ROUSCH, M.D.

NEW HAVEN, W. VA.

While the fatality from typhoid is not so great as it was at all times previous to 1870 or 1875, and a better understanding and treatment of the disease is gradually being brought about, still there is a large percentage of deaths, and no uniformity in the management and medical treatment of the same, and as a consequence great disparity of results follows.

When I was a student of medicine at the college, and for a long time following, there was no treatment advocated and none practiced which had any, or at least very little, specific influence to modify its progress or abridge its duration.

Furthermore, I am satisfied that the majority of physicians at the present time, including among the majority men high in the councils of the profession, who do not believe for an instant in abridgment, much less its abortion by medical instrumentality.

Quite a large number of the profession who have used the Brand method of treatment believe and know that the disease is modified, its duration lessened, and the percentage of death-rate made very low—they think lower than by any other method of treatment. Against this way of treating I have not a word to say, but for a long time I was at sea as to how this curative influence was brought about, but after the investigations of Robin, in which he proved that a much greater quantity of waste matter existed in the blood in fevers than in health, and that the quantity was proportional to its severity, and that through the influence of cold baths a greater quantity of oxygen was inhaled, a better oxygenation took place, at the same time the urea was in-

*Presented to the Section on Practice of Medicine, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

creased to 20 per cent., I could begin to see and know something of its *modus operandi*.

But after the experiments of Roque and Weil established the fact that certain toxins were found in the blood in typhoid-fever patients, and that after or during the bath treatment, the excretion of the kidneys increased five-fold until convalescence occurred, then it was plainly enough seen how this method had its influence. I knew it could not be due to the temporary influence of reduction of temperature alone, but must be due to some change produced upon the system by effect upon some organ or organs.

In the hospitals and in the cities where you have all the facilities, as bath-tubs, trained nurses, etc., this treatment certainly should be advocated and practiced, as any treatment should which reduces the mortality to as low as 9 and sometimes to 2 per cent.

But this treatment can not be carried out in private practice in the country. It is simply impossible to use the full bath treatment. Just think of it for a moment—not one bath-tub to every 1000 inhabitants, not one trained nurse in a county in some of the counties of West Virginia, and no money to buy one or hire the other; and sometimes but little to pay the doctor. What are we going to do about it? We will exercise common sense and do the best we can under the circumstances, and of this I am going to treat. Now, as to therapeutic principles, what are they? I will explain as I go along, but I might say in advance in one word they are eliminative and antiseptic—the identical principle established and brought about by the cold-bath treatment, but to some extent through different organs and by a different way.

I know the common opinion that the drug treatment is of no avail; that it has long been tried and found wanting; that a great many agents have been heralded to the world as having specific influence, and they have been tried in the crucible of experience, and not found to answer the expectations raised by their advocates. I have tried many of these myself, and have been sorely disappointed more than once, but an experience founded on the treatment of 143 cases in the last four years has taught me the value of certain remedial measures about which I cannot be mistaken.

First Therapeutic Principle.—The bowels must be acted upon by cathartics. Calomel is the best; two to six grains once a day for the first six or eight days. Give it, diarrhea or no diarrhea; if no diarrhea to prevent it, if diarrhea to cure it. The typhoid stool must be changed to a bilious stool, or at least to a stool with little odor. Always give it at any stage for the diarrhea which has the typhoid stool, but be observant enough to know when you have the action of your medicine, and not confound the free action from the calomel with diarrhea, or the diarrhea with the action of the calomel. You can combine soda bicarb. or salol with the calomel if you desire.

The second agent is salicylate of ammonium or sodium. I prefer the ammonium, as it agrees better with the stomach, and is probably more of a stimulant to the heart, and possibly to the secretions and excretions. Five grains every two hours is the average dose, continued night and day, while fever remains above 102 in the evening; when it falls below, then only during the day. This is continued from first to last. If it disagrees with the stomach, add aromatic spirits of ammonia or spirits or compound tincture of cardamon. Sometimes it disagrees at first, but it will not continue to disagree after the first three or four days.

What is the effect of this combined treatment? In four days, usually, but scarcely ever later than the end of the fifth day, the fever is permanently lessened, the patient comfortable, the pulse full and not fast, no tympanitis, the skin and tongue moist; he sleeps at night, is not sick; you would scarcely know he had fever if you did not use the thermometer. He goes on in the same way to the tenth, twelfth, fourteenth, sixteenth, and sometimes to the twenty-first day, but rarely so long, and is free of fever, is convalescent. This usually comes along about the eleventh to the sixteenth day.

But some other measures are to be mentioned. All the water the patient wants, all the tea or coffee he may wish to have should be given. Sponging the surface once, twice, or even three or four times a day with water is agreeable to the patient. If fever is very high, when at its hyperpyrexia, use cold water. The higher the fever the more sponging is necessary; it always helps the patient. All the foregoing measures are for reduction of fever and elimination and destruction of germs and toxins.

Second Therapeutic Principle.—Do not give food at first, unless the patient desires it. As a rule he needs no food until we have eliminated from his blood, tissues and urine the greater portion of the toxins. It is useless, worse than useless, it is injurious to give food during the first week of the disease; besides all this, it is unphysiologic. The patient is living upon himself. Let him live that way. It is Nature's way, and do not burden him with material, which further disorders the digestive, assimilative and excretory powers. Nothing is gained, but a great deal is lost, and what is the sense in forcing food on a patient who loathes the very sight of it. Nature never speaks in louder tones than she does in this way, but we do not listen. We are governed by an idea, a theory, and it must be carried out.

Time and again I have seen more diarrhea and more fever produced by the improper use of food at an improper time, and my rule is very little food during the first eight or ten days, as I know from observation, he is better off without it, and will convalesce sooner.

Third Principle.—No patient has been treated exactly right who has or continues to have tympanitic bowels. It is the worst symptom, aside from events like hemorrhage or perforation, that the patient can possibly have, even if the tympanitis is only moderate, or especially if very great. Nearly every patient that dies has tympanitis, has had it nearly all if not all the time. Why is it a bad symptom, a dangerous symptom? Because it greatly lowers the powers of life. The pulse gets weak and quick. The patient is restless, can not sleep; delirium and unfavorable symptoms supervene.

I said that no patient was treated properly who has it. How and what are the causes that bring about this condition? Continued typhoid stools, intoxication from same, lessening the powers of the whole nervous system, but especially the great sympathetic system. Gas is generated in the bowels, distension for want of muscular power from the innervation; continuing, they get beyond the power of the muscular coat of the bowels to contract; result peritonitis and death.

This is no fancy sketch; we have all seen it take place dozens of times in all probability. If, unfortunately, we have this condition, what is to be done? Administer small doses of calomel and salol frequently repeated, and large doses of strychnin; also equal parts of turpentin and camphor liniment to the bowels. This will likely overcome it, if it has not gone to that stage where

too great distension has taken place, or peritonitis has not supervened.

After the tenth day I usually give strychnin and continue to convalescence and during the same, then dilute hydrochloric acid in place of salicylate of ammonia in three or four days after fever disappears.

Administration of food begins after the sixth, eighth or tenth day; the first choice is always milk—sweet milk, or good fresh buttermilk; fruit juices from first to last. The patient will often relish some kind of fruit juice at the first. It is not a food in one sense, but every one knows its beneficial influence in sickness or health. It does not derange the stomach or bowels; it refreshes, makes the stomach better, and helps the patient in ways that we know nothing about, physiologically. It ought always to be given as a rule with but few exceptions. Do not use a bedpan. Let the patient get up. My patients get up themselves; they know what they are about; they are not too weak. Do not let that bugbear, perforation, scare you out of your wits. It does not often occur; I practiced thirty-two years with two cases only. It helps the patient to get up, gives him an airing, changes his position, and he feels better afterward. I am satisfied that it arouses his vital energies, and is a factor in preventing his getting into that dormant state which I saw so frequently in my early practice.

Now for the results: The thirty-first case died from overeating and eating improper food on the fifth day of convalescence. The patient was a young woman with her first child, 10 months old, and had poor health from the time of its birth; was anemic. Overeating caused indigestion, sick stomach, vomiting, diarrhea, prostration and death, but no return of fever.

The sixty-second case died on the twenty-second day, from hemorrhage. Pneumonia ensued on the fifteenth day. The patient was a young man, 22 years old.

The seventy-third case was a young man who was convalescent on the fifteenth day; got up, went to the cupboard, ate too much, and had a relapse. On the twenty-first day, when he was better again, perforation took place on the evening of that day, which caused his death. In the ninetieth case, the patient had a relapse three weeks after the first attack, with perforation on seventh or eighth day of relapse. He had been treated by another physician, but I treated him after the relapse.

In the one hundred and tenth case I was not called until the eighth day. The patient was unconscious, and death took place three days afterward. I did not have a chance to even commence treatment. It is hardly fair to count this case, but I have done so.

The sixth and last case was a married lady, about 45 years of age. She was the tallest and most slender woman I ever saw. She seemed overcome by the disease from the start, and did not have any rise of temperature but one day. She was really the weakest mortal I ever treated, and the sequel showed she really had no vital resistance, as she died on the eighth or ninth day with typhoid fever, when she had no fever.

Leaving out the one hundred and tenth case, which it is surely not fair to count, so far as treatment is concerned, this would show 3.5 per cent. of deaths.

Now, while I might have occasion to revise my statistics in the future in a way which would not make so favorable a showing, my opinion is that I could make a more favorable percentage even than I have made.

Of three things I am certain: that the treatment will greatly mitigate the symptoms, will shorten its duration, and greatly lessen the danger of death.

Whoever will may deary the medical treatment of typhoid fever as much as he pleases. I am sure of its influence, and look upon it as an established fact in medical science, and when called to a case, undertake the treatment without any apprehension as to the result. Whenever we can arrive at this state of mind in a disease like typhoid, which carries off its thousands of the youngest and fairest, with the highest hopes and the brightest prospects, then we have accomplished something for ourselves and for humanity of which we may well be proud.

ACETANILID IN TYPHOID FEVER.

WITH A REPORT OF SIX CASES.*

BY EDMUND C. BRUSH, A.M., M.D.
ZANESVILLE, OHIO.

The physician who has been in active practice for twenty-five years and followed the current medical literature has read of many cures for consumption and of methods of aborting typhoid fever. He has also read of many methods of treating typhoid fever and perhaps has tried some of them. I have never believed that typhoid fever could be aborted; I have never seen it aborted. Long ago I settled down to the idea that good nursing, judicious feeding and medicines to meet symptoms, as they arise, is the best plan of treatment. As you all know, some cases defy any and all methods of management and run a vicious and seemingly unmanageable course.

My home is in Zanesville, Ohio, situated in the Muskingum River valley, where typhoid fever is with us always; varying in frequency in different seasons of the year and also in different years. The severity of the type also varies in the same way.

The prime object in any plan of treatment is to control the fever; the severity of a given case and its outcome depending largely on the height of the temperature. It is not proposed to mention even the many plans, past and present for accomplishing this end.

The purpose of this paper is to report six cases in which acetanilid was used to control the fever. These are not the only cases in which I have used that drug, but the six in question were treated in a hospital, where records could be kept. They occurred at the same time, and all originated at Camp Thomas, Chickamauga, Ga., during the latter part of August and early in September, 1898. The patients were soldiers belonging to one organization and of an average age of 22 years. They were sent home from camp with the disease in various stages. Two had rose-colored spots, and all had either diarrhea or a tendency to it, when admitted to the Zanesville Hospital. One had a persistent cough with sore throat. Three suffered at times with epistaxis. All had distended abdomens, but in only two cases was it pronounced. Not one had any hemorrhage from the bowels. The shortest run of the fever was twenty-four, the longest thirty-five, and the average thirty days.

In addition to the six cases reported, I saw ten others among the same body of men. These were taken care of in their respective homes by home people. I think it is generally known that the typhoid fever in the camp mentioned was not of a mild type. One of the ten cases, seen by me outside of the hospital, died in the fourth week of the disease, from persistent and violent hemorrhage from the bowels. All the others recovered.

CASE 1.—Longly, aged 17 years, was probably in the

* Presented to the Section on Practice of Medicine, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

tenth day of disease when received. He had rose-colored spots on the abdomen, and diarrhea when admitted. There was no delirium and but slight distension of the abdomen. He had fever for fourteen days after admission, the average morning temperature being 99.6; average evening temperature, 101. At noon on the day after admission his temperature was 104.

CASE 2.—Tucker, aged 25 years, was probably in the eighteenth day of disease when received. The rose-colored spots disappeared soon after admission. He had epistaxis on the twenty-second and twenty-eighth days of disease and a troublesome cough throughout, with mild diarrhea and slight distension of the abdomen. He had fever for twelve days after admission, average morning temperature being 99.2; average evening temperature, 100.4. The highest temperature was 103, on evening of the twenty-third day. This patient had a decided yellow tinge to his skin and conjunctiva during the whole course of the fever.

CASE 3.—Trump, aged 21 years, was probably in the seventh day of disease when received. The rose-colored spots were well marked, and there was considerable delirium with subsultus tendinum when admitted. He had some diarrhea, and abdomen was distended. On the sixteenth day, after using acetanilid, his temperature at 6 p. m. was 98, and he complained of feeling chilly. He had fever for twenty-four days, average morning temperature being 100; average evening temperature, 101. The highest temperature was 103.2, on the evening of the eighteenth day. This patient had a pronounced yellow tinge to his skin and conjunctiva throughout his sickness.

CASE 4.—Rambo, aged 22 years, received about the ninth day of the disease. He had a troublesome cough and a persistent sore throat; was nervous, delirious and could not sleep; had subsultus tendinum. Some diarrhea and vomiting occurred at times, with well-marked distension of the abdomen; severe epistaxis on the thirteenth, eighteenth, twentieth and twenty-sixth days of disease. In the fourth week he had severe conjunctivitis, and had fever for twenty days after admission, the average morning temperature being 100.8; average evening temperature was 101.8. The highest evening temperature was 103.4, on eleventh day.

This was the only case in which acetanilid was used in doses larger than three grains. For the first three days after his admission this patient's temperature was hard to control, so that the dose was doubled and six grains was given, and on several occasions during those three days, this dose was repeated in one hour because the first dose did not produce any perspiration or reduction of temperature. After the third day of his admission and the twelfth day of the disease, the temperature was controlled with three-grain doses.

CASE 5.—Worham, aged 25 years, was received near the beginning of attack. He had diarrhea all through sickness, but easily controlled, and had some cough and nausea at times. Late in the disease he suffered from insomnia; this was relieved with sulphonal. This man had a relapse due to tobacco brought in surreptitiously. He had fever thirty-five days, including relapse, the average morning temperature being 99.4, average evening temperature 101. The highest evening temperature was 103.4, on the eighteenth day.

CASE 6.—Hahn, aged 21 years, was received on the third day of the disease. He had well-marked abdominal distension, with diarrhea, followed in the second week with constipation; had epistaxis on twelfth, thirteenth and fifteenth days. He had no delirium when awake,

but talked a good deal when sleeping; had fever for twenty-eight days, the average morning temperature being 100.8, average evening temperature 101.8. The highest evening temperature was 103.4 on the twelfth day. This man was raised in our Children's Home, and during his sickness was home-sick. Frequent visits from the matron of the Home helped the nostalgia.

On several occasions he complained of feeling chilly after taking acetanilid. Calomel followed by castor-oil was given for the constipation and had to be used a number of times. Whenever this patient's bowels did not move almost daily he complained of distress. This distress was always relieved by a laxative, and the patient said he felt better after it. As the pulse and respiration in all the cases were in ratio with the temperature, they are omitted.

The foregoing report shows that the cases were typically typhoid and not of a mild character. Three of them were in the first week, two were in the second week and one in the third week of the disease when they came under my charge. All had diarrhea at times, of more or less severity. Milk with lime water formed the chief article of diet, varied with malted milk, beef broth, whites of eggs, ice cream and corn-meal gruel. Ice and water were not restricted. The distended abdomens were freely anointed with turpentine. Antiseptic mouth washes were used. For the diarrhea, a tablet consisting of opium and camphor each $\frac{1}{4}$ -grain, ipecac $\frac{1}{8}$ grain and acetate of lead $\frac{1}{6}$ grain was given. Bismuth or essence of pepsin generally relieved the nausea or vomiting. When a laxative was needed, calomel was administered, followed by castor-oil with a few drops of laudanum.

As many of the comrades of these men suffered from malarial troubles, it was deemed best to use some quinin in these typhoid cases. This was given in two-grain doses three times a day, or with the acetanilid. No whiskey was used. All were given a cold sponge-bath every morning.

Acetanilid was the antipyretic used, and it was efficient and effective. The directions given the nurses were to give three grains of acetanilid every three hours whenever the temperature was over 101, until it fell to that point or below. If, after giving a dose, the temperature showed a decided tendency not to fall, a second dose was given in two hours.

As an illustration, the following is taken from the record of one of the cases reported. At 5 a. m. his temperature was 102.6. Three grains of acetanilid was given at once and this was followed by free perspiration. In two hours the temperature was 100.6 and only one dose had been given. At 2 p. m. the temperature was up to 103; acetanilid was again given and in two hours the temperature was 101, and did not go above that point that evening.

Nearly all patients broke out into a good perspiration after the first dose, and the temperature began to decline; the second dose made the perspiration more free and the decline in the temperature more decided. In every case there was comparative ease in controlling the fever by the method given. There was no effort to reduce the evening temperature below 101. It often went below that point, and the patients would only complain of being chilly. There were no bad effects noted from the use of the drug. It was not given in large doses, it was not given often. Frequently two doses in one day were all that a patient required. When, however, a high temperature persisted, the drug was used until the fever gave way. The nurses showed apti-

tude in administering the acetanilid as soon as the idea of its use was explained; instructions were carried out carefully.

It is to be remembered that these patients were robust young men, that the feeding and care given them was systematic, and they never questioned what was to be done.

I do not present this paper because I think that I have found the treatment for typhoid fever, but because in using acetanilid, I had success, and I believe that, used with judgment, it is a valuable remedy in treating typhoid fever. Please observe that no attempt was made to produce a sudden fall in the temperature by using large doses. I preferred to give small doses and by repeating them produce a gradual decline in the fever. Excepting one case, three grains was the largest dose given.

Furthermore none of the remedies used were given unless their need was clearly indicated. The whole idea was not to medicate, but to pilot the patients through the rapids of the disease and to land them on the shore of recovery.

DISCUSSION ON PAPERS OF DRs. BOODY, TAYLOR, BOUSCUI AND BRESCH.

DR. J. A. WITHERSPOON, Nashville, Tenn.—This subject is one of the most important that we have to deal with. If I understood the gentleman correctly, he stated that malarial fever had about died away, and that most fevers today were of typhoid origin. Now, gentlemen, the differences in the treatment of typhoid fever in recent years has made it evident, in my humble judgment, that the fever mentioned is a different type of fever altogether. I do not know what you have in this part of the country, but I do know that we have in Tennessee, and in that section of the country, a fever that has none of the etiologic or clinical factors of typhoid fever or malaria. We never find, after the tenth day, the typhoid bacillus in the stools, or the malarial plasmodium in blood. We never have the nervous symptoms of typhoid fever. The temperature goes up suddenly without any incubation period. With the fever there is at once great prostration. It is a fever with leaky skin, and not the dry skin of typhoid; with general abdominal tenderness and the scaphoid belly; with rather constipated bowels, with small scybala actions at first, and not the mushy stools of typhoid fever; a fever that runs a rather low and favorable course if not over-treated; a fever without enlargement of the spleen and liver; one where the effect on the nervous centers is very slight; one with markedly fluctuating temperature. It takes one general purge at first, in these cases. I can not imagine any worse treatment than giving an active purgation of 3 to 6 grains of calomel every day for six days to get up a stool as frequently as one wants to, as mentioned. In typhoid fever we have an irritation in the intestinal canal, of the solitary follicles, an inflammation of Peyer's patches with ulceration, and by this active purgation you absolutely add fuel to the fire, running the risk of the formation of a quick slough. In my limited experience with cases of typhoid fever, I believe they do better when the bowels are moved with a gentle enema, rather than by a purge. I do not believe in continuous constipation, but I do believe in enemas, and not in the use of purgatives at all. Another point: there is no treatment of typhoid fever to be applied to every case. We should meet the conditions as they arise. If I should select any one treatment, it would be cold water inside and outside. It is by far the safest and best treatment ever introduced. It is not the treatment of the disease, but the treatment of the patient. One should carefully consider the vitality of the patient and treat according to the symptomatology.

The gentleman who read the last paper stated that the essential element in the treatment was to control the fever. Why, the toxemia is the dangerous thing we have to deal with. The toxins are sent out into the system and overwhelm the nervous centers. The fever plays but a little part. If any man thinks that the Brand method of treatment is for the purpose of lowering the temperature only, he has a wrong conception of it. The temperature plays but a little part. As to acetanilid, I want to place myself on record as saying that I do not think that any of the coal-tar derivatives have a place in the treatment of typhoid fever. Any drug that lowers the resisting powers of the patient and acts on the heart muscle itself, should have no place in the treatment of typhoid fever. There-

fore, I oppose any coal-tar derivatives. The best treatment is rest, water, regulation of the diet, careful nursing, regulation of the bowels, and, if you do not treat too much, the vast majority of the cases will get well.

DR. C. H. MILLS of Illinois—I have been in the habit of treating typhoid fever since 1856 with rest, feeding with toast-water, some milk and six drops of turpentina made into an emulsion and given every three or four hours; this is the treatment of Dr. G. B. Wood of Philadelphia. I advise occasional enemas of either water, or water and turpentina. Occasionally typhoid fever is modified by the presence of malarial fever, and this is usually spoken of as typhomalarial fever. It is a combination of the two diseases. Where this occurs I give quinin, 60 grains in twenty-four hours, which eliminates the malarial part. In ordinary practice I can not use the cold bath. This use of cold water was common when I commenced practice and is common to-day. Turn the water on the wrist and on the head and do not disturb your patient. The great trouble is that we interfere too much with the patient. Give rest in a well-ventilated room.

DR. W. WOOD, of Tennessee—I only wish to add to Dr. Witherspoon's statement. I find that he gives it very nearly right. If I am called to treat a suppurating wound, I use drainage and antiseptics. If I am called to see a case of typhoid fever, which means that the alimentary canal swarms with bacilli, I use drainage and antiseptics.

DR. L. L. MATTHEWS, Joplin, Mo.—I thoroughly agree with the remarks made by Dr. Witherspoon. I have had the same serious doubt, in reference to the type of fever we have in the West that Dr. Witherspoon seems to have. He did not say that we have a special type of fever, which differs from malarial fever or typhoid fever in the West; he did not say that, but I think he believes it. I know that I believed it for many years. Many years ago I read a paper that demonstrated conclusively, to my mind at least, that what most of the physicians were calling typhoid fever was some peculiar, distinct disease different from typhoid fever, it being neither typhoid nor malarial. Soon after I had a number of these cases, in which the last four running much the same course, developed fatal intestinal hemorrhage. While I believe, in the West, we do not have the typical cases of typhoid, as described in text-books, I now believe that all of them are due to the bacillus typhosus. My experience has taught me to pay but little attention to the fever. If I am called to see a case with remarkably high temperature, and yet with a good pulse, I feel secure; but if I am called to see a case with low temperature, with quick, rapid pulse and with indications that the disease is going to be one of prostration, with probably heart failure, I then am apprehensive. Pay attention to the heart, rather than the temperature.

DR. SCOTT of Iowa—It has been my opinion that the origin of the bacteria in infectious diseases in general is from outside the human body. The illustration of the endemic of typhoid fever, as given by the author of the first paper, is evidence of this fact. It is developed from some outside source, as decomposing vegetable or animal matter. The symptoms of typhoid fever are due to toxins which are developed within the cells, which, being absorbed by the body, produce effects on that body, especially the nervous system. The treatment of infectious diseases in general, and typhoid fever in particular, must necessarily be the removal of the toxins from the system. The fever should be treated by removing its causes, i. e., its toxins. This may be eliminated: 1. By the use of water internally, so eliminating it through the kidneys. 2. By the external use of water. 3. By action on the liver, which is the organ, when properly stimulated, that destroys or reduces the amount of toxins and so gets rid of them. 4. By the use of intestinal antiseptics. 5. By nourishment. The administration of nourishment from the beginning of the disease is necessary. In regard to getting up for stool, there should be no hard and fixed rule in this matter. During the first week the patient should be allowed to get up, but not during the last stages, when there is danger of perforation of the bowels. I do not believe that acetanilid has any effect in this fever. It seems to me that the giving of any drug should depend on what other agent is given with it; acetanilid, in small doses, given with caffeine or whisky, may be valuable.

DR. HERRINGTON of Ohio—It will be a long time before we settle how to treat typhoid fever. The fact that we treat typhoid by different means shows that there are a lot of things we do not know. But I hope and trust that every physician will aspire in the treatment of typhoid fever to the extent of trying to abort the fever and not to that of curing it. The question to-day is, can typhoid fever be aborted? I am among those who claim that it can be aborted. Most of you expect to have a low muttering delirium, tympanites, etc. To prevent

this, commence early in the disease, with mild catharsis, using small doses of 1/60, 1/80, or even 1/960 of a grain of calomel, and give it every few minutes, and so keep up a light-colored abnormal discharge from the bowels and try to bring the discharge to the normal. The liver is not acting properly and the discharge comes at first from the lower part of the bowel. This prevents the tympanites and aborts the disease in quite a large majority of the cases in not over fifteen days.

DR. LOUIS BRISNOR, New York City.—This discussion covers the treatment of typhoid fever thoroughly. I would like to make a prophecy that the time is not many years distant when we will have an efficient antitoxin treatment. It has been shown by experimental means that typhoid fever can be prevented by the use of the antitoxin made from the typhoid bacillus. Dr. Welch of Johns Hopkins Hospital, Baltimore, in an address before the New York Academy of Medicine, gave the details of the work of bacteriologists, showing that the time is not more than a few years distant when we shall have an antitoxin treatment for typhoid fever. At present I believe that the best treatment for this disease is the cold water treatment, externally and internally. I have measured the urine in patients who have been subjected to the cold bath, and I have seen it about double itself as soon as the treatment was placed in operation. I believe that the success in the cold bath is largely due to its elimination of the toxins.

DR. J. C. WILSON, Philadelphia.—It is clear to me that such an interchange of opinion as this must be of more value than we at the moment realize. The interchange of opinion and experience of practitioners living at distant points and in different parts of the country is most useful.

I may be permitted to speak of our experience in the German Hospital in Philadelphia, where we have always a great many cases of enteric fever, and during the recent outbreak had as many as sixty-eight cases in the wards at one time. In that institution the cases are treated systematically by cold bathing, according to the method of Brand, but under no circumstances do we use the internal antipyretics. In theory our object is to eliminate the toxins of the disease as rapidly as possible, and we avoid introducing into the blood-current toxic drugs, such as acetanilid, phenacetin, etc., the perturbing effects of which are so marked.

Brand and all those who have carefully carried out his treatment on an extended scale concur in the view that the cold bath treatment is not of itself an antipyretic method. The reduction of temperature is one of a group of effects produced by systematic cold bathing. Another effect to which too little attention is paid is the action of the cold bath on the kidneys as organs of elimination—the toxic coefficient of the urine after the bath having been demonstrated to be increased from five to six times.

Albuminuria is much more common and more marked in cases treated by systematic cold bathing, than by the expectant method, but it is a transient condition, disappearing with the recovery, and in this respect resembles the albuminuria of yellow fever.

I desire to speak of our experience with reference to the posture of the patient in bed during the attack. We have adopted the plan of having the bath-tub stationary in our small fever wards and, due consideration being had to the condition of individual patients, allowing them to walk to the tub with the assistance of the attendants. In this way the patient is aroused from his recumbent posture regularly every third hour, walks to the bath or is carried there by the attendants, and returned to his bed afterward. We have practiced this plan since Jan. 11, 1897, and the results have been entirely satisfactory. In 165 cases of enteric fever treated during the year 1897 the mortality was 6.5 per cent.

DR. JENKINS of Iowa.—More than fifteen years ago I was satisfied that house flies were the greatest carriers of the contagion, and during the late war we had much typhoid fever in the camps, brought on by house flies. The excreta should be destroyed. We could not put soldiers in a more perfect hotbed for the development of the disease than we did in the late war. They were placed in the camps, and when they were taken with typhoid fever they were removed to the hospital; from the hospital they went to the camp, and so carried infection. Good water was to be had, but nearly everybody who was susceptible to typhoid fever was infected in these camps. This is a very important thing, and the medical profession should speak out and see that no such thing should again happen.

DR. GEORGE BOODY, Independence, Iowa.—In connection with the external use of water, it should be given in regularly prescribed quantities internally. During the last epidemic I carefully watched Widal's reaction day after day, in all my cases, in a number of cases treated by neighboring physicians who wished their diagnoses confirmed, and in one case from Jack-

sonville, Fla., a specimen of blood having been sent to me by a nurse in my service who went to the camp there; and as I saw in each case the same reaction, the bacilli clumping and perishing in a short time before my eyes, I could not help thinking that in the not distant future there would be a typhoid serum or antitoxin which would give the same results in the prevention of typhoid fever as we now obtain by the use of antitoxin in diphtheria.

DR. L. F. ROUSCH, New Haven, W. Va.—I wish to speak in reference to what the gentleman from Tennessee said about the cathartic action of medicine. He made it appear that I used calomel in doses large enough to produce an irritative effect. While it is well enough to use large doses, as advised, it is not continued.

PERIOSTEAL CARIES FROM BACTERIAL ORIGIN.*

M. H. FLETCHER, D.D.S., M.D., M.S.
CINCINNATI, OHIO.

Of recent years my attention has been called to a number of cases of neuralgia, the exciting causes of which were obscure, as is frequently the case. Among others was a case of supposed tic douloureux accompanied by the apparent death of the periosteum over a larger portion of the lingual surface of the inferior maxilla of the left side. While the exciting cause in this case may have been central, it apparently was peripheral; it yielded to local treatment, which fact strengthened belief in the peripheral origin. The finding of this lesion was the result of desperate effort, every logical treatment, both systemic and local, having been resorted to, aside from nerve section, and all without relief.

CASE I.—Mrs. X., aged 55 years, suffered with paroxysmal pains resembling tic douloureux; these continued with increasing tendency for three or four years, always including the first molar, which was the only tooth remaining back of the first bicuspid, and it was finally extracted, after having been devitalized and properly treated. For a short period this gave some relief, but the paroxysms returned with increased severity.

There was nothing abnormal in the macroscopic appearance of the bone, flesh, or mucons membrane, and no tenderness nor swelling; no pus could be detected. Thinking that something abnormal might possibly be discovered with a magnifying-glass, one was used, and a tiny slit was found, not to exceed one-sixteenth of an inch in length, and situated on the summit of the alveolar ridge, at the former seat of the offending first molar. My first impression was that I should find here a portion of the root of a tooth, but none could be discovered; the probe, however, after being forced between the lips of the opening, went into a large pocket on the lingual surface of the bone without further resistance; careful probing showed this pocket to reach from the summit of the alveolar ridge to the inferior border of the jaw, and from the first bicuspid back to the angle, including the inferior dental foramen. The surface of the bone, instead of being rough and necrotic, had the feel of being emburnated and without periosteum; of course, the exact conditions of such cases can only be verified by post-mortem examination, and as yet no opportunity has offered for such investigation.

It is held by others that the periosteum in this case is probably still present, and either divided, or entirely adherent to the supervening soft tissues, and I believe that all known laws of pathology would support this theory. There are some facts, however, which go to support the hypothesis that the periosteum is dead, in this and all similar cases.

*Presented to the Section on Stomatology, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

In studying the subject, with the conditions in mind as recited in the above case, many old cases can be recalled, and many new ones have been presented which are interesting, as bearing on the pathology of the subject.

Two or three will be described as typical, and I believe will show sufficient reason for advancing the hypothesis of necrotic, or carious periosteum and periodental membrane. The writer holds that the periosteum and periodental membrane are identical in every thing excepting thickness.

pain, the paroxysms becoming more frequent and severe as time passed; the greatest intensity and most frequent seat of the pain was in the lower molars of the left side.

On examination little or no calcareous deposit was found, excepting on the backs of the lower centrals, but the pain never seemed to locate itself in this place. About the molars and bicuspsids, more especially around the molars on the left side, there was very apparent difficulty in the form of necrosed bone; the septa, especially

No. 1.—Section of cat's jaw. Tissues in situ. Blood-vessels injected. B. i. Pl., arterioles in periosteum; D, dentine; B. i. Pl., Blood-vessels in pulp; C. i. P., capillaries in pulp.

No. 3.—Section of cat's jaw. Tissues in situ. Blood-vessels injected. B, bone; P. D. M., periodental membrane; D, dentine; B. i. Pl., Blood-vessels in pulp canal, showing capillaries on the surface.

No. 2.—Section of cat's jaw. Tissues in situ. Blood-vessels injected. B. i. Pl., blood-vessels in pulp; D, dentine; P. C., pericementum; P., periosteum; B. i. P., Blood-vessels in periosteum; B, bone.

No. 4.—Section of cat's jaw. Tissues in situ. Blood-vessels injected. Flat surface of periosteum, showing arterioles, with a few capillaries. Arterioles are 1-60 of an inch in diameter, while capillaries are 1-3000.

CASE 2.—Miss Y., aged 35 years, after having suffered with neuralgic pains on both sides of the face for some months, presented herself for treatment. The pain was paroxysmal in character, distributed on both sides of the face, being excited by foods, especially sweets, sour and salts, sometimes lasting for hours, there being very few meals passed without more or less

between all the molars, were more or less dead, some more than half way to the apices from the necks of the teeth; about the latter mentioned teeth in some places a smooth broach could be pushed clear to the apices of the roots, without pain or bleeding, showing the periosteum to be absent in much of the socket, but on cutting the septa away a sensitive and bleeding condition was reached about half way from the neck to the apex. The

lingual and labial portions of the bone did not present so extended a lesion, but death of the periosteum, however, seemed to progress more rapidly, and cover a much greater extent of surface than the dead bone.

In none of these localities, where there was little or no tartar, was there much apparent inflammation in the soft tissues, and no tenderness in bone or flesh, until live tissue was reached below the necrosis. Where the calcareous deposit was greatest—on the backs of the lower centrals—there was some redness and possibly some pus with the bleeding, but no yellow or watery pus as in typical cases of pyorrhea.

Another case where a single tooth was the cause of much trouble will suffice.

CASE 3.—Mr. Z., aged 50 years, indicated constant pain, varying in intensity, sometimes in the angle of the jaw and ear, but often in the lower first molar on the left side, or its vicinity—the only molar remaining on that side below. Half the crown of this tooth had been worn away, and a protection of gold had been built on, and a large cavity in the anterior approximal surface had also been filled with gold. This gold work was going to pieces and had to be replaced; it was found that decay had proceeded under the approximal filling so that the pulp had to be capped, after this the pain increased in intensity and frequency of paroxysms. The next step was to remove the pulp, and obliterate the pulp cavity and root canals; this gave only slight improvement, so search was made for bone and periosteal trouble. It was discovered that a probe could be passed beneath the soft tissues on top of the ridge, for fully half an inch behind the first molar, the same condition of bone surface being present here that was found in Case 1; further search also showed the septum to be largely dead between the molar and bicuspid.

Numerous cases could be reported to fill in all the varieties of this trouble, between the two extremes, both in extent of lesion and pain, and this not only from my own records, but from those of some of my confrères, notably, Drs. Heise, Callahan and Le Ferré, who have become interested in this particular lesion as distinct from pyorrhea alveolaris and other lesions of bone.

The principles of treatment have been the same in all this class of cases, viz., removal of dead bone, if such could be discovered, and the sterilization of the pockets with escharotics. The remedies usually employed have been alcohol as a menstruum for tincture of iodine, the strength of the latter being used according to locality and symptoms, from almost full strength to a 5 per cent. solution, to which was added 2 or 3 per cent. of oil of cinnamon.

In all cases recovery has been slow, varying from a few weeks to a year in duration.

In going back over these cases as to the extent of lesion, we have, first, cases in which the septa between the teeth become denuded of periosteum, then follows death of the septum; the former lesion at times invading the alveolar process on the lingual or buccal surface of the bone. In this condition there is no difficulty in deciding as to dead bone and periosteum, although the soft tissues, aside from the septa of gum, still remain in shape and show little signs of inflammation.

Now as the trouble creeps down on the outside or inside of the jaw—as in Case 1 fully described—where the bone is much thicker and the collateral circulation much more extensive, the surface of the bone feels to the touch of an instrument as though it were eburnated and not dead, and if the sense of touch can be relied upon, the periosteum is absent, as far as the surface of the bone

is involved; it may be adherent to the supervening soft tissues, but the writer is of the opinion that it has been destroyed. If progressive lesion of the periosteum on the outer or inner surfaces of the alveolar process is accompanied with confinement of pus, as it often is, we then have what is recognized as gingival abscess, and if the lesion about the roots and periodental membrane is accompanied with a perceptible flow of pus, it would be termed pyorrhea alveolaris, but both these conditions are to be distinguished from the one under discussion; nevertheless, this lesion may result in a collection of pus, and if this occur, a name is given it according to its locality, such as felon (onychia), empyema of the maxillary sinus, etc. Another phase of this lesion, in the writer's opinion, is, that this periodental caries, or mycotic destruction, precedes the so-called uric-acid or serumal deposits about the roots of teeth, which deposits are secondary to a lesion, and not primary to it.

There would seem to be no impossibility in the position that the periosteum may be destroyed, and the bone remain alive, as in Case 1, since the collateral circulation could certainly supply the necessities of life for an indefinite period to a bone so large as the maxilla; then, too, the progress of the disease is so slow that the surrounding tissues have ample time to adjust themselves to the new conditions, and we all know that Nature is ever ready to adapt herself to change, when compelled to in order to preserve the life of the organism. As to the periosteum being lifted off the bone, and remaining adherent to the supervening soft tissues, this can only be decided by post-mortem examination. I believe it will be admitted that all lesions of the periosteum are attended with pain of a neuralgic character. In cases of confined pus within or upon the surface of bone, the pain is often almost beyond endurance.

In osteomyelitis, previous to the death of the parts, Senn says: "Pain may be absent at the seat of the necrosis, and referred to some other part or locality." This is true in the cases observed, for the sensation was largely referred to some other place or locality, rather than the seat of the lesion, many times the patient not being able to locate it.

Etiology.—As to etiology, Senn further remarks, under "Necrosis": "The same bacteria which produce inflammation frequently, if present in sufficient quantities also cause cell necrosis," and he quotes his authorities for such belief. The above statement and the supporting authorities, in company with the knowledge of the methods and destructive attacks of bacteria on dentine, could almost convince one that once a suitable culture of bacteria or cocci had been started in the horny-like fibers of periosteum, they could produce continuous destruction of this membrane, much as they do that of dentine, and this opinion is held for the following reason: The study of the periosteum in my own laboratory shows it to be a very compact membrane of connective-tissue fibers, and histologically much more the nature of the hard tissues than of the soft, hence the application of the word "caries"; in one of its layers it is found carrying arterioles in great numbers, but having very few, if any capillaries anywhere in its substance, and no blood-vessels at all in one layer, although the supervening soft tissues are plentifully supplied with them. (See illustrations.)

If this be true, then it seems rational to hold that this membrane during life can, and does, form a good and sufficient pabulum for the growth and development of bacteria, and this to its own destruction, the neighboring capillaries not being in a position to combat the inroads

of the enemy much better than they would in caries of dentine. In the capillaries lies the power of resistance to inroads of an enemy, as well as that of recuperation, it being known that migration of leucocytes, and diapedesis takes place almost exclusively in the capillaries, protection and repair being amongst their most important offices, hence in tissues where they are absent or few, bacteria might be expected to thrive, and the writer is of the opinion that they do, and that the lesion in question is resultant upon the conspicuous absence of capillaries in the periosteum, and they seem especially few in the periodental membrane, as the accompanying illustrations show, which fact may explain many of the phases of the disease of this membrane and the alveolar process.

The exceedingly slow recovery of these cases under germicidal and stimulating treatment would also tend to support the hypothesis of the death of the periosteum by bacteria, and if the death is caused in this way, then the process might be called "caries of periosteum." This hypothesis, however, can not even attain to the dignity of a theory until some one of ample time and opportunity takes up the subject and carries it through clinical and laboratory tests sufficient to establish it beyond question. The writer is convinced, however, that one would be highly justified in undertaking such a series of tests, and if such a theory could be established, many cases of so-called rheumatism, obscure neuralgias and headaches could be traced to a progressive lesion or death of the periosteum in the bones involved.

In what seems to be a complete recovery from amputation, or compound fracture, pain is often continuous and severe, and not easily accounted for, and in chronic disease of the accessory air-cavities and the mastoid cells, neuralgic pain is a prominent symptom, and at certain stages is of a character much as has been described in cases herein reported, and the writer believes may come from the lesion described, and should be investigated with that idea in view.

Regarding periosteal caries from bacterial origin in cases of amputation or fracture, where thoroughly aseptic methods have been employed, one might be skeptical, but the infection may be carried through the blood from many distant sources, and if there were no other source, the gums, teeth and alveolar process are in many people the most perfect of incubators and are abundantly supplied with pathogenic microbes, especially that of pus, so that from this source, if from no other, pus microbes and possibly other pathogenic germs could be taken up by the blood, and by locating at the point of least resistance, result in the lesion under discussion, it being known, that under different environment the same microbe may produce different results.

Roswell Park, under "Source of Infection," says: "The oral cavity and pharynx are never free from bacteria. Miller studied over one hundred species that he has found under various circumstances in the human mouth. Some of these are pathogenic, others are apparently absolutely innocent. Many of the forms which grow in saliva will not grow in ordinary media. Miller has also shown that all forms of dental caries are but expressions of bacterial invasion, even of those apparently most solid structures, the teeth; and of late we have been taught more fully that such invasion may extend far beyond the confines of the teeth alone, and may spread to various, even to distant, parts, and produce possible fatal mischief. Abscesses in the brain and extensive septic infections have been clearly traced to invasion along the line of the dental troubles. One of

the most virulent of all the common inhabitants of the mouth is the pneumococcus of Frankel . . . which getting into general circulation through the tonsils or other possible ports of entry about the mouth causes serious septic and inflammatory disturbances in widely distant regions. Aside from dental caries, a widely opened port of entry is often afforded by those ulcerations around the margins of the gums which are produced by accumulation of tartar. Disease in the antrum of Highmore, for instance, and many other local destructions are frequently caused in this way."

Now is it not rational to believe that in lesions of the periosteum, whether traumatic or otherwise, and regardless of what bone of the body it may be on, we could have the progressive destruction of that membrane as above described?

The writer believes we can, for we certainly have in a very large percentage of people a constant source of infection, and in every person the conditions in the minute anatomy to permit of what might be termed "periosteal caries" from bacterial origin.

NOTE.—In the discussion of this paper, the term "caries" has been largely objected to, and those of "ulceration" and "necrobiosis" have been suggested. Ulceration is not appropriate, in the writer's opinion, for it implies death of tissues in which the cells are composed of liquid protoplasm; a condition which does not obtain in the cells of the periosteum; the same is true of necrobiosis or coagulation necrosis, which processes attack the cells with protoplasm and not the connective tissue between the cells; the periosteum, being composed of connective tissue, could not come under any of these heads.

Klebs found that "karyolysis is due to the action of chemical products of bacilli," hence mycotic necrosis, or karyolysis of periosteum seems next appropriate to caries.

Miller, in treating of "dental caries," says: "Dentine may be defined as a dense glue-giving basis substance, etc. . . . The relations of Sharpie's fibers to the progress of decay in the cementum is very significant, etc. . . . They (Sharpie's fibers) thereby facilitate the invasion of bacteria, etc." Now, Sharpie's fibers when decalcified are composed of connective-tissue substance, and when *in situ* are many times continuous with the fibers of the periosteum, being like it in composition.

Now, all the connective-tissue substances of the body are glue-giving, and the substance of the periosteum is composed entirely of these fibers, hence caries, which is always mycotic, seems as appropriate for the bacterial destruction of periosteum as to the other glue-giving tissue of the body. Mycotic periosteal caries might possibly be better than the title used, but caries signifies mycosis, hence does not need qualification.

MEDICINE.

ITS PROGRESS, PROBLEMS, AND PROSPECTS.*

BY J. BRUYERE, M.S., M.D.

SURGEON TO MERCER HOSPITAL.

TRENTON, N.J.

(Continued from p. 529.)

In the future, the various internal organs may prove to be luxuries rather than necessities. Ribs, the sternum, and portions of the chest wall are now resected with impunity. Tumors of the spine, and in fact all tumors, are now far more amenable to treatment than formerly. The advance in plastic surgery has been very great. Senn's method of making intestinal anastomosis has greatly advanced abdominal surgery, and we now remove portions of the intestine that are injured or diseased. In cancer of the rectum, large portions have been resected—in some cases as much as twelve inches—with a mortality of 20 per cent., and permanent cures in one-third of the cases. Dr. Giuseppe Ruggi reports the "successful resection of ten feet and nine inches of the small intestine of a small boy," 8 years of age. In five weeks the child was perfectly well. Dr. Dressman, in thirty

* Read before the Mercer County (N. J.) Medical Society, at its Fiftieth Anniversary, May 23, 1888, and subsequently revised.

or more cases, has resected the intestine by the yard. Suprapubic cystotomy, an operation that was reintroduced in 1875, has greatly facilitated the removal of certain conditions of the bladder. Formerly there was only palliative treatment for enlarged prostate; now the patient can have his choice of prostatotomy, orchidectomy, or resection of the vas deferens. The radical cure of hernia is modern, and we have rarely a death or a recurrence of the trouble. Fifty years ago the removal of goiter was almost surely fatal. Gibson tells us that "favorable terminations are extremely rare," and that the operation "is attended with difficulties which should dismay the most expert and enterprising surgeon." We now operate on goiter, and remove laryngeal growths, with great success. In 1895 Kocher reported 1000 operations on goiter with only 1 per cent. mortality. According to Reverdin, the mortality in 6103 operations has been 2.88 per cent. For interglandular enucleation, and in uncomplicated cases, the mortality has been about zero. Subcutaneous osteotomy was introduced by Langenbuch in 1854. In 1873 Esmarch introduced the rubber bandage, making many operations bloodless—thus adding to the convenience and safety of operations. Orthopedic surgery, operations on nerves, etc., have been largely developed during the last half century. Billroth "made the first resection of the larynx and of the stomach."

America has contributed largely toward the advancement of surgery. She gave to us anesthesia, the successful ligation of the arteria-innominate, the operation for vesicovaginal fistula, ovariotomy, intestinal anastomosis, cholecystotomy, etc. Wells and Morton gave to us anesthesia. Valentine Mott first tied the innominate artery, and was the first to successfully extirpate the clavicle for tumor. Marion Sims discovered the operation for vesicovaginal fistula. McDowell performed the first rational ovariotomy, and Nicholas Senn gave to us intestinal anastomosis. Cholecystotomy was first performed by Bobbs of Indianapolis. John Collins Warren first successfully tapped the pericardium, and Henry J. Bigelow performed the first excision of the hip in this country, and in 1852 invented the operation known as litholopaxy. Nathan R. Smith invented the anterior splint. Many other operations, together with instruments, splints, mechanical devices, and methods of technic have been the result of American genius. We cannot pause to describe these various operations, but will give a brief history of ovariotomy.

The first successful ovariotomy was performed by a sow-gelder of Germany, on his daughter, in 1517, but the first rational and deliberate ovariotomy was performed by McDowell of Kentucky in 1809. This operation, however, was not established till 1858, when Wells took it up. Gibson, whose surgery was published in 1845, does not mention ovariotomy, but "Liston and Mütter's Surgery," which was published in one small volume, in 1846, speaks of the "Removal of Ovarian Tumors," in the following language: "I need not tell you that wounds of the abdomen are dangerous; patients perish from trifling operations where the viscera are at all involved, and yet you are aware that, of late years, the belly has been opened intentionally with the view of ascertaining the existence of tumors, and of taking them out. Some people do not hesitate to make a hole in the abdomen, put in their fingers, and feel what is there, strangely enough exemplifying what Iudibras says: 'As if a man should be dissected to see what part is diseased.'" Liston condemns the operation, and Mütter says that "in a few years it will be confined to the

oblivion it so richly merits." Meigs, in 1862, declares that those who operate should be indicted for murder, as the operation is a crime, and Dieffenbach, one of the boldest of surgeons, in 1843, wrote that ovariotomy was murder, and that every one who performed it should be put into the dock. Now if these cases are not operated upon it would be considered as culpable neglect. Mütter states that from 1809 to 1846 there had been seventy cases of ovariotomy reported, and he gave the particulars of thirty-one cases. "Out of these," he says, "sixteen died; in some of them there was no tumor, and in some it was not removed." In 1847 there had been less than forty ovariotomies performed in America, and the mortality was over 50 per cent. Notwithstanding this high mortality, the operation finally became a popular one, and it is said that some surgeons have performed from one to two thousand operations with a present mortality of about 3 per cent. Tait of Birmingham, and Keith of Edinburgh, in 1886, reported a mortality of only 3 per cent. Lately Dr. R. L. Morris succeeded in transplanting the ovary, in two out of five cases, and pregnancy followed. Even a small piece of an ovary is sufficient for transplantation. Sims and Emmett were the pioneers in American gynecology. The first journal devoted to obstetrics and gynecology appeared in 1868, but the speciality of gynecology was not recognized exclusively by any medical journal until 1869, when the *Journal of the Gynecologic Society of Boston* was published, by the first society of its kind in this country or Europe. The medical schools, at this time, had no department of gynecology—obstetrics covered all this ground. Dr. Atwood, in 1745, became the first obstetrician in America. At this time obstetrics was regarded as unbecoming a gentleman. Owing to the great prejudice against male accoucheurs, and the treatment of female complaints by men, the special diseases of women were comparatively unknown until a recent date. From the days of Hippocrates until quite a recent period they speak of ulcer of the cervix, pyometria and dropsy of the uterus. Emmett first showed that those so-called ulcers were simply lacerations or tears, and devised the operation of trachelorrhaphy for their cure. Pyometria we now recognize as pelvic abscess, and dropsy of the uterus as ovarian cysts. In early Roman times, Soranus and Themison described vaginal hysterectomy, and in 1507 Brengarius described the removal of the inverted uterus. The first operation for the removal of a malignant uterus was performed by Patella in 1812. In 1813 J. C. M. Langenbeck performed a vaginal hysterectomy for the removal of a cancerous uterus, which Senn tells us was "the first deliberate attempt for removal of the uterus through the vagina for cancer." This operation was a success. On April 16, 1850, Paul F. Eve, an American, performed a vaginal hysterectomy. The third deliberate operation was performed in 1882 by Sauter. Ambroise Paré revived the use of the speculum used formerly by Soranus. Récamier gave us the uterine sound and curette, and Lambelle, Boivin and others added greatly to the development of gynecology. Simpson, by his original and vigorous writings, did much to advance the study of uterine displacements and uterine pathology, and Bennett did much to extend our knowledge of inflammation of the uterus. But it remained for America to give to gynecology its greatest impulse. "If all that Sims had done for gynecology were suppressed, we should find that we had retrograded at least a quarter of a century," says T. Gaillard Thomas. Sims' "Clinical Notes on Uterine Surgery," published in 1863, completely revolutionized gynecology, and gave such dignity and importance to the

special diseases of women, that professorships of gynecology, that were formerly few and unworthy the name, now sprung up in every medical school, and assumed a high degree of importance. Sims' silver wire, perforated shot, and especially his speculum, which allowed a thorough inspection of the vagina, made the treatment of vesicovaginal fistula practicable. Owing to the great advance in gynecology it is said that abdominal hysterectomy is now no more dangerous than was ovariectomy five or six years ago.

The advance in surgery and the allied sciences has given us many delicate instruments for diagnostic and other purposes, such as the stethoscope, cystoscope, gastrodiaphanoscope, electric headlight, clinical thermometers, ophthalmoscope, laryngoscope, otoscope, spectroscope, specula, endoscope, proctoscope, aspirator, retractors, hemostatic forceps, transfusion apparatus, sphygmograph, cardiograph, kymograph, blood-counter, hemometer, hematokrit, tambours, centrifuge, and various electric apparatus. The phonendoscope, which has just been invented by Blenchi and Bazzi of France, is said to gather up all vibrations, condense them, and carry them to the ear far better than the stethoscope. The scientific progress in surgery is due more to the development in bacteriology, pathology, embryology and comparative anatomy; to the discovery of anesthesia and antiseptics and to delicate instruments of precision, than to any improvement on old methods in the technic of the operation, or to any increased skill on the part of the modern surgeon. In quickness and manual dexterity the surgeons of the past may have exceeded us. It is said that Mareschal, surgeon to Louis XIV, performed eight lithotomies in half an hour. Instruments of precision have greatly aided diagnosis and facilitated operations. For example, Kelly's urethral speculum and the knee-chest position enable us to see the mucous lining of the bladder to catheterize the ureters, and to pass the long elastic catheter into the pelvis of the kidney itself. The unique and startling discovery of X-rays, in 1895, for example, has done much to increase the diagnostic skill of the surgeon. Facts are now clearly set forth by radiographs that were formerly smothered in surmise. By means of the skiagraphs we detect foreign bodies in the soft parts and recognize the existence of fractures, dislocations, irregularities, deformities, new growths, calcareous infiltration of arteries, calculi in bladder and kidneys, malformations, etc. The skillful and proper use of the Röntgen rays will mark an epoch in the history of medicine. Great has been the advance in surgery. All splints, dressings and surgical appliances have been greatly improved. Cohnheim's experiments, in 1867, greatly increased our knowledge of inflammation, and of the treatment of fractures. Previous to a knowledge of bacteriology, antiseptics, and the true nature and cause of inflammation, compound fractures were regarded as very serious. The mortality was said to be two out of three, now it is scarcely more than two out of every hundred. Inflammation was formerly regarded as essential to the repair or the healing of wounds, and suppuration was looked upon as normal. Now we regard inflammation as independent of the healing process, and suppuration as the result of pyogenic organisms. Wounds are now kept aseptic, and suppuration is almost unknown. Nussbaum says that "antiseptic catgut is without doubt Lister's greatest discovery," as it did so much toward keeping wounds aseptic. Senn expressed the same view, and said that "the aseptic absorbable ligature is one of the greatest achievements in modern surgery."

Owing to the great advance in surgery, surgical diseases are differently classified, and differently treated. Improved classifications and methods; the great number of trained laboratory and clinical workers; and the great number of libraries, laboratories, journals and societies, all indicate future advance, as well as present attainments. This increase in surgical knowledge has added much to the comfort, happiness and length of life of suffering humanity. Many that were helpless cases, in 1848, are now operated on with success. The results of antiseptic surgery have been so wonderful that surgeons are tempted to depend more upon the brilliant and spectacular results of the knife than upon the slower and less impressive methods of nature. It has been said that "the modern surgeon, clad in antiseptics as the Lady in Comis was 'clothed round with ephastis,' defies the rabble rout of microbes, and dares things, which only a short time ago, were looked upon as beyond the wildest dreams of scientific enthusiasm." There is enough that is heroic in modern surgery to please the grim prophet of hero worship. The ambition to discover something new and brilliant often leads to hasty conclusion, and blinds one to scientific thought and patient research. Notwithstanding this, medical science, and especially the science of surgery, is in advance of all others. The surgery of the future will be remedial rather than radical—preventive rather than curative. We will then remove diseased portions of an organ rather than the entire organ. The tendency is toward conservative surgery. A greater knowledge of natural and acquired immunity, of serotherapy, etc., is tending to make surgery remedial and preventive. A conservative, efficient, and conscientious surgeon, who realizes that his first duty is to his patient, is a Christian altruist and a benefactor to the human race. With this very brief and imperfect narration of the progress in surgery, we will pass on to a very brief consideration of dermatology, and conclude with a few words on present problems and future prospects.

Fifty years ago dermatology was in a state of chaos. John Hunter divided skin affections into "those which sulphur could cure, those which mercury could cure, and those which the devil himself could not cure." Willan and Bateman, in 1808 and later, attempted to reduce this chaos to cosmos. This attempt met its greatest fulfillment by the publication of Orasmus Wilson's work, on "Diseases of the Skin," in 1851. But later Hebra's writings completely revolutionized dermatology and formulated a classification based on the pathologic anatomy of the skin. Previous to this time it is said that the doctor in his treatment of skin diseases "aimed at nothing and hit it." Professor James C. White first introduced Hebra's teachings, in 1859, and in 1861 "gave the first course of lectures on diseases of the skin, at Harvard." The first American text-book on dermatology appeared in 1845, written by N. Worcester. Nearly all dermatologic lore at this time was obtained from Paris and Vienna. The first lectures on dermatology were given in some of the medical schools of New York, in 1846. The *American Journal of Syphilography and Dermatology* was founded in 1870, and The American Dermatological Association in 1877. Up to this time America had contributed but little to dermatology; now Duhring, White, Bulkley and others, are recognized as high authorities. The development of microscopy and bacteriology led to a more accurate diagnosis, a better classification, and to an increased knowledge of the nature and cause of skin diseases. The etiology of most of the skin diseases is now accurately known. It is known that many diseases are due to parasites and microbes.

Lupus, leprosy, carbuncle, glanders, syphilis, furuncle, impetigo contagiosa, and most probably syphilis, eczema, psoriasis, alopecia areata, acne, and certain forms of erythema, seborrhea, etc., are of microbic origin. This knowledge has led to the use of the parasitocides and germicides, which, together with the use of serums and organic extracts, promises much for the future of dermatology. It may be long before a complete classification of diseases of the skin is possible, still great advance in this line is being made. We now leave nature more to herself, and we soothe and strengthen rather than irritate and deplete. Pathologic investigation has determined the nature of the various skin excrescences or growths, and the various other branches of medicine are adding greatly to our knowledge of the treatment of skin diseases, so that a continuous advance in dermatology is assured.

In conclusion, we will briefly consider some of the present problems and the future prospects of medicine. As great as has been the progress in medicine during the last fifty years there are still many problems that remain unsolved. Seneca said that "there is always something left to do, and that even after a thousand centuries no one will lack the opportunity to discover more." Those who come after us will find plenty of occasion to wonder at the ignorance of their forefathers, for medicine is still an unfinished science, and an imperfect art. Medical knowledge is at present a segment and not a perfect circle, hence medicine is still full of mysteries, and some medical truths are as yet imperfectly grasped. The attitude of every true, conscientious, scientific student of medicine, is that of a humble seeker after truth, for there are none so wise that truth becomes to them a perfect circle. Unprejudiced and intelligent observation of the phenomena of nature characterizes the medical profession of to-day. This has accomplished much in the past, and has brought us to the dawn of still greater discoveries. There is no science to-day that has made greater strides than that of medicine. The progress of the past is a guarantee that the problems of the future will receive earnest attention, and final solution. But as yet we do not know the cause of many phenomena that daily confront us. There still remain many problems in diagnosis and therapy. The bedside study of cases is still essential, for no specialist in his laboratory, no microscopist, can always give us an accurate diagnosis. There must be still clinical study and observation superadded to all instruments and appliances for diagnosis. Improved methods can never take the place of thought and rational observation. We must rely upon self, as well as upon machines. In so doing we will often find that clinical observation is more reliable than mechanical aids alone. For example, almost every pathogenic germ has been found in the secretions of healthy individuals. The bacillus of diphtheria has been found on the fauces of hundreds of healthy children. The microscope often fails to reveal the tubercle bacillus, when consumption is known to be present. Dr. Hencage Gibbs, one of the foremost bacteriologists, recently denied the "importance of bacteria as a causative factor of disease." He declares that he "has conducted hundreds of autopsies on consumptives without finding a trace of the bacillus of tuberculosis." The microscope, and nearly all tests and appliances are, from a diagnostic standpoint, far from accurate. Ehrlich's diazo reaction in the urine and Vidal's reaction in the blood of typhoid cases are important and quite constant; but not distinctive or pathognomonic, as these reactions are found in a number of other infectious diseases, and are sometimes want-

ing when typhoid is present. These reactions, therefore are of general, not of special significance. The degree of the reaction usually indicates the severity of the disease. The limitations of the microscope, and the fallibility of many instruments and tests, greatly add to the problems in diagnosis, and also in therapeutics, for the application of remedies must be based on skillful diagnosis, rather than upon the nomenclature of disease. We need a more correct diagnosis and a better nomenclature of disease, before we can trace, by cause and effect, the result of remedies and formulate a cure. Symptoms should be classified in a scientific manner so as to aid us in making our inductions. We could then more easily determine the beneficial symptoms from these that are detrimental. In order to do this we must understand the exact nature of disease and must ascertain the various causes that produce disease. This is most difficult, for we now know that disease is not an entity due to a simple or specific cause, but is usually the resultant effect of many causes. We have, therefore, no distinct diseases, hence "no absolute specific character belongs to any disease." The great problem in diagnosis, therefore, is how to ascertain all the casual factors that constitute any given disease, so that we can remove these causes, and prevent their evil effects. The increase in our knowledge of the causes of disease is an index of the real progress that we are making in the science of medicine. We now doctor causes rather than symptoms, for prophylaxis is the very essence of cure.

(To be continued.)

CRIMINAL MORPHOMANIA AND CHRONIC MORPHINISM. DISCUSSION.*

DR. C. H. HUGHES, St. Louis, Mo.—In regard to Dr. Crothers' clinical presentations, I should hardly characterize those as cases of double personality in the sense in which we are accustomed to regard mental phenomena. They are alterations of personality, varying conditions of personality, alternative personal states exhibited in all forms of opium addiction when the morphia is withdrawn. There is always a contrast between the patient with morphia in him and with morphia out; that is, the opium habitué, the patient who has become a true victim of the opium psychosis.

The medicolegal aspect of the subject is interesting. I remember being called on to testify in regard to a patient who had been connected with an asylum in Fulton, Mo., many years ago; the Cowgill will case, in which I had occasion to introduce the altered mental state of the patient. This man made a will which the courts did not sustain. I made a statement then that opium changed the personality of the individual, and that it had a tendency to undermine the moral sense of the individual; that opium patients were not to be trusted when the opium was out of them; that they would resort to any means to get morphia or obtain money in order to satisfy their appetite. Almost any opium habitué who is out of opium and has a brass watch will try to pass it as a gold one to get money to buy morphia. An opium habitué, when the morphia is entirely out of him, suffers as we know in such a way psychically and physically that it must resort to any means, as a dying man catches at a straw or a starving man steals to satisfy his hunger.

There certainly must take place a degenerative change in the psychic neurons after the long influence of opium toxicity. We ought to arrive at some consensus of opinion in this matter in order to testify correctly in courts. But I should not call these Jekyll and Hyde cases that we so often see in opium habitués true cases of double personality. In the latter cases, as seen in asylums, the individual is one day absolutely one thing, and the next quite another, having completely changed

*This discussion accompanied the papers of Drs. T. D. Crothers and A. J. Pressey (see JOURNAL, August 12, pp. 388 and 391), and should have been printed at that time.

his identity, and retaining no vestige of his former self, such conditions as we find in the automatons of the epileptic and epileptoid states.

As to the treatment, it is a good safe rule to endeavor to size up your patient and gauge your dose according to his capacity for reduction. When you have once reduced the dose, endeavor to make no backward steps; if the symptoms of too rapid withdrawal appear, the sore muscles, and the psychic symptoms, and the diarrhea, the best plan is to stop right there and make no further progress until you have built your patient up to that point. The wisest plan is to gauge your doses so as to endeavor not to bring on these symptoms.

DR. BLOCK—We had a young physician, with a good practice, whose faculties seemed to become more keen after the use of morphin, and who was the greatest thief in the town; he would steal bicycles and take them to pieces, and typewriters and change their parts. When he would be accused of the fact, in the most artful and unassuming and innocent way he would explain the matter and convince everyone that he was the wrong person. It was only after the greatest effort that the courts could be convinced of his innocence: that his acts were due to morphia, which caused the hallucination, and that they were not due to his rascality.

DR. DANIEL R. BROWER, Chicago—I thank Dr. Crothers very much for his very interesting presentation of this important subject. The cases are a little different from any that I have ever had under observation, and I can readily conceive why such cases may not be quite frequent. I think that we all recognize the fact that morphia, very much more than alcohol, deranges, disturbs or alters the personality. There is no question about the fact that these morphia people are deceivers ever.

As to the treatment of these cases, while I indorse Dr. Pressey's method in great measure, I want to take exception to one point that he seemed to emphasize, and that is the undesirability of treating these cases in general hospitals. I have been treating them in general hospitals for twenty-five years. All that I desire is a good nurse, and I do not find that they need so much personal attention if this requirement is fulfilled. I have for years been satisfied of the great advantage of the gradual and systematic withdrawal, and at the hospital we have this very simple proceeding: A certain solution is prepared, each teaspoonful of which represents at the beginning what is the ordinary dose of the patient—i. e., the least dose that will suffice to keep his nervous system in fair condition—and then for every teaspoonful of the morphin solution that is taken out the nurse is instructed to put a teaspoonful of water in, and in this way a very gradual withdrawal takes place.

I almost invariably practice putting these patients to bed and giving them daily massage and faradic electricity, and I think the great perturbations that occur in the nervous system when they get down to a certain point are vastly diminished by the prolonged continuous rest and by the use of the massage and the electricity, recognizing, with Dr. Pressey, the great advantage of strychnia and the other remedies which are tonics to the nervous system and circulation.

DR. E. S. PETTYJOHN, Alma, Mich.—I have found that all morphin habitués are very much alike; doctors of divinity are just as prone to tell what is not true as anyone else. I would suggest that at the close of the treatment, when the amount taken is small, we often make a mistake by thinking that we can drop it when it is down to 1/16 or 1/20 gr., but that is the hardest time for the patient during the whole treatment. We would have better success if we continued the small amount for a somewhat longer time.

As to Dr. Brower's plan, I would hardly know when to stop using out of his bottle. It would be a little difficult to tell, unless we have all the time there is—and we do not usually have that much—when to stop. I am in the habit of using hydrotherapeutics, electricity and massage, and am sure that we help the patient a great deal by aiding the elimination. We ought to get down to 1/32 gr. and hold the patient there for some time before finally withdrawing the drug.

DR. HAMLIN of Tennessee—I am a general practitioner, meeting with cases in country communities. We treat these various cases in our country villages and we know our conditions individually. In the cities you know your patient at your office, or hospital, or sanitarium, but you do not know his private life

or family history; you get what they give you for their family history, but you can not say you know the family history of your patients. I wish to emphasize the point made by Dr. Pettyjohn, as I believe that we ought to keep beyond the 1/32 or 1/64 gr., and keep up the hypodermic dose of water. In one case in my experience the reduction was gradual and the patient's health was not affected, but after reducing the dose down to 1/64 gr. I told the nurse to omit the morphia and continue the hypodermic injection, impressing the patient with the fact that the same injection was being given. After the morphia had been omitted for two weeks, the patient was told what had been done, and the same train of symptoms at once resulted that we would have had from a sudden withdrawal of the morphia.

DR. L. B. TUCKERMAN, Cleveland, Ohio—I am also only a general practitioner, and I feel that you neurologists ought not to be quite so hopeless as to what the general practitioner can do, because it is the exception, and not the rule, that those that we have to treat are able to go either to a private asylum or the hospital. Although theoretically, from the specialists' standpoint, all cases are hopeless if treated by the general practitioner, practically I venture to say that two-thirds of the cases that occur must be treated under those *a priori* hopeless conditions. The interest of the general practitioner would be greatly increased if that hopeless feature were not emphasized so much. I remember an opium fiend in a private family, where they followed the plan outlined by the last speaker. They bought the usual amount of opium, and made an extract of thoroughwort, and mixed the opium with that, gradually reducing the proportion of opium in the mixture until they got the patient entirely weaned from the opium and taking the pure extract of boneseet without knowing the difference.

DR. C. H. HUGHES, St. Louis, Mo.—I did not attempt at all to discuss the treatment of the morphin habit. Since the introduction of eocodia I have always preferred its use. The dyonin treatment is, I think, going to be the best substitute treatment. Quinia is one of the best substitutes for the morphia addiction that you can use during its withdrawal.

DR. A. E. STERNE, Indianapolis, Ind.—While I heartily subscribe to the old plan of gradual reduction of morphin. I do not adhere to any set rule or principle, and do not follow a routine treatment. I have had a great many of these cases to treat. I have not heard a word in this discussion as to the why or wherefore of the gradual reduction. You have not explained the cause or origin of these abstinence symptoms in any form. It seems to me that until they are explained we can not form a thoroughly rational theory of these cases.

DR. Pressey spoke of the rapid treatment, and spoke of those subjected to it as being persons of extreme courage. I must disagree with Dr. Pressey. If the case when it comes to me, seems strong enough physically—and if I fear a heart collapse I substitute some other stimulant in the place of morphin—certain cases of morphinism never get one particle of a grain of morphin after they come under treatment. I have yet to see the case where abstinence symptoms arose to any marked extent, even among members of our profession who knew what the so-called abstinence symptoms were. The abstinence symptoms arise, not because we take away the morphia, but because the system is acidulated, and by the use of bicarbonate of soda and vichy water we do not fear these symptoms. I believe that by the chemical method, with lavage of the stomach, with the neutralization of the acid, and by the use of faradic electricity, we get quicker and more permanent results than we do by the slower method, and with a much less waste of time.

DR. T. D. CROTHERS, Hartford, Conn.—My object in presenting these cases, and the new facts which they point out, is to show that the phenomenon of criminality has, in many cases, a distinct physical origin, also that in drug taking, particularly from morphia, criminal impulses and acts occur that are unknown. They are literally forms of insanity not known or understood at present. In the treatment of morphinism, the withdrawal of the drug is of much less importance than the building up and strengthening of the system against the possibility of relapse in the future. The exact methods of withdrawal will vary with the physician, but the results will be the same in all cases. The real treatment will be the degree of vigor that can be cultivated in the patient. These cases are

exhausted and poisoned, and require the most complex variable treatment suitable to the wants of each.

DR. A. J. PRESSEY, Cleveland, Ohio.—I can hardly understand how it would prove that the patient was insane because he became so when you take away the morphin, because any patient would do that. The patient is always so affected by the withdrawal of the drug. In regard to the reduction of the morphin by adding water to the extent of the morphin taken out of the solution, I can not understand how you could tell when the patient was off the morphin, unless a new solution was made.

Dr. Crothers' statement to the effect that he considers the manner in which the morphin is withdrawn the least important of any part of the treatment, I feel sure will not meet with a hearty response by those who have been treated, both by the method I have described and either of the older forms of treatment. Patients have a right to that form of treatment which produces the least possible discomfort consistent with their best interests while being treated for this or any other ailment. We know that patients do suffer terribly while undergoing the sudden withdrawal, the rapid reduction, or the usual slow reduction methods. With the method that I have described, properly carried out, more than 90 per cent. can be cured and feel fully as comfortable while having the morphin withdrawn as while using it *ad lib.* In my opinion the manner of withdrawal is very important.

Therapeutics.

Rhinopharyngitis in Young Children.

A simple procedure for local treatment is recommended by Gaston, viz., the introduction into the nostrils, three or four times a day, of a cotton tampon rolled to a point, covered with borated vaselin, with or without the addition of an astringent, such as the following:

R. Antipyrin	gr. viii xvi
Acidi borici	gr. vi
Vaselin	3v
M. Ft. ungt. Sig. External use.		

If the child greatly objects to the tampons one or two drops of the following mixture should be instilled into each nostril night and morning:

R. Menthol	gr. viii
Olei amygdalæ dulcis	3i
M. Sig. External use.		

If the direct treatment of the pharynx seems indicated it may be swallowed with iodin in glycerin, equal parts. —Doizy.

Vesical Irritation and Prostatic Hemorrhage.

R. Tinct. veratri viridis	3i
Morphine sulphatis	gr. ii
Ext. ergotæ fluidi	3iv
Syrupi zingiberis	3i
Aque, q. s. ad	3iii
M. Sig. Teaspoonful in water every two or three hours.		

For the Relief of Pain and Vesical Spasms.

R. Ext. opii	gr. vi
Ext. hyoscyami	gr. iii
Olei theobromatis, q. s.		

Misce et fiat suppositoria No. vi. Sig. Introduce one into rectum and repeat in two hours if required.

Infantile Colic.

R. Sodii bicarbonatis	gr. ii
Olei ricini	3i
Tinct. opii camphoratae	gtt. ii

M. Sig. One dose, for acute indigestion, in infant six to eighteen months old.

R. Aque menthæ viridis		
Aque camphoræ		
Aque, ʒi.		3iv
M. Sig. Teaspoonful as required for pain and flatulence.		

Acid Urine and Frequent Urination.

R. Lithii citratis	3ii
Tinct. opii camphoratae	3i
Infusi lupulini, q. s. ad	3xvi
M. Sig. Tablespoonful in water after meals.		

For Alkaline Urine.

Chlorin Water in Typhoid Fever.

The chlorin-water treatment of typhoid comes from India. The usual dose is a dram every three hours. Wilcox' conclusions, based upon an extended use of the remedy, are:

1. Chlorin can be safely used till complete disinfection of the alimentary canal is obtained.
2. It improves the appetite and digestion, lessens the fever, and cleans the tongue. The only odor to the stools is that of chlorin.
3. It causes increase of strength and lessens the nervous symptoms.
4. It shortens the duration of the disease, and under its influence the patient usually makes a rapid and complete recovery.

—Medical News.

Ptyalism (Idiopathic or Mercurial).

R. Tinct. myrrhæ	3i
Potassii chloratis	3vi
Aque camphoræ, q. s. ad	3xvi
M. Sig. Shake. Use as mouth wash every two or three hours.		
R. Formaldehydi (40 per cent. sol)	3i

M. Sig. Rub into scalp night and morning, in syphilitic subjects, also in loss of hair after prolonged illness.

—*Med. News Form.*

Abdominal Palpitations.

Nitroglycerin should be given in these cases. It may be taken during the attack, but it is better to give it once or twice a day, or, if needful, more often. A small dose will generally be found sufficient to affect the disorder. One one-hundredth of a grain every night is often sufficient. But if, as the palpitations subside, the other symptoms remain, it will be necessary to attend to them. However, it is surprising how the equalization of the circulation affects the other miscellaneous symptoms in many instances.—*W. Wade in Brit. Medical Jour.*

The following old prescriptions are perhaps more valuable than many newer and more elegant combinations:

Anti-Bilious Mixture.

R. Podophyllin (resinoid).....	gr. cxxviii
Cream of tartar, pure.....	ʒxvi
Buchu leaf.....	ʒxvi
Leptandrin (resinoid).....	ʒi
Gentian, ground.....	ʒii
Alcohol.....	Oiii
Water, boiling.....	Ov

Dissolve the cream of tartar in three pints of the water, to which have been added four ounces of powdered borax. Boil for five minutes, allowing the mixture to cool, and then filter. Dissolve the resinoids in a pint of the alcohol, and add to the cream of tartar solution; also add the remaining alcohol, water, and the gentian and buchu, macerate for fourteen days. Express and filter. Dose, a teaspoonful.

Diuretic Mixture.

R. Buchu, long.....	ʒvi
Uva ursi.....	ʒiv
Juniper berries, bruised.....	ʒiii
Acetate of potassium.....	ʒiiss
Alcohol.....	ʒviii
Water.....	ʒviii

Macerate for fourteen days, and filter through paper. Dose, one to two teaspoonfuls three times a day.

Cough Syrup.

The Control by Arsenic of the Ill Effects of Thyroid Extract.

In the *Medical News* of July 8, reference is made to an article in the *Rev. de Therap.*, by Mabile, who hopes that he has found in arsenic a means of preventing the ill effects of thyroid extract, which are produced in some patients by this drug. The increased use of the thyroid gland, not only for myxedema, but for obesity, goiter, certain skin diseases, and in general for malnutrition, makes it important that there should be some means of controlling the vertigo, palpitation, dyspnea, anxiety, etc., from which patients who are particularly sensitive suffer. The writer observed that these symptoms disappeared in one of his patients when she was taking Fowler's solution and reappeared when she stopped the arsenic. From 2 to 12 drops of Fowler's solution at a dose was found to be sufficient to prevent any unpleasant symptoms even when taking 12 grains a day. Two other patients took arsenic with thyroid extract, with happy results, and the arsenic did not weaken, apparently, the force of the thyroid extract.

Apomorphin in Strychnin Poisoning.

Dr. H. B. Stanley of Elgin, Ore., says, in the *Medical Summary*: "The best way to administer it is by hypodermic injection. If administered hypodermically, $\frac{1}{4}$ grain should be injected into the cellular tissue of a strong, healthy man; if given by the mouth at least $\frac{1}{2}$ grain should be given and followed by copious draughts of water.

"Even if cramping and convulsions have begun they will cease as soon as the remedy begins to act on the system.

"This remedy, if given hypodermically, will prove a sure antidote if given so as to act any time before the respiratory nervous center becomes paralyzed."

To Prevent Abortion.

AMERICAN.

1. **Ureteral Anastomosis.**—Noble first describes and discusses the various operations of ureteral anastomosis, and concludes that each case must decide the operation best suited for its repair. If a primary operation, the point where the ureter is cut will probably decide it. High injuries preclude implantation and tend to make the anastomosis easy, low down or near the bladder they make it difficult and favor implantation. Between these there is a region not well defined, that will allow of some latitude of selection; when a long section has been removed the problem is a difficult one. In such cases the disposition of the proximal ureter is a serious question. Intestinal implantation has its dangers and discomforts. Skin implantation means all the distress of the repulsive fistula. Connection with the opposite ureter is probably only practicable when undertaken with coexisting dilatation as a tube larger than the ampulla is liable to obstruct the flow of urine from above. This might be overcome by giving the ureter to be transplanted an upward curve and anastomosing it to the wider portion of its fellow at the pelvis of the kidneys, or into the latter cavity even, if a lumbar incision is required. Implantation into the bladder will be required when the ureter is cut low down, and in secondary operations for injuries of the inferior extremity, for the cut off portion becomes occluded and shrunken so that anastomosis is impracticable.

2. **Inversion of Uterus.**—After noticing the history of this accident, Browne reports six cases, in the last of which he describes a new operation as follows: Bowels and bladder having been evacuated, the patient was then etherized and the inverted fundus drawn outside the vulva with a strong vulsellula forceps; the openings of both Fallopian tubes were brought plainly to view and an incision one and one-half inches in length was made through the posterior portion of the uterus, avoiding the tubes and the larger vessels. Through this incision Sims' large dilator was passed up into the cervix and expanded to the largest extent. The rigid tissues of the cervix were felt to relax; then on withdrawing this dilator, Nos. 2 and 3 Hank's hard-rubber dilators were passed through the cervix; the finger was also passed to feel that there were no adhesions. The incision in the uterus was then sewed up with carbolic silk-worm gut, and with slight manipulation the fundus was easily replaced through the now passable constriction. Recovery followed. Conclusions: 1. This operation is not proposed to supersede ordinary taxis in the reduction of chronic inversion of the uterus. 2. It is not more dangerous, but much more certain, than prolonged or rapid taxis. 3. We avoid the danger of bruising the tissues and rupturing the vagina. 4. As an operation for inversion it is less dangerous than laparotomy. 5. Unless there be adhesions, which rarely exist, we can always feel certain of reducing the inversion at one operation.

3. **Rectal Irrigation.**—The following are the conclusions in Hyde's paper. Rectal irrigation has been found to have a distinct value in: 1. Leucorrhæas. 2. As a substitute for vaginal douching in young girls. 3. Acute and chronic ovarian and tubal lesions, with the possible exception of pyosalpinx. 4. Intestinal paralysis following sepsis. 5. After major pelvic operations to relieve any abdominal discomfort or tympanites. 6. Intestinal colic. 7. Doubtful in constipation. There is a distinct trend toward individualizing one's own particular line of treatment, and essaying to maintain an independent position. Established ideas are rarely rejected in preference to innovations, unless the latter are qualified to merit careful attention. Of these, rectal irrigation commends itself to gynecologists for thoughtful and unprejudiced consideration, as having seldom failed to meet the test on fair trial.

7. **Spondylolisthesis.**—Williams describes, in detail, the history of a colored woman who died in child-birth after symphysiotomy for pelvic deformity, in whom was found a rare case of spondylolisthesis or displacing of the fifth lumbar vertebra forward and downward over the sacral articulation. He reviews the literature of the subject and discusses the etiology. The deformity was evidently of recent origin, as she had passed through labor without difficulty four years previously. He is inclined to believe that it was due to deficient ossification and downward pressure. The patient had been in the habit of carrying heavy loads. As regards the frequency of the condition, he thinks it is more common than has been supposed. This is, however, the first one known that has come to autopsy in this country. It has probably passed unnoticed in many cases, as Dr. A. D. Bevan, Chicago, has stated to him that he has seen it several times in the dissecting-room. The article concludes with a bibliography of some fifty-seven titles.

8. **Fibroid Tumors.**—Noble reviews the history of operations for fibroids, reporting and listing the early operations. He gives to Kimball the credit of having first deliberately performed hysterectomy for fibroid, with successful results. He notices Koerber's paper as giving an excellent résumé, but criticizes him for trying to make it appear that he had priority in this operation.

9. **Perineal Tears.**—In this article Kelly follows up former publication on direct union of the torn sphincter in complete perineal laceration, and describes his method in detail with illustrations. He reports twelve cases.

10. **Transplantation of Ovaries.**—McCone reports results of experiments on thirty animals, previously noted in the *JOURNAL*, May 13, p. 1634. He made his experiments in three series, the first having for its purpose the demonstration of the accepted facts that pregnancy may occur where there is no contact between the ovaries and Fallopian tubes. These may be passed. In the second series he reports successful results in transplanting the ovaries from one part to another part of an animal, or to a different animal of the same species. In these he succeeded in obtaining normal reproduction in rabbits from which he had removed the ovaries and grafted in those of another animal. In the third series, however, he shows that the ovaries of a dog can be successfully transplanted into a rabbit and continue to functionate. His conclusions are: 1. Contact between ovaries and tube is not essential for conception. 2. Ovaries grafted from one part of an animal to another part of the same animal continue to grow, to functionate, and pregnancy can and does occur. 3. An ovary grafted from one animal to another of the same species continues to functionate, and maintains the normal condition of tubes and uterus. Pregnancy can occur. 4. Ovaries grafted from one species to another continue to functionate, and seem to prevent post-estrastion atrophy of tubes and uterus. 5. Best results are obtained where the raw surface of the transplanted ovary is sewed to a denuded surface. He suggests that in certain cases the grafting of animal ovaries in human subjects may be beneficially employed to prevent atrophy and post-estrastion nervous symptoms, etc. He is now intending to continue his experiments and to test the rabbits with dog's ovaries with semen from both species.

11. **Hyperostosis Cranii.**—Ellis reports a case of this disease in a man 60 years of age, causing exophthalmus and blindness, and describes the condition generally. The diffuse

form to which this case belongs is rare or seldom recognized, and its causes are very obscure. Treatment is ineffective.

18. **Retinal Disturbances from Arteriosclerosis.**—Zimmerman reports a case of thrombosis from arteriosclerosis of a branch of the central retinal artery. He excludes embolus in this case, from the fact of its being non-observed, and particularly to there being no heart trouble and no complete blindness in the beginning, each of which points to endarteritis proliferans as a cause.

20. **Amaurosis from Dynamite Gases.**—Brose reports two cases of complete temporary blindness caused by descending into a well after the explosion of dynamite. In one patient the vision has been permanently impaired. In the other, who was less exposed, the trouble was only temporary. In both cases there was unconsciousness from the gas. He attributes the loss of vision to an acute retrolubar neuritis caused by toxic agents taken up by the blood, affecting also the higher centers of consciousness.

35. **Fever and Its Treatment.**—Hare combats the idea that fever is necessarily a harmful process. His propositions are: 1. That fever when excessive or prolonged is harmful. 2. That moderate fever, not too prolonged, may be of distinct advantage to the patient. 3. That moderate fever, not too prolonged, if it is not advantageous may be, on the other hand, not deleterious but may be regarded by the physician, without any anxiety, as a characteristic concomitant symptom, which we would naturally expect to find in a patient suffering from the disease which is present in the patient's system. Fever is a condition developed in all healthy animals as soon as they undertake to resist infection, and he does not, therefore, consider it a useless coincidence. He would therefore not employ antipyretic drugs to combat fever, since, as a rule, they interfere with the protective action of elimination of poison, the development of antitoxins, and the stimulating and supporting fever. The cold bath, on the other hand, while relieving the fever if it is excessive, in no way modifies these protective efforts.

36. **Immunity.**—After first undertaking to show that there is not any absolute immunity, but that it is affected by various conditions, temperature, diet, symbiosis of bacteria and modifications of their virulence, McFarland combats the idea that the blood of the normal animal is and must be the secret of successful therapeutics of the infectious disease. Antitoxin is something added to the blood and not normally present in it. He does not attempt to show what it is, and thinks that no one else can show it either.

44. **Fractures of the Cranium.**—Jonas reports four cases of cranial fractures, showing points of special interest. In the first there was a large loss of brain substance and a large amount of foreign matter, dirt, etc., imbedded in the cerebral structure, which was almost impossible to wash out. Nevertheless, the patient made a good recovery in four weeks. In the second case there was a condition of apparent unconsciousness for over two weeks, with subsequent and complete amnesia of the period. In the third, in spite of there being an extensive tear of the longitudinal sinus, it was successfully sutured, with an uneventful recovery. The fourth case was notable on account of the specially marked localizing symptoms. Jonas thinks the most important indications in the management of these cases are: 1, thorough disinfection; 2, adjustment of bone fragments; 3, control of hemorrhage. He gives details as to how he met them.

47. **Complication Following Surgical Operations.**—Davis calls attention to the importance, in operations, of attending to the eliminative action of the kidneys, of the most painstaking care to preserve asepsis, and searching for any serious infections from without and within. Shock may be avoided or modified by care in giving anesthetics, and as to the temperature of the room. Pneumonia, in his experience, has followed the use of chloroform as often as that of ether. Excessive vomiting after operation is distressing and somewhat dangerous; probably lavage of the stomach is most effectual as a means of stopping it. Other complications mentioned are ileus, iodiform

intoxication, also the leaving of sponges or forceps in the abdomen, and secondary hemorrhage.

53. **Malarial Toxæmia.**—The author of this article, Dr. McBride, has spent a great portion of his life in practice along the river bottoms of the Arkansas, Grand and Verdigris rivers in the Indian Territory, an intensely malarial district, where he has had splendid opportunities to observe disorders of this kind. In the present paper he calls attention particularly to the bad effects of quinin in certain forms of pernicious malaria. Quinin given in the usual doses in such cases will produce intense and even fatal intoxication. Sometimes it produces a simple hematuria, sometimes a hematuric fever with jaundice more or less severe, with all the symptoms of a fatal intoxication of the blood. Quinin, he says, will produce hematuria under two conditions: 1, chronic malarial intoxication, and 2, a particular individual idiosyncrasy. The latter is the special predisposing cause, the malaria, the condition that determines in the organism, this intolerance to quinin. Given in such a case, it does not have its well-known salutary effect, but causes instead a new febrile attack differing from the malarial paroxysm in coming on at a different hour and presenting different symptoms. The attack appears from one to six hours after taking quinin. While the patient is tranquil and without fever, he is seized with a convulsive tremor with lowering of temperature and mental trepidation. After one or two hours of this state the temperature rises rapidly, sometimes reaching 105. There is vomiting of bile, or bilious diarrhea, an uncontrollable desire to urinate, and the patient passes a large amount of bloody urine, repeated at frequent intervals. The paroxysm usually ends in twenty-four to forty-eight hours, and all the symptoms disappear except the jaundice, which may persist for several days. If no fresh intoxication takes place the patient regains his health after a long convalescence, but if the paroxysm is repeated by continuance of the quinin, and the dose is increased, he rapidly passes into a state of collapse and death ensues from cardiac paralysis. The treatment given is first to clear up the urine, which McBride does by ten-drop doses of turpentin every four hours; to evacuate the bowels; to repair the damage done to the blood and blood-vessels by tonics and preparations of iron, and to give an antimalarial remedy, which he finds best in crescin.

58. **Medical Treatment of Nervous Diseases.**—Metzler's paper is largely a protest against therapeutic nihilism in the treatment of nervous disorders. He endeavors to point out the general indications for the different classes of cases, especially the degenerative types, and those due to toxins in the blood; those also of the vasomotor origin, in which the doing nothing plan certainly has no rational excuse with the remedies at our command. He notices the extreme views held by some, reflex action having been so overworked as a cause of nervous troubles that some have come to question such an etiologic factor altogether. "The passing of the reflex" is evidently not a catch word with him.

59. **Rational Treatment of Diarrhea.**—The first indication in the rational treatment of diarrhea is to expel the offending matter, but this, as Eccles says, does not constitute the treatment or work a cure. Lesions have been established and functions perverted, and the germs that work the mischief may still be lurking in the intestinal canal. The antiseptics have their part and, while we can not sterilize the intestines, we can make them as unwholesome for the bacteria as possible. Calomel is probably as effective as many of the newer drugs, but it has serious limitations. Salol, naphthalin, guaiacol, etc., in combination with a suitable astringent, are probably more satisfactory. As to the selection of the astringent, the author thinks tannic acid would be one of the most valuable, provided it could exert its action through the whole length of the intestinal tract, and he finds that tannalbin or tannated albumin meets the indications, either alone or in combination with ichthallin and leaves little to be desired as regards results. Tannalbin is so harmless that its maximum dose has not been decided. From 10 to 30 grains every two hours are given, and even oftener if necessary. He adds a number of prescriptions containing these drugs, which he recommends.

60. **Chloral Hydrate.**—After noticing the dangers of chloral hydrate, the author asks, "What is it good for?" and replies that it is beneficial in vomiting from whatever cause, unless

it be from obstruction of the bowels, though even there it affords relief. For hicough, even in the aged, and in typhoid fever patients, it is almost a specific. In infantile convulsions, injected into the rectum, it gives quiet sleep. It is a boon to the woman during pregnancy and in puerperal convulsions. In conclusion he reports a case in which he thought great benefit was derived from 10-grain doses at bed time, in a case of atheroma of the arteries, and he believes also of the cardiac valves.

61. **Ichthyol.**—Powell recommends the internal use of ichthyol in gastric fermentation, as better than all other remedies, and he has also been surprised to see its good effects in cases of locomotor ataxia, especially in the gastric disturbances of this disorder. In psoriasis the beneficial effect of the internal use of ichthyol is at once apparent. The disease is greatly modified by the remedy, but he has not yet seen a cure. He has found that it gives relief to some extent in aneurysm of the aorta, and has seen most gratifying results from its use in conjunction with compound valerianate pills in hysterical conditions.

62.—66. **Summer Diarrhea in Infants.**—This is a symposium on the proper treatment of summer diarrhea in infants. Dr. A. Jacobi, after noticing the matter of dress, which should be light and easy, the nature of food, etc., as prophylactics, remarks that more infants get sick from overfeeding than from underfeeding. The eliminating organs are overtaxed and fermentation and putrefaction of the retained matter takes the place of digestion, so that gastric and intestinal disorders result. Summer diarrhea is not a pathologic entity, but covers all forms of excessive diarrheal discharge, from acute catarrh to follicular enteritis and streptococcal or biliary gastro-enteritis. The main symptoms are excessive discharge of mucous, serous, and fetid matter with desiccation of the tissues and general anemia, leading to insufficient nutrition and thromboses and absorption of toxins. When any of the above disorders are complicated with gastric disturbances, vomiting results and the stomach should be emptied. Gastric irrigation in the young is easy and should be done with salt water, 7 to 1000, in a funnel or fountain syringe which, as it is raised or lowered, introduces and siphons out the stomach contents. The temperature should be according to the body temperature, low when it is high and higher when it is low. The intestines should be emptied speedily by purgatives and enemas, the latter under the same general rules as stomach irrigation. The purgative may be castor-oil or calomel in small doses every hour. Food should be withheld in the beginning and no milk permitted, as under these conditions it feeds bacteria. The first diet should be simple strained barley, toast or ice water, and if the discharge ceases to be thin and malodorous, white of eggs thoroughly beaten and mixed with barley or ice-water may be given. In most cases the stomach and bowel contents are hyperacid and need neutralization. For this purpose he prefers carbonate or phosphate of calcium, as not being purgative, .5 to 1 grain every one to three hours. Bismuth subnitrate or subgallate should be given every two hours. In case general collapse or thorough exhaustion exists, stimulation with hot rectal injections of water with 1 to 5 per cent. whisky are required. Pain may be relieved by warm fomentations over the abdomen. Opium, after the bowels are thoroughly emptied, has its value, and he would give to a baby of 6 months as much as 4 to 10 drops of paregoric every two, three or four hours. Intestinal disinfectants may be used, such as calomel, bismuth, creosote, etc. After the urgent symptoms of the disease have passed, if there is exhaustion and want of appetite, he gives strychnin in doses of 1/60 grain daily, and orexin tannate 1 to 3 or four grains several times a day, some time before meals. Fresh country air and plenty of it is almost essential.

Dr. Griffith's views in the main coincide with Dr. Jacobi's. He finds that after the toxic substances have been removed, and only the catarrhal condition of the intestines remains, and diarrhea still continues, nothing is better than bismuth, 4 to 5 grains every two or three hours, even in very young infants. He believes opium often essential after the early stages, but he knows of nothing requiring more judgment than the decision whether or not to give opium. Many cases of severe summer diarrhea appear to be due to heat exhaustion, and he thinks that the coolest of clothing, cool baths, sending children to the parks or on the water the best mode of treatment in many cases.

In enterocolitis, bismuth in full doses is probably one of the best remedies. Starch water enemas given slowly, and sometimes astringent enemas, are of use. Change of air and diet are of great importance. Cholera infantum is not so common in his experience, and the profuse exhausting discharge from the bowels must be met at once with opium. Pseudomeningitis depending on diarrheal disease is frequently seen, and there is sometimes a curious condition with apparently a paralytic condition of the vasomotor and probably pneumogastric systems without simulation of meningitis. In such a case the child breathes constantly with great rapidity, shows flushings in parts of the body, has rapid, feeble pulse, and may die at once without any apparent cause. This is undoubtedly a toxic state, and while not neglecting the condition of the bowels, the chief efforts must be directed to the nervous system. Strychnin in full doses, nitroglycerin, digitalis and atropin will aid most.

Dr. Holt's article dwells especially on gastric and intestinal irrigation, and describes the method, also noticing the drug treatment. The preventive treatment is the most important and this should embrace: 1. A proper application of the well-established rules regarding infant feeding; for it is chiefly infants who have previously suffered from digestive and nutritive disturbances arising from a violation of these rules who furnish us with our severe and most of our fatal cases. 2. Careful inspection of milk in cities, and the exclusion of that the temperature of which when received is 60 F. or above; and closer supervision of those who sell milk than is now employed. 3. The adoption of means by which the poor in cities may be furnished during the summer with milk sterilized under competent supervision, either free or at a nominal cost. 4. The general employment of Pasteurized or sterilized milk as an infant food during summer; Pasteurized, among the better classes, where the procedure can be more intelligently done and ice is abundant; but sterilized, among the poor and in tenements, or wherever no ice is to be had. 5. The avoidance of all solid food during the summer in children who are under 18 months old. 6. The prompt and radical treatment of all the milder forms of indigestion and diarrhea during the hot season.

He says: "In our management of infants suffering from intestinal disorders, the great importance of the adoption of energetic measures at the outset can not be too strongly emphasized. Doing the proper thing in the first twelve hours of an attack is vastly more valuable than correct treatment during the whole of the succeeding week."

Dr. Fischer's paper reviews at length the etiologic factors, which are outlined as follows: 1. Food, improper quantity and quality of the same, be it breast, or hand-feeding. It is a well-known fact, cited by Jacobi among others, that breast milk can also cause this disease. 2. The most frequent cause is certainly improper bottle-feeding, wherein food unsuited to the infant's digestive abilities is continued, in spite of Nature's effort to warn us, as frequently manifested by either vomiting or diarrhea, or both. 3. Milk from mothers suffering with tuberculosis or syphilis. Pregnant women, menstruating and all anemic women, secrete such poor milk that gastroenteric derangements are exceedingly common. 4. The influence of the weather on digestion, especially the extreme heat of summer. 5. Improper disinfection of the nipples after feeding, and consequent decomposition and formation of micro-organisms, causing infection; all unsanitary conditions deleterious to the healthy child.

He notices the importance of stomach washing and advises the use of calomel or castor-oil to clear the bowels, and follows it with bismuth and intestinal antiseptics and astringents. In some forms of collapse he would give hypodermics of 10 to 20 drops of whisky. Rectal and colon flushing are mentioned and methods described. As regards feeding, milk should be discontinued in all forms, for at least a week, unless the child is breast-fed, and in the latter case for at least one-half or one day. He gives directions for making rice, barley, farina, sago and cornstarch water with a tablespoonful of either to a pint of water boiled for a short time and strained, and enough boiled water added to keep the amount up to a pint, and he also gives directions for making a flour ball. Cool bathing and cold applications to the head are also valuable in reducing temperature and toning up the nervous system. He is opposed to antipyretic drugs and prefers hydropathic measures.

Dr. Graham's article follows along the same general lines as the others, adding only a few more details.

67. **A Study of Rabies.**—After noting and describing the causes and symptoms of rabies and its treatment, Greswell gives an account of a recent outbreak in Colorado, which came under his own observation. He believes that man is one of the animals least susceptible to the virus of rabies, and that cauterization of the wound within twenty-four hours of its reception by fuming nitric acid is a preventive of such infection.

68. **Tracheitis and Laryngitis.**—Love reports a case of a child 3 years old, who died practically from suffocation without any exudate or persisting edema in the larynx or trachea, which parts were only reddened. The infection, as determined by bacteriologic examination, was by the staphylococcus pyogenes aureus. There must have been present some edema existing ante-mortem that was not found visible after death. Symptoms were simply those of spasmodic croup.

70. **Rheumatism.**—The theory of rheumatism here advanced is that there is some disturbance in the condition of the white blood-corpuscles, and that any medicine which has power to decrease these corpuscles relieves the disease.

74. **Urine in Diagnosis and Prognosis.**—Hill's paper goes over the subject of the urinary symptoms in various diseases: specific infection, circulatory disorders, respiratory diseases, gastro-intestinal, hepatic, and pancreatic lesions, osseous, articular and constitutional disorders, nervous diseases, skin infections, purgative disorders and poisoning.

75. See title 109.

76. See abstract in JOURNAL, August 12, p. 414.

81. **Clinical Notes.**—Royster considers labial chancre, compound fracture of the lower end of the femur, with rupture of the quadriceps extensor femoris, and an unrecognized rupture of the uterus.

91. **Hernia.**—Hollis' paper gives full description of the method of radical operation for hernia devised and followed by Dr. A. H. Ferguson. The description of the operation in detail was printed in the JOURNAL of July 1, pp. 6-14.

92. See JOURNAL, § 81, p. 536.

93. See abstract in JOURNAL, June 3, p. 1254.

95. **Full Bath in Scarlatina.**—This paper points out what the author considers a superlative treatment in scarlatina where there was high temperature in the early part of the disease, severe nervous symptoms, or where one or both are present. The method is simple and consists in putting the child in water at 90 F., sufficient to cover the body and extremities. A large wash boiler or tub will generally suffice, and has generally been used in his cases. The child should be constantly rubbed while in the water, so as to change the blood in the skin as rapidly as possible. The time necessary to remain in the bath is about eight minutes. Dry quickly and put to bed, not taking time to put on a night gown or other clothing. Repeat the bath whenever the temperature gets to 103 or above, or, if the attendant is not able to take temperature, whenever the child becomes restless. Hanson reports two cases. He sums up its effects as follows: "1. It reduces temperature, which is probably the most important part of its action. 2. It favors elimination, yet its effects are so quickly apparent that this feature can be beneficial only in a minor degree. 3. It stimulates the circulation and strengthens the heart's action, thereby relieving the capillary stasis in skin more particularly, but probably in internal organs as well; this change can be most beautifully seen by observing the relief to the congested conjunctiva noticeable in those cases where skin is dark and capillary circulation sluggish, often stupor or unconsciousness present. 4. It inhibits the action of the toxins in some manner upon the circulatory, respiratory, and reflex nerve-centers. By repeating the bath as indicated until nature comes to the rescue, nerve exhaustion can be minimized and convalescence hastened. While patient is in bath, by constant friction to the skin we constantly change the blood in the skin, also the water in contact with the skin, and thereby bring almost in contact a large part of the blood in the body and the water in which patient is submerged. I believe that this contact of blood containing the germs inhibits their activity; thereby limiting the amount of toxins they produce, and minimizing the deleterious influence upon the economy. Possibly some of the toxic elements may be dissolved out of the skin and washed away."

96.—**Reflex Nervous Disorder in Children.**—Kinsman calls attention to the lack of inhibition in children as producing disorders special to their age; more particularly the reflex disorders, in which spinal and splanchnic nerves form the arc.

97. See abstract in JOURNAL, June 24, § 63, p. 1425.

99. **Chronic Suppurative Otitis Media.**—Somers' paper, here credited with being an abstract, is instead the paper he presented at the recent meeting of the ASSOCIATION, in the Section on Laryngology and Otolaryngology.

100.—See JOURNAL, August 26, § 154, p. 539.

101. **Succedaneum to Digitalis.**—Dalton, in this article, presented before the Section on Materia Medica, Pharmacy and Therapeutics, at the recent meeting of the ASSOCIATION, calls attention to the value of strophanthus as a substitute for digitalis. In many cases they are identical in their physiologic action as cardiac tonics, but strophanthus materially diminishes arterial ischemia and causes a faster flow of blood in the veins. It does not give greater work to the heart by contraction of arteries, and is entirely devoid of emulative action. Digitalis has an unfavorable effect on nutrition of the heart muscle by excessive arterial tension, which is not the case with the other agent.

103. **Passiflora Incarnata.**—Fisher points out that the belief that the root is poisonous is a mistaken one, and that the whole plant is generally employed. The dose is from 10 drops to 2 drams, repeated as required. He refers to the researches in the physiologic action of passiflora, especially that of Dr. Isaac Ott of Philadelphia.

104. **Diphtheria Antitoxin.**—Morgan reports his experience in the treatment of diphtheria by antitoxin. He has used it 125 times and finds it a valuable remedy, seeing beneficial results follow its use in the third and fourth day of the disease.

105. **The Anthemion.**—The author of this article sees a sort of resemblance between certain conventional arrangements in the brain and an ornament used in Greek temples, the anthemion. He asks whether the ancient Egyptians, Greeks and Assyrians who used this as a sepulchral device could have known of the analogous appearance in the brain of man and cattle, and answers, no. The connection, therefore, is a fanciful one, and we notice the paper here to explain its title.

107. **Gunshot Wounds of the Chest.**—Greenleaf reports seventeen cases of gunshot wounds of the thorax, in the Spanish-American War, and calls attention to the fact that while the modern projectile in this instance is in a measure comparatively humane, we have a sufficient percentage of unfavorable results to modify the claim. He gives suggestions as to the necessary methods of treating these cases, avoiding sepsis and infection of the lungs.

109. See title 75.

111. **Pneumonia and Antipneumonic Serum.**—Faroni reports six cases of pneumonia treated with Pano's serum, generally given morning and evening while the fever exceeds 104 F., all other medication being suspended. He thinks it a safe and reliable remedy in the treatment of pneumonia. The dose given is from a minimum of 10 or 20 c.c. to a maximum of 120 c.c. He concludes: 1. Pano's antipneumonic serum is the rational remedy in pneumonia. 2. Injections with this serum are not painful. 3. Serum over five months old is no longer active and produces no results. 4. It will not do harm, even if given in doses of 100 to 150 c.c. in twenty-four hours. 5. In all these cases it has shown wonderful efficacy. 6. In any lobar pneumonia, especially if the prognosis is grave, it is the duty of the physician to use this serum, and if he fails to do so there is no excuse for such an act, except ignorance of the work that has been done in the field of the serunotherapy of pneumonia.

113. **Excision of Superior Cervical Ganglion for Glaucoma.**—Ball reports a case which he thinks is the first in this country, of excision of the superior cervical ganglion in glaucoma. The result was immediate relief of pain for which alone he thinks the operation was justified.

115. **Heart Disease.**—Janevay notices the various phenomena of heart disease, among them the spontaneous disappearance or outgrowing by the patient of mitral insufficiency. He also notices the disappearance of the murmur of this condition in Graves' disease, the two conditions apparently being sometimes antagonistic. In his experience in private practice recovery is the rule in Graves' disease. Mitral stenosis is a disorder

more often overlooked, and he has observed it in a number of cases occurring after violent exercise in high altitudes. He thinks that in about one-third of the cases one can make a probable diagnosis by listening at the back of the chest below the angle of the scapula, where a murmur is heard, though not so marked as in front. He also calls attention to the substitution of the mitral systolic murmur for the presystolic as the heart compensation is markedly disturbed. Ulcerative or infectious endocarditis is another condition of which he speaks at some length, and he points out the difficulties of diagnosis. The most difficult of the acute cases to recognize are those where there is no heart murmur and where the lesion is on the right side and the secondary effects are more particularly in the lungs. In the former cases, by paying attention to the petechiae, especially if combined with irregular nervous phenomena, we may be able to make a correct diagnosis. In the latter the difficulty is in determining which is primary, the lung or the heart trouble.

116. Gymnastic Treatment of Lateral Spinal Curvature.—Truslow gives the results of experience with this method in the New York Hospital for Ruptured and Crippled, during the last year and a half. He concludes as follows: Varying conditions among curvatures do not prevent efficient work in groups of fifteen to twenty-five, but a gradation according to age and ability to work is necessary when many patients are treated. The class method ensures the treatment of many more patients than would be possible by individual supervision of exercise. The Swedish educational gymnastics is used because well adapted for three objects: 1, to isolate activity in groups of muscles; 2, the immediate and effective correction of faulty positions; and 3, the development of intelligent and purposeful co-operation of the patient. Nearly all of those who faithfully pursue the treatment show marked improvement.

118. Correction of Spinal Deformity in Pott's Paraplegia.—Goldthwait reports 9 cases, 3 in children and 6 in adults, of Pott's disease treated by correction of the spinal deformity by plaster-of-paris jackets, etc. In every case the correction of the spinal deformity has been followed by a very rapid relief from the paralysis, though in some of the cases inability to hold the spine in the correct position, or to manage the after-treatment, prevented this relief from being permanent. In others the results have been very good.

119. A Hospital Clearing-House.—Blake, suggests a central bureau where examination of applicants for hospital treatment can be made with better care; and it will prevent the class of hospital "rounders" from imposing on the charities.

120. Volunteer Aid Work in Foreign Territory.—The work of the Massachusetts Volunteer Aid Commission, during the Spanish War, is remarked on by Brackett, with some general comments on the subject. He thinks that, viewed from the experience of last summer, in order that this work should be carried on successfully, it is necessary that: 1. It should be directed toward supplying such needs as have resulted from the confusion and hurry in the initiating of a large campaign. 2. It must be carried on with deference to the judgment of the regular officers in the command, and should be particularly directed to supply the needs which have been found lacking, and which they better than any others are in a position to appreciate. 3. The work must be accomplished without call on the regular service for aid, either in transportation or distribution; that is, it must be a stream of supply from an independent source, and one whose presence is felt only by the relief it brings.

122. Case Treated With Yellow Fever Serum.—Doty briefly reports the case of Mr. Lackey, who was received at the New York Quarantine suffering from a well-marked case of yellow fever, and which was successfully treated by serum prepared under the direction of the Health Department of New York. While most cases brought to northern climates in this condition succumb, this patient rapidly improved under the treatment and made a good recovery.

123. Bright's Disease.—The article by Mills is very lengthy and almost monographic, covering the whole subject of Bright's disease.

124. Mucocoele of Maxillary Sinus.—Scheppegrell points out that the conditions that have been described as hydrops and mucocoele of the antrum were in a great majority of cases

due to cysts, and this is true also in many cases of empyema; that cysts may be present in the antrum for an indefinite period and their diagnosis is not always simple. They have sometimes been mistaken for malignant tumor. Their prognosis is better than in case of chronic empyema. He reports a case in which all the characteristic features ascribed to the old cases of mucocoele were present.

125. Circumcision.—Miller calls attention to the bad results of the performance of ritual circumcision by an unqualified layman, and protests against its being thus performed. The lack of aseptic precaution and the danger of inoculation of disease are pointed out.

126. Hernia of Vermiform Appendix.—Hill reports two cases of hernia including the vermiform appendix, and discusses the statistics of the condition by various authors, especially in Italy. He concludes that the vermiform appendix is found in about 1.5 per cent. of hernia, and that in not quite 3 per cent. of these cases the appendix is found on the left side. It is most frequent in children. He has been unable to find the report of a case in which the appendix was the sole occupant of the left femoral sac or an umbilical or ventral hernia.

128. See abstract in JOURNAL, May 20, p. 1117.

130. *Ibid.*, June 10, p. 1316.

131. *Ibid.*, April 29, p. 937.

132. Climatology of Nudity.—After discussing the physics of light, and its probable effect on the human subject, Duffield calls attention to the fact that the present state of the human skin is one of degeneration from overcovering, and thus one of the most important organs of the body has its functions more or less perverted and reduced, yet seldom is there any call for developing the skin. In fact, the tendency is toward substitutions which supplant its functions.

133. X-Rays in Stomach Diagnosis.—Metcalf calls attention to the value of the X-ray in determining points essential in the diagnosis of diseases of the stomach. He uses for this purpose what he calls his bismuth emulsion, which is non-toxic, non-irritating, and can be made antiseptic. The best work is done with the fluoroscope, and he considers the mica-plate static current the best, most practical, and safest means for exciting the Crooke's tube, inasmuch as the power of penetration is greater, the light is steadier, and there is no danger of X-ray burns.

134. Some Uses of Pilocarpin.—Harnsberger notices the value of pilocarpin in several conditions not mentioned in this connection in the latest text-books, among them orchitis; cholelithiasis, where it brings on relaxation of the system and relieves tension in the affected parts; in tonic spasms of the diaphragm and certain cases of hicough when firm pressure on the base of the tongue fails to give relief; and he would suggest its use in that rare and remarkable disease, arthrogryposis, which consists of persistent and refractory tonic spasms and contractures of one or more of the extremities. He also thinks it might be advantageously employed in connection with other remedies in certain cases of stricture and obstruction of the intestines, and in tetanus.

135. Nasopharyngeal Disease.—Lenox Browne calls attention to a fact not generally accepted, but which he thinks is reliable, that the wider the distance between the soft palate and pharynx, the more surely may one expect to have postnasal trouble. He holds that in a very large proportion of cases called atrophic rhinitis, it is a misnomer to apply the term atrophy to a structure that has never been satisfactorily developed. Atrophic rhinitis, he believes, is associated with an undue patency of the nasal orifice, nasal vestibule, nasal fosse, and of the nasopharyngeal vault.

Lancet, August 12.

Arrest of Pulmonary Tuberculosis.—J. KINGSTON FOWLER.—This author refers to a former work of his on the arrest of pulmonary tuberculosis, in which he reports obsolete tubercle as found in about 9 per cent. of 1943 autopsies. Others have found much larger percentages, but he does not attempt to explain the discrepancy. The process of arrest is important. Three varieties may be recognized: Pigmented tubercle that has undergone fibrosis containing small caseous or caseous-calcareous nodules. This is the most common form of the arrested

tuberculosis, and fortunately the one least likely to subsequently cause reinfection. 2. A caseous mass of considerable size, surrounded by a fibrous capsule. This is a condition fraught with great possibilities of danger, and he reports a case in which a lesion had existed for forty years, when the capsules being destroyed the contents were discharged into the bronchus and the patient died of acute tuberculosis in twenty-eight days. The third form of arrest may take place after the formation of a cavity. This is not so favorable as the first described, but is still compatible with long life. He thinks, however, that in these cases the patients generally die sooner or later of some pulmonary trouble. He rather protests against the general favor with which the open-air treatment is being received, not that he does not appreciate its value, but he thinks that people do not realize the long period of treatment it requires. The effect of climate is to a certain extent becoming underestimated. He recognizes the advantages of sanatoria as giving better chances of control in treatment, and he calls attention particularly to the gain in weight, which may be exaggerated as to its importance if the patient is ingesting a large amount of food. He also insists on the importance of taking temperature and noticing the difference between rectal and oral temperatures. The question of exercise will be largely determined by the presence or absence of pyrexia, hence the importance of temperature being taken.

The Prevention of Syphilis. FRANCIS H. WELCH.—Dr. Welch reviews the subject of syphilis, especially in the army. He thinks that the right future course to adopt in its prevention lies not "in any one isolated line of action, but in bringing to bear on the disease and its diffusing agency all the powers which our present civilization places at our disposal; and these are: *a*, normal and religious advance—to strengthen the higher elements of our nature; *b*, proper housing of the poorer classes—to render possible growth of modesty and chastity, and rational healthy amusements of mind and body away from our crowded thoroughfares—to curtail the present fostering influences of precocity and animalism; *c*, social action—to facilitate marriage for those not having the gift of continence, to remove the possible resort to selling the body for prostitution as a means of livelihood, and to curtail the twin contributing vices—intemperance; *d*, municipal action—to prevent solicitation in the streets and public gathering places and so remove the present temptation to the youths of both sexes, to eliminate agencies and localities for the pursuit of vice, and to make in all ways prostitution difficult; and *e*, hygienic rules—to necessitate from the votaries of prostitution proof (in the shape of a periodic certificate satisfactory to a magistrate) of physical purity as a guarantee that in their illegitimate practice they are not disseminators of disease as well as vice, to make sufficient and proper hospital accommodation for those not in a position to obtain adequate private treatment, and to furnish the means for compulsory segregation when necessary."

Note on Twelve Cases of Epileptic Insanity Treated by Means of Bromid of Strontium. J. G. SMITH.—This author concludes his article by saying: "It would seem, therefore, that whilst bromid of strontium is in some cases apparently of greater value than bromid of potassium in controlling epileptic seizures, yet on account of the more rapid action of the latter and its more lasting effect, the smaller dose required and lastly, its cheapness, bromid of potassium must be regarded as the more generally useful drug in the treatment of epilepsy."

Glasgow Medical Journal, August.

Three Years' Inductions of Premature Labor for Contracted Pelvis in the Glasgow Maternity Hospital. MALCOLM BLACK.—This article gives the tabulated results of the experience of the Glasgow Maternity Hospital in the matter of inductions of premature labor for contracted pelvis during the three years of hospital service of the author, and describes the conditions in which this method is employed, viz., when the true conjugate is under three inches or between three and four, and still dangerous for the mother. The method of inducing the labor is Krause's, viz., to insert an elastic bougie in the uterus between the membranes and the uterine wall under antiseptic precautions. When labor is not produced, Barnes' bags or, ultimately, De Ribes' bags may be required. The total number of cases is fifty; there were two deaths of

the mothers; all the rest were dismissed well, 5 labors were completed by craniotomy; 15 children were still-born; 10 were born alive, but died shortly; and 20 were saved. The tables are analyzed and many of the cases briefly detailed.

Journal of Laryngology, Rhinology and Otolaryngology (London), August.

Remarks on Treatment of Deflection of the Nasal Septum. DUNDAS GRANT.—The author notices the recent discussion on "Treatment of Nasal Stenosis Due to Deflective Septa," in the New York Academy of Medicine, and describes the various methods there mentioned (see JOURNAL, June 17, '94-99, p. 1381), suggesting that more attention should be paid to the result of these operations than has hitherto been given by the rhinologists. As regards the formation of perforations, he thinks they are not a matter of indifference, they may cause little inconvenience if large and situated well forward, while if small they may produce a whistling sound during respiration, and discomfort is apt to be caused by the accumulation in the perforation of mucus or mucopus.

Semaine Medicale (Paris), August 9.

Calculus of Ureter or of Appendix. TUFFIER.—A sound was inserted in the ureter during a nephrotomy, with a silver wire inside, and radiographs taken showing the course of the ureter, and attention called to the fact that it passes through McBurney's point, although at a different level from the appendix. A calculus in the ureter and a calculus in the appendix may thus cause deceptively similar symptoms, and it is in the line of the diagnosis of appendicitis that we are still deficient. An important means of differentiation from urinary lithiasis is afforded by study of the urine. A case in which a calculus in the ureter was diagnosed and found as expected is described in detail, the only certain means of differentiation being the presence of red corpuscles, a few leucocytes and epithelial cells in the apparently normal urine on microscopic examination. This microscopic hematuria, he reiterates, is evidence of urinary trouble; it is usually most apparent after certain movements or efforts, and persists. The urine in appendicitis, on the other hand, is usually decreased in amount; the salts and coloring matters may increase to simulate hematuria, but there is no true hematuria.

Berliner Klinische Wochenschrift, July 31.

Differential Diagnosis of Appendicitis. R. MÜHSAM.—"It is extremely important to examine closely into the anamnesis of cases suggesting appendicitis, and enquire especially in regard to pains in the stomach region." Mühsam describes several cases in which differentiation was difficult or impossible: perforation of a tumor in the duodenum in an adult; a case of intestinal invagination in a boy of 5, and one of perforation of typhus ulcerations. In four cases operated on, peritonitis consecutive to perforation of a gastric ulcer with abscess formation in the ileocecal region, was discovered in two cases. In another, pain from carcinomatous stenosis of the sigmoid flexure was felt in the ileocecal region. Abscesses in a fourth case were caused by the migrations of a pin in the tissues.

Renal Insufficiency Tested by the Freezing Point of the Blood. P. RICHTER.—Koranyi's statements that the amount of urea and uric acid retained in the blood can be determined by establishing its freezing point, have been confirmed by Richter's experimental research. The freezing point of normal blood is 0.56 to 0.58 degrees below that of distilled water. If both kidneys are removed the freezing point drops to 0.646. Small doses of cantharidin lower it to 0.62; larger to 0.70. The products retained, which induce this change, can not be the salts and must be the products of the destruction of the albumin. The question whether a diseased kidney can be removed is therefore capable of elucidation by determining the freezing point of the blood, which Senator calls an epoch-making discovery.

Centralblatt f. Chirurgie (Leipzig), August 5 and 12.

Influence of Incising the Parenchyma on Inflammatory Processes in the Kidneys. ISRAEL.—This intervention has proved particularly beneficial in cases of suppression of urine and a group of renal colics and hemorrhages which are usually classed as nephralgia. One case is described at length: ascending pyelitis with surgical kidney and anuria in a patient whose right kidney had been removed nearly a year before for tuberculosis. The anuria was the result of the tension of the organ enclosed in its solid capsule and obliged to assume the functions of the missing kidney. This pressure had increased, owing to

some slight inflammation, until the capillaries had become compressed. Every factor that can contribute to an increase of pressure in the kidney, torsion of the vessel stems, renal tumors, etc., induces inflammation and congestive swelling of the organ, which is usually manifested by nervous phenomena. Slitting the parenchyma removes this pressure and eases the nervous troubles. Cases that have been operated on for supposed calculi, tuberculosis, etc., in which nothing of the kind was found, were cured by the intervention. Israel also states that he has been investigating preparations from these cases anew, and in every case finds evidence of some degree of inflammation. It is important to further bear in mind that with the kidney, even very slight processes may produce colics. The best results have been attained in his experience by not suturing the kidney at once, but allowing it to granulate.

New Invagination Method of Lengthwise Intestinal Anastomosis. D. MORISANI.—This method avoids the use of any button and is distinguished by the fact that the sutures and anastomosed portions do not come in direct contact with the contents of the intestine. The proximal end is inserted in the distal end, after a strip of the mucous membrane of the latter, 4 to 6 mm. in width, has been removed from around the inside close to the end. The proximal end is invaginated to a depth of several centimeters, and is held with a few stitches taken through the edge of the distal stump and the corresponding portion of the invaginated stump, but not allowing the needle to enter the mucous membrane of the latter. The suture is then carried entirely around the intestine, the stitches slanting a little, and fastening the serosa of the proximal to the raw surface of the distal end, with the mucosa of the former intact. Sections of the intestine of dogs thus operated on show that the cohesion between the stumps is perfect and watertight in twenty-four hours, and that the inner stump shrinks in a few months nearly to the level of the suture. Clinical experience has confirmed the harmlessness and value of the method.

Centralblatt f. Innere Medicin (Leipzig), No. 30.

New Kind of Elementary Granules in Human Blood, Sputa and Tissues.—L. GRÜNVALD.—In this preliminary communication the statement is made that a large number of cells which have been supposed to contain merely homogeneous protoplasm, are in fact filled with granules which the author calls hypsophilous granules. They are stained with eosin, but decolorized again by acids or alkalis, and appear fuchsian red in Ehrlich's triacid stain, contrary to the usual eosinophilous granules, which stain orange. The granules are encountered in the round cells of the sputa, seropurulent effusions in the pleura or pericardium, pus and inflammatory neoplasms, also in the blood in the mononuclear or polynuclear leucocytes.

Dermatologisches Centralblatt (Berlin), August.

Hysterical Cutaneous Affections. C. RASCH.—Thirty cases of gangrenous ulceration of the skin in hysterical subjects have been reported. Almost all were young women and the affection almost invariably appeared on the front of the body, most frequently on the left arm, and lasted months and years. Rasch describes another typical observation of multiple bullous and gangrenous ulcerations on a housemaid, 18 years of age, with unmistakable evidences of hysteria and family history of mental disturbances. He insists on the term: hysterical cutaneous affections, as even if it does not proceed exclusively from vasomotor disturbances, and there may have been primarily self-inflicted injuries, yet the impulse to these acts proceeds from the mental affection, the hysteria, in which the brain is always abnormal. There is usually a history of sluggish healing of wounds from childhood up. The only treatment is purely psychic and is best carried out with complete isolation in a hospital service. The choice of local applications is immaterial, although powerful agents should be avoided on account of the low vitality of the tissues. It is best to refrain from paying much attention to the lesions, and merely seek to win the confidence of the patients to enhance the effect of suggestion. The prognosis depends on the prognosis of the hysteria. While the lesions are merely transient in some cases, in others they are so persistent and imposing, and accompanied by such pronounced mental symptoms, such as suicide in Doulteupont's case, that hospital treatment is absolutely necessary.

Deutsche Medicinische Wochenschrift (Berlin), August 19.

Wound of the Left Ventricle Cured by Suturing.—**PAGENSTECHER.**—The rarity of perforating wounds of the heart ventricles, requiring intervention, should induce the publication of observations to familiarize the general surgeon with the simple technic. Ten such observations have been published, including the subject of this communication. All the patients seemed doomed to speedy death, but six were cured, an encouraging result compared with Fischer's extensive statistics, which show that only 10 per cent. spontaneously recover, and Brentano's more limited number with 20 per cent. The indications were excessive hemorrhage in 5, with 2 recoveries; tamponing the heart and pericarditis in 4, with 3 recoveries, and suppurative pericarditis in 1, with recovery. The heart was sutured in 6 cases—in 4 the left and in 2 the right ventricle—with three recoveries. In the 7 cases of stab-wound, 2 were so slight that no suture was required, and in another the coronaria had also been injured, and death ensued, as must probably always occur when a main branch of the coronaria has been opened. In the observation reported, the young man—17 years old—was brought to the hospital immediately after the stabbing, in extreme collapse; death seemed imminent; no hemorrhage from the external wound, but indications of hemothorax; radial pulse imperceptible. The area of dullness had extended over the entire left half of the chest by the sixteenth hour, and intervention was decided on. The pulse was then 120, small and irregular. Ether was used and an incision along the fifth rib, with resection of 6 cm. After slightly enlarging the wound in the pleura and pericardium, the wound in the side wall of the left ventricle became visible, about 3 cm. above the apex, 3.5 cm. long and slanting from the rear downward and forward, the edges sharp and scarcely gaping, but a small bright-red stream trickling continuously from it. The wound in the pericardium was at a higher level. There was scarcely any blood in the pericardium. Three deep stitches and one superficial were taken with a Hagedorn needle and celluloid thread in the ventricle, not including the endocardium. The bleeding did not interfere with the suture, but the stitch in the upper rear portion of the wound was only possible during the forward movement of the heart. As soon as this stitch was successfully taken, there was no further difficulty, and the flow of blood ceased as soon as the threads were tied, the ends left hanging out for drainage. The action of the heart did not seem to be at all affected by the manipulations. The opening in the pleura was then enlarged, when an enormous mass of dark blood and clots and finally clear red blood poured out, and the entire thoracic cavity was stuffed with alternate sterile and iodoform gauze, which finally arrested the hemorrhage as the lung retracted. The wound in the pericardium was closed with catgut. All hemorrhage had been definitely arrested; sepsis was maintained, although a pneumothorax with a moderate, non-purulent effusion continued for some time. Temperature was never above 38.5 C. In six weeks the patient was employed about the house and garden. A small fistula persisted until the fourteenth week, when normal conditions in the thorax were completely restored, and the health has since been robust, now ten months since the trauma. Death is seldom immediate after a stab-wound in the heart, unless the co-ordinating center in the septum atriorum is involved, which at once stops the heart. Hemorrhage from a wound in the heart is less dangerous than from a wound in a large vein, other conditions equal. Less blood escapes and it only issues during systole if the wound is not large. The heart musculature may also contract and spontaneously close the hole, or a thrombus may form, favored by an oblique direction of the passage, and ragged edges, which explains the natural healing of wounds from small-calibered revolvers. The first loss of blood and the unconsciousness from the shock reduce the blood pressure and thus contribute to these spontaneous recoveries. Pagenstecher concludes by a description of a method of opening up the heart, like Rydygier's method outlined in the JOURNAL, xxxi, p. 1534; see also vols xxxii, p. 48; xxxi, p. 1580 and 1436; xxix, p. 756 and xxviii, p. 1036.

Muenchener Medicinische Wochenschrift, August 8.

Serum Treatment With Serum from Human Convalescents. WEISBECKER.—The results of this method of serotherapy have proved so satisfactory that Weisbecker of Geden, Oberhesse, now communicates the details of his technic (see

JOURNAL, XXXI, p. 1068). Measles scarlet fever, typhus, pneumonia and diphtheria have been aborted or remarkably attenuated by serum derived from persons convalescing from the same disease. A single injection of 10 to 15 c.c. for an adult, or 5 to 8 c.c. for a child, is usually sufficient, repeating the injection if a relapse occurs. It is used the same as Behring's serum, restricting it to severe cases, and is most effective the earlier it is applied, the third day the limit in pneumonia, for instance. It is powerless against septic complications and after-affections, except in so far as its early use prevents their appearance. The serum is taken from blood obtained from a vein at the elbow, caught in a small glass jar with a metal screw cover, with a capacity of 150 to 250 c.c., three-quarters filled. It is set aside in a cool place for twenty-four to forty-eight hours, when the serum is usually separated and can be aspirated with a syringe and transferred to smaller vials, containing the amount for one injection. He has kept serum thus derived for years, without its altering, but as a few bottles have spoiled he adds a few drops of a 0.5 per cent. carbolic acid solution to each dose. The serum sometimes requires several days to separate completely; this can be hastened by squeezing the clot below, in which case the serum will be cloudy. The entire blood can be utilized by leaving it for several months to become completely macerated by the serum, shaking it from time to time, but it spoils readily and is less reliable than the clear serum. The chief point to be borne in mind is that no serum can be utilized except that from otherwise sound, normal persons, with a typical, classic case of the disease, which has not been treated with serum or medicine of any kind, and has passed into the unmistakable convalescent stage, the fever permanently banished, and not later than three to four days after the decisive fall of the temperature in measles, scarlet fever, pneumonia and diphtheria, and four to five days with typhus. There may be some fever in the first day, but the second and third must be free. The limit for whooping-cough, influenza and tetanus has not yet been definitely determined. The patient must have the appearance of a convalescent, show some appetite, although lesions in the throat or exanthemata may still linger. The amount of blood that can be withdrawn depends on the case, from 100 to 500 c.c., and no inconveniences have been observed from this venesection, 200 to 220 c.c. will provide serum for twenty to twenty-two other cases. Asepsis in every particular is vital. All medication, baths, alcoholics, must be avoided; the diet, milk, bouillon, eggs, with plenty of water, and the cure left to Nature. He gives *ut aliquid fiat*, a solution of hydrochloric acid.

St. Petersburg Medicinische Wochenschrift, July 22 and 20.

Experimental Study of the Sensibilities of the Skin. H. HILDEBRAND.—Donaldson, Goldscheider and others assert that there are certain points on the skin representing the terminals of specific nerves, which transmit the sensations of heat, cold, pressure, etc. Goldscheider's articles on the subject have recently been collected and republished with his methods of research. Hildebrand has been carefully testing them on numerous subjects, but his experience absolutely fails to confirm the isolated point theory. Testing a small region of the skin with a fine needle, it was found equally sensitive all over, either to heat, cold, pain or pressure, with no specially sensitive points, with the exception of the hair follicles, which are more sensitive to pressure.

Wiener Klinische Rundschau, August 6.

Dermoid Cysts of the Ovaries. B. NOVY.—The proportion of dermoid to other ovarian tumors varies from 2.2 to 24 per cent., according to various authors. Forty-two were noted in 411 ovariectomies at Pawlik's clinics: 22 in the right; 15 in the left, and in 5 cases, in both ovaries. One patient was a little over 10; 9 over 20; 18 over 30; 10 over 40; 3 over 50, and 1 over 62 years old. The stem was twisted in 6 cases, once to such an extent that the tumor only received nourishment from the vessels of the adherent omentum. In 7 cases the tumor required operation three months after the first indication of its existence had appeared; in 8 others, six months had elapsed; in 5 a year, and in 7 two years, but in another case the tumor had been noticed twelve years before, but caused no disturbances until the last six months before intervention. In one case the tumor had appeared at 16, and caused suspicion of pregnancy, but remained stationary during eight normal pregnancies, not

requiring removal until a year and a half after it started to grow again, at 37½ years. Another woman of 53 noticed the tumor at 18. It remained stationary until the menopause, when it increased until removed three years later, when it contained fifteen liters of fluid. The longest interval was fifty-one years, the tumor first noted during the patient's fourth year, regressing three times and reappearing, never very large, until the menopause, when it attained twice the size of a man's head. Permanent and milk teeth were found together in some cases, all with enamel, "several that could have served to embellish the mouth of the bearer," also fragments of bone resembling portions of jaw and skull, etc. Hairs were found 30 cm. long; black, red and blonde hairs were sometimes found in the same cyst. Brain substance was found in 8 cases; glia tissue in 1, and tissue resembling the mucosa of the alimentary canal, air-passages, and trachea, thyroid, etc. Novy announces, as the results of his microscopic research, that the dermoid cysts of the ovaries form an independent group, distinguished histologically and genetically from the dermoid cysts of other portions of the body. Although resembling a teratoma in some respects, it is yet morphologically and genetically distinct, and might be called a cystic "rudimentary parasite of the ovary." A teratoma of the ovary does not differ from a teratoma in other parts of the body, and is due to inclusion fetus in fetu. The cystic parasite of the ovary, on the other hand, develops from the ovum still in the follicle, which is fully matured and has received the impulse to further, partially complete, segmentation. The nature and cause of this impulse are yet undetermined. These tumors do not produce metastases in the manner of malignant tumors. He concludes by asserting that "Küster's sign" has no pathognomonic significance, as he established in his numerous cases.

Greece Medicale (Syra), July.

New Exploratory-Operative Process for Abscess of the Liver. A. P. Petridis.—A number of convincing observations are described showing the inefficacy and even the dangers of the usual exploratory puncture and manipulations in a certain class of abscesses of the liver, and a new method is proposed, by which the largest portion of the surface of the liver is exposed in the most favorable region for discovering the one or more abscesses that are causing the classic symptoms. Petridis calls it horizontal polipeurodiaphragmotomy, temporary or prolonged, a simple, harmless and surprisingly effective means of reaching otherwise undiscoverable and inaccessible pus collections, and saving many cases hitherto supposed hopeless on account of the impossibility of evacuating the contents. The first step is a horizontal incision with the thermo-cautery, starting at the mammary line on a level with the seventh rib, and carried toward the center of the area of hepatic dullness, to the axillary line and even beyond. The seventh, eighth and ninth or tenth ribs are then resected for a distance of 10 to 15 cm.; then a new parallel incision is made with the thermo-cautery on the diaphragm as far as Glisson's capsule, exposing the liver as the lips of the wound are drawn apart, and upward with a couple of wide retractors. The eye, the fingers and the needle can then be used for exploration, all under control of the eye. The abscess or abscesses are then evacuated by the Zancarlo method, which he considers infinitely superior to the Lamel-longue and Stromeyer-Little methods, which have survived their usefulness.

Revista Medica del Uruguay (Montevideo), June.

Sympathectomy in Glaucoma. L. DEMICHELI.—Three observations are recorded in which chronic glaucoma was treated by resection of the cervical sympathetic, as recommended by Jomesson. In one case of almost total blindness from absolute glaucoma, mydriasis with atrophy of the iris and horny cataract in one eye, and chronic irritable glaucoma in the other, with patches of atrophy in the iris, and increased intraocular tension; Y-1, 50, lateral resection of the cervical sympathetic with extirpation of the superior and inferior ganglia (the middle ganglion was absent), was followed by restoration of Y to 2-3; visual field and intraocular tension normal. This improvement has persisted to date, three months, accompanied by the gradual disappearance of the patches of atrophy in the iris. In another patient, 81 years old, with simple chronic glaucoma, the vision was reduced to fingers at 1 meter, right eye, and movements of the hand, left eye. The latter was restored to

2/3 in two days after resection of the left cervical sympathetic. Slight ptosis, ocular tension below normal and extreme myosis appeared at once and have persisted during the two months since.

Societies.

American Academy of Railway Surgeons.—The next meeting of the American Academy of Railway Surgeons will be held in Omaha, Neb., October 13 and 14.

International Dental Congress.—The date for this congress at Paris is Aug. 8 to 14, 1900, and "it is hoped that it will continue the traditions so happily initiated at Paris in 1889 and Chicago in 1893." Secretary-general, E. Sauvez, 17 rue de St. Petersburg, Paris.

International Congress for Physical Education of Youth.—An international technical committee is being organized in connection with this Congress, to be held at Paris, next year. The object of the committee is to study the application of scientific data to the perfecting of the human form divine, and substitute them for the prejudices which at present have altogether too large a share in the education of children.

Congress of Electrotherapy and Radiography.—The French Society of Electrotherapy and Radiography has decided to hold in Paris an International Congress and annual exhibition of the latest appliances in this branch of medical science, to which all interested are invited. The next Congress will be held during the Exposition, and promises to be of unusual interest. The executive committee is composed of Apostoli, Boissac du Rocher, Branley, Oudin, Mutier of Paris, and Donnier, 57 rue Nicolas Leblanc, Lille, to whom all communications can be addressed.

National Academia de Medicina de Brazil.—The Academy recently celebrated the seventeenth anniversary of its foundation by a special meeting at Rio Janeiro, notable for the remarkably fine projections of photographs, in colors, of the results of recent research by the members, especially of the symbiosis of the ocellus iteroides and a fungus, to which de Lacerda has been calling attention. (See JOURNAL, July 8, p. 100.) He showed the marked difference in growth of the bacillus with and without the fungus and the latency of the latter during the winter, while the bacillus iteroides is not affected by the cold. He also announced the new and most significant fact that this fungus is found in great numbers in houses in which yellow fever has occurred, in the paper, walls, furniture and in the dejecta of flies.

British Medical Association.

Annual Meeting, Portsmouth, Eng., August, 1899.

THE MEDICAL SERVICES OF THE ARMY AND NAVY.

(Continued from p. 548.)

ALEXANDER OGSTON, M.D., in his address in surgery, after the preliminary remarks on the demands of modern times on surgery, and the effect of Lister's discoveries and doctrines, alluded to the unsatisfactory status of the British naval and medical military services. He said in part:

A standard of work at least equal in excellence to that of the civil surgeon ought to be expected of army and navy medical officers. Senn, of Chicago, chief operating surgeon with the United States Army recently in the field, and one who has done much for surgery, points this out in the following axioms:

1. That in theory and practice military surgery is equivalent in every respect to emergency practice in civil life.
2. That the wounded soldier is entitled to the same degree of immunity against infection as persons in civil life suffering from similar injuries.
3. That all formal operations in war must be performed where the wounded can receive the full benefit of aseptic and antiseptic precautions.
4. That operative interference is indicated in all penetrating wounds of the skull.

5. That gunshot wounds of the chest should be treated under the strictest antiseptic precautions.

6. That laparotomy in penetrating gunshot wounds of the abdomen is indicated in all cases where life is threatened by hemorrhage of visceral wounds, and the general condition of the patient is such as to sustain the expectation that he will survive the immediate effects of the operation.

These are reasonable demands, many might ask more, but nothing that falls short of some such standard can be accepted as satisfactory. Statistics prove that of all wounds in battle there are 7.4 per cent. of the brain, 7.5 per cent. of the chest, and 4.7 per cent. of the abdomen, amounting to 20 per cent. of all wounds. There must, therefore, in the next great campaign, be an enormous field of usefulness to properly trained antiseptic surgeons, and a fearful waste of life if they be not there to occupy it. It scarcely, moreover, requires to be pointed out that gunshot wounds of other parts besides those of head, chest and abdomen offer a field for modern surgery that has scarcely yet been entered on. No extensive campaigns have been conducted since antiseptic surgery was fully introduced, but the smaller ones have shown the need for a class of surgeons more highly trained than hitherto to carry the best methods of antiseptics into the domain of gunshot wounds, where septicity is a danger greater and more frequent than in any other class of injuries whatsoever. And I am convinced, from a study of wounds inflicted by modern projectiles, on which it would be out of place to enter here, that in gunshot wounds of the soft parts and extremities a very much larger proportion of lives and limbs than hitherto can be saved, and another great field of modern conservative surgery opened up by the application of improved methods and principles of treatment, in the hands of those who really know how to employ them.

In all that pertains to surgical work, it will not be questioned by those aware of what is now required, that our military and naval surgeons have, in peace, virtually no training to fit them for what they may at any instant be called on to undertake in war. Who that compares the conditions under which the civil surgeon is formed with those existing in the Royal Army Medical Corps or the Navy will be so bold as to say that the latter furnish any adequate means of familiarizing their surgeons with the highly complicated and difficult procedures which they ought to be able to carry out with dexterity and success?

Dr. Ogston goes on to say that Great Britain, of all countries, should be the first to care for its naval service, and one can hardly appreciate the actual facts.

He pointed out that in the event of a naval engagement of any magnitude the wounded on board British ships of war would have to be attended to in a small dark room, unprovided with any save the rudest appliances and a few cots, where at most half a dozen men could be handled, and which is moreover, in many vessels, as much exposed as any other part of the ship to the fire of the enemy. Were such a fighting bay rendered untenable, the wounded, however great their need, could be attended to only by being lowered, slung in a vertical posture, down the narrow hatchways, where the shot is brought up from the magazines to the guns, and even these would not be available during the heat of an action. Everything on board ship that can destroy life is in the highest perfection, everything that can save it is of the rudest description and behind the age. In the case of a gunshot wound through the abdomen the only chance of recovery is laparotomy performed within twelve hours, but on board none of Her Majesty's fleet is there any possibility of performing such an operation; there are neither accommodations, instruments, nor accessories. Or were 20 per cent. of the men of one of her battleships or cruisers killed and disabled in action, the wounded among them could not, in the present state of things, receive the attention that ought to be given them.

Yet there is no reason why the constructors of the navy should not arrange under the water line, shielded from the enemy's fire by the turtle-back armor deck of the vessel, a sufficiently large, and well-lit space, fitted with all that is required for wounds, compound fractures, and operations on the main cavities of the body. In these the wounded could be lowered through hatchways made capable of transmitting

men on stretchers or litters even in the midst of an engagement, so that all emergency operations could be satisfactorily performed.

Matters are even worse on board the smaller vessels, which have no surgeon and few surgical appliances. On torpedo boat destroyers there are no materials for making splints, only a box of antiquated remedies like those supplied in the vessels of the mercantile marine, where the sailing master acts as the doctor. It would not sensibly retard the speed of such a boat to carry a surgeon—or at least several men specially and fully instructed in first aid, and really capable of efficiently affording it—and to furnish such appliances as would enable them to deal with wounds and compound fractures.

The requirements of naval warfare must always, more or less, impede the carrying on of surgical work on shipboard during naval actions. No person will impugn the principle that the efficiency of war vessels as fighting machines has first to be considered, and as much accommodation as possible allotted to their fighting armament. It is inevitable this should be the chief consideration in fitting out the navy. To keep the communicating doors of water-tight sections open during action, in order to convey the wounded to the surgeons, might cost the lives of all on board. It may also be that in naval warfare, especially in some vessels, success may occasionally best be purchased by throwing aside, for the time being, all considerations of dealing with the wounded. But the principle may be, and is being, carried too far: for it is a duty to see that, short of interfering with the perfection of the fighting machine, no suffering is left unrelieved or life needlessly sacrificed, and no means neglected of bringing wounded men the earliest and best attention that can be given. No questions of economy should be allowed to prevent officers and sailors wounded in naval warfare receiving such early and effectual help as their condition so urgently demands. The cost of a couple of twelve-pounder guns would probably cover all that is required for such ship.

Criticisms without suggestions are usually better unmade; and to call attention to defects in the services, without indicating the lines of remedy, would be almost unpatriotic. I have already ventured, to some extent, to indicate how I think defects may be made good, though some of the suggestions have been more of detail than principle. It would be out of place to dwell at length on minor suggestions; but it may now be desirable to state generally the lines on which the services can be brought into harmony with the requirements of modern science, so as to ensure the wounded in war the most enlightened treatment, and for the medical officers the means and training for carrying on their work in a manner that will bear comparison with that of their civil counterparts.

It would be easier to do so if we possessed universal military service, as we might then look for guidance from Continental examples. In countries where this obtains the most eminent civil surgeons are at the disposal of the authorities in time of war, and in peace hold rank in the army, receiving promotion like those actively serving. They are soldiers in reserve, and can be made use of wherever their eminence and special qualifications make them most useful in war. The idea of adopting this system among ourselves, but on voluntary lines, is no new one; although it has recently been brought prominently into notice by Lord Lansdowne's creation of the Central British Red Cross Committee. If the committee make an endeavor to attach a number of our most capable civil surgeons to the Royal Army Medical Corps, by conferring on them military rank and titles, with special privileges and emoluments, on condition that their services be at the disposal of the government in time of war, some good may be done. There are obvious difficulties, but they do not seem altogether insuperable, and, at any rate, such a plan is worthy of the attention of the War Office. But anything short of this, as for instance, the old desultory method of inviting civil practitioners to volunteer their aid when war breaks out, and so supply the defects of the service, is doomed to failure; because, though capable young graduates are thus obtainable in considerable numbers, they are not the class of experienced surgeons who are wanted, they can not replace the military or naval medical officers, and are at best but a species of superior

dressers. Few, if any, of the men who would be of real value will come forward, save perhaps in the event of an impending national calamity. The system was tried in the Crimea, and has since occasionally been carried out by the National Aid Society; but I am sure those who have seen it in operation must admit that it is at least a comparative failure.

Although the arrangements of foreign services can not be directly adopted in our own, much that is instructive may be learned from the medical services of Germany, where compulsory service exists. In that empire every medical man who has served possesses a fixed military rank, even if engaged in civil practice, and is liable to be called on to serve where and when required. Those who have not served in the regular army, but are in private practice, annually receive an inquiry addressed to them by the war office as to whether they are prepared to serve their fatherland in case of war. Every German medical man who has served in the army at all is maintained for nineteen years under military orders—that is, he possesses a fixed rank, and is allotted, even in time of peace, a known military post which he would occupy if war broke out. Thus the university professors hold high military rank, corresponding with their eminent civil position and scientific attainments, and are required to give annual courses of instruction to the medical officers serving in the army or navy. Such well-known surgeons as Bergmann, Bruns, Trendelenburg, and Mikulicz have to teach these classes during the Easter holidays, so as not to interfere with the winter and summer sessions of the universities. Each professor has his fixed military rank assigned to him in case of war; most of them rank as lieutenant-generals, some as generals, and even higher, and in the event of war they act as consulting surgeons to the medical officers of the army in the field or base hospitals. They receive the same pay as the military surgeons, as do also the other surgeons who are liable to be called out in case of war; and some of the latter have places assigned them in the sanitary corps, etc., so that their skill and experience are utilized in every department of the service.

In time of peace German army surgeons have the development of their professional culture ensured by the following measures: The most promising surgeons and assistant surgeons are sent to do duty for a year at a time in the medical, surgical, and gynecologic departments of the hospitals connected with the universities, and in other large public hospitals unconnected with them. The junior and assistant surgeons are also annually sent to attend the special courses of instruction in anatomy, surgery, and operative surgery mentioned above. The senior medical officers, nearly corresponding with our surgeons-major, at least the most competent and promising of them, have to serve in rotation in the large military hospitals, in which are treated, not merely soldiers, but all kinds of ordinary patients; there they have to act as teachers and attend and take a share of the tutorial work among the pupils in the classes of the various professors; or they may be sent to do duty for a year in the general hospitals, not only in the surgical, but also in the medical and gynecologic wards. They have also to attend, as they may be ordered, annual courses of bacteriology; or they may be furnished with funds for traveling in other countries and studying their medical and sanitation arrangements.

All surgical instruments and appliances in the German army are provided by the state, and in their navy this is likewise the case; every hospital in which the medical officers serve has its complete armamentarium provided for it, so that no unwise economy hampers the most thorough and modern practice of the healing art; the same thing is true in regard to their naval medical service.

In the Russian army and navy similar care is taken of the professional culture of the medical officers. Russia possesses 6 large and 300 small hospitals connected with the army, besides smaller lazarettos; and in some of these the equipment is far in advance of anything the services possess in this country. Thus the military hospital of St. Petersburg, wherein are treated all medical, surgical, gynecologic, ophthalmic, and other diseases, consists of five separate clinics or infirmaries, each of which is complete in itself, and possesses departments for every class of disease, and even wards for paying patients. The wards are excellent, and replete with

appliances of every kind; and there are bandage rooms, purifying rooms, operating theaters, bacteriologic departments, rooms for physical research, laboratories for teachers, and laboratories for students, all excellent and complete. Each clinic possesses 850 beds, 120 of which are for women's diseases, and 20 for children's; and about 45,000 patients are treated per annum. In these clinics the students and assistants have to work in the most thorough manner, and study every kind of case. The hospital possesses a staff of 34 professors, 70 privatim doctores and 47 assistants. Each department is furnished with an ample annual allowance for instruments and apparatus, and can apply for and obtain additional grants for anything more that is required, or for anything new and expensive. They have liberal provision of everything calculated to assist the most advanced work and investigation; X-ray rooms, photographic rooms, electric rooms, immersion lenses, centrifuges, etc., to an extent that excites the marvel and envy of British visitors. The work in the wards, such as case taking, temperature recording, and every sort of examination and study of the cases, is of the very highest character; and the operations and dressings are carried out by the surgeons and qualified assistants in a fashion that is above praise.

Russia has 3000 surgeons in her army, and any of these may, if he show ability and powers of work, apply for and be ordered to return to study in the hospitals for a period of two years. There he has to work as a regular assistant, and on proving his capacity may attain a place among the teachers of the institution; or he may be transferred to the hospital of some provincial city, and there continue to perfect himself in his profession, and further qualify himself for his duties in time of war.

The Russian naval hospitals are arranged like their army hospitals; they exist in many parts of the empire, there being five large ones at different ports, besides one or two smaller ones; they admit civil cases of all kinds; and in them the medical officers possess opportunities of training themselves in all manner of high-class professional work. In the Russian navy the medical officers who show ability can obtain permission to return for two years to the hospitals, and can there advance by merit, ten every year, to become privatim doctores, and so proceed to the position of professor. And they have the same privilege as those of the army of obtaining, after ten years' service, two years of study leave in the hospitals and schools, during which time they are granted extra pay.

The Russian state supplies its army, its navy, and their hospitals with instruments of the newest construction, embracing appliances for special diagnosis and treatment; the operation instruments, and even the boxes that contain them, are arranged so that they may be readily sterilized by heat or otherwise; and Schimmelbusch's sterilizers, and apparatus specially constructed for carrying out antiseptic and aseptic treatment under the difficulties of a campaign, are supplied with them. The drugs are prepared for the services in the form of tabloids, with the active principles accurately dosed and made up by the newest machinery. Dressings, bandages, and such like are prepared, sorted, made up, sterilized, and sent out from factories which are ideals of purity, ingenuity and care, in a way that is an example to the world.

In the French army post-graduate courses, expressly for medical officers, are conducted by professors at the different universities throughout the republic, and the cost is borne by the army medical departments, while a certain number of the medical officers of the active and reserve army are yearly ordered to attend them, extra pay being drawn by those who do so.

Dr. Ogston then suggested, in detail, a scheme of reform, which lack of space precludes printing here.

(Concluded from Page 485.)

RELATION OF CHILDHOOD TO ADULT DEFECT AND DISEASE IN ITS PULMONARY AND CARDIAC ASPECTS.

DR. WILLIAM J. BUTLER—The lungs form an interesting subject to the pathologist and clinician, whether considered in childhood or adult life. But the relation of childhood to adult pulmonary defect and disease appears particularly attractive

because of the much discussed predisposition to pulmonary lesions and the important bearing of the same on the life of the individual. The demonstrable congenital defects are rare, and while they form an interesting pathologic spectacle, they are clinically unimportant so far as the adult is concerned. They might be dismissed with the mention of their occurrence. Cases of an absent or remnant of lung are reported, as are likewise the more frequent cases of defective development as the result of intrauterine disease or defect producing lung compression, and as a result defective lung development, as through diaphragmatic hernia, etc. That an absent lung, however, is not incompatible with an extended existence is illustrated in the autopsy of a German soldier who died at the age of 24 years, in whom was found but one lung. However, of far more importance, could we throw any light on it, would be that subject which still beggars a scientific explanation and denomination, which the pathologist speaks of as undemonstrable qualitative lung changes, and the clinician as a predisposition, both of which, while tolerable as somewhat expressive, in reality convey little definitely.

While there are certain appearances in subjects, which experience teaches are characteristic of those that later develop pulmonary infection; that there are those who do not present the same and who later develop chronic pulmonary disease, and those that are models of these signs who never develop the same must be acknowledged. It is not our purpose to deprecate the use of these terms in speculating on the future of the child who shows them; but, however, we contend that they must be considered with caution in estimating as to future disease of adolescence, and that the same can only be permitted done when dealing with pathologic changes that permit of interpretation from physical signs. It is notable that while acute pulmonary diseases may be among the most frequent disorders of childhood, chronic affections are quite uncommon, and that pulmonary tuberculosis, so far as our clinical observation goes, is quite rare in children under 10 to 12 years of age. Some of our acute affections may, however, terminate in chronic ones that assume great importance as to the future of the child, namely, the lung and pleural thickenings presenting after a pneumonia, lobar or lobular, or the pleural thickenings following a pleurisy. These exert a decided influence on the future of the child who may succumb early in life as the result of recurring acute attacks of pneumonia and pleurisy, or from tubercularization of the foci. Bronchiectasis, however, is quite rare, at least on the post-mortem table. In those patients who survive a period of years, marked displacement of the mediastinum and heart may be observed, if the chronic inflammatory process has extended beyond the pleura to the surrounding tissues. And under such circumstances we not infrequently see varying degrees of dextrocardia in right-sided affections of the chest. There are also noted marked deformities of the chest as the result of the contracting and retracting processes. These latter, however, are not among the frequent results.

The results of such changes on the adult, so far as defect and disease are concerned, assume a great importance both in the gradual advance of the chronic process, the greater vulnerability of the organ to infections, both acute and chronic, and not the least important its effect on the right heart as the result of increased resistance offered to pulmonary circulation. This latter consequence is most beautifully illustrated in the pulmonary atelectasis resulting from pronounced thorax deformities as the result of Pott's disease or rickets. In such cases proportionate to the pulmonary compression, obstruction is occasioned in the pulmonary circulation, to overcome which the right heart must increase its propelling power, which it effects by hypertrophy, thus producing a condition similar to that found in a lesion at the mitral end of the pulmonary circulation, and presents an identical picture with the same, and is attended with similar periods of cardiac incompetency, which is so often a cause of death in subjects with greatly deformed thoraces.

In regard to the relation of childhood to adult defect and disease in its cardiac aspects, this would require classification, at least into the two divisions, congenital and acquired cardiac lesions.

The congenital lesions, according to Sindes, Rokitansky,

Orth and others, are to be considered the result of developmental defect and not of endocarditis. If we are to consider them in their relation to adolescence, we should take up those that involve the pulmonary conus, orifice and artery, with accompanying septum defect, open ductus Botalli, etc., as these are the lesions that assume the greatest practical importance, as they are far more compatible with a comparatively prolonged existence than those still rarer lesions of the tricuspid valve. The most frequent of the pulmonary lesions are narrowing of the conus, with septum defect and varying relation of the patency of the foramen ovale, or narrowing of the entire trunk of the artery with septum defect and varying relation of the foramen ovale.

The pulmonary orifice lesions offer an interesting study in those that survive, as they at times present a peculiar aspect and decided secondary changes. As a rule, they are poorly developed, may be cyanotic, and not infrequently are the subjects of pulmonary tuberculosis. The frequency of the latter in pulmonary stenosis is variously estimated by different observers. Whatever the discrepancy in statistics, it is notable that they frequently develop and die of it.

Concerning the acquired heart lesions, we have to deal not only with endocardial, but pericardial affections. Pericarditis in childhood is said by Baginsky to be probably more frequent than in adult life. An opposite position to this is maintained by Da Costa. On the other hand, Dukinson, from pathologic observations, says that it is less frequently observed in children than adults, and that the rheumatic form is almost invariably associated with endocarditis. However, its occurrence portends serious consequences for the child, as but few of them pass beyond the age of puberty.

Endocarditis, on the other hand, is not an infrequent phenomena in children, though probably not so frequent as diagnosed. Its occurrence, however, causes at once a serious outlook for the child, not only as to its immediate results, but as to his future in the way of recurring attacks of endocarditis, cardiac incompetency, etc., as a heart lesion tends to progression and not regression. As in the congenital lesion, so too in the acquired, children usually develop less satisfactorily, and proportionate to heart hypertrophy may arise chest deformities in the so-called heart humps.

It is needless to mention the enormous preponderance of acquired endocarditis on the left side of the heart over that on the right, which equally or even more so characterizes the congenital form as to the right over the left heart, although there congenital mitral stenosis has been recorded and we have seen acquired right heart endocarditis "posted."

It was previously noted that in the congenital pulmonary stenosis, pulmonary tuberculosis was a frequent cause of death; with equal prominence may be mentioned the fact that death from tuberculosis is exceedingly uncommon in mitral lesions, and that cases of pulmonary tuberculosis that develop mitral lesions may be given a favorable prognosis as to their tuberculosis, and likewise an early acquired mitral lesion protects the subject to a great extent against tubercular pulmonary development. This is dependent on the principle that has been recognized for ages, namely, that a chronic passive pulmonary congestion is unfavorable to the growth or development of tubercular processes. The acquirement of this passive congestion is assured by the development of a mitral lesion. This infrequency of pulmonary tuberculosis in mitral stenosis is contested by some, but we can not but recognize the worth of the observation of such eminent pathologists as Conrad and Kolisko, and the clinicians Bomberg, Neusser and Kovacs, all of whom held this view.

Concerning aortic lesions, their presence alone would have no bearing on pulmonary conditions other than forming a *locus minoris resistentiæ* during acute pulmonary affections.

Cardiac insufficiency in aortic lesions is always a grave prognostic sign, and pulmonary congestions that so arise are usually of short duration.

The prognosis of children, as to life, who early develop heart lesions, is variable in great part with each case, as they are at all times liable to recurrent attacks of endocarditis, each one of which exerts its deleterious influence on the heart muscle and often increases the existing lesion or adds another thereto.

DENTAL ASPECTS OF CHILDHOOD IN THEIR RELATION TO ADULT DISEASE AND DEFECT.

DR. A. E. BALDWIN.—In looking over the list of the different headings of "Childhood in Its Relation to Adult Disease and Defect," I was impressed with the many aspects of this question, each one of which has a bearing of very great importance, it being almost impossible to separate either one from the other. There seems to be a relationship between all of them, but I shall try to restrict myself to the topic assigned to me. The dentist, or one who makes the dental part of our anatomy a specialty, notices many of these defects more frequently than do other specialists or those engaged in general practice. We all know, from observation, that heredity plays an important part in the diseases of childhood. Heredity occupies an important part in the field of defects from a dental standpoint. When I say a dental standpoint, I do not mean to refer simply to the teeth, but to the appearances thereof as well. It is not necessary for me to call your attention to the many-shaped faces and the many shapes of the teeth characterizing the different nations. There are characteristics especially belonging to each. I shall only call your attention to one feature in this connection, and after having made dentistry a specialty in the last sixteen years of my practice, I consider it a very important feature, and that is the care of the milk teeth, so-called, or the first set of teeth, as to the prevention of deformities of the face. We know that the tendency of the teeth is universally to move forward or toward the front of the mouth, and if certain teeth are extracted out of time and before the time for others to come in to take their place, the space becoming smaller than necessary for the proper alignment of the teeth, as a consequence there will be produced irregularities of the teeth. The lower part of the face must be developed or expanded in a different way from most any other part of the human organism, and this is largely brought about by the pressure of the incoming teeth expanding the jaws. The teeth form in the jaws, attain a certain size, are erupted, and then remain during life. When being erupted, the teeth crowd and oftentimes appear to be leading to strong irregularities, and dentists are approached to extract these teeth adjacent to the ones coming in, so as to allow them to come in regularly. This is part of Nature's plan of developing the jaw, and I want to warn our confrères against giving away to the tendency of extracting such teeth to make room for the new teeth that are coming in, thus dwarfing the jaw and preventing its proper expansion. Our field for humanity is to do as much as we can to prevent any such irregularities from taking place, and not allow those things to be done for our patrons, for their interests and for humanity at large. By so doing we will prevent a great many abnormal and partially developed jaws.

Another point is with reference to the care of the child's teeth. It is not necessary for me to do any other than to make a suggestion which will lead you into the thought I wish to convey. You know that in childhood habits are formed, and if attention is not directed to the infantile or milk teeth how easy it is to produce a train of diseases or a suitable soil for a train of diseases which will take almost any of the forms spoken of in this list, notably nervous diseases, and diseases of the alimentary canal. What I may say has occurred to most of you a great many times, but it is to my mind of very great importance, that is the care of the molar teeth of children, not for the direct as much as for the indirect effects. The indirect effects are these: The child must not only sustain life by the food it takes, but the nutriment must also be such as to allow for expansion. It is more important to the child that it should have a good masticating apparatus than it is for the adult. Take a child whose molar teeth are not properly attended to—I am speaking now of the milk teeth—and that child will not masticate its food; consequently food will be taken into the stomach and the work which should devolve on a variety of organs is thrown on one. If the child be of a nervous organization, in many instances we will find dyspepsia developed with its consequent train of symptoms. If the habit is formed, it will probably remain during life with all its consequent irritations and troubles that develop in various lines. By preventing the habit of bolting food, or by encouraging the proper mastication of food and mixing it with saliva, we will in this way relieve the stomach and alimentary canal, and we will

greatly tend to preserve the health and prevent the adult organization from disease.

PROCTOLOGIC ASPECTS OF CHILDHOOD IN RELATION TO ADULT DISEASE AND DEFECT.

DR. JOSEPH B. BACON—It is impossible to give more than a synopsis of the vast amount of literature and to touch on some of the main faults of interest in this most important subject without making this paper too voluminous for the purpose it is intended to occupy in this general discussion.

Digestion and assimilation are two very important factors in the growth and proper development of a child; yet neither of these conditions can be normal when there is habitual constipation or impaction of feces in the rectum, the serious effects due to the absorption of fecal products on the nervous system even causing insanity, disorganizing the blood—indeed, the whole body may be deprived of normal development by this autoinfection. In fetal life the rectum is composed of a blind pouch that finally descends deep into the pelvis and becomes attached to another blind pouch inverted at the anus and forming the anal canal; the union of the blind ends of these canals, and the absorption of the membrane ending the septum, results in a permeable gut or true rectum. Normally this septum is all absorbed, but frequently it remains in part and thus forms a constriction of the rectum or a congenital stricture, resulting in chronic constipation alternating with impaction. Again, a sensitive polypus forms in the lower rectum. At the time of defecation the feces drag it down near the anus. If this sensitive polypus is now compressed by hardened feces, pain is reflected back to the sacral plexus, then over the pudic to the inferior hemorrhoidal nerves to the sphincter and muscles, producing a spasmodic contraction. The peristalsis of the gut above, together with the voluntary intra-abdominal pressure, forces the feces through a spasmodically contracted anus, often producing a tear of the mucous membrane resulting in a chronic ulcer or fissure. The enormous supply of sensory nerves distributed to the anus makes even a small tear or ulcer so extremely painful when soiled by feces at the time of defecation, that the child dreads to have a stool, voluntarily avoids it, obstinate constipation results and, if neglected, impaction occurs.

I have seen chronic cases of impaction where the rectum and sigmoid were so distended that all the pelvic organs were displaced. The rectal walls had been so distended and thinned that normal contraction never occurred, and through life the bowel never became normal in muscular action, so that the patients were continually compelled to use enemas and purgatives. One young man with a history of chronic impaction of feces of the rectum and sigmoid in childhood, had had intermittent attacks requiring anesthesia and mechanical means to relieve him. I examined him, found no obstruction, but an enormously thinned and dilated rectum. I explained to him the danger of the gut rupturing if he allowed impaction to recur, and prescribed laxatives, diet, etc., but in less than a year, in spite of his care to avoid it, impaction took place and the gut ruptured, followed by fatal peritonitis. The post-mortem report described the rectum and sigmoid as dilated to many times the normal size and almost a complete loss of mucous elements in the gut walls. This case could have been saved if care had been exercised in looking after it in childhood.

Chronic impaction of feces in the rectum in a female compresses all the organs of the pelvis, delays the normal development of uterus and ovaries, misplaces the bladder upward and produces vesical irritation and nervous symptoms, etc., compresses the ureters and disturbs the functions of the kidneys, produces pressure atrophy of the levator ani muscles, thins out the perineal triangle and superior and inferior fascia of the levator ani muscles, and elongates the uterosacral ligaments, weakening the supports of the pelvic organs and subjecting the patient to visceral ptosis later in life. Hemorrhoids are very rare in children and usually are symptomatically cured by removing the primary cause, such as constipation, prolapse of mucous membrane, chronic diarrhea, disordered portal circulation, etc.; but when hemorrhoids occur in children they are very apt to recur in adult age. The rectum usually contains pathogenic microbes and its mucous membrane is more frequently abraded by indigestible substances taken with the food. Hence we frequently find chronic ulcers, or a blind internal fistula the result of an abscess. This pus-forming fistula causes amyloid visceral change if neglected, and usually affects the patient's chances for health in adult life. More rare affections, such as primary tuberculosis, syphilis, gonorrhoea, adenoids and multiple polypi, prolapse, proclitica and malignant disease, while very important,

require too much discussion to be properly considered here. Much might also be said concerning reflex nervous symptoms that call attention to conditions remote and serious that continue through adult life.

HABITS OF CHILDHOOD IN RELATION TO ADULT DISEASES.

DR. W. X. SUDDUTH—Prenatal, intrauterine and infantile diseases expend themselves in childhood or adolescence, seldom or never persisting to maturity. They either result fatally at the time or are cured in infancy, or possibly may drag along into the early years of adolescence, when they carry the victim off. In some instances, though, they persist as surgical defects which limit the usefulness of the part operated on, but seldom or never endanger the life of the adult. The conditions of childhood, however, which do persist into adult life, are the vicious functional and bodily habits which are perpetuated through the mental habitude of the individual, consciously or subconsciously, and make or mar the adult life. My subject, therefore, contrary to the views of the previous speakers, is the most important one on the program. The habit aspect of the condition of childhood manifests itself throughout life in the production of diseased conditions at maturity. I use the word habit in two senses. It may be used as representing an involuntary act. A person may have the habit of constipation, and that may continue, without any organic lesion, into adult life. The word may also be used as indicating a tendency toward disease which may have been established in childhood and carried out in mature life. The word "vicious" may have two aspects also, that of immorality, which is the old idea, or better, as I prefer to use it, in the sense of perniciousness.

Almost every condition has within itself the possibility of the formation of a habit. We may have the common one—pain habit; as, for instance, an acute inflammation gives rise, by well-known pathologic conditions, to pain, but pain is not necessarily a condition *per se*, but the perception of an injury rather than the injury itself. We know that such an acute inflammation may be entirely relieved until there is no more manifestation of it; yet the pain may continue and be persistent, not only throughout childhood, but throughout adult life. "Pain habit" may thus be established and persist entirely independent of any inflammatory condition we can discern.

One particular habit which seems to me to be as important or more important than any of the above is the constipation habit. Habitual constipation is a term we use constantly in our conversation, and yet there may be no organic lesions which account for it, and in the majority of cases it depends more on habit aspect than it does on any organic lesion that may be found. If we discuss the question of vicious bodily habits, that is, immoral habits, may we not refer to the practice of masturbation in childhood and in adolescence, and its effects on the adult. There is no question at all but what masturbation comes to be a habit as practiced by some individuals. Masturbation, as practiced, however, by the majority of youths, does not become a habit, i. e., a condition over which the individual has no control, or a condition that requires extraordinary arrest of attention in order to break off the habit. The question came up in a conversation with Dr. Scott as to whether masturbation was not a normal condition at certain periods of the life of the boy. I do not look on masturbation as a disease necessarily, except as it manifests itself almost in the form of insanity, as it does in some instances. It is not a physical disease; it is the effect, however, of physical conditions. In a great many instances masturbation is practiced for its sedative effect, pure and simple. I recall the case of a boy who learned that it was possible to relieve pleasure by manipulation of the parts, by going in swimming when comparatively a young man, and coming in contact with a log on which he manipulated and from which act he experienced pleasurable sensation, and thus, in many instances as it proved by chance, masturbation is found out and followed later as a means of sedation; a sure method of letting down the nervous tension of the body which the individual finds to be comfortable.

There are many other questions which might be referred to under the head of vicious habits, that are simple in themselves, but which lead to graver consequences in maturity. I presume, however, the one that is most important from my standpoint is that of emotional prodigality, the habit of indulging the emotions: unrestrained emotional prodigality. In my line of practice there is no one thing that is so pernicious and so productive of vicious conditions in the adult as emotional prodigality. It covers almost the entire field of nervous diseases. It is the basis of a great many of the functional derangements of maturity, and to my mind, in the great majority of cases, it is the forerunner of insanity in many of its forms.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Those new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, SEPTEMBER 2, 1899.

BENIGN AND MALIGNANT ENDOCARDITIS.

It is not improbable that the symptom-complex clinically designated acute articular rheumatism is of multiple and varied origin, and it is not less improbable that the etiology of endocarditis is likewise not uniform. It is known, in fact, that both arthritis and endocarditis may arise in conjunction with a considerable number of infectious processes, and it is not surprising, therefore, that the course and termination of the two affections should vary accordingly. The endocardial lesions, further, may assume various forms, as indicated, for instance, by the pathologic qualifications verrucose, polypoid, villous, ulcerative, suppurative, and by the clinical qualifications benign and malignant. All of the differences hinted at must be attributed to variations in the etiologic factors, and many of the problems that are bound up with this interesting and complex subject must await their solution at the hands of the bacteriologist and perhaps of the physiologic chemist; and who knows but that the precise determination of the cause may in turn result in the discovery of an efficient and specific therapeutic agent.

In an address delivered recently before the Berlin Medical Society, Litten¹ pointed out that there sometimes occurs in the course of acute rheumatism a severe, almost invariably fatal, variety of acute endocarditis, which differs essentially from the ordinary benign variety of rheumatic endocarditis in not becoming stationary and leading to connective-tissue contraction, but, with progressive increase in the symptoms, in advancing steadily to a fatal termination. This form of endocardi-

tis is to be distinguished from the septic-septic variety generally designated "ulcerative" in not giving rise to suppurative processes. It is further characteristic of the variety of endocarditis under consideration that the articular rheumatism on which it is consequent responds promptly to the administration of salicylic acid.

Rheumatic endocarditis is characterized by deposition of the fibrin of the blood in places where the endocardium has been injured, and especially on the valves, which then undergo sclerosis, with resulting insufficiency and obstruction. The condition is probably dependent on the activity of micro-organisms, whose identity has not yet been established. Rheumatic endocarditis manifests a tendency to attack only the valves of the left side of the heart, in contradistinction to the fatal and malignant varieties. It may be looked on as a distinct localization of the rheumatic process rather than as a complication. It never gives rise to infective abscesses and malignant metastases, but to simple infarcts and anemic necrosis, and only in branches of the aortic tree. It exhibits a marked tendency to recurrence, so that recent endocarditis is often observed in association with old valvular disease. It is frequently complicated by fibrinous pericarditis. It presents no characteristic temperature-curve, as do the malignant varieties, but it may pursue an insidious course, so that a valvular lesion may develop without recognition of the stages of acute endocarditis. The contents of the swollen and painful joints are clear or slightly turbid, but never purulent. The promptitude of action of salicylic acid in its effects on the general and the articular condition is characteristic and typical of acute rheumatism in contradistinction from all other varieties of arthritis.

The septic, so-called "ulcerative" variety of endocarditis is not necessarily attended with ulceration, which is but an incident of the morbid process and may not even be present, while, on the other hand, it may attend other varieties of endocardial inflammation of different etiology and clinical course. This septic endocarditis is dependent on virulent micro-organisms, especially of pyogenic activity. In contrast with rheumatic endocarditis it exhibits a marked tendency to destruction of the affected valves. It attacks the right as well as the left side of the heart, and gives rise to malignant metastases and abscess formation, which may appear in any organ. The causative micro-organisms are derived from putrid and disintegrating venous thrombi, and the endocarditis may be but one symptom of the general process. When peritonitis occurs as a complication, it is always purulent. The endocarditis is usually accompanied by hemorrhagic nephritis. Etiologically, diphtheria of the placental site following abortion or normal labor or of the bowel, of the soft palate, of the labia majora, of the endometrium, severe disease of the uterine appendages in conjunction with thrombophlebitis, phlegmonous parametritis, purulent cellulitis of the neck, for instance following scarlet fever or typhoid fever, are the most important factors. The disease is

¹ Berliner Klin. Wochn., July 10, 17, 1899.

characterized clinically by its acute and grave course, almost always terminating fatally, and by the height the temperature reaches, with erratic chills of quotidian, tertian or aberrant type. Cutaneous and retinal hemorrhages occur in the large majority of cases. Besides, suppurative processes occur in the skin and in the eye. Frequently mild manifestations of nephritis are present, with albumin and tube-casts in the urine and in the cases of hemorrhagic nephritis also with blood and blood-casts. The diazo reaction is seldom absent at the height of the attack; usually it is quite pronounced. The spleen is invariably enlarged, though during life not invariably so. When the spleen is the seat of abscesses these may be recognized by the development of perisplenitis, with palpable friction. When abscesses form in the lungs, and especially at the periphery, putrid pleurisy may readily develop. The endocarditis may be suspected from alterations in pulse, in cardiac activity and in respiration, in contrast with the rheumatic variety, which may pursue an insidious course. The rapidly fatal termination is characteristic of septic endocarditis. In the blood, especially after the chills, the same micro-organisms are found, when a positive result is obtained, as are present in the joints, and, in the event of death, also in the vegetations on the valves and in the spleen, of greatest significance with regard to the general process are the putrid and disintegrating thrombi.

The malignant rheumatic variety of endocarditis was first described by Litten², and he has studied altogether twenty cases of the disease. The disorder presents the characteristics of a severe general infection, with, as a rule, profound and extensive objective symptoms referable to the heart. The patient becomes anemic, cyanotic, apathetic. The temperature is relatively low, though at times it may be high and be interrupted by irregular, intermittent chills. The spleen is enlarged, the diazo reaction is present and hemorrhage takes place beneath the skin and the mucous membranes and into the retina. Acute hemorrhagic nephritis, with blood and blood-casts in the urine, is relatively frequent. The metastases that occur assume the form exclusively of simple infarcts and anemic necrosis, malignant and purulent metastases being entirely wanting. The course of the disease may extend over weeks or even months. Death is the usual termination.

The special variety of endocarditis under consideration sets in in the course of an attack of acute articular rheumatism or of chorea complicated by acute articular rheumatism, and the treatment of which the salicylates are successful. The endocardial lesion, however, instead of terminating in contraction of valve segments, progresses to ulceration and destruction and eventually to death. Sometimes it involves the right as well as the left side of the heart. Pericarditis is often an associated condition. The contents of the affected joints are never purulent, but serous, and clear or turbid. The action of the heart is greatly accelerated and arrhythmic.

and there may be palpitation, with oppression and dyspnea. The most important and most characteristic feature on post-mortem examination is the total absence of any suppurative process of thrombophlebitis. In the contents of the joints during life, and in the blood and in the endocardial vegetations and in the spleen after death, Litten has in two cases, among seven examined bacteriologically, found a coccus capable of cultivation and possessing pathogenic activity for mice and guinea-pigs.

HYPERPLASIA AND TUBERCULOSIS OF THE PHARYNGEAL TONSIL.

The etiology of adenoid vegetations in the nasopharynx, to the existence of which Wilhelm Meyer first called our attention, is still obscure. Meyer himself vaguely expresses the consideration that these vegetations might possibly stand in some relation to "scrofula." Others, as for instance Hopmann, looked on this hyperplasia of lymphatic tissue as due to constitutional conditions.

Isolated instances of tuberculosis of the pharyngeal tonsil were soon reported by Wendt and others. Lernaoyez described two cases of tuberculosis of the pharyngeal tonsil in the living, and fully recognized the importance of this localization of tuberculosis. Soon afterward Dieulafoy made a more extensive investigation; he implanted pieces from the pharyngeal and faucial tonsils into the subcutaneous tissue of guinea-pigs, with the result that in 20 per cent. tuberculosis developed. These results have been properly criticized by Cornil and others. In the first place the point of inoculation into the abdominal wall might easily become secondarily infected; in the second place it is quite likely that tubercle bacilli are often accidentally present on the surface of the extirpated non-tuberculous tonsils. At any rate, this contingency can not be excluded, inasmuch as Dieulafoy neglected to examine the material histologically.

Broca, Brieger, Goure, and others examined pharyngeal tonsils for tuberculosis with negative results. Goure, whose material included 201 instances, did not find tuberculosis in a single case, although eighteen of the cases gave a family history of tuberculosis and seventeen were actually tuberculosis. Goure came to the conclusion that while tuberculosis of the pharyngeal tonsil probably occurs, it must be very rare. Wright, Brindle, Bottstein, Pluder and Fisher, Gradenigo, and lately Piffel have also studied hyperplastic pharyngeal tonsils with reference to tuberculosis. In Piffel's recent article³, where these facts are stated, it appears that, excluding Dieulafoy's investigation, 655 pharyngeal tonsils have been examined histologically—and in some cases by means of inoculations—for tuberculosis, which was found to be present in 19 cases, or 2.9 per cent. Including the figures of Dieulafoy and others, the total number examined becomes 764, and among these 30 were tuberculosis, or 4 per cent. Piffel's own study includes 100 cases of hyperplastic pharyngeal tonsils, of which three were

² Zeitsch. f. Klin. Med., B. ii, 1881.

³ Zitt. f. Heilkunde, 1896, xx, p. 297.

found to be tuberculous, by histologic examination, the presence of the tubercle germ being demonstrated in only one case. The family history and other clinical points in connection with these 100 cases were carefully investigated, but the results do not indicate that tuberculosis plays any general rôle in causing hyperplasia, whose character in the ninety-seven non-tuberculous cases did not present anything striking.

The study of the three tuberculous cases brought out the fact, already known, that there is no definite way of distinguishing between a tuberculous and a non-tuberculous hyperplastic tonsil, except by means of the microscopic examination. A study of all the known cases of tuberculosis of the pharyngeal tonsil showed a family history in nine. Tuberculosis of the pharyngeal tonsil should be thought of in cases of hyperplasia in patients with hereditary predisposition and when there are tuberculous processes in the surrounding tissues, especially those that are connected with the tonsil by means of lymphatic vessels.

The manner of infection in tuberculosis of the pharyngeal tonsil is probably through inspired air. There are three possibilities to be considered: 1, the inspired air; 2, through tuberculous sputum; 3, through the blood and lymph. The nasopharyngeal cavity presents several anatomic and physiologic peculiarities which predispose to primary infection, as for instance the presence of lymphoid tissue whose surface is not smooth but is provided with crypts and irregular depressions; the surface is not lined with ciliated epithelium throughout—in the crypts, especially in the young, flat epithelium may occur; catarrhal conditions often arise in the nasopharyngeal mucous membrane, leading to epithelial denudation, which may also be caused by mechanical lesions. These remarks apply with particular force to the pharyngeal tonsil, and especially so when this is in a condition of hyperplasia. Piffel and others are therefore inclined to believe that in the majority of cases of tuberculosis of the tonsil the bacilli are deposited on the tonsil from the inspired air.

The second mode of infection i. e., through tuberculous sputum, presupposes a primary focus in the lower respiratory tract or in the lungs, and the presence of such a focus has been rarely demonstrated in the recorded cases.

The third possibility, namely, infection from the blood or lymph, probably need not be considered, inasmuch as it will be likely to occur only in connection with acute general miliary tuberculosis, in which it is not to be denied that miliary tubercles might also develop in the tonsil. The histologic study of tuberculous tonsils also rather indicates that the process generally extends inward from an infection near the surface.

Tuberculosis can not, therefore, be regarded as playing any general etiologic rôle in the production of hyperplasia of the pharyngeal tonsil. It would rather seem as if the hyperplastic tonsil is little likely to become infected and that the infection, when it does take place, is a

secondary process, added to the already existing hyperplasia, whatever its real cause might be. The fact, however, that tuberculosis of the pharyngeal tonsil may occur should always be borne in mind, because of the danger of further spread of the disease. This also furnishes one of the strongest indications for the removal of this structure, even when the seat of but comparatively slight hyperplasia, and it goes without saying that its removal should be as complete as possible. Lermoyez says that it would be better, in case tuberculosis should exist, not to meddle with it than to remove it only in part.

THE DANGERS OF SANITARY OFFICIALS.

A story has been going the rounds of the secular press that a public health officer in Pennsylvania held up a boarding house at the muzzle of a revolver and compelled the unwilling inmates to undergo vaccination. A corrected statement followed in some cases, that the doctor was threatened by some persons present and that he simply defended himself by showing that he was armed. Accepting this last version as correct, it throws a better light on the matter, but shows also that the perils a sanitary official has sometimes to incur in the course of his duty are not altogether confined to the "wild and woolly" West or the Mexican frontier. Our latest European importations in our seaboard states are often as lawless and dangerous as border ruffians or mountain outlaws.

COMPULSORY NOTIFICATION OF TUBERCULOSIS.

A prosecution of a Detroit physician for not reporting a case of tuberculosis as ordered by the Board of Health, has ended by his being fined \$50 and costs. Unless this judgment is set aside by a higher court, physicians will neglect to report cases of tuberculosis at their peril. Whether the health authorities will order placarding of the victims and their houses is perhaps questionable, but it might be predicated from the zeal which not long since prohibited public funerals of consumptives. (See *JOURNAL*, August 26, p. 553.) It appears to us that the health authorities of Detroit are a long way ahead of their time; in fact, it is possible that the sober sense of the rest of the world may never overtake them. If the testimony given in this trial has been justly reported, some very unguarded opinions have been expressed, such, for example, as that of one witness that he would dread being in a room with a consumptive more than with a case of smallpox. While one may not be able to deny the truth of such a statement in the particular case, it has hardly the true note of sincerity and certainly sounds extravagant. While all reasonable safeguards should be insured for the protection of the public, needless fears and extravagant precautions will in the long run only tend to make their advocates ridiculous.

AS OTHERS SEE US.

Professor Mosso of Turin, the eminent Italian physiologist, has been visiting this country, and according to the Rome correspondent of the *Lancet* has sent home some of his impressions. Speaking of the physical development of Americans he says, in the letter quoted: "It is enough to look at the passers-by in the American streets to be convinced how much more developed and

strong they are than our compatriots. The boys and girls in point of physique are far superior to ours. . . . America teaches us by the plainest and the most impressive of examples that physical education may be carried to perfection without any military object. . . . "It has been so much the rule with us to consider the average American physique as not quite what it should be that it is refreshing to have such testimony from a competent foreign observer. It is probable that we have been given too much to self-depreciation; it has been as much too common to underestimate ourselves in some respects as to glorify ourselves in others. The average American may be less plump than his British fellow Anglo-Saxon—if it is correct to call him so—but in bone and muscle and nerve he is in all probability at least his equal if not, taking all classes together, his superior. This is, of course, mentioned only as an anthropologic fact.

INFLUENZA AND THE DEATH-RATE.

The July *Bulletin* of the Chicago Health Department has some interesting data in regard to influenza. The city has not been free from the disease at any time since the epidemic of 1891, in which year there were 336 deaths reported from this cause. In subsequent years the reported deaths were as follows: 1892, 103; 1893, 88; 1894, 51; 1895, 165; 1896, 17; 1897, 15; 1898, 281, and 304 up to the end of July, 1899. It would appear from these figures that we are entering on another period of special prevalence of the disease, and the figures are more significant when we remember that the deaths directly due to the disorder represent only a small proportion of the total in which its agency has existed. Thus, as the *Bulletin* shows, while the reported deaths from influenza in the epidemic of 1891 added only 1.25 per cent. to the total mortality of the year, yet through its fatal complications of other diseases it added 17 per cent. to the total mortality, and while this year, thus far, the influenza mortality is only 2.25 per cent. of the whole, yet the total is still over 14 per cent. greater than the average of that of the last five years. The lesser proportion now than in 1891 may very properly be credited to the existence of influenza during that period. While we are dreading the possible advent of the plague, leprosy and other disorders, and possibly educating the public, a little too much as to the dangers of tuberculosis, it would be well to give some attention to the public peril from a disease that is efficient to a greater or less extent in adding one-sixth or one-seventh to the normal average mortality, while that of tuberculosis hardly exceeds one-eighth or one-ninth. Neither cholera, small-pox, nor any other epidemic has been responsible for more deaths in this country than has influenza during the past ten years, yet as its own special death-rate is small we are apt to overlook its pernicious activity.

HIGH ALTITUDES AND THE BLOOD-COUNT.

In the "Transactions of the American Microscopical Society," Vol. xx, Dr. A. Mansfield Holmes of Denver publishes some experiments made at Manitou, Colo., and the summit of Pike's Peak, on the effect of sudden changes of altitude on the number of red blood-corpuses. Similar observations made hitherto have been as a rule under conditions requiring the lapse of a con-

siderable period of time between the blood-counts at the different altitudes. The immediate effects were therefore less assured, but at Pike's Peak the railroad afforded the means for a very rapid change of altitude of nearly 8000 feet. He found that the ascent caused at once an increase of 11.5 per cent. of the red corpuscles, which had increased, three hours later, while still on the mountain top, to 14.42 per cent. The descent in the evening was accompanied by a decrease of 9.56 per cent., though still over 4 per cent. above what it was before the ascent. It was also found that the blood of a person accustomed to residence at a high altitude was less reduced in red corpuscles than that of one not so acclimatized. Dr. Holmes is inclined to account for the phenomenon, in part at least, by the fact of the diminished amount of oxygen in the rarified air of high altitudes. The organism has to obtain the oxygen it demands, and does this by calling into action and circulation many red cells that had been in a quiescent state in the deeper tissues, but he does not attempt to describe how far this or other influences may be responsible. The study has not, so far as we are aware, been before made in this country with the special conditions of rapid change insured by Dr. Holmes, and it is therefore of some interest.

LIQUID AIR IN MEDICINE AND SURGERY.

While liquid air is not likely to realize all the sensational prophesies of magazine writers, it is possible that it may have an important and rather striking future in therapeutics. At present we have only a few positive facts, but these are suggestive. Dr. Campbell White, New York City, whose experience with this agent seems to have been more extensive than that of any other physician, and whose communications on the subject have been noticed in the *JOURNAL*, evidently has confidence in its value, and his published statements as to its apparent curative action in lupus, nevus and other skin affections are certainly encouraging. Even in cancer he has hopes of its proving an effective remedy, at least in some cases. As a local anesthetic its efficiency is evident and he has apparently demonstrated the remarkable fact that the intense cold of this agent may have no permanent bad effects. It is not to be expected that with it one could realize Edmond About's fantasy of the "man with the broken ear," but it does appear possible that some human tissues can undergo freezing with liquid air and yet preserve their vitality, notwithstanding the excessively low temperature to which they have been subjected. As a benumbment of local pain, liquid air might be expected to have some value, and experience seems to have demonstrated it, but further than this it has been claimed that it has more than a mere temporary effect in neuralgia. As a local tissue stimulant and a retardant of bacterial activity, its usefulness seems to be assured by Dr. White's experience, while its possibilities in reducing temperature are self-evident. The medical and surgical utilities of this agent are as yet only partially tested, but from what has thus far been shown, its future is apparently a promising one. The facilities for its production have so far been limited mainly to one locality, but if the expectations aroused are realized, which we believe doubtful only to a certain extent, we may expect to see its manufacture widely extended.

HUMBUG AGAINST HUMBUG.

Chicago has been having a very refreshing exposé of the doings of Dowie and his followers during the past two or three weeks. The newspapers have been investigating the sect and have shown that this flourishing crowd has been working its followers and its victims unmercifully. While these revelations have not divulged anything that the members of the profession did not know, it has opened the eyes of the citizens to such an extent that Dowie will probably find it too hot to remain in Chicago. This note, however, is written to call attention to the fact that the "Christian Scientists" have become aware of the fact that the exposé of religious (?) healing might have a bad effect on them, and they have organized a society for the prevention of malpractice in spiritual healing. This amusing development reminds one very much of the thief-catch-thief idea. Just where the difference between Dowieism and Eddyism comes in is not quite easy for us to see. Possibly the followers of Mrs. Eddy have been a little more circumspect in their financial methods, although this is not so extraordinarily self-evident. Another development of the week is the reported "conversion" of Schweinfurth to Eddyism. This fellow, a few years ago, had nearly as large a following as Dowie now has, which promised to develop into a wonderful sect if his actions toward some of his female followers had not aroused the newspapers to show him up. Schweinfurth claimed, if we remember rightly, to be the Christ, and his place he called "Heaven," and it will be interesting to observe what reception he obtains in the major religious-medical sect. The present move of the "Christian Scientists" is a suspicious one in that it appears to be an attempt to exploit their quasi recognition in the Illinois medical practice act. We trust that the authorities will be in no way off their guard, and it is believed they will not. "Christian Science" is in need of as full a dose of legal treatment as is Dowieism itself.

EMPLOYMENT EXCLUSIVELY OF NUTRIENT ENEMATA.

There are times and conditions amid which it is highly desirable to afford rest to the stomach, and perhaps also to the upper bowel, and to avoid the administration of food by the usual channels. Subcutaneous feeding has not proved entirely practicable and at best its field of usefulness can only be limited. The use of the lower bowel for this purpose is attended with certain well-known recognized difficulties and it has not been extensively followed. Of late, however, numerous reports of the administration of nourishment by the rectum have found their way into literature exclusively, and Ross' details the plan of procedure pursued successfully in Ewald's service at the Augusta Hospital of Berlin. Absolute rest in bed is required of all patients subjected to the treatment. In the morning a cleansing enema is given, after the lapse of an hour the first nutrient injection and in the course of the day two further nutrient injections. A soft, vulcanite rubber tube is used, through which, with the patient in the lateral decubitus, the food is slowly injected as high as possible with gentle pressure by means of a syringe. Each enema consists of 250 c.c. of milk, the yolk of an egg, a small quan-

ty of table salt, a small amount of flour and a moderate quantity of red wine, the daily amount reaching about 800 c.c. Pulse and temperature are carefully observed and this treatment is carried out for six days and occasionally longer. The mode of procedure has been successfully pursued in the treatment of diseases of both stomach and bowel, such as gastric ulcer and erosion, with or without hematemesis, gastroenterorrhoea, gastric dilatation and atony, acute and chronic, diarrhea, and in some cases of pulmonary tuberculosis and of chlorosis. When thirst or collapse is marked, physiologic salt solution may be injected into the bowel or beneath the skin. It was found that from 30 to 95 per cent. of the nutrient substances injected was absorbed. It is important that the amount injected be not too large and that the injections be not repeated too frequently and that they be given by competent persons. A small amount of opium may be added if necessary to insure retention. After the sixth day, if all goes well, the patient is put on a milk diet for a week. The milk, cooled, is given at first with a teaspoon, 250 c.c. on the first day, 500 c.c. on the second, and so on, in gradually increasing amounts up to 1500 c.c. At the end of this time purée of potato, and chopped or ground meat may be added; and later light pastry. In the fourth and fifth weeks the diet may be still further enlarged, avoiding alcohol, spices, and tough fibrous vegetables.

Medical News.

DR. W. L. BALLENGER, Chicago, has returned from London, where he went to attend the International Congress of Otologists.

BY THE WILL of the late Dr. Chas. J. Stillé of the University of Pennsylvania, the department of political economy of Yale is to receive \$75,000.

IT IS STATED that the Church Missionary Society of England has received a report stating that 40,000 persons have died of famine on the east coast of Africa.

THE CHAIR of pathology in the University of St. Andrews, Aberdeen, has been filled by the election of Dr. Lewis H. Sutherland of Glasgow, assistant to the late Professor Coates.

DR. E. H. STARLING, F. R. S., lecturer on physiology at Guys' Hospital, has been appointed to the chair of physiology in University College, London, left vacant by Professor Schafer.

THE GOVERNORS of the Toronto Western Hospital have just completed the purchase of the McDonell property on Bathurst St., comprising several acres, and will at once begin the erection of a new structure.

DR. LISTON H. MONTGOMERY sailed from New York City, August 13, on the *Noordland*, for Brussels, to attend the forthcoming international conference for prophylaxis of syphilis and venereal diseases.

ANOTHER Dowie victim is a child of eleven years, of Chicago, who died August 27. The inquest showed that death was due to hydrocephalus. "Elder" Dinius, who had charge of the case, escaped with a censure.

DRS. N. SENN and D. R. Brower, Chicago, have returned from the Hawaiian Islands. An interesting letter from Dr. Brower relating to the Islands, and especially to the lepers there, will be found in the correspondence columns.

AN EPIDEMIC of diphtheria is reported in the northern section of Baltimore, Md., thirty-one cases to date. Dr. Jones, health officer, has secured a large amount of anti-toxin, and is now immunizing affected families and all who have been exposed.

ADVICES to the press state that yellow fever is still spreading in Tuxpan, Mexico, and that on an average ten deaths occur daily. The city of Tampico has taken active steps toward preventing its introduction into that territory.

Dr. McWILLIAMS, Thamesford, Ont., has reported a case of hydrophobia to the Provincial Board of Health, and since then three or four more cases have developed. All of whom will be immediately sent to the Pasteur Institute in New York City.

Dr. F. R. WALTERS, physician of the North-London Hospital for Consumptives, describes the Massachusetts State Hospital for Consumptive and Tuberculous Patients in the *Lancet* of August 19, a page of illustrations accompanying the article.

AT THE county branch of the Manhattan State Hospital for the Insane, N. Y., one male patient was recently killed by another. The men had both been considered harmless, and one was employed in the field grubbing roots when seized with the murderous impulse.

THE AUXILIARY cruiser *Panther*, with provisions and supplies aggregating \$50,000, left Philadelphia on the 23d inst. destined for Porto Rico. It is also stated that the Government will on September 1, dispatch the transport *Wright* from Baltimore, with supplies also destined for that destitute country.

PROF. ROBERT BUNSEN, the noted scientist of Heidelberg, is dead. Professor Bunsen devoted much of his life to analysis of gas, of mineral waters, to the phenomena attending combustion, to stellar chemistry, and was the founder of spectrum analysis. His name is a household word through the burner which bears his name.

Dr. MACNAUGHTON JONES, London, president of the British Gynecological Society, tendered a dinner to some of the members of the International Otological Congress on August 10. Among those present from this country at the dinner were Dr. Barkan, San Francisco; Dr. Dench, New York; Dr. Knapp, New York; Dr. Moore Lindsay, Salt Lake City.

THE MEDICAL faculty of McGill University, Montreal, will commence the session of 1899-1900 with two additional professorships, Dr. T. J. W. Burgess having been appointed to the chair of mental diseases, and Dr. C. T. Martin to the assistant position of classic medicine. Both positions were created at a recent meeting of the corporation of the University. The new professors are both graduates of McGill.

NEW YORK CITY is having trouble in regard to the water-supply of the city passing into the hands of a company, similar to that which occurred recently in Philadelphia, and resolutions have been passed opposing the execution of the proposed contract between the city and a private company, and advocating the continuance of the present policy of municipal ownership in operation of all the city's water-supply.

ANOTHER death attributed to "Christian Science" treatment is reported from Needham, Mass., in the case of a child named James Van Alst Hedenberg. The child became ill with dysentery August 1, and died August 18. The case has attracted considerable interest on the part of the physicians of Needham, and it is

reported that some action will be taken in order to apprehend the guilty party who in this case offers the excuse that she did all she could.

A REPORT of the quarterly examinations, held by the Illinois State Board of Health, August 1 to 4, shows that the following institutions were represented: Barnes Medical College, Beaumont Medical College, and the College of Physicians and Surgeons, St. Louis, Mo.; Northwestern University Woman's Medical College, Chicago, and the University of Erlangen, Germany. The candidates from these institutions all passed.

THE PLAGUE, according to the *British Medical Journal*, August 19, is now officially declared present in Oporto, Portugal, and in Mauritius 40 cases with 32 deaths occurred during the week preceding the report. Reports from Alexandria, Egypt, August 13, show that after a week's interval one fatal case occurred on August 10, and 3 new cases and 2 deaths during the week ending August 13. In Hongkong the number of new cases during the week ending August 14 was 20, with 23 deaths.

THE BOARD OF HEALTH of San Juan, Porto Rico, on August 18 stated that the number of people killed during the recent severe storm in that country was 1973; missing, 1000; houses destroyed, 6421; persons homeless, 22,046; cities in need of physicians, drugs, and hospitals, Caguas, Yabucoa, Maunabo, Utuado, Coamo and Corosal. It is estimated that 2500 persons were killed at Ponce, and that 2000 are still missing. In consequence of the putrefaction of bodies in Arroyo, typhus fever has developed.

PRESS dispatches, dated Liverpool, August 21, state that a cablegram has been received by the Liverpool School of Tropical Diseases, from Major Ross, stating that the malarial mosquito has been found. Major Ross was recently sent by the above-named school to Sierra Leone or the "white man's grave" in Africa, in order to determine the casual relationship existing between the mosquito and malaria. It is reported that the British government will also send out a force of scientists to assist Dr. Ross.

HEALTH OFFICER DOTY, New York City, has officially declared that in view of the appearance of the bubonic plague in Portugal and Italy, the New York Quarantine is fully prepared to prevent its introduction into this country, should any cases arrive on any incoming vessels. The agents for the two steamship lines between New York and Portugal have agreed that from now on, until all danger is past and the disease declared extinct there, no passengers whatever will be carried here by their lines from points in Portugal.

AN EPIDEMIC of typhoid fever is reported from the town of Woodstock, Western Ontario. So far, some twenty odd cases have been reported to the medical health officer, Dr. T. G. Rice, who attributes the prevalence of the disease to the unsatisfactory condition of the wells in that town. Dead toads and other refuse have been allowed to accumulate in many of these wells, and in one, where a child one and a half years of age died from the disease, Dr. Rice reports that no less than a dozen dead toads were found.

FROM OUR foreign exchanges we learn that the Germans refrained from participating in the International Congress of Gynecology and Obstetrics which opened at Amsterdam, August 8, on account of hostility to the president, Prof. Hektor Treub, who spoke so disparagingly of German science on the occasion of Professor Döderlein's call to Groningen, two years ago. Even those who had accepted and whose addresses had been

published, remained away, thus depriving the Congress of its strictly international character. President Treub's address was in French, to which he added a summary, repeating it in turn in English, Italian and Dutch.

As a result of the physical examination made of the soldiers composing the Tenth Regiment of Pennsylvania, who have recently returned from the Philippines, the United States officers in charge at San Francisco announce that there were but few soldiers who were un-sound as a result of the hardships in those islands.

A DOMESTIC, 22 years of age, in Philadelphia, under the influence of bromid of ethyl for the extraction of a tooth, recently died within thirty seconds after the anesthetic had begun to be administered. It is stated that the drug was given in the usual manner, and that the proper precautions had been taken.

EXTENSIVE preparations have been made for the entertainment of the throng of people who will attend the G. A. R. encampment to be held next week in Philadelphia. In order to render proper protection a medical corps consisting of 125 physicians has been organized to attend those who fall ill during the festivities. The members of the committee are: Dr. Lewis C. Wessels; Dr. A. W. Hendricks; Dr. W. H. Zeigler; Dr. W. H. Hult; Dr. W. Batt and Dr. W. W. Lamb. Chief Surgeon T. H. Andrews will be medical director, assisted by Dr. A. H. Hulshizer.

THEY DO things scientifically out in Falls City, Neb. A man there, on August 22, criminally assaulted a little girl, and was quickly arrested and placed in jail; not, however, before a crowd of would-be avengers had tried and failed to get the prisoner away from the officers. Along in the small hours of the morning, several hundred men got together, marched to the jail, broke in the doors, and one of the number—"perhaps a physician," the newspapers have it—"performed a surgical operation which will prevent the prisoner from committing any more such crimes."

WHILE EVERY effort is being made in this country to raise the standard preliminary to a medical education, the French have lowered theirs, and by a recent decree, are to admit graduates from the so-called "modern" course—chemistry, physics and natural history—and no longer exact the diploma of the "classic" course—letters and philosophy. A similar movement has been agitated in Germany, but is frowned on in official circles, which even refuse to accept the classic diplomas of the Swiss universities, on account of the fact that Greek is optional and may be substituted by a modern language.

THE CALIFORNIA ASYLUM TROUBLE.—The investigation into the condition of affairs at the State Lunatic Asylum at Agnews, California, previously mentioned in the JOURNAL, and resulting from the finding of a female patient pregnant, culminated on August 23 in the dismissal of the superintendent of the Asylum, Dr. Sponogle. Governor Gage delivered a lengthy report on the investigation, with its findings, and his own investigation of the evidence submitted. His report says in part: "I have carefully considered all the testimony taken on the 12th and 13th days of July of this year, relating to the investigation of affairs at the State Hospital at Agnews, especially having reference to the unfortunate female patient known as Mrs. Chaffers, and have reached the conclusion therefrom that Dr. Sponogle is and has been culpably negligent in the premises, and from the testimony already taken and also from other investigations had, I have reached the further conclusion that he is and has been a person of immoral character for years,

and should be dismissed forthwith; should be deposed on the ground of incompetency and also on the ground of immorality of character and general unfitness. Such a startling and infamous outrage as has been permitted to fall on this helpless patient is also just cause for the dismissal of both of the other physicians, at least on the ground of insufficient care in the conduct of their offices." The report also alleges other crimes against Dr. Sponogle, who has announced through his attorney, his refusal to retire from his position and his intention to file a suit for \$100,000 damages, for libel and defamation of character, against Governor Gage.

Correspondence.

Hawaiian Islands, Climate, Leprosy, Insanity, Crime.

(Special Correspondence.)

(On Board Steamship *Australia*, en route to San Francisco.)

I left Chicago on July 7, and in three days reached San Francisco, and there met Prof. N. Senn, who had just completed, with great eclat, the Lane lectures at the Cooper Medical College. President Lane of this college, with an unheard of generosity, gives \$2,000 a year for a course of ten lectures, that are intended, first, for the students of the Medical College, and second, for the practitioners of the coast generally. Dr. Senn's lectures were on military and emergency surgery, and were the fourth course. The first course was given by Macewen of Glasgow, on "Cerebral Surgery," the second by Heath of London, on "Practice of Surgery in England," and the third by Clifford, on the "Heart." The course given by Dr. Senn gathered together a much greater number of practitioners than any of the others, and was received with great enthusiasm. The great surgeon added to his laurels by these brilliant lectures. He is now engaged in making them the basis of a new book on surgery.

We left San Francisco on the *Mariposa*, and on the seventh day landed in Honolulu, on Oahu, not the largest, but the most populous of the eight populated islands. Just before entering, our steamer was boarded by Dr. F. R. Day, the port physician, an active member of the Hawaiian Board of Health, and a successful practitioner. But having no sickness on board we were permitted to land without delay. These Hawaiian Islands are a remarkable group; they are in the tropics, and yet the maximum temperature in the shade in Honolulu at sea-level is only 83 F. in August, and the minimum 62.9 F. in February. This remarkable condition is due, probably, to two causes: 1, the constant trade winds from the northeast, bringing coolness from Alaska; and 2, the small size of the islands, the temperature of the ocean being about 80 F. You can have almost any climate you desire: wet or dry, by getting on the windward or leeward side of the islands; warm or cool, by staying at sea-level or ascending the mountains. We spent a week on Molokai Island at an elevation of 1500 feet, and slept under blankets every night.

There was great excitement in Honolulu when we arrived, on account of the recent eruption of a volcano on the Island of Hawaii, and catching the enthusiasm, we engaged passage by the first steamer for this island—the steamer *Kinau*, a little tub, with a capacity for rolling and pitching that exceeded by far any previous experience of either of us, but by maintaining the recumbent posture most of the time I got there without "feeding the fishes." Dr. Senn has had no personal experience with mal de mer, and really enjoyed the trip. Hilo, the principal port of the island, is about 200 miles southwest of Honolulu. The rainfall on this island is greater than that on Oahu, and consequently vegetation is more luxuriant, as it is more tropical. The trip to the volcano was over thirty-one miles of a superb mountain road, through a luxuriant tropical

forest, with here and there a clearing for a sugar or coffee plantation, or a picturesque cottage, surrounded by tree ferns, tropical fruit trees and flowering shrubs. The eruption had ceased before we got there, but we could see the new crater and new lava from the Volcano House, and contented ourselves with visiting the almost extinct crater of Kilauea, the largest, but one, on the island, if not in the world. It is almost circular in form and about three miles in diameter; there is much smoldering fire beneath the lava and considerable steam and sulphur fumes constantly escaping from one portion of it. They have utilized the sulphur fumes at the Volcano House for bathing purposes.

One of the most interesting studies of the islands is leprosy. This disease was introduced from China in 1853, and has spread with frightful rapidity among the natives; somewhat among the other races, but to a very trilling extent among the Anglo-Saxons. The want of resistance to this bacillus, among the Hawaiians, may be due to their almost universal infection by syphilis. The government began the work of segregating them about thirty years ago, selecting for that place a tongue of land on the Island of Molokai, ten miles long and one mile in breadth, bounded by the ocean on one side and a perpendicular precipice 2000 to 3000 feet high on the land side. The soil is fertile, water abundant and pure, and no better place could be found in the country for a leper asylum. The lepers are the wards of the government, and are generously cared for. Numerous cottages have been built for their use and no expense has been spared in having them organize comfortable homes of their own, the property reverting to the government at their death. Every inducement is offered, even to money prizes, to have them cultivate trees, flowers, vegetables, and excellent pasturage is furnished for horses and cows. They are furnished rations, clothing, bedding and, indeed, every thing necessary for their comfort—all this at a cost to the islands of \$100,000 annually. There are now about 1200 lepers at the settlement, only six of them whites. The total population of the islands is 109,000, so that the cost is about \$1 for every inhabitant. The total native population is about 31,000, hence deducting about 200 from the population of the settlement, for those who are not natives, leaves a proportion of 1 to about every 31 of those that are segregated, and they have not been ferreted out. This must be by all odds the largest proportion of leprosy to total population of any nation. There are on the settlement two homes provided by philanthropic individuals, one for orphan girls and helpless women, the other for orphan boys and helpless men; they are in charge of Roman Catholic sisters and lay brothers, who are doing admirably a most self-sacrificing work. It is interesting to note that although this work has been going on for about fifteen years, none of these good people have become infected. One government physician, Dr. Richard Oliver, lives in the settlement, and fills this lonely post with skill and fidelity. He has been there about eight years, and has also escaped infection. The only precaution these faithful workers seem to take is careful cleanliness, especially of the hands. The care of the lepers is directly under the Board of Health, the physicians of which are Drs. F. R. Day, C. B. Wood, N. B. Emerson, R. P. Myers, and H. W. Howard; assisting them are the various government physicians of the islands, of whom there are from three to six on each island. These government physicians, the sheriffs and police find the suspected cases and send them for study and examination to the receiving station, about four miles from Honolulu; here the above medical members of the Board of Health meet and diagnose each case. The examination is very thorough and includes not only the clinical history and physical examination, but in all doubtful cases a bacteriologic study as well. If the case is determined to be a leper, he goes to the settlement as soon as possible; if there is doubt he is called a "suspect" and either remains at the station for further study or is permitted his liberty, but required to report to the government physician at

least once a month, when he is before the board again if necessary. I had the privilege of being present at one of these examinations, and can testify to the care and scientific skill displayed. I was surprised to find that several of the cases had been lepers for two or three years, due to the fact that so soon as a native suspects that he has the disease he hides himself, and his family and friends, having no fear of the disease, aid without hesitation. Leprosy is slowly diminishing. The rate would be more rapid if all cases could be segregated earlier. The average duration of life of the tubercular form is about seven years, of the neurotic form about twenty.

A free discussion of the subject with these several physicians, and my own observation, lead up to the following: The period of incubation is uncertain, probably not less than four years. Heredity diminishes resistance, but alone can not produce the disease. The disease is the result of inoculation. There is a home for the girls of leprous parents at Honolulu, that has been in operation for fifteen years; twenty-five have been under observation for this period and no case has developed and, indeed, in no inmate of shorter duration. The youngest child who has become leprous was 4 years old. Direct evidence in favor of the theory of inoculation are two cases, one, that of a man condemned for murder, who was inoculated in the arm and in due time developed the tubercular form of the disease, in that arm, and died a leper. In this case there has been some contention as to heredity, but I think it well established that while there is and was leprosy in collateral branches, yet there has been none among his direct progenitors. The other is the case of a German, who, with a varicose ulcer, slept in a bed, on several occasions, that had been occupied by a leper with the tuberculous form; after about eight years he developed the disease in that limb and died a leper.

Dr. L. F. Alvarez, the accomplished bacteriologist of the Board of Health, is earnestly endeavoring to procure pure cultures of the bacillus of Hansen and to produce the disease experimentally. He thinks he has made some impression on the mongoose, an animal imported to destroy the rats in Hawaii, but further inoculations are necessary. The very close morphologic relation of this bacillus to that of tuberculosis is interesting, being so near like it that an expert is necessary to differentiate. Yet their natural history is different.

The palliative treatment found most beneficial is hot baths, tonics, iron, quinin and strychnin, intestinal antiseptics, salad especially, and an abundance of easily digestible and nutritious food. I have no doubt the native's diet, consisting almost entirely of "poi," a preparation made from the taro, a plant much like arrow-root, and fish, usually raw, has something to do with his want of resistance to the bacillus lepre. There is much said in Honolulu of the benefits to be derived from the baths of Kusatsu Hot Springs, Japan. Sulphur is the principal ingredient, in the form of sulphates of iron, aluminium, calcium, magnesium, soda and potash, with a large percentage of free sulphuric and hydrochloric acids. This water, artificially prepared at the settlement, has been found no better than ordinary hot water. The springs are situated in the mountains in a very salubrious climate, which doubtless has much to do with the benefits derived—no cases have been cured.

Our recent acquisition of territory, and our close commercial relations with China and Japan make the question of leprosy one of increasing importance.

We visited the Oahu Insane Asylum with Dr. F. H. Humphris, the acting superintendent, and found there 89 males and 23 females; the excess of males is quite surprising. We found every patient out of doors under the shade trees, or on verandas; such is the climate that this is possible every day of the year, artificial heat never being necessary. Of the numbers above given, 35 were Hawaiians, 33 Chinese, 3 American. The number of Chinese on the island almost equals the number of natives. Paresis, paranoia and suicides are never

found among the natives, and the types they do present are not very active. The buildings, ground and general management deserve commendation.

The great questions of criminology must be considered more seriously by the people of the islands as elsewhere, for here, also crime is increasing. I visited, with Dr. Chas. B. Cooper, the Oahu Prison, the penitentiary of the islands. We found there 155 males and 1 female, who were as well taken care of as possible. I have no doubt they will soon erect a new building and arrange for the better employment of these delinquents. From the last report of the Attorney-General of the Republic, there were in two years 19,177 arrests and 13,344 convictions. This is no small proportion for a population of only 109,000. The total number of prisoners in jails was 1325 during the period of 1896-1897; of these 937 were for misdemeanors, the principal being drunkenness, gambling and possession of opium. The crimes against property and persons number 288, of which the chief were larceny, assault with weapons, and distilling liquor. The number of criminal cases before the Supreme and Circuit Courts has increased in ten years from 165 to 837.

We left the islands with great reluctance, and will ever be mindful of the generous hospitality that we met on every side, well satisfied that in these gems of the Pacific we have a great acquisition, and one in which most important racial problems are in process of solution, regretting that without any prophetic power one can easily see the passing of the Hawaiian.

D. R. BROWER, M.D.

The Government Hospital for the Insane.

NEW YORK CITY, Aug. 20, 1899.

To the Editor:—Notwithstanding the fact of numerous applicants for the post of superintendent, the vacancy in the Government Hospital for the Insane yet awaits a successor to the late incumbent whose death occurred several months ago. We learn from Washington that the delay in making the appointment is a matter of no small concern among those interested, who are chiefly the applicants for the position, the hospital attendants and the inmates themselves, many of whom, though of unsound mind, have enough intelligence to feel and express a lively interest in the matter.

That this institution, so well endowed by the Government, and having so many possibilities in the way of clinical material that might be utilized for the advancement of science, should have a competent specialist in mental and nervous diseases as its medical head is a consummation devoutly to be wished. We have no unkind remarks of any sort to make concerning superintendents of insane asylums, many of whom are among our best friends, but candor forces us to admit that as a class they have been criticized for old fogyism and non-progressive-ness. At a meeting of the AMERICAN MEDICAL ASSOCIATION, a few years ago, it was the general agreement of the speakers who debated the question that when a member of our profession becomes the superintendent of an insane asylum he ceases to be a physician, his multifarious duties obliging him to be a farmer, a politician, a gardener, jailer, boarding-house keeper, disbursing officer, and the like. Besides, it does not appear that any one ever connected with an insane asylum has made any important discovery regarding the brain or nervous system, nor has any one of them written a book of importance, or done anything to improve the condition of the insane; all such discoveries and improvements having originated with persons unconnected with asylums, just as advances in army sanitation and in ordnance have originated with civilians.

Despite these facts, it is a common fallacy among the populace, and even among lawyers otherwise well informed, that a superintendent of an asylum must necessarily know a great deal about insanity, and his testimony is accordingly often sought in courts where a medicolegal question is being considered; but as a matter of truth, most of them are profoundly in-

nocent of any great erudition in psychiatry or neurology, and lack the accuracy, credibility, and skill of the real expert. On this subject a high authority compares the janitor of a medical school, who for years sees cadavers come into the dissecting-room by the hundred, but does not know as much about anatomy as any intelligent medical student who has dissected but half the body. It is therefore not the great number of cases of insanity that one sees, but rather the amount of intelligent study and observation brought to bear on a few cases that make one an expert.

It is probably owing to the false system of selection, more than to other causes, that the services of incompetent men are secured in asylums. Few of them, before appointment, have had either practical or theoretic experience in the treatment of mental or nervous disease, while those who have had asylum experience, having seen chronic cases only, are totally unfamiliar with the incipient stages of insanity and are uninformed in contemporary neurology. Hence, it is not surprising that a superintendent of an asylum adds luster to the profession when on the witness stand, in a matter of life and death, he solemnly tells the court there is no such thing as nocturnal epilepsy; that quinia has no effect on the brain; that heredity is not a factor in insanity; and that there is no such thing as hysteric insanity, or he would have heard of it in his thirty years of asylum experience.

An average medical student in his first course would make a better showing than this, although he may not know that at least fifty treatises have been written on hysteric insanity; that it is also mentioned in Le Grand Du Sault's "Legal Medicine," and in Campbell Clark's "Mental Diseases," not to mention the fact that numerous cases are treated by neurologists.

Arraignment, we are aware, does not include the whole class of whom we write, for judicial fairness obliges us to say there are notable exceptions, but to particularize them would be invidious and foreign to the present purpose, which is merely to express condemnation of a vicious system of appointment that secures incompetent men.

We trust that President McKinley, in making a selection, will secure the services of some competent and up-to-date neurologist who has the confidence and support of his colleagues. That there are such among the members of the American Neurological Association, we all know, but it is a matter of grave doubt whether the small salary attached to the position is an inducement that would tempt any specialist of the kind with even a fair practice.

Locomotor Ataxia Has No Relation With Syphilis.

NEW YORK CITY, August 25, 1899.

To the Editor:—The German correspondent of the *Phila. Med. Jour.*, August 19, page 333, speaking of Heidelberg clinics and the dread nature of syphilis, says: "Professor Erb, from his researches in one thousand cases, believes that 'tabes' (locomotor ataxia) is almost without exception due to syphilis."

How would Professor Erb explain the fact, that in Japan, where syphilis has scourged the population for 1300 years, locomotor ataxia is unknown? In a venereal clinic of ten thousand cases I did not find a single case of locomotor ataxia. Nor did I meet a native physician who knew of such a disease as "tabes."

Opposed to this opinion of Professor Erb, in Germany there stands that of Professor Virchow, who believes that syphilis has no relation whatever to locomotor ataxia.

ALBERT S. ASHMEAD, M. D.

[Apropos of the above from Dr. Ashmead, we quote the following abstract from the August number of the *Journal of Nervous and Mental Disease*, referring to a paper on "Tabes Dorsalis and Syphilis," by A. Guttmann (*Zeitschr. f. Klin. Med.*, 35, 1898, p. 212): "The reaction, evident of recent years, against the view of the etiological significance of syphilis in

tabes, is made more pronounced in the statistics of the author. In all some 136 cases of tabes were closely studied, and of these, deducting six doubtful cases, 28.6 per cent. had had syphilis, while 71.4 per cent. were distinctly nonsyphilitic." The author also considers the evidence derived from the fruitfulness of syphilitic medication, and gives his approval of the general methods used to strengthen the body—baths, massage and electricity."—[Ed.]

"The Spooner Bill."

MILWAUKEE, Wis., August 26, 1899.

To the Editor:—In a communication from Dr. H. M. Bracken of Minneapolis, in the August 5 number of the JOURNAL, appears the statement that, at the annual meeting of the Conference of State and Provincial Boards of Health of North America, held at Richmond, Va., "as a matter of fact there were probably not more than twenty voters in the room when an indorsement of the Spooner bill was called for." This statement gives the impression that the Spooner bill was indorsed at this Conference by a very small faction. The facts are, however, that by actual count there were thirty-six in the room at the time the vote was taken, and when it is borne in mind that those thirty-six represented about twenty or more states in the Union, the vote was more significant than would appear by Dr. Bracken's statement.

The positive statement in the communication of Dr. Bracken: that "the Spooner bill will never give an organization established on as firm a foundation as the army or navy, or the marine-hospital service" strikes one with astonishment when one considers its source as against the combined intelligence of the AMERICAN MEDICAL ASSOCIATION, the largest medical organization in the country, and the American Public Health Association, the largest sanitary body in the world, and the New York Academy of Medicine, together with many state medical societies and the great majority of leading sanitarians of the country.

Respectfully,

U. O. B. WINGATE, M.D.

London.

(From Our Regular Correspondent.)

LONDON, Aug. 15, 1899.

BRITISH MEDICAL ASSOCIATION.—Whatever benefit the recent unprecedented hot weather may have been to the harvest, it sadly interfered with the success of the sixty-seventh annual meeting of the British Medical Association at Portsmouth. The most hospitable and elaborate arrangements had been made by the local committee, but of the 1890 members anticipated hardly 800 turned up, and the Isle of Wight and the New Forest saw more of a third of these than did the sections. And no wonder, for the weather was stiflingly hot. The president's address was delivered to a fair audience, largely of townspeople; the address in medicine had about 200 hearers—at the beginning; the address in surgery had hardly 75, and the final general meeting could not have secured a quorum if two dozen were the minimum. The medical and surgical sections were, as usual, the best attended, with about 150 to 200 in each, but the oft-denounced "lack of interest in scientific medicine" brought the attendance at the section on pathology down to an average of about fifteen, and in that of anatomy and physiology there were at one painful epoch precisely three persons present in addition to the chairman and the reader of the paper. These facts are mentioned not in any fault-finding or even critical spirit, for considering the weather and the abominable ventilation of the rooms, with reference to the limits of human endurance, the attendances were excellent, but simply to console those of our own brethren who think the American profession is "going to the dogs," because the excursions and entertainments seem to draw more attention and attendance than the scientific sessions of the A. M. A. Even the English profession, with its high standards and solemn sense of duty and

dignity, is human like the rest of us—and we like it all the better for it.

A curious touch of picturesqueness and ceremony was given to the general meetings by the custom observed by the president of the Association and the deliverers of the addresses, of appearing in the scarlet gowns of their university or college degrees.

The rôle played by the general meetings was certainly much less than our own annual gatherings, the real business of the Association being evidently transacted by the powerful, well-organized General Medical Council. After the addresses had been delivered, the "business" matters were often discussed by a mere handful of members, there being almost as many on the platform as in the body of the hall, at times. There seems to be a general impression that the Council shapes the ends of the Association about as it chooses, let the members roughen them as they will, and so this gentle amusement is left to a mere handful of hopeful enthusiasts. A vote of censure was passed on a certain action of the Council at this meeting by a vote of 16 to 5, and some 800 members were registered as in attendance.

The management of the programs in the sections was excellent, most of the papers were mercifully short and to the point, and the discussions followed suit. Those who ran over their time were promptly checked, either by the chairman or by a most unmistakable change in the atmosphere at the meeting. There was no attempt to lay out a complete program for the four days, the list of papers for each day being issued early that morning, and those who were to read being notified the evening before. There was the usual overcrop of papers, but by grouping together papers on kindred subjects for simultaneous discussion, or introducing epitomes of them into such of the big discussions as they were germane to, the docket was cleverly cleared in nearly all sections. The great discussions on set subjects were the chief centers of interest and attendance, as with us. No better way of getting a clear and illuminating working conception of a subject or problem, from all points of view, has yet been invented. Their only fault is that they flatten the separate papers into a hopeless background, and the object of such meetings is to encourage original work as well as to diffuse information and broaden the view of the profession.

VACCINATION.—The Leicester Board of Guardians has decided not to appeal but go manfully to prison, sooner than comply with the mandamus and appoint a vaccination officer, as referred to previously in these columns.

Canada.

(From Our Regular Correspondent.)

TORONTO, Aug. 26, 1899.

CEREBROSPINAL MENINGITIS IN ONTARIO.—The bacteriologist of the Provincial Board of Health, Dr. John J. Mackenzie, in his report before that body, deals with this subject. The laboratory during the first four months of the year, received four specimens from cases of suspected cerebrospinal meningitis. After dwelling on the characteristic differences between the diplococcus of pneumonia and the specific organism of cerebrospinal meningitis, the diplococcus intracellularis meningitidis, and the appearance of epidemics within the past year in Boston, Baltimore and Philadelphia, he states the first specimen was received on March 20, 1899. To quote from the report: "The specimen was from a fatal case with an illness of about forty-eight hours. The specimen consisted of about 25 c.c. of bloody cerebrospinal fluid, with a white sediment and containing white flocculi. On centrifuging it separated into a layer of reddish sediment with a clear blood-stained fluid above. A number of cultures were made from the material on different media, but they all remained sterile. Stained preparation showed that the sediment consisted of red blood-corpuscles, polynuclear leucocytes and large mononuclear leucocytes. Certain of the polynuclear leucocytes contained diplococci some-

what flattened 1.0 m. by 0.75 m. in pairs. These organisms did not take the Gram stain. Two grey mice were inoculated, one subcutaneously with .5 c.c. of the fluid, the other intraperitoneally with .25 c.c. of the same material. Both animals lived, the second showing slight illness for a day. The germs were apparently dead when received. "Within a month, three other specimens were received from the same county; but in no case could a positive diagnosis be made, although in one the same intracellular diplococci were found." Dr. Mackenzie emphasizes the importance of physicians throughout the Province making thorough diagnoses in these cases in order to prevent the possibility of any epidemic such as occurred in Boston and elsewhere.

THE GRASS BACILLUS.—The same bacteriologist has also lately been making investigations into the character of a bacillus found in grass, resembling the tubercle bacillus. He states in the same report, this bacillus was first described by Moeller, but that its first recognition was due to Rabinowitch, in butter. Dr. Mackenzie found this organism present in different specimens of hay, and from one succeeded in isolating it in pure culture. "Its growth in culture-media is not unlike that of the bacillus of tuberculosis except that it is much more luxuriant and rapid. It stains with ordinary tubercle stain, and in cover-glass preparations looks so like the tubercle bacillus as to give rise to doubt to one not well acquainted with the true form." He was able to demonstrate that its peculiar staining characters were due to a fatty envelope, as in the bacillus of tuberculosis. This fatty envelope can be readily dissolved off with alcohol, and on being boiled in the same medium the organism will not then take the peculiar stain. There is danger of confusing it with the tubercle bacillus in butter and milk.

STUDYING THE TENIA ECHINOCOCCUS IN MANITOBA.—Dr. Gordon Bell has been making experimental studies in the laboratory of the Manitoba Medical College. From Dr. Chown of the same city, Winnipeg, who had operated on the liver of a patient, the experimenter received a few hours after such operation, daughter hydatid cysts, which he fed to two dogs. Subsequently, after the lapse of five weeks, one of the dogs was killed, but either on account of the time being insufficient for the development of worms, or else because of the scolices being unable to obtain a hold—the animal being affected with an intestinal catarrh at the time, there was nothing whatever found. In the case of the other dog, nine weeks were allowed to elapse before the animal was killed and examined, when it was found that hundreds of mature tenia infested the lower part of the duodenum and upper part of the jejunum. Their appearance was that of delicate white filaments, ranging from 1/8 to 1/6 of an inch in length, the head being firmly planted in the villi of the intestine. They could not be dislodged under the force of a stream of water, and even after being placed in a solution of formalin, they still retained their hold. Viewed microscopically they consisted of four segments, the last one alone containing eggs, and in some of them the proscelox could be made out quite distinctly. Clear refractive granules were scattered throughout all the segments, including the head, but their significance not determined. This was the first instance of the mature tenia having been demonstrated in Manitoba, although hydatid cysts are more common there than in any other part of America. Still withal, there is no instance of a case having originated in this country, they being without exception imported from Iceland.

SEWAGE FARM AT MONTREAL.—Montreal is to have a sewage farm; and it is expected that the work, which is an experiment on the part of that city, will be fully completed by September 1. The plan, which is similar to that in several English and Continental cities, in Canton, Ohio; in Marlboro, Mass.; at the Asylum for the Insane in London, Ont., at the St. Laurent College and in St. Laurent, Jacques Cartier County, P.Q., consists in bringing the sewage waters on a field prepared especially to receive them. Then they are filtered through the earth, purified

and ultimately returned to their natural water-courses. In this case the natural water-course will be Back River. The farm comprises an area of ten acres, which will be used as a truck farm with thirty beds, 77x100 feet across, which will be employed for the purpose of raising melons, cauliflowers, cucumbers, etc. The tank-house will be twenty-four feet square, and the work of laying the pipes is now proceeding under the direction of the contractor. Nothing will be lost by this system; the waste separated from the water, by filtration, will become in turn fertilizer for the farm. The sewage will be passed through large eighteen-inch mains, and the water, filtering down through the earth, will then pass through perforated farm tiles laid three and one-half feet underground, covered over with one foot of coke. When completed the work will cost in the neighborhood of \$20,000.

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

Acknowledgement of all books received will be made in this column, and this will be deemed by us a full equivalent for those sending them. A selection from these volumes will be made for review as dictated by their merits, or in the interests of our readers.

INTERSTITIAL GINGIVITIS OR SO-CALLED PYORRHEA ALVEOLARIS. By Eugene S. Talbot, professor of Dental and Oral Surgery, Northwestern University, Etc. Octavo. Cloth. Pp. 192. Seventy-three illustrations. Philadelphia: The S. S. White Dental Mfg. Co. 1899.

TEXT-BOOK OF DISEASES OF THE NOSE AND THROAT. By D. Braden Kyle, M.D. Clinical Professor of Laryngology and Rhinology, Jefferson Medical College; Consulting Laryngologist, Rhinologist and Otologist, St. Agnes' Hospital; Bacteriologist to the Philadelphia Orthopedic Hospital and Infirmary for Nervous Diseases, Etc. Octavo. Illustrated. Pp. 646. Price, Cloth, \$4.50; Sheep, \$5. Philadelphia: W. B. Saunders. 1899.

THE HYGIENE OF TRANSMISSIBLE DISEASES: THEIR CAUSATION, Modes of Dissemination and Methods of Prevention. By A. C. Abbott, M.D. Professor of Hygiene and Bacteriology, and Director of the Laboratory of Hygiene, University of Pennsylvania. Octavo. Cloth. Illustrated. Pp. 312. Price, \$2. Philadelphia: W. B. Saunders. 1899.

GENERAL PATHOLOGY, or the Science of the Cause, Nature and Course of the Pathologic Disturbances which occur in the living subject. By Dr. Ernst Ziegler, Professor of Pathologic Anatomy and of General Pathology of the University of Freiburg in Breisgau. Translated from The Ninth Revised German Edition, by Drs. Theo. Dunham, E. M. Foote, Philip H. Hiss, Jr., Walter B. James, Wm. G. Le Boutillier and Matthias Nicoll, Jr., New York, Dr. B. Meade Bolton of Philadelphia, and Drs. Leonard Woolsey Bacon, Jr., John S. Ely, and R. A. McDonnell, New Haven, Conn. Editor, Dr. Albert H. Buck of New York. Complete in one octavo volume of 621 pages, illustrated by 544 wood engravings in black and numerous colors, and lithographic plate. Extra muslin, \$5, net; brown sheep, \$5.75, net. New York: Wm. Wood & Co. 1899.

TRANSACTIONS OF THE AMERICAN MICROSCOPICAL SOCIETY. Edited by the Secretary. Twenty-first annual meeting held at Syracuse, New York, Aug. 30, 31 and Sept. 1, 1898. Volume XX. Octavo. Paper. Pp. 369. Lincoln, Neb.: Hunter Printing Co. 1899.

MIND AND BODY, HYPNOTISM AND SUGGESTION APPLIED IN THERAPEUTICS AND EDUCATION. By Alvan C. Halphide. Illustrated. Octavo. Cloth. Pp. 231. Chicago: Published by the Author. 1899.

SELECTED PAPERS ON STONE, PROSTATE AND OTHER URINARY DISORDERS. By Reginald Harrison, F.R.C.S. 8vo. Cloth. Pp. 190. Price, \$1.75. London: J. & A. Churchill. Philadelphia: P. Blakiston's Son & Co.

THE GROSS AND MINUTE ANATOMY OF THE CENTRAL NERVOUS SYSTEM. By H. C. Gordinier, A.M., M.D. Professor of Phys-

iology and of the Anatomy of the Nervous System in the Albany Medical College; with 48 full-page plates and 213 other illustrations, many of which are printed in colors, a large number being from original sources. Octavo. Price, net, \$6, cloth; \$7, sheep. Philadelphia: P. Blakiston's Son & Co. 1899.

ARCHIVES OF THE ROENTGEN RAY (formerly Archives of Skiagraphy). Edited by THOMAS MOORE, F.R.C.S., and Ernest Payne, M. A. (Cantab.). Nos. 3 and 4. Quarto. Illustrated. Price \$1 a part. London: The Rebmam Publishing Co. 1899. American Agent, W. B. Saunders, Philadelphia.

PRACTICAL ANATOMY, including a Special Section on the Fundamental Principles of Anatomy. Edited by W. T. Eckley, M. D., Professor of Anatomy in the College of Physicians and Surgeons, University of Illinois; Professor of Anatomy in the Northwestern University Dental School; Professor of Anatomy in the Chicago Clinical School, Etc. With 347 illustrations, many of which are in colors. Octavo. Price, \$3.50, net, cloth; \$4, net, oil-cloth. Philadelphia: P. Blakiston's Son & Co.

A TEXT-BOOK OF PHARMACOLOGY AND THERAPEUTICS, OR THE ACTION OF DRUGS IN HEALTH AND DISEASE. For the use of Students and Practitioners of Medicine. By Arthur R. Cushny, M.A., M.D., Aberd. Professor of Materia Medica and Therapeutics in the University of Michigan Medical Department, Ann Arbor. In one octavo volume of 728 pages, with 47 engravings. Cloth, \$3.75, net. Philadelphia and New York: Lea Brothers & Co. 1899.

INTERNATIONAL CLINICS: A Quarterly of Clinical Lectures on Medicine, Neurology, Surgery, Gynecology, Obstetrics, Ophthalmology, Laryngology, Pharyngology, Rhinology, Otology and Dermatology, and Specially Prepared Articles on Treatment and Drugs, Etc. Edited by Judson Daland, M.D. Volume II, Ninth Series 1899. Octavo Cloth. Pp. 310. Philadelphia: J. B. Lippincott Co.

Deaths and Obituaries.

MAX THORNER, M.D., Cincinnati, Ohio, a graduate of the University of Munich, Germany, 1884, died suddenly August 26 at his home in Cincinnati. Dr. Thorner was 40 years of age, professor of clinical laryngology and otology in the Cincinnati College of Medicine and Surgery; laryngologist and aurist to the Cincinnati Hospital, and a member of the Cincinnati Academy of Medicine. AMERICAN MEDICAL ASSOCIATION, Ohio State Medical Society, and others. He was also at one time president of the Cincinnati Medical Society and was secretary of the section on otology at the first Pan-American Medical Congress. He was a Fellow, and in 1889 vice-president of the American Laryngological, Rhinological and Otological Society, and a Fellow of the Berlin Laryngological Society and the American Academy of Medicine. At a called meeting of the medical profession, August 28, on which occasion Dr. E. W. Mitchell, president of the Academy of Medicine of Cincinnati, presided, the following resolutions were adopted:

WHEREAS, The medical profession of Cincinnati having met on Monday, August 28, for the purpose of taking action on the death of Dr. Max Thorner, adopted the following resolutions:

In the death of Dr. Max Thorner the profession has suffered a severe loss. He was a man of eminent professional attainments and broad, progressive and generous character. He was a man of high ideals and constantly strove to attain the greatest possible professional skill. His devotion to the science of medicine was intense and disinterested, and in all his relations with his fellowmen his zeal for what was good and worthy distinguished him.

The profession has lost a beloved member and the public a citizen of probity, learning and industry.

The medical profession desires to extend to the bereaved family its sincerest sympathy.

T. V. FITZPATRICK,
PHILLIP ZENNER,
H. W. BETTMAN,
WM. C. HARRIS,
A. H. FREIBERG,

Committee.

Also at this meeting the following resolutions from the medical staff of the Cincinnati Hospital were read:

WHEREAS: We learn with profound regret of the death of our esteemed colleague, Dr. Max Thorner. Therefore be it

Resolved, That in the death of Dr. Thorner the Cincinnati Hospital has lost a very able and useful member of its medical staff. One whose conscientious and honorable conduct rendered his services especially valuable to the institution.

Resolved, That the members of the medical staff extend their sympathy to the family of the deceased in its sudden and untimely bereavement.

J. C. OLIVER,
G. A. FACKLER,
S. E. ALLEN,
Committee.
W. EDWARDS SCHENCK,
Secretary of Meeting.

JOHN J. LINSON, M.D., New York Medical College (now extinct), 1856, died of cardiac disease at Tarrytown, N. Y., August 27. He was a Civil War veteran, having served with the 6th New York Heavy Artillery, and was at one time surgeon of the provost marshal's office in his residential district. He leaves two daughters and four sons, one of them ex-Senator John J. Linson of Kingston, N. Y.

SAMUEL BROWN WYLLIE MCLEOD, M.D., died at his home in New York, August 23, after a brief illness, remotely attributable to an accidental fall from a trolley car. He was of Scottish ancestry, a son and a grandson of a clergyman, as well as a cousin of the late Dr. Cornelius R. Agnew. His birthplace was Galway, N. Y., and his entrance on a collegiate career began in 1849 in his 20th year, at the University of Pennsylvania, while his grandfather was both provost and professor of languages. After graduation in 1852 from the College of Physicians and Surgeons, New York, he went to Paris for the continuation of his studies. His life was full of medical and charitable activities, besides being identified with the theological seminary attached to the church over which his father presided. As a staunch member of the AMERICAN MEDICAL ASSOCIATION and a high official in many medical societies he was widely known to the profession. He was an authority on obstetrics and to a certain extent in medical jurisprudence.

J. PEMBERTON THOM, M.D., Baltimore, Md., died August 21, after an illness of six months. He was born in Culpeper County, Va., 71 years ago, and served gallantly throughout the Mexican War. He was graduated at Jefferson Medical College and entered the navy as surgeon and had been a member of the City Council and Speaker of the House of Delegates of Maryland. He was also one of the founders of the Hospital for the Women of Maryland. Dr. Thom retired from practice a number of years ago.

JOSEPH COBLENTZ, M.D., formerly of Reading, Pa., died, aged 72 years at Vaughn, Wash., August 6.

SAMUEL B. GILMORE, M.D., a graduate with the last medical class of the University of Pennsylvania, died in Philadelphia from typhoid fever, August 13, aged 23 years.

ALEXANDER CRAIG, M.D., Jefferson, 1865, died of apoplexy, aged 61 years, at his home in Columbia, Pa., August 17.

JAMES L. KORTRIGHT, M.D., College of Physicians and Surgeons, New York, 1881, formerly of Brooklyn, N.Y., died at Middletown, N.Y., August 14. He was born in Brooklyn in 1859, and as a gynecologist was favorably known. He was at one time an attending physician at the Kings' County Hospital, New York State.

WILLIAM A. JACOBS, M.D., Centre Hall, Pa., died in that township on August 16. Dr. Jacobs served in the Civil War as second lieutenant of Company G., 148th Pa. Vols. He was a graduate of the University of Pennsylvania.

JOHN FISHER, M.D., aged 38, died August 15, of hemorrhage of the lungs, in Baltimore. He was born in Germany and came to Baltimore thirty-two years ago, and received his degree of M.D., from the College of Physicians and Surgeons of Baltimore in 1862.

GEORGE W. AMMON, M.D., Reading, Pa., died August 13, aged 37 years. . . . Randolph V. Barksdale, M.D., Danville, Va., August 21, aged 83 years. . . . John Binney, Mount Olive, Ill., August 14. . . . S. G. Blythe, Nora Springs, Iowa, August 10. . . . John W. Dederick, M.D., St. Francisville, La., August 19, aged

80 years. . . John S. Harris, M.D., Dublin, Miss., August 8. . . R. C. Holladay, M.D., Hot Springs, Ark., August 23. . . J. M. Logan, M.D., Kansas City, Mo., August 12, aged 54 years. . . J. C. Maxwell, M.D., Greenwood, S. C., August 12, aged 62 years. . . Julius Northleifer, M.D., St. Louis, Mo., August 14, aged 43 years. . . Emory Pedigo, M.D., Edmonston, Ky., August 11, aged 55 years. . . Joseph Shields, Punksutawney, Pa. . . Andrew Schrenk, M.D., New York City, August 20. . . Edward Sprague, Cornopolis, Pa., August 12, aged 65 years. . . Edward T. Shepard, New Orleans, La., August 12, aged 55 years. . . James L. Stone, M.D., Roanoke, Va., August 17.

DEATHS ABROAD.

Professor Balbiani of the College de France, the last of the group that surrounded Claude Bernard. His research in comparative embryology, histology and physiology is now classic. Descended from a titled Italian family, he was born at Havana in 1823, educated in Germany, and became professor at Paris, where he founded the *Archives d'Anatomie Microscopique*.

Canadian Medical Association.

(Thirty-Second Annual Meeting, held in Toronto, Ont., Aug. 30, 31 and Sept. 1, 1899.)

[Telegraphic report by the JOURNAL'S Special Representative.]

FIRST DAY—MORNING SESSION.

The opening session was held in the normal school building, at 10:30 a.m., under the presidency of Dr. Irving H. Cameron of Toronto, Dr. F. N. G. Starr of Toronto acting as secretary. After the routine business was transacted, Dr. A. J. Johnson presented the report of the Committee on Arrangements for the guidance of visiting members to the city.

SIGNIFICANCE OF BOVINE TUBERCULOSIS.

PROF. J. GEORGE ADAMI, of McGill University, Montreal, read a paper on the "Significance of Bovine Tuberculosis and Its Eradication and Prevention in Canada." He pointed out that, in connection with this, three main questions have to be asked and answered: 1. Is tuberculosis in cattle a source of danger to other cattle, so as to seriously affect their well-being and to be a source of loss to the owners? 2. If infectious from animal to animal, is it infectious from animal to man and thereby a grave source of danger to the human race? 3. If infectious from animal to man, what are the commonest modes of infection and, as a sequel to this, how are we to diminish the danger?

To the first question he gave an unqualified affirmative answer and further stated, we have abundance of evidence here in Canada that the introduction of an infected bull into a herd previously free from the disease, has been followed within a short time by symptoms of the disease in members of the herd. He then proceeded to compare statistics between Canada, Berlin, Leipzig, Saxony, Bavaria, England and Scotland, to the infinite advantage of his own country. These were taken from slaughter-house records. In Leipzig alone, from 1868 to 1895, the spread of the disease, according to tables by Professor Conn, shows a growth of from 11.1 to 33.3 per cent. Comparing these with statistics of our own country, he stated, no country could point to such favorable results as in Canada. Of 90,000 cattle inspected at Montreal in 1894, only sixty animals were rejected by the inspectors and, of these sixty, two were recognized as suffering from tuberculosis, and even in these this was local.

The Doctor emphasized the importance of keeping all imported cattle for breeding purposes in quarantine for at least seven weeks, when, if at that period they fail to react to the tuberculin test, they may be handed over to their owners. He then considered the results of this disease on the animal itself as to its value as a milker, breeder and meat giver.

His answer to the second question was unhesitatingly affirmative, but he thought the reliable evidence of direct transmission of tuberculosis from cattle to man, singularly slight. After demonstrating the differences between bacilli gained from the human and bovine species, he took up the question of children developing the disease through the alimentary canal, by the milk of tuberculous cattle, and stated that there was a lack of positive evidence afforded in these cases. So far as he can see there is no large tract of country in the North Temperate Zone in which cattle are so free from tuberculosis

as are the Canadian cattle. In 1894, the lungs of 2504 animals were examined in the abattoirs of Montreal, St. Johns, N. B., and Halifax, N. S., and among these there were only fourteen cases of tuberculosis, a percentage of 0.6. No other country can show such low figures. Speaking of prevention, a corps of inspectors might be empowered to make complete and perfect visitations, kill off all animals showing clinical evidence, isolate or buy at full value and place on government reserves all animals reacting to tuberculin.

The discussion on the different matters dealt with in the paper was by Professor Oldright of Toronto University, Dr. J. J. McKenzie, bacteriologist to the Ontario Provincial Board of Health, Dr. Clarence Starr of Toronto, Dr. Turnbull of Pennsylvania, Dr. P. H. Bryce, secretary of the Provincial Board of Health of Ontario, and Drs. Roddick and F. Montzambert of Ottawa.

RESULTS ALREADY ACHIEVED AT THE MUSKOKA COTTAGE SANITARIUM.

DR. J. H. ELLIOTT, medical superintendent of this institution, presented this topic, giving the results already achieved there and a detailed historic review of the establishment of this institution, with the present methods of management. He stated, in his classification of cases, that he followed Trudeau, employing the terms incipient, advanced and far advanced. On discharge they are classified under the terms: "Apparently cured," "disease arrested," "improved," "stationary," "failed" or "died." After defining these terms, the Doctor gave a statement of 72 cases discharged during the last nine months of the year up to June 30, 1899. The average stay was 152 days. Of the 72 cases, 61 had bacilli on admission and 47 had them when discharged. A total of 25, or 35 per cent. of those treated, had no bacilli on discharge. Of the 72, 83 per cent. gained in weight, the average gain being 11½ pounds. The maximum gain for one month was 18 pounds, and the maximum total gain 43 pounds. This, Dr. Elliott stated, was a much more satisfactory result than achieved in the first year of the institution's history. Of the 17 incipient cases, 11 or 65 per cent. were apparently cured; 80 per cent. might have been with a longer stay. From twelve to eighteen months have now elapsed since the discharge of the patients of the first year. Twelve were reported apparently cured, and in none of these has there been a return of the cough, and all are in perfect health.

The treatment, broadly speaking, is rest when prexia is present, regulated exercise in apyretic cases, suitable diet, and hygiene and fresh air the entire twenty-four hours daily. There is constant supervision of the patient's daily life.

Dr. Powell of Ottawa, Dr. Lafferty of Calgary, N. W. T., Dr. N. A. Powell of Toronto, and Dr. T. H. Adams of Toronto discussed this paper.

FIRST DAY—AFTERNOON SESSION.

"CHRISTIAN SCIENCE."

Prof. J. H. Richardson of Toronto University was the essayist on this subject, and the manner in which he dealt with Eddyopathy was singularly effective. He elicited a good bit of hilarity from his auditors when he announced that this illustrious, or rather notorious, expounder of this "ridiculous muss," as he styled it, had thrice been left a widow. His remarks were closely followed, being both humorous and sober.

PRESIDENT'S ADDRESS.

DR. I. H. CAMERON delivered a scholarly address, taking for his subject the overcrowding of the profession and the means necessary to overcome this evil. He pointed out that all students, before entering on medical studies, should have a good English education. This would no doubt keep out undesirable practitioners. He also thought the younger men were not showing the respect due the older members of the profession. He spoke of the high compliment paid the medical fraternity when Her Majesty conferred the honor of knighthood on three members of the profession in England, Michael Foster, Burdon Sanderson, and Mitchell Banks, and he referred feelingly to the recent deaths of prominent members of the Association in Canada.

AN EXPERIENCE IN FORMALDEHYDE DISINFECTION.

DR. F. MONTZAMBERT, director-general of public health, Ottawa, read an interesting account of the recent smallpox outbreak on board the *Lake Huron*, twenty-five days out from port on the Black Sea. The vessel had 2400 Doukhobors on

board, bound for northwestern Canada, and was ordered into quarantine. All of the passengers were landed on June 9, just three days after the vessel was first sighted, and a new crew was in charge by June 14. For disinfection, formaldehyde was used, and twelve ounces of this solution was allowed for each 1000 cubic feet of space. Two and one-half months have since elapsed and there has not been reported a single outbreak of the disease.

MASSAGE AND RELIEF OF EYE STRAIN IN THE TREATMENT OF GLAUCOMA.

Dr. GEORGE M. GOULD, Philadelphia, Pa., contributed a paper on this topic. He illustrated his work in this direction by citing several cases he had treated in this manner, with beneficial results in all. By this method of massage, in these cases, all spaces with venous and lymph stasis are cleared and broken. He fully described how this massage was performed with the soft parts of the thumbs and tips of the fingers. At the conclusion of his paper, Drs. Reeve and Burnham complimented him on his results in this direction.

TREATMENT OF ACUTE DIGESTIVE DISORDERS OF INFANCY.

Dr. A. R. GORDON, Toronto, read a paper with this title. After going carefully into the causes of these disorders, and describing them fully, he detailed his treatment. He thought that cow's milk should be the very last of the diet to be followed, while some of the malted foods might be used first. He dwelt on the importance of purgatives, such as calomel, castor-oil and gray powder, to be first employed to clear the alimentary canal; also washing out the stomach and flushing of the rectum and colon. Even after the child is showing signs of recovery, phosphate of soda or aromatic syrup of rhubarb might be used to keep the bowels in condition. He was dubious about the employment of antiseptics, considering bismuth, in large doses, the best sedative, and opium indicated in some cases.

Dr. HOLMES, Chatham, Ont., contributed to the discussion by relating his experience and the good results achieved from systematic bathing and cold sponging.

Dr. BENEDICT, Buffalo, N. Y., deprecates antiseptics, and never gives opium to children. He has found catnip tea a good sedative.

A CASE OF SUBCUTANEOUS EMPHYSEMA.

Dr. FRED FENTON, Toronto, reported this case, which occurred in a child 6 months old. It began at the junction of the clavicle and sternum and spread over the neck, face and head, and downward over the chest and abdomen, to Poupart's ligament on either side. At the autopsy, the lungs, spleen and liver were found tuberculous. The child had had two or three attacks of acute bronchitis between 3 and 6 months of age. The father, aged 50, was tuberculous.

SPECIFIC IRITIS.

Dr. G. H. BURNHAM, Toronto, gave the histories of the successful treatment of three cases of specific iritis by his combined plan of treatment. He employs pilocarpin, hypodermically, 1/10 to 1/4 grain. This is given in a series of sittings of from ten to fourteen injections. The intervals between sittings range from three to eight weeks. During this time the patient is having the bichlorid and iodid of potash administered internally. The patient is made comfortable in a room at 75 degrees before each injection. This procedure requires from three months' time to three years, according to each case. In some cases, a few months' treatment will suffice.

BEST METHOD OF DEALING WITH THE CONSUMPTIVE POOR.

Dr. E. J. BARRICK presented this subject. He advocated governmental sanitaria and the levying of a tax, if necessary for their maintenance. Each county, or at the least a group of three or four counties, should have a sanitarium for this class of cases.

Dr. BRITTON, Toronto, took issue with Dr. Barrick on this subject, and thought the hospitals should deal with these cases. The attendance for the first day was about three hundred.

(To be Continued.)

Miscellany.

Spotted Typhus.—To prevent the spread of spotted typhus in the Caucasus, where so many persons go to seek work, from the famine-stricken districts of Russia, quarantine inspection and disinfection of cars and baggage has been ordered.

Intoxication from Silk Waist.—A robust young woman recently died with symptoms of intoxication ascribed to a green silk waist. The perspiration made the color come out under the arms, where there happened to be some pimples.—*Vienne Freie Presse*, August 11.

Pathology in Art.—Several portraits by Titian and Velasquez are pronounced types of neurosthenic subjects, and the recent exhibition of the collected works of Lucas Cranach has called attention to the rounded backs of the women in the days before the corset was invented. Scoliosis is apparent in at least one portrait.

Temperance Restaurants.—One of the practical results of the international antialcohol congress is the opening of a subscription for temperance restaurants, by Dr. Legrain, physician-in-chief at Ville-Evrard. One subscriber gave \$5,000, and a home-like restaurant has been opened in a poor neighborhood in Paris, with reading and lounging rooms. The prices are very low, and a single glass of wine or beer is served with the meals, none at other times, but tea, chocolate and coffee can be had at any time for from 1 to 2½ cents. The success of the "Petits Repas Hygieniques," as it is called, has amazed even the most enthusiastic promoters.

Queries and Minor Notes.

PRACTICE IN CALIFORNIA.

TOPERA, KAS., Aug. 28, 1899.

To the Editor:—Will you kindly inform me of the requirements of the law to practice medicine and surgery in California? Very truly yours,

H. O. T.

ANSWER.—Any one intending to practice in California must present his diploma to one of the three state examining boards—regular, homeopathic or eclectic—with affidavit relative to medical studies pursued. If the diploma and affidavit are found satisfactory and genuine, a certificate will be issued, for which a fee of \$5 is required. The applicant must also present an affidavit that he is the lawful possessor of the diploma and is the person named therein. The boards meet monthly, at the offices of their respective secretaries. For blanks or for additional information address the secretary of the Board of Medical Examiners. The secretary of the regular Board is Dr. C. C. Wadsworth, 1104 Van Ness Ave., San Francisco, Cal.

RAILWAY HYGIENE.

DENVER, COLO., Aug. 16, 1899.

To the Editor:—Interested as I am in railway surgery, I am seeking information on the subject of hygiene in its application to railway service and travel. Can you refer me to any literature on the subject?

Very truly yours, W. W. G.

ANSWER.—The subject of railroad hygiene is rather a wide one, but it has as yet apparently not been treated in a monographic way in our language. There was a work published in London in 1867, by Fletcher, on railways in their medical aspects, but that is hardly modern. Its literature is scattered through a large number of journals in various languages, only a comparatively small portion of it, it would seem, in our own. The most extensive recent memoirs noticed in the "Index Catalogue" and *Index Medicus* are those of Braehmer, "Handbuch der Hygiene," Jena, 1897-7, vi, pp. 239-311, and the reports of the International Conference on Railway Sanitation, etc., Brussels, 1898. A number of valuable articles bearing more or less directly on the subject have been published in this country, as those of Conn on "Car Sanitation" (*JOURNAL*, xxiii, 1894, p. 757), and elsewhere on "Hygiene of Railroad Employees"; of Lemen, on "Sanitary Regulations of Railroads" (*Ibid*, xvi, 1896, 102); of Pritchard on "Diseases of Railroad Men" (*Ibid*, xxviii, 1899). The list of titles covers over a page in the "Index Catalogue" (First series).

ST. LUKE'S HOSPITAL AGENCY.

KANSAS CITY, MO., Aug. 25, 1899.

To the Editor:—The St. Luke's Hospital Association of Niles, Mich., are representing some one, whom they style "Professor of Surgery in the Kansas City Medical College," a member of their staff. This is misrepresented. No one associated with the Kansas City Medical College, has graphed certificate of membership, nor is in the slightest manner connected with the above named hospital. Yours truly,

FRANKLIN E. MURPHY, Secy, Faculty Kansas City Med. Coll.

PRACTICE IN SOUTH CAROLINA.

WILLIAMSBURG, KY., Aug. 14, 1899.

To the Editor:—What are the regulations of the State Board of South Carolina governing the practice of medicine?

E. S. M.

ANSWER.—All applicants for a state certificate to practice are examined, provided they hold diplomas from reputable medical colleges or schools, in the following branches: Anatomy, general and regional physiology and histology, chemistry, toxicology, practical urinalysis, materia medica and therapeutics, surgery and surgical pathology, practice and diseases

of children, obstetrics and gynecology. An average of at least 75 per cent. on the whole list of subjects must be obtained by each applicant and he must not make less than 60 per cent. in any one branch. Examinations are held in May, on the third Tuesday, at Columbia, and elsewhere as may be necessary. The fee for examination is \$5, which is refunded if the applicant fails to pass. Temporary licenses are granted after an oral examination.

THE WIDAL TEST.

NEWCASTLE, COLO., August 17, 1899.

To the Editor.—Just what is required and how is the "Widal Test" for typhoid fever made? If this is asking too much, where can I secure the information?

W. G. L.

ANSWER.—The Widal test, as modified by Wyatt Johnston, is given in Hare's "Practical Diagnosis" as follows: "The lobe of the patient's ear having been pricked, the drop of blood is placed on a clear glass slide as follows: Lay a loop (drop) upon it up by a loop of platinum of bouillon culture of the typhoid bacillus is now placed on an absolutely clear cover-glass and to this is added a large drop of a watery solution of the dried blood. From the mixture of blood and typhoid bouillon a "hanging drop" preparation is made and examined with a one-sixth or one-eighth dry objective when it will be noticed, if the patient is suffering from typhoid fever, that the typhoid bacilli rapidly forms clumps."

As described by von Jaksch, in his "Clinical Diagnosis," twenty-five drops of Koch's nutrient bouillon are deposited by means of a platinum loop on an ordinary microscope slide and each drop is then inoculated with a young typhoid culture, previously examined under the microscope to make sure of the bacilli being in active motion. A drop of the suspension is added and the whole well mixed together and one drop placed in the cavity of a glass slide and examined under an oil-immersion lens. Von Jaksch prefers this 1-25 dilution as better than higher ones that may react only with severe infection or lower ones that are not decisive for typhoid. The macroscopic test as given by him is as follows: "3 c.c. of Koch's nutrient bouillon sown with typhoid bacilli from fresh culture—under one day old if possible—are mixed with five drops of serum. If this be a typhoid patient will be noticed that the sample turns turbid, the liquid becomes flocculent, and in twenty-four hours the bottom of the test-glass will be covered with a flaky sediment.

Widal's reaction is probably not exclusively met with in typhoid, but its occurrence in other disorders is exceptional and not so characteristic. The status of the reaction on medical opinion was stated rather fully in an editorial in the JOURNAL of April 15, last. We would advise our correspondent to read R. C. Cahot's work on "The Serum Diagnosis of Disease," published by Wm. Wood & Co., New York. The price is \$1.50.

STILL MORE COMMERCIALISM.

In this column last week, under the caption "For Sale to the Highest Bidder," we published a letter from a physician asking for bids for his practice. We did not publish the letter, but we thought we fully in the way we ought to have done so, as it would then have given those surgeons who give bribes for patients—if there are any—a chance to make a bid.

Appropos of this kind of commercialism we have just received a letter from Dr. C. D. Wescott, Chicago, in which he says: "Enclosed I hand you a letter which is sure will interest you. I know nothing of Dr. D., save that he is a homeopath living on the west side." Accompanying the above is a mimeograph circular letter supposed to have been written by the general manager of a mineral water company. The letter says: "It has been suggested that we make a special proposition to prominent medical men, something like this: We pay you fifty cents per case for all orders received through your aid. The average number of cases now being treated by this patient is about ten each; consequently you will observe, it will not require many customers to largely increase your revenue. Please advise us at your earliest convenience if this proposition interests you. You can easily send us names of people to whom we will send circulars, and if you like, we will attach a slip saying: 'Show this circular to your physician, and ask his opinion of the analysis of this natural water.' That will give you an opportunity to both recommend and endorse the water to mutual benefit."

"P. S.—Dr. C. D.—, of Chicago, mentioned your name favorably to us."

Note what a smooth game they propose to work by the "slip": "Show this physician and ask his opinion of the analysis of this natural water." The question arises: Can such an outrageous insult to honesty and intelligence be met as it ought to be? It is a species of bribery, and a low species at that.

In the same mail came the following:

FERRVILLE, OHIO, Aug. 28, 1899.

"I enclose herewith a letter and card which I have just received and which are self-explanatory. You may well believe I was thoroughly disgusted with their contents and the liberal 'proposition' made by this 'hereditary' specialist.

"Believing that it is the duty of self-respecting physicians to expose these 'bleeders' whenever they make such propositions, I forward these to you once with the request that you publish in your esteemed JOURNAL the liberality of this great reformer of 'exploded' theories. I wish to express my appreciation and emphatic endorsement of the warfare or rather crusade which you are making against this class of persons. I trust you will favor me by lending your great influence against this man."

L. P. H., HARBENBERG, M. D.

Following is a copy of the letter sent to Dr. Babcock, which you will find you send make you a proposition:

"Any person afflicted with cancer who may call on you for treatment, if you will bring to meet them my services, will give you 20 per cent. of the money I receive for treating each patient you may send to me. My charges for treating and curing a cancer are from 50 to 250 dollars. Kindly let me hear from you."

Circulars and "pictetes" tell what wonders are being done by this miracle-worker. "My father and grandfather cured cancer when I was an infant," he tells us, and for this reason, as the circular says elsewhere, he is, "by inheritance, by intuition, by study, and by a broad and varied experience, thoroughly qualified to practice my specialty—treating and curing all forms of cancer." Further comment will be made later.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including August 24, 1899.

Robert W. Andrews, appointed lieutenant and asst.-surgeon, Vols., to rank from August 7, 1899, and assigned to the 49th Inf. Vols., at South Framingham, Mass.

Frank E. Artand, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 45th Inf. Vols., at Fort Snelling, Minn.

Charles L. Baker, acting asst.-surgeon, from Leetown, W. Va., to Washington, D. C., reporting to the surgeon-general for instructions.

Shadworth O. Beasley, appointed lieutenant and asst.-surgeon, Vols., August 10, 1899, and assigned to the 11th Cav. Vols.

Edward G. Beeson, appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 39th Inf. Vols., at Fort Crook, Neb.

William Duffield Bell, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 42d Inf. at Fort Niagara, N. Y.

William F. Bernart, acting asst.-surgeon, to duty at the Army and Navy General Hospital, Hot Springs, Ark.

R. M. Bonar, acting asst.-surgeon, from Hebron, Ohio, to duty in the Department of California.

Ira C. Brown, major and surgeon, Vols., from the Division of Cuba to duty in the Department of California.

Euston Burchard, appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 40th Inf. Vols., at Fort Riley, Kans.

George L. Cable, acting asst.-surgeon, from Matanzas, Cuba, to New York City, to await orders.

Joseph T. Clark, captain and asst.-surgeon U. S. A., relieved from Madison Barracks, N. Y.; appointed major and surgeon, Vols., August 17, 1899, and assigned to the 47th Inf. Vols., at Camp Meade, Pa.

William Cogswell, appointed major and surgeon, Vols., August 17, 1899, and assigned to the 46th Inf. Vols., at South Framingham, Mass.

Samuel F. Cottrell, acting asst.-surgeon from Camp Meade, Pa., to accompany the 29th Cav. Vols., to Manila, P. I.

George D. DeShon, appointed major and surgeon, Vols., to rank from August 10, 1899, and assigned to the 11th Cav. Vols.

Frederick S. Dewey, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 38th Inf. Vols., at Jefferson Barracks, Mo.

Frank Donaldson, appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 45th Inf. Vols., at Fort Snelling, Minn.

E. W. Fowler, acting asst.-surgeon, from the hospital ship *Terry* to duty in the Division of Cuba.

Chas. W. Fry, acting asst.-surgeon, from Huntington, Ind., to Vancouver Barracks, Wash., for duty with the 33rd Inf. Vols.

Charles L. Furush, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 44th Inf. Vols. at Fort Leavenworth, Kans.

Alexander D. Ghiselin, appointed captain and asst.-surgeon, Vols., August 10, 1899, and assigned to the 11th Cav. Vols.

John G. Gibson, major and surgeon, U. S. A., orders to Manila, P. I., revoked; he is assigned as attending surgeon and medical superintendent of transportation at San Francisco, Cal.

James D. Glennon, captain and asst.-surgeon, U. S. A., relieved from Fort Myer, Va.; appointed major and surgeon, Vols., August 17, 1899, and assigned to the 38th Inf. Vols., at Jefferson Barracks, Mo.

Herman W. Groves, acting asst.-surgeon, previous orders directing him to accompany the 29th Inf. Vols., to Manila, P. I., revoked.

John Sturgeon Hill, acting asst.-surgeon, previous orders directing him to report for duty in the Department of California revoked.

Deane C. Howard, captain and asst.-surgeon, U. S. A., from temporary duty at West Point and from further station at Fort Columbus, N. Y., to duty at Fort Hancock, N. Y.

Merritt W. Ireland, captain and asst.-surgeon, U. S. A., relieved from Fort Wayne, Mich.; appointed major and surgeon, Vols., August 17, 1899, and assigned to the 45th Inf. Vols., at Fort Snelling, Minn.

Thomas T. Jackson, appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 44th Inf. Vols., at Fort Leavenworth, Kans.

D. J. Johnson, acting asst.-surgeon, former orders revoked; he is relieved from Fort Terry, N. Y., and assigned to duty with the 47th Inf. Vols., at Camp Meade, Pa.

George H. Jones, acting asst.-surgeon, from Toledo, Ohio, to Jefferson Barracks, Mo., for duty with the 38th Inf. Vols.

Frank M. Kemp, lieutenant and asst.-surgeon, U. S. A., from Fort Hamilton to West Point Military Academy, N. Y.

W. L. Kneeder, captain and asst.-surgeon, U. S. A., to duty on the hospital ship, *Missouri*, now at Brooklyn, N. Y.

Henry H. Lee, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 46th Inf. Vols., at South Framingham, Mass.

William F. Lippitt, Jr., captain and asst.-surgeon, U. S. A., relieved from Washington Barracks, D. C., appointed major and surgeon, Vols., August 17, 1899, and assigned to the 44th Inf. Vols., at Fort Leavenworth, Kans.

Morris S. Lord, acting asst.-surgeon, to duty at Madison Barracks, N. Y.

Arthur W. McArthur, acting asst.-surgeon, from Chillicothe, Mo., to Fort Niobrara, Neb.

Walter D. McCaw, captain and asst.-surgeon, U. S. A., relieved from

Fort Porter, N. Y.; appointed major and surgeon, Vols., August 17, 1899, and assigned to the 42d Inf. Vols., at Fort Niagara, N. Y.

Thomas R. Marshall, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 41st Inf. Vols., at Camp Meade, Pa.

Edward B. Moore, major and surgeon, U. S. A., previous orders revealed; he is relieved from the Presidio of San Francisco, Cal., and will proceed to Manila, P. I., for assignment.

Edward L. Munson, captain and asst.-surgeon, U. S. A., relieved from duty in the office of the surgeon-general and assigned to Washington Barracks, D. C.

Seaton Norman, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 39th Inf. Vols., at Fort Crook, Neb.

Thomas U. Raymond, captain and asst.-surgeon, U. S. A., relieved from duty as attending surgeon and medical superintendent of transportation in San Francisco, Cal., appointed major and surgeon, Vols., August 17, 1899, and assigned to the 40th Inf. at Fort Riley, Kan.

William E. Richards, lieutenant and asst.-surgeon, U. S. A., sick leave extended.

Edward A. Romig, appointed captain and asst.-surgeon, Vols., August 17, 1899, and assigned to the 40th Inf. Vols., at Fort Riley, Kan.

Allen M. Smith, captain and asst.-surgeon, U. S. A., relieved from Fort Hancock, N. J.; appointed major and surgeon, Vols., August 17, 1899, and assigned to the 41st Inf. Vols., at Camp Meade, Pa.

Henry D. Snyder, captain and asst.-surgeon, U. S. A., relieved from post duty; appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 43d Inf. Vols., at Fort Ethan Allen, Vt.

Alexander N. Stark, captain and asst. surgeon, U. S. A., to turn over the hospital ship, *Terry*, to the quartermaster's department and report for duty in the Division of Cuba.

Henry R. Stiles, captain and asst.-surgeon, U. S. A., from duty with the *Relief* at San Francisco, Cal., and from station at Fort Preble, Me., to duty at Benicia Barracks, Cal.

William J. Wakeman, captain and asst.-surgeon, U. S. A., to examine certain recruits at Camp Meade, Pa.

Philip G. Wales, captain and asst.-surgeon, U. S. A., relieved from Fort Niobrara, Neb.; appointed major and surgeon, Vols., August 17, 1899, and assigned to the 39th Inf. Vols., at Fort Crook, Neb.

Joseph M. West, appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 43d Inf. Vols., at Fort Ethan Allen, Vt.

Oddillon B. Weed, acting asst.-surgeon to duty at Fort Wayne, Mich.

George Reeves White, acting asst.-surgeon, from New York City to duty in the Department of California.

Movements of Navy Medical Officers.—Changes in the medical corps of the U. S. Navy for the week ending August 26, 1899:

Medical Inspector C. U. Gravatt, ordered to duty at the New York Navy Yard as member of board of medical examiners, September 5.

P. A. Surgeon C. F. Stokes, detached from duty as member and recorder of board of medical examiners at the New York Navy Yard, September 5, and ordered to continue on duty at the naval hospital, New York.

P. A. Surgeon M. S. Guest, ordered to the Boston Navy Yard.

Pharmacist S. Englander, detached from the Mare Island Navy Yard and ordered to the New York Navy Yard.

Pharmacist L. R. G. Lewis, detached from the New York Navy Yard and ordered home and to await orders.

Marine-Hospital Changes.—Official List of Changes of Station, and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended August 17, 1899.

Surgeon Fairfax Irwin, to proceed to Marseilles, France, and Lisbon and Oporto, Portugal, for special temporary duty.

Surgeon Eugene Washin, to report at Washington, D. C., for special temporary duty.

P. A. Surgeon H. D. Geddings, to proceed to New York, N. Y., for special temporary duty.

P. A. Surgeon A. C. Smith, to proceed to Hampton, Va., and report to Surgeon J. H. White for special temporary duty.

P. A. Surgeon W. C. Richardson, to report at Washington, D. C., for special temporary duty.

Asst.-Surgeon T. F. Richardson, detailed as quarantine officer for the port of Neivitas, Cuba.

Acting Asst.-Surgeon F. J. Schug, granted leave of absence for 30 days from August 15, 1899.

Hospital Steward C. H. Woods, granted leave of absence for 15 days from August 16, 1899.

Hospital Steward S. W. Richardson, to proceed to Birmingham, Ala., for special temporary duty.

Hospital Steward F. H. Peck, to proceed to Hampton, Va., and report to Surgeon J. H. White for special temporary duty.

Hospital Steward E. J. Thurston, to be hospital steward and chemist.

PROMOTION.

Board convened to meet at the U. S. Marine-Hospital, New York, N. Y., at 10 o'clock, a. m., August 16, 1899, for the physical examination of a candidate for appointment to the Revenue Cutter Service.

Detail for the Board: Surgeon George W. Stoner, Chairman; Asst.-Surgeon W. C. Hobdy; Asst.-Surgeon W. C. Billings, Recorder.

A board of officers will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, October 4, 1899, for the purpose of examining candidates for admission to the grade of Assistant-Surgeon in the U. S. Marine-Hospital Service.

Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college and must furnish testimonials from responsible persons as to character.

The following is the usual order of the examination: 1. Physical. 2. Written. 3. Oral. 4. Clinical.

In addition to the physical examination candidates are required to certify that they are free from any ailment which would disqualify for service in any climate.

The examinations are chiefly in writing, and begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene.

The oral examination includes subjects of preliminary education, history, literature and natural sciences.

The clinical examination is conducted at a hospital, and when practicable candidates are required to perform surgical operations on the cadaver.

Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order as vacancies occur.

Upon appointment the young officers are as a rule first assigned to duty at one of the large marine hospitals, as at Boston, New York, New Orleans, Chicago or San Francisco.

After five years' service, Assistant-Surgeons are entitled to examinations for promotion to the grade of Passed Assistant-Surgeon.

Promotion to the grade of Surgeon is made according to seniority, and after due examination as vacancies occur in that grade. Assistant-Surgeons receive sixteen hundred dollars, Passed Assistant-Surgeons two thousand dollars, and Surgeons twenty-five hundred dollars a year. When quarters are not provided commutation at the rate of thirty, forty or fifty dollars a month, according to grade, is allowed.

Surgeons above the grade of Assistant-Surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years up to forty per centum after twenty years' service.

The tenure of office is permanent. Officers traveling under orders are allowed actual expenses. For further information, or for invitation to appear before the Board of Examiners, address, Supervising Surgeon-General, U. S. Marine-Hospital Service, Washington, D. C.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended August 25, 1899:

SMALLPOX—UNITED STATES.

Florida: Jacksonville, August 14 to 29, 1 case.

Louisiana: New Orleans, August 12 to 19, 1 case.

Massachusetts: Boston, August 12 to 19, 2 cases.

Ohio: Cincinnati, August 12 to 19, 2 cases.

Pennsylvania: Allegheny, August 12 to 19, 5 cases.

Virginia: Portsmouth, August 12 to 19, 3 cases.

SMALLPOX—FOREIGN.

Brazil: Rio de Janeiro, July 7 to 14, 11 deaths.

Colombia: Panama, August 1 to 8, 2 cases, 1 death.

Egypt: Cairo, July 15 to 22, 4 cases.

England: London, July 29 to August 5, 1 case.

Greece: Athens, July 29 to August 5, 7 cases, 3 deaths.

India: Bombay, July 11 to 25, 14 deaths; Madras, July 1 to 8, 2 deaths.

Mexico: Chihuahua, August 7 to 14, 1 death; Mexico, July 31 to August 6, 4 cases, 3 deaths; Nuevo Laredo, July 5 to August 12, 1 death.

Russia: Odessa, July 29 to August 4, 4 cases, 1 death; St. Petersburg, July 22 to 29, 8 cases.

YELLOW FEVER.

Brazil: Rio de Janeiro, July 7 to 14, 6 deaths.

Costa Rica: Port Limon, August 18, 1 case.

Cuba: Havana, August 3 to 17, 25 cases, 5 deaths; Sancti Spiritu, August 24, 2 cases; Santiago, July 30 to August 12, 10 cases, 5 deaths.

Mexico: Tuxpam, July 31 to August 8, 5 deaths; Vera Cruz, July 27 to August 10, 32 cases.

CHOLERA.

India: Bombay, July 18 to 23, 2 deaths; Calcutta, July 8 to 15, 7 cases.

PLAGUE.

India: Bombay, July 12 to August 25, 121 deaths; Calcutta, July 8 to 15, 3 deaths.

Portugal: Oporto, August 16, 39 cases, 13 deaths.

Turkey: Smyrna, July 30, 4 cases, 3 deaths.

CHANGE OF ADDRESS.

Adams, W. T., to 2453 5th Ave., Pittsburg, Pa.

Ash, J. C., from Chicago to Good Hope, Ill.

Burrell, R. H., from 332 Madison St. to 213 13th St., Ann Arbor, Mich.

Beacharach, H., from Chicago to Fairbault, Minn.

Chapman, J. A., from Hillsboro, Texas to 841 N. Rampart St., New Orleans, La.

de Beque, W. A. E., from Des-Moines, Iowa to Mexico City, Republica Mexicana, Sucubras B. Apartado, No. 2067.

Deming, N. L., from 29 E. 39th St. to 2907 Prairie Ave., Fort Wayne, Ind.

Green, G. W., from 326 to 298 Beacon St., Boston, Mass.

Wiley, W. H., from Martinsburg, W. Va. to 704 2d St., Evansville, Ind.

Forster, J. D., from St. Louis, Mo. to Wellston, Mo.

Frish, Marie, from Tuscon, to Pole House, Madison, Ill.

Goldspohn, A., to 517 Cleveland Ave. Sta. A., Chicago.

Garwin, W. G., from Vassar to Willington, Mich.

Gardiner, W. C., from 1432 to 1455 Erie St., Toledo, Ohio.

Gammot, C. F., from Chicago, Ill. to Fomeroy, Wash.

Grier, D. F., from Fargo to Adrian, N. D.

Grasse, M. J., from Denver, Colo. to 785 Sheridan Road, Waukegan, Ill.

Hotovick, J. M., from Minneapolis to 2807 Prairie Ave., Chicago.

Herzog, M., from 277 Seminary to 174 E. Chicago Ave., Chicago.

Koenick, T. A., from New York City to 107 Pelham St., Newport, R. I.

Klokke, W. E., from 235 So. Lincoln St., Chicago, Ill. to 2033 Park Ave., St. Louis, Mo.

Kennedy, F. P., from Dublin to Topaz, Texas.

Lockwood, W. D., from St. Joseph to No. St. Joseph, Mo.

Lull, H., from 1276 Adams to 2387 Prairie Ave., Chicago.

Lyons, E. W., from 612 Dix Ave. to 759 Junction Ave., Detroit, Mich.

McDill, J. R., from 209 Wisconsin to 470 Jackson St., Milwaukee, Wis.

Martin, M. L., from Galveston to Denton, Texas.

McClure, H. J., 475 Ogden Ave., Chicago to 610 Olive St., St. Louis, Mo.

Stagg, W. H., from Washington to Whitehouse, La.

Snow, B. G., from Caldwell to Tamarack Mine Hospital, Calumet, Mich.

Schmidt, Oscar, from Campbellsport to Mendota, Wis.

Hilgen, H. J., 475 Ogden Ave., Chicago to 610 Olive St., St. Louis, Mo.

Veldhuis, J. G., from Great Falls to Ft. Benton, Mont.

Vacien, W. E., from Priost to Triune, Tenn.

Wright, S. D., from 140 Ashland Boul., Chicago, Ill. to 409 E. Prospect St., Cleveland, Ohio.

A FALLACY OF THE REST-CURE TREATMENT*

BY GEORGE M. GOULD, M.D.

PHILADELPHIA.

Even in this day of enlightenment as regards etiology and pathology, there are thousands, very many thousands, of patients being systematically treated for functional diseases of the body that are due to diseases of the eyes. There are other thousands being treated for organic diseases of the body which originally were caused by ocular diseases. In both cases neither the patient nor the doctor has the remotest suspicion of the ocular origins of the functional and organic abnormalities. Sneering and top-lofty contempt of the specialist "hobby-rider" will not change the facts, nor lessen the hobby-riding. Moreover, the assertion that the patient has been in the hands of an ophthalmologist of good reputation does not in the least lessen the truth for which I contend.

Out of perhaps a hundred classes I wish to-day to choose one small class of cases illustrative of the general thesis. This group is composed of "nervous" hysterical patients, usually women, neurasthenics, who, when we do not know what is the matter with them, and when we can relieve them by no other means, we call "nervous breakdowns," and order the rest-cure. Modern medical practice is made up in too large degree of this sort of work in the dark—I mean with patients whose diseases we may name but can not thoroughly diagnose, and the treatment of which we order with a sickening feeling in our own hearts that we are blind and ignorant of any clear reason for our doing. In no class of cases is there such great reason to look after the eyes as in this class of hysterics and neurasthenics, which, by a morbid philology we allow to be called "nervous." I am told that Dr. Spivak of Denver has advanced the theory that hyperchlorhydria and other functional gastric troubles are the principal affections relieved by the rest-cure. To this I would add that nothing is more certain in my mind than that such functional gastric derangements are frequently the direct result of eye-strain.

Out of a large number of such cases I have seen permit me to epitomize in simple language, I mean without the cacophonous jargon of the oculist, three typical ones:

CASE 1.—Six years ago a woman came to me with a long history of sick-headaches, functional digestive trouble, anemia, and the hundred ill-defined symptoms of nervousness, hysteria, etc., so often conjoined in our pathetic, characterless, useless, childless, muscleless, hothouse flowers of modern womanhood. I found a complex unsymmetric astigmatism—the fruitful mother of

such daughters. The woman at once took fright and with horror asked me, "But Doctor, I will not have to wear glasses, will I?" I said, "If you come to me you will not only wear glasses, but spectacles, and you will wear them every hour of your waking life. If not, I can not be your adviser." She would not listen to this. The devil of pride ruled her heart and was stronger than her belief in me, and she at once consulted an oculist who allows his patients to do as they please in regard to treatment. In the years that have flown since then the woman has taken several rest-cures. She thereby gets fat; of course, the doctor is praised and the fame of the mythical metaphysical treatment gains ground. But somehow the nervous breakdowns recur, institutions of various styles of euphuistic titles—one certainly a family inheritance and hence inalienable—are visited for long or short terms, the husband's business and mind grow weedy, and the slow journey down the tragical road, a literal *descensus averni*, continues with increasing speed and certain ending.

CASE 2.—Five years ago a school-girl of 16 years was sent me because of poor vision, headaches, and sundry nervous phenomena. She had an enormous astigmatism and with the best glasses I could give her there was only two-fifths vision in each eye. My spectacles were worn and the vision in a month had regained normal acuity, the headaches entirely disappeared and perfect health was enjoyed for two or more years. Then as the young men gathered about the lovely flower, the glasses were left off, the health ran down, malnutrition, headaches, the Lord knows what not, returned, and, of course, the great nerve-specialist had to be consulted. He never asked or said a word about eyes, but put her to bed for three months, and she got as "fat as butter," and "Great was Diana of the Ephesians." Then after the neurologist's victory she was brought to the poor little oculist again, "just to show him, etc.," and "to get new glasses should they be needed now," and lo, again the vision reduced to one-half or two-thirds of the normal! I hope she has her husband by this time—but I pity him!

CASE 3.—The patient was a young man—and when you find a young man needing the rest-cure, I would advise looking into the matter with all the 'scopes at command, and for a hundred or two years at least! He had for ten years suffered everything that a strong, fine organism could suffer and not die. The reflexes from a pair of eyes with high compound unsymmetric astigmatism had expended themselves on mysterious functional digestive disease. Every kind of dieting, every treatment suggested by the finest physicians had been tried; he was wearing glasses from an ophthalmologist of national reputation; his natural intellectual mind was getting "fuzzy" with ten years of torment, loss of business, failure in ambition, etc. Reading for ten minutes "tied his stomach into a knot," and because he had no loss of visual acuity, and no pain or trouble whatever with the eyes—these are just the cases that wreck lives—

*Presented to the Section on Practice of Medicine, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

and because he had glasses from a great oculist, even his quick perception had been unable to see that the eyes were the cause of the trouble. For a diabolical refraction-error he was wearing simply and only a pair of weak prisms in his spectacles. It would have done him more good to have buried a lock of his hair at midnight at the crossing of the country roads, with a black cat held by the tail over the grave. Well, the neurologist put him to bed with forced feeding, stopped his reading, and gave him back his lost forty pounds of flesh. When he got about again, his stomach began tying knots when he read, and the old woes began their old round. The heretofore unused mydriatic, when he came to me, gave instant relief of all symptoms and so long as the ciliary muscle was paralyzed there was no stomach-tie or misery of any kind. A few days' gymnastic exercise of the weak muscles of the eyeballs made disappear the exophoria for which he was wearing prismatic spectacles. Glasses correcting his far-sightedness and his unsymmetric astigmatism were ordered, switching of the axes watched, and the almost-ruined neural and digestional functions will, it is hoped, right themselves in time. Perhaps, however, cure will not be effected, because it is a simple truism that in disease, stopping the cause does not always stop the effect. Secondary diseases may have been induced, and such injuries that health can not be perfectly restored. Functional disease leads to organic disease.

I should be sorry to be misunderstood. I by no means say or believe that in every case, or that in the majority of cases requiring the rest-cure, the origin or chief factor of the disease is eye-strain. I do not say or believe that the rest-cure is unnecessary even in cases of reflex ocular neuroses. What I do believe and wish to emphasize is:

1. It is positively criminal negligence to ignore eye-strain in any case requiring the rest-cure treatment.

2. It is not enough to know that the oculist has examined the eyes, especially if it has been done without a mydriatic.

3. To mydriaticize a pair of eyes for a month or two would often do more good, would certainly be more logical, would be an infinitely better means of differential diagnosis in obscure nerve-trouble and functional nutritional diseases than to put the patient's body to bed for the same time.

DISCUSSION.

DR. G. BETTON MASSEY, Philadelphia—I have had some experience with the rest-cure treatment in cases of neurasthenia and I merely wish to take exception to the assumption of the reader of the paper that the "rest cure" is a proper method of treating this affection. The results of my observations have been that the rest-cure treatment is most effective in hysteria, not neurasthenia. After many years' experience with such cases I have never heard of any cure by this means in neurasthenia. In cases of hysteria and anemia, approaching the neurasthenic condition, this treatment may prove thoroughly effective, but it will often do harm in non-hysterical neurasthenia.

CATAPHORIC TREATMENT OF CANCER.*

BY G. BETTON MASSEY, M.D.

PHILADELPHIA.

The insertion of nascent salts of mercury within the human body by electric diffusion in a strength that will deluge a given tract of tissue or a growth with these germicides without materially affecting the remainder of the body constitutes a novel therapeutic procedure which the writer contributed to medical science as a

cure for cancer, in a paper before this Section of the ASSOCIATION at its Philadelphia meeting, in 1897. Further experience with this method in primary cancers and local recurrences in accessible situations has demonstrated an even greater usefulness than was anticipated, as the technic has improved and greater currents have been used.

The importance of this method of destroying germs within the body would be sufficiently great if its applicability to the cure of local cancerous foci is alone considered, for cancerous affections are increasing rapidly in frequency throughout the country, but an examination of the method will show that it may be used for the destruction of any accessible focus of germ growth of any kind, there being but one essential condition to its use, and that is a path for drainage of the products of the dead germs, with which, in the worst cases, certain portions of the stroma are separated. It is, therefore, a most convenient, certain and speedy method of destroying tuberculous deposits in any part of the body except the brain, lungs and abdomen. It may be used to destroy the germ of carbuncle, under ether, leaving a painless and aseptic core to be separated in two or three weeks without inconvenience. It may be used to destroy the infection of wounds, when yet local, and all torpid or indolent ulcerations. I will not dwell at great length on these possible applications of the method, further extensions of which will readily occur to you, but will proceed at once to state in what the method consists, and what success has been attained by it in the treatment of cancer since my last report.

Since the method, in its major applications, is a painful one, it is necessary to place the patient under an anesthetic, and this gives full opportunity for the immediate destruction of all the germs in a cancer, no matter how large it may be. With the patient thoroughly anesthetized, therefore, and lying on a large pad connected with the negative pole of a battery of sufficient power, a small tubular gold electrode that has been amalgamated with mercury is inserted into the growth through a small opening, and an excess of metallic mercury is injected into it through a rubber tube and glass syringe connected with the instrument. This gold-mercury electrode is connected with the positive pole of the battery, this being the pole from which these substances may be radiated. When, now, a strong current is gradually turned on through this circuit electrolysis of the growth and of the mercury occur simultaneously, resulting in the formation of an oxychloride of mercury, which is radiated from the electrode in all directions toward the opposite pole. The effect of the diffused chemicals is evident to the sight in a few moments when a powerful current is used, a whitish-gray color spreading in all directions from the electrode. The exact speed at which the atoms of mercury travel has not yet been experimentally determined, but it is dependent on the voltage of the current. At a pressure of 110 volts it is probably nearly a centimeter in ten minutes. The density of the diffused chemical is, of course, greatest at the point of diffusion, at the electrode; this results in the area nearest the electrode receiving the diffused chemical in such proportion as to necrose all protoplasm in this situation, producing an area of total destruction, the limits of which are shown not only by the discoloration but by the subsequent formation of a line of demarcation. Beyond this line of demarcation the diffused chemical infiltrates the tissues in a decreasing density, producing a zone of infiltration within which outlying germs and colonies of cancer are destroyed

* Presented to the Section on Practice of Medicine, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

while a mere physiologic reaction occurs in the healthy tissues.

The essence of the method, therefore, is the production of an area of total necrosis coterminous with the apparent limits of the cancer, beyond which a zone of infiltration causes the death of outlying colonies and latent germs, thus insuring against local recurrence. All this is accomplished in a time varying from fifteen minutes to an hour and a quarter, in accordance with the size of the growth. The aseptic and odorless slough occupying the area of necrosis separates painlessly in from twelve days to three weeks, leaving a cavity that rapidly fills with healthy granulations.

The method is mainly applicable to primary cancerous foci, though certain infected glands may also be destroyed at the same time as the primary growth, and also early recurrent carcinomas and sarcomas may be placed under the method. When the infection gains access to the blood-vessels or to inaccessible portions of the lymphatic system this method is useless. In the larger growths it has been found wise to conjoin the cauterant action of the oxychlorid of zinc from amalgamated zinc electrodes with the pure mercuric cataphoresis for the quicker production of the area of necrosis.

SUMMARY OF CASES.

Since the paper previously read before this body¹ twenty-six cases of carcinoma and sarcoma have been subjected to this method in some manner, in my hands, many of them extremely bad cases—mere forlorn hopes. Of these 10 were operable cases and results are as follows:

Operable cases—Cured, 8; probably cured, 1; failed to cure, 1.—Total, 10.

Inoperable cases—Cured, 2; probably cured, 1; failed to cure, 13.—Total, 16.

Recapitulation—Cured or probably cured, 12 cases; failed to cure, 14 cases.

The fact that two cases have been cured and one probably cured out of sixteen inoperable cases of cancer is a sufficient excuse for the effort to determine the usefulness of this method in advanced cases of malignant disease, but in spite of this modicum of success it is my wish to avoid further efforts in this line, though it may be said that nearly all these unfortunate patients were benefited temporarily by the palliative action of the applications.

It is far different when we consider the result in the operable cases. Among these but one failure occurred, due to neglect on the part of the patient to submit to a second application—a recurrence in an accessible group of glands of the region where the primary growth had been destroyed. All other operable cases—nine in all since the former report—are well to-day and bid fair to remain well. Many of these patients, moreover, retain the organ affected, such as the breast, etc., with unaltered functions, since it is possible by this method to destroy an incipient cancer in an organ without destruction or removal of its unaffected portions.

DETAILS OF SUCCESSFUL CASES—SECOND SERIES.

CASE 1.—W. O., aged 39 years, an employe of a sugar refinery in Philadelphia, consulted me Oct. 11, 1897, with a rapidly growing neoplasm of the upper jaw projecting into the mouth. It had been first noticed by a dentist six months before, on the occasion of some teeth dropping out. It had displaced, by thus loosening them, four healthy teeth in this situation, and the part projecting into the mouth was about two inches by one inch in

diameter. There were evidences, however, of much greater penetration into the upper maxilla, for the cheek on this side showed a decided projection, and what was even more significant, the hard palate was flattened downward on the right side. The clinical evidences thus pointed to sarcoma of the superior maxilla, and this diagnosis had been confirmed by the chief surgeons at the Hospital of the Jefferson Medical College and at the Medico-Chirurgical Hospital, where extirpation of the superior maxilla had been advised.

On Oct. 27, 1897, he was placed under ether, and the pure mercuric cataphoresis with 300 milliampères was applied by means of a gold electrode, for fifteen minutes, with the assistance of Dr. Lindsay and in the presence of Dr. E. P. Bernardy. It was found that the gold instrument was too short to be used conveniently within the mouth, and the application was discontinued before we were certain that a complete effect had been obtained. The next day it was seen that some of the diseased tissue remained, but that the greater portion was well included in the area of necrosis. When the devitalized portion had separated, two weeks later, it was determined to see what could be done by office applications of sharp zinc-mercury points, the growth being but moderately sensitive, though painful as a whole. This was accordingly begun with an average strength of 30 milliampères, and fully completed at the end of two months. This left a healthy sinus extending into the antrum.

This patient has been under frequent inspection since and remains well at this date, a year and a half after. The projection of the cheek bone below the malar prominence has disappeared, and even the flattened arch of the hard palate has receded into place.

CASE 2.—Mrs. B., aged 63 years, of Philadelphia, had had the right breast and a diseased gland in the axilla removed for carcinoma ten months before consulting me for several recurrent nodules situated in the line of the lymphatic vessels leading from the scar to the clavicle. There were seven of these lumps the size of hazel nuts.

On Dec. 11, 1897, with the assistance of Drs. Ida E. Richardson and W. C. Thompson, she was placed under ether and pure mercuric cataphoresis employed with 500 milliampères distributed between three small gold electrodes. The duration of the application was but fifteen minutes, at the end of which time all the lumps were soft. The area of necrosis separated promptly and the cavity healed in five weeks. This patient has remained well during the year and a half that has followed the application with the exception of two minute spots of suspicious texture higher up in the line of the infected lymph vessels. Each of these spots has been removed in ten-minute office applications under the local use of cocaine, a small zinc-mercury needle being used with about 10 milliampères of current.

CASE 3.—Mrs. S., aged 56, of West Philadelphia, applied for treatment Dec. 21, 1897, with an indurated and foul ulceration under the left side of the tip of the tongue. A lump had been growing in the situation of the left sublingual gland for six months. Two months before seeing me ulceration began, and it was then so painful as to confine her to liquid diet and leave her sleepless.

On Dec. 28, 1897, she was placed under ether, with the assistance of Dr. S. J. Gittleton, and gold-mercuric cataphoresis was applied with a current of 350 to 400 milliampères for thirty minutes. The ulceration was found to be a cavity in the sublingual gland with indurated edges, about the size of a horse chestnut, emitting probably the foulest odor possible, the surrounding

¹ Medical Record, July 31, 1897.

tissues being deeply indurated. After the current had been flowing fifteen minutes this odor disappeared entirely and did not return subsequently. But little pain remained the next day after the reaction had subsided. Separation and healing were complete in four weeks, except for a small spot in which the disease still existed. She was accordingly given a second application with less current, the healing this time being free from doubt. At the present time, a year and a half after the application, the patient remains well, the mouth being normal except for some cicatricial awkwardness of the lingual movements.

CASE 4.—Miss B. of Philadelphia, aged 51, presented herself Nov. 11, 1898, with a growth in the outer and lower quadrant of the left breast about one by two inches in dimensions. It had appeared only recently and was

Appearance of scar in Case 4 six months after application. The two minor elevations near external corner show where unused mercury came away after healing. They have since disappeared.

beginning to give much pain. On palpation the growth was found to be movable and to present the contour of an acinous carcinoma of the breast. The case had been seen by Dr. Bruce Burns of Frankford, who pronounced it malignant, and advised removal of the breast. On Nov. 16, 1898, she was placed under ether at her home, and a major application of mercuric cataphoresis made, with the assistance of Dr. W. Oakley Hermance. A small gold canula-electrode was inserted into the growth, through which the mercury was injected, and 350 mil-

liampères of current turned on. The current was subsequently raised to 475 milliampères. A grayish necrosis began to form immediately around the electrode, and it was shortly noticed that the malignant hardness began to soften at the periphery of the growth, this softening progressively increasing from without inward. At the end of thirty-five minutes the whole growth had softened. It was now thought best to impregnate the region with the oxchlorid of zinc also, so the current was turned down and the gold instrument replaced by an amalgamated zinc electrode, the current being again turned on for five minutes, making forty minutes in all.

During the following night there was some pain in the zone of infiltration surrounding the necrosed area, readily controlled by morphia, but this pain did not recur again throughout the convalescence. At the end of six weeks the dead portion had come away, leaving a cavity with healthy walls which quickly filled with normal granulations. Several globules of mercury came away during the healing process, showing that an excess had been used. There were no evidences of general absorption of the mercury in a dose capable of detection.

At the present time the breast is soft and movable and entirely free from disease. It shows only a narrow linear scar about one and a half inches long with a depression in the breast at its site. (See cut.) This is the first case in which a carcinoma has been eradicated from the breast—with full preservation of the healthy portion of this organ, under the use of cataphoresis.

CASE 5.—A gentleman aged 79, a resident of Philadelphia, was referred to me by Dr. M. J. Grier, who had removed a wart from the face at the angle of the nose two years before by means of negative electropuncture. The growth had recurred in the same situation, being the size of a small strawberry, and giving evidence of mild malignancy. The problem was to remove or control this growth without detriment to the very feeble health of the aged patient, who could not possibly stand general anesthesia. The effect of very slight currents of but 2.5 milliampères was accordingly tried, applied by means of a sliver of amalgamated zinc inserted into it slightly. Each application of this extremely mild cataphoric method has appeared effective in destroying a bit of the growth, and at the present time only an infected base remains that could easily be cleared away were it possible to make a very slight increase in the current or frequency of application. Meantime the growth is kept under full control.

CASE 6.—A physician of York, Pa., aged 66, had been the subject of rodent cancer of the face for twenty years, during which time the growth had been operated on once at the Hospital of the University of Pennsylvania with but temporary results. On January 16 last he applied for treatment by the cataphoric method. The erosion was at this time about four inches long by two wide, extending from above the eye on the right side of the face to the middle of the cheek. The right eye was being threatened, the orbicular muscles and outer canthus being eroded through, and the outer table of the skull had been eaten away, leaving the skull exposed over a small area.

As the patient dreaded anesthesia, he was treated by the mild method, with prolonged daily applications of small zinc-mercury points and currents varying from two to ten milliampères, the pain being lessened by the local use of cocain. The effect of each application was immediate, both locally and at a distance, and now as a result of about three months' treatment, with intervals of non-treatment, all malignancy has been eradicated

and the site of the growth has filled in with healthy skin by extension from the edges. This case was a beautiful instance of the efficacy of the zone of infiltration, by which a remedial effect was obtained far beyond the mere area of cauterization.

CASE 7.—Mrs. M. S., aged 57, a patient of Dr. A. F. Müller of Germantown, Pa., who kindly referred her to me, was suffering from a carcinoma involving the whole of the left breast. The growth had been discovered about ten months before and was rapidly increasing in size and beginning to give pain. The axillary and supraclavicular glands were healthy.

The condition here was a completely diseased breast that could easily have been removed entire with the knife. The problem was to so remove the disease as to insure a greater immunity from recurrence than the knife gives. The large bulk of the growth, situated just over the heart, suggested to me that the greater portion of it could be impregnated with the chemicals by a local circuit, which would permit a larger current and greater expedition than would otherwise be possible in this situation. With the kind assistance of Drs. Müller and Hernance, the patient was etherized and a ring of zinc-mercury electrodes was inserted around the periphery of the growth, each electrode pointing toward the center. All were connected to the positive pole of the battery. On the center of the growth was placed a cotton-covered disc, saturated with Fowler's solution, to act as the negative pole. When the current was turned on the mercury and zinc radiated from the peripheral electrodes and arsenic from the central disc, thus attacking the growth from both directions, the two sets of materials rapidly devitalizing the whole substance of the cancer. Eight hundred milliampères were found to be possible in this manner, though above this amount had a temporarily depressant action on the circulation and respiration. After complete softening and necrosis of the growth had been secured the negative cord was shifted to a large pad on which the patient lay, the current being turned off, and 400 milliampères were employed for a time in this monopolar way to produce an efficient zone of infiltration. The total time of application was an hour and a quarter, and the subsequent history of the patient was the same as that of Case 4. The whole tumor, consisting of the entire breast and underlying fatty tissue, came away on the twenty-second day, having been odorless and painless throughout. The cavity left on separation measured 7 by 4 inches, which has greatly lessened in area in the healing process.

I will not occupy further space with the details of the remaining cases, in one of which, a carcinoma of the breast, a diseased gland in the axilla was destroyed at the time of the application to the breast, for sufficient time has not yet elapsed to insure accuracy of results.

CONCLUSIONS.

1. The massive diffusion of nascent mercuric salts within a growth or cavity of the body by an electric current constitutes a novel therapeutic procedure of great value in the destruction of foci of malignant or non-malignant germ growths, when said growths are so situated as to permit of penetration and drainage.
2. This cataphoric destruction of the germs of a primary cancerous growth in situ, including outlying colonies and so-called roots of prolongation permits the preservation of the unaffected portions of the organ in which it is situated, and offers greater security against a recurrence of the growth than efforts to remove the living malignant organisms by cutting operations.
3. While the cataphoric method may be employed as a

palliative in non-operable malignant growths, and may at times cure them, its chief value is in the total destruction of the malignant germs in the early stages of primary growths, and in the same stages of purely local recurrences.

TREATMENT OF ANEURYSMS BY EXTIRPATION: WITH REPORT OF CASE OF POP-LITEAL ANEURYSM TREATED BY THIS METHOD.*

BY JOHN CHADWICK OLIVER, M.D.

Surgeon to the Cincinnati Hospital; Professor of Descriptive Anatomy, Miami Medical College; Surgeon to the Presbyterian and Christ's Hospitals.

CINCINNATI, OHIO.

The following report of a case of traumatic aneurysm of the popliteal artery occurring in a syphilitic subject can be used as the text for a few remarks on the general subject of aneurysms, but more particularly on those which develop in the popliteal space.

John Taylor, a strong, well-developed negro, 29 years of age, had enjoyed good health until six years ago, at which time he contracted syphilis. Primary and secondary manifestations left no doubt as to the nature of his malady. He was admitted to my service in the Cincinnati Hospital, Feb. 24, 1899. Four weeks previously he had slipped and in falling had struck his ankle and the outer surface of the left knee against the curbstone. He is not certain as to whether a swelling was immediately apparent, but a dull, throbbing pain was present almost from the time of injury. This pain was always worse at night, and was increased by attempts to extend the leg. Sometimes there was a feeling of numbness in the leg. He had been treated for rheumatism.

When admitted to the Hospital his pulse was 80 and his temperature 99.6 degrees. He complained of great pain and walked with much difficulty. The left leg was semiflexed and held rigid because of the pain produced by extension or movement. The typical symptoms of aneurysm were present, but the tumor seemed more superficial than would be expected in true aneurysm. The swelling extended more toward the outer than the inner side of the popliteal space.

Because of the ease with which fluctuation could be elicited, and because of an elevated temperature—ranging between 99 and 101—it was deemed expedient to rule out the possibility of the swelling being dependent on an abscess. A hypodermic needle introduced into the mass withdrew a syringeful of clear blood. The knee of the left side was one and one-half inches greater in circumference than its fellow. Pulsations in the dorsalis pedis artery were not present, nor could we be sure as to their presence in the posterior tibial; sometimes there seemed to be slight pulsations, but they were never so strong as to remove the element of doubt from our observation.

It seemed good policy to thoroughly prepare the patient for operation by the administration of iodid of potassium in large doses. This remedy was not given for the purpose of producing any direct action on the aneurysm, but to, theoretically at least, put the artery in a better condition to retain a ligature. Codeia was given to relieve pain. The leg was immobilized by bandaging it to a posterior splint. This treatment was continued for three weeks.

On March 16 the operation was performed. Two Es-

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

march straps were used, one above and one below the knee; the upper one being placed sufficiently low to permit of ligation of the superficial femoral at the apex of Scarpa's triangle, should such a procedure become necessary. No particular difficulty was experienced in locating the nerve and vein, nor was there any embarrassment in identifying the sac of the aneurysm. During an attempt to get around the aneurysm from its inner side—the popliteal vein was on the outer side—the sac was ruptured, and a large blood clot was expressed. This accident proved to be of service in two ways: it showed conclusively that we were dealing with a false aneurysm, and by exploring the interior of the sac the points of entrance and exit of the artery were made plain; these served as excellent guides.

The vessel was dissected out and divided between ligatures one inch above the aneurysm. An attempt was now made to completely isolate and remove the sac, but because of its extreme tenacity and fragility the effort was but partially successful. During the attempt to remove the sac *en masse* a lateral tear in the popliteal vein occurred, which was repaired by lateral suture with fine catgut. The artery below the aneurysm was cleared to its point of bifurcation, and ligatures placed just above the bifurcation, at which point the vessel was divided. The original rupture in the vessel had taken place on its posterior surface. The anterior portion of the vessel could be identified as constituting part of the anterior wall of the sac. All of the vessels arising from this part of the vessel were exceedingly soft—ligatures applied with but moderate force would readily cut through the walls of the arteries.

The after-history was perfect except that the patient continued to complain of continual, dull, crampy pain on the dorsum of the foot and on both sides just behind the malleoli. This was at first attributed to ischemia, but when six or seven weeks had passed without relief some other explanation became imperative. Dr. F. W. Langdon was asked to see the case. He discovered marked ankle-clonus of both feet, hyperactive reflexes, weakness of right hand and arm—which the patient first noticed March 10—ptosis of left eyelid—this was an old condition, having been present many years—an area of anesthesia over the first metatarsal bone and plantar surface of the foot—the temperature sense was also absent in this area. Dr. Langdon gave it as his opinion that there was enough to justify a diagnosis of cerebrospinal syphilis, and that the symptoms were probably produced by thrombi.

The patient at the present time has entirely recovered from the operation, but the symptoms on the part of the nervous system persist but are much less pronounced.

Any method of treating an aneurysm must accomplish two objects: it must remedy the diseased condition, and this must be accomplished in such a manner as to inflict a minimum of damage on the tissues. The oldest method, that of Antyllus, which consisted in ligating the artery above and below the aneurysm and then splitting the sac, possessed one great drawback, i. e., it left a suppurating mass in the popliteal space, which took many weeks to close. This suppuration must have done harm by causing useless cicatricial contraction, and it also predisposed to the occurrence of secondary hemorrhage. In the treatment of popliteal aneurysm this method gave way to the Hunterian operation—ligation of the artery at some distance above the aneurysm. Time has proven this method to be inferior to that of Antyllus. Nevertheless, it has been adhered to as the classic operation. Mr. A. A. Rowley¹ makes the statement that

at St. Bartholomew's Hospital the superficial femoral had been ligated twenty-two times in the preceding ten years, for the cure of popliteal aneurysm. Gangrene of the limb took place in four cases—18.2 per cent.—and recurrent pulsation in two—9.1 per cent. These results were not the sequence of injury to the femoral vein. The number of cases here quoted is entirely too small to justify one in drawing general conclusions, but a method giving more than 27 per cent. of failures can not be considered an ideal one. This procedure is open to the objection that it is by no means a certain cure for the diseased condition, and it inflicts more damage on the limb than is necessary or advisable. It would appear therefore that the Hunterian operation should be abandoned providing a better method exists.

It can not be gainsaid that one single method may not be applicable to all varieties of aneurysm, so the present discussion will be limited to a consideration of the treatment of popliteal aneurysm.

The method by extirpation presents some advantages and some disadvantages. A proper appreciation and weighing of these may lead to an accurate opinion of its value and its range of application.

The first advantage of the method by extirpation lies in its attacking the disease directly. There is a double advantage in this—it gives one a very clear idea of the local conditions, and it permits the operator to vary his procedure in order to meet the exigencies of the particular case. The Hunterian operation has the double disadvantage of leaving one in doubt as to the local condition and it permits of no variation. It is simply the classic operation of tying the superficial femoral artery at the apex of Scarpa's triangle.

A second advantage of the method by extirpation is that it interferes with the circulation of the leg much less than does the operation of Hunter. Only that portion of the vessel which is involved is obliterated, and the ligature is much farther from the heart than when the superficial femoral is tied. This permits of the more ready establishment of the collateral circulation and diminishes the risk of gangrene.

A third advantage of the method of extirpation consists in the greater certainty of cure. When one comes to deal with this statement he finds that the figures are small, but the deduction seems to be irresistible. Ransohoff² records twenty-eight cases in which aneurysm of the large vessels of the extremities was extirpated. All were cured. Gangrene and secondary hemorrhage did not occur at all. A comparison of these figures with those of Bowlby (quoted above) seems to prove the very decided advantage of extirpation as a curative measure. Aside from the greater probability of cure the mortality following extirpation is less than that of proximal ligation. Delbet places the mortality following extirpation at 11.32 per cent., and that following proximal ligation at 18.92 per cent.

Certain disadvantages, some real and some imaginary, have been urged against extirpation of popliteal aneurysms. In the first place it is said that the operation is a harder one than that of tying the superficial femoral. Even granting this to be true one can scarcely urge the difficulty of its performance as an argument against its adoption. The same line of argument would deprive us of many of the modern operations. If the results are better, mere difficulty of performance can not be held as a valid objection to its use. We all know that ligation of the superficial femoral is a classic operation, but one

¹ British Med. Jour., Nov. 29, 1890, p. 1237.

² Annals of Surgery, 1894, p. 83.

may well doubt whether it is in all cases easier of performance than is ligation above and below with extirpation of the sac. Injury to the femoral vein will almost certainly eventuate in gangrene and amputation; while injury to the popliteal vein has frequently been reported—it occurred in the case reported above—without any evil after-effects.

A second objection urged against extirpation is the likelihood of the vessel, in the immediate vicinity of the aneurysm, being the seat of disease. Bowly has shown that this assumption is unwarranted, and that there is just as much likelihood of the femoral being diseased as of the popliteal. The non-occurrence of secondary or recurrent hemorrhage in a single case is the very best answer to the above assumption.

A third, and real, disadvantage is the greater danger of infection with its attendant consequences. The parts are more disturbed and torn in extirpation than in proximal ligation, still there is no reason why, under proper asepsis, suppuration should be a frequent sequence. The ill effects of suppuration are well illustrated by a case reported by C. E. Harrison.² In this case extirpation was practiced after compression had failed; suppuration occurred, followed by gangrene and secondary hemorrhage. Amputation was necessary to save the patient's life. The aneurysm, in this case, followed a penetrating wound of the popliteal space, and this was undoubtedly infected prior to the extirpation. This case may also prove that it is unwise to resort to prolonged compression as a means of treating aneurysm.

A fourth objection to the operation of extirpation is the length of time required for its performance. In the case of a young, vigorous person this feature is not a serious one, but when dealing with the old and decrepit it assumes increased importance. One may safely assert, however, that a person who is too weak to stand the additional time required, is, in all probability, not a proper subject for any such serious surgical operation.

Kubler⁴ has collected 40 cases of aneurysm treated by extirpation; 28 of these cases were arterial, and 12 arteriovenous aneurysms. The aneurysms were non-traumatic in 11 cases, and the result of injury in 29 cases; 39 of these cases were completely successful and no mention of either gangrene or secondary hemorrhage is made.

The latest statistics of this method of treatment are those of Dr. W. Kopfstein³, who records 86 cases of aneurysms, in various localities, which were treated by extirpation—27 were spontaneous and 59 traumatic. He also reports 16 cases of arteriovenous aneurysms similarly treated—2 spontaneous and 14 traumatic. Twenty-nine cases of popliteal aneurysm treated by extirpation gave 27 successes and 2 failures—1 death from gangrene and 1 amputation secondary to extirpation. This is a much better showing than that given by Bowly for the Hunterian operation—6 failures out of 22 cases.

Kopfstein also records the extirpation of 15 femoral aneurysms with 14 successes and 1 death from secondary hemorrhage on the tenth day. The method was uniformly successful in 4 cases of aneurysm of the anterior and posterior tibial arteries, in 3 of the carotids, in 1 of the subclavian, 3 axillary, 9 brachial, 7 radial, 5 ulnar. In 10 aneurysms located in various vessels, 9 were successful, and 1 of the posterior occipital, gave a fatal result from primary hemorrhage. In 86 cases of aneurysm in various parts of the body there were 82 complete successes. Death occurred in but 2 of the 86 cases—about

2.33 per cent. Failure to cure is recorded in but 4 cases, 4.66 per cent.

These figures are suggestive and indicate that a much more extended trial of this method is advisable. From the facts quoted above, the following conclusions seem to be justified:

1. The operation by extirpation is the most scientific of all methods thus far proposed for the treatment of aneurysms of the extremities.
2. It is by far the safest method.
3. It gives a greater percentage of cures and a less percentage of deaths than any other method.
4. The operation by extirpation should be resorted to without previous attempts at cure by any other method.

DISCUSSION.

DR. LEONARD FREEMAN, Denver, Colo.—As regards Dr. Oliver's interesting paper, I agree heartily with it, and if I should have a similar case, I should treat in the same way. Dr. Rickett's paper¹ is a good one, but he has left out of consideration gangrene of the lower extremity due to the injury of the vessels in the popliteal space. This is probably not due so much to the vascular injury or to the absence of collateral vessels, as to the fact that much blood is extravasated beneath the popliteal fascia, stopping the feeble circulation by its pressure. I would suggest that in the operation which Dr. Oliver has given us for extirpation of a popliteal aneurysm, it would be well to pay marked attention to this feature, and provide ample drainage.

DR. J. P. LOEB, Omaha, Neb.—I want to detain you a moment to recite a case bearing on the first paper. I was asked by a physician of Omaha to see a patient, in consultation with him, who had just come from the country, and who three months previously had been thrown from a wagon in a runaway. The young man was 20 years of age and had sustained an injury of the knee. He was laid up for about ten days with this injury, and then he was able to get about on crutches. The knee became no better and took on considerable enlargement. He came to Omaha. I saw him on his bed. There was this quadrilateral shape of the knee seen in hydrops articuli, and there was some local heat, from which I inferred that there had been infection. There was some edema of the foot, which indicated to my mind that this extensive accumulation about the knee had simply interfered in a mechanical way to produce this swelling. The parts were very painful because of a slight amount of inflammation, the temperature was only about 101 degrees, and I immediately made a diagnosis of abscess, of tubercular knee, incited by the trauma. The parts being very tender, I did not make a careful examination, finding that there was some fluctuation. In view of the fact that I thought an amputation might subsequently be a necessity, I made a lateral incision for the evacuation of this accumulation within the capsule of the knee. Much to my surprise I found a very extensive blood clot. This had extended half way up the thigh, underneath the quadriceps extensor muscle, and finding that it came from below and from the midst of the joint, I began to dig out the wound, when my hand went into cancellous bone structure, which seemed to be very much absorbed and very ragged. I then apprehended that we were dealing with an aneurysm of the popliteal artery, traumatic in character. Having gone this far I decided to clear out the blood clot, which I did. In the midst of this, a very free hemorrhage took place, which necessitated the immediate application of the Eschmarch, and on extending the incision I found, for a distance of four or five inches posteriorly, the bone had been completely hollowed out, so that there was simply a small spicula of bone anteriorly that held the shaft together. This was broken in our effort to hold up the limb while the tourniquet was being applied. Here was a desperate situation; consent for amputation had not been secured, but the amputation was done. I found on examination of this specimen that the distal end of the artery was completely occluded by blood clot, and here was this enormous accumulation from this traumatic aneurysm, and it was most incredible to me that this man had suffered from this condition for three months without any more disturbance of circulation in this extremity. It occurs to me also, that, had a diagnosis been early arrived at in this case, this limb might have been saved by the proper treatment, as indicated by the first paper.

SOME COMPLICATIONS RESULTING FROM RECTAL OPERATIONS.*

BY WILLIAM M. BEACH, A.M., M.D.

Surgeon to Presbyterian Hospital; Fellow of American Proctological Society.
PITTSBURG, PA.

To sacrifice the minimum tissue and preserve the perfect function of an organ is the highest art in an operation for the eradication of disease. This proposition is especially germane to operative measures involving the anorectal region, for the reason that the mutilation of a single anatomic structure may determine disastrous sequences in the health and comfort of the patient. The notion is wide-spread in the profession, and taught by proctologic writers, that bold incisions and dissections of this region entail no permanent loss of function, trusting to the reparative processes of Nature to restore perfect order out of chaos.

Legitimate surgery of the anus and rectum involves the consideration of certain anatomic landmarks that must not be disregarded. Martin writes: "The three typical visible topographic features of the anal rectum are the white line of Hilton, the pecten of Stroud, or anal pilasters and the linea dentata." The integumentary membrane of which these visible landmarks are a part rests on a quantity of loose connective tissue, which permits of a great range of mobility of these features independent of movement of the structures, constituting the palpable landmarks of the fixed rectum. Marked pigmentation of the anal skin is observable in a circumscribed area about the anus; beneath this area of darkened skin lies the surgically unappreciated corrugator cutis ani.

In addition to these delicate structures that have peculiar physiologic functions pertaining to the act of defecation, the gut is poised and controlled by a motor apparatus, exact in its arrangement and composite in action. This muscular automaton consists, as stated above, of the corrugator cutis ani, the rectal sphincter whose aggregate fibers passing between the coecyx and central tendon form an ellipse surrounding the terminal portion of the gut. In the female, these fibers continue to form the sphincter vaginae by a figure-of-eight. At the central tendon, fibers of the transversus perinei unite with it. The function of the rectal sphincter is accessory to the anal sphincter in controlling the escape of the fecal column, and is for the most part voluntary, while the involuntary terminal circular fibers or anal sphincter regulates, through the cerebrospinal centers, the passage of rectal contents. The levator ani is a broad muscle forming the basis of the pelvic floor, and serves to lift the relaxed anus over the fecal mass in its descent.

With these perfunctory observations before us, we now pass to a brief consideration of some complications following operations or injuries on the fixed rectum, or that portion limited above by the levators ani, and below by the corrugator cutis ani: 1. Incontinence. 2. Stricture. 3. Elongation of the anal rectum. 4. Ulceration and hemorrhage. 5. Loss of rectal sense organs. 6. Suppuration and phlebitis. Any or all may be the sequelae to operations for the removal of hemorrhoids, fistulae, adenoids, fissure or malignant neoplasm, but the writer has in mind the minor operations only.

Incontinence is probably the most common complication arising from the operation for fistulae; especially is this true if the disease occupies the anterior quadrant, because by the surgeon's severing the fibers of the

rectal sphincter, the incised extremities are kept apart by the contracted transversus perinei, and thus prevent union.

In a recent exhaustive paper by Dr. Kelly, on rupture of the perineum, he lays important stress on the function of the anal sphincter, and its repair necessary for complete control of the bowel. These fibers retract permanently when cut or torn, by aid of the transversus perinei—hence to avoid this accident the divided portions should be adapted by suture. Multiple incisions are to be avoided, since the fibers will retract toward their points of insertion and be held up by levators ani, and we are constantly reminded that the muscle is to be cut but once in the lateral quadrants even in multiple fistulae.

Incontinence is liable to follow divulsion in syphilitic and tubercular patients. In such cases the efforts of the proctologist to relieve his patient will be followed by disgust and ingratitude—indeed, what more unenviable position could a patient be placed in? It ostracises him completely. Incontinence may follow the removal of hemorrhoids explicable on the ground of muscular impairment.

The direct antithesis of incontinence is stricture. This is the result of vicious cicatrices consequent on the unskillful use of the clamp and cautery, and hence is a not uncommon complication following operation for the removal of piles. The danger in the clamp and cautery is the removal of too much tissue, especially the integumentary membrane, which will be followed by contraction. An operation is recommended for the cure of pruritus ani, which consists in the dissection of the peri-anal skin. Though it may be the lesser of evils, contraction is almost certain to follow, besides complete destruction of the integumentary muscle. It is argued that stricture following operations, readily and permanently yields to secondary divulsion.

Elongation of the anal rectum is a permanent contraction due usually to the removal of internal hemorrhoids without complete divulsion, or vicious cicatrices from incisions for fistulae. This complication is a corollary to stricture.

Hemorrhage is a temporary danger following cutting operations. This is especially true of the removal of polypi, since they are exceedingly vascular, each being supplied by an artery in the pedicle. In this connection it is pertinent to state that hemorrhage is a complication most to be feared in valvulotomies, and requires special instruments for its control.

The "hemorrhoidal inch" will sometimes form the site of single, multiple or continuous ulcers following operations, which become a nidus for bacteria and toxins, producing tenesmus and chronic diarrhea, or rather mucorrhea. These patients will complain of a seeping and a constant sense of moisture. Post-operation ulcers may be avoided by antiseptic measures to encourage healthy granulation.

In lieu of the existence of the special rectal sense of Stroud being necessary to the healthy activity of a normal rectum, any operation conceived that will destroy this organ is to be deplored and condemned as unsurgical and unscientific, especially in the removal of piles. For this reason, we mention Whitehead's operation only to reject it. The pectinæ, in which resides the end bulb, form the basis of the pile, and care should be taken to remove such portions of the hypertrophy as will leave the end organ intact. Destruction of the rectal sense organ leads to delayed defecation and constipation with the usual train of sequelae.

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

Wounds not healing by first intention invite infection, which leads to suppuration and phlebitis. The occurrence of ischio-rectal cellulitis and abscess is a complication that entails disfigurement incomparably greater than any disease for which a minor operation is required. Healing by first intention should always be encouraged if possible, by the free use of catgut sutures, and the period of convalescence be thereby materially lessened.

The technic of minor operations on the anal rectum, and the strict application of the principles of antiseptics will contribute incalculably toward success, and remove that fear extant among the laity that operative measures are fatal, or are not conducive to permanent cure.

DISCUSSION.

DR. J. R. PENNINGTON, Chicago.—While it is true that strictures, ulcerations, incontinence of feces, etc., occasionally follow rectal operations when done by the inexperienced operator, yet we rarely find these sequelae when the operation has been performed by a skilled proctologist and efficient after-treatment administered. I believe that in many cases the final result depends as much on the after-treatment as the operation itself. After most of my rectal operations, especially those for hemorrhoids, I introduce into the rectum a rubber-covered rectal tampon. I find this a most valuable method, far superior to any gauze dressings. Its removal is painless and it leaves the wound in such a condition that the bowel movements are also painless, a point which seems to us of much importance.

DR. CHARLES MARTIN, Cleveland, Ohio.—It seems to me that a more fitting title would be, "Bad Results of Bad Surgery and How to Avoid Them." There has been much mutilation practiced on the rectum. There are one or two points suggested in this paper on which I would like to make comments. There has been during the past few years practiced in this country an operation known as "the American operation," a most un-American procedure—for it is American to permit the greatest individual liberty and privilege and to encourage the accumulation of possession and the retention of those things which we have. I sent, into the central western states three years ago, 7000 circulars, to the profession, inquiring as to the results of the mis-called "American operation," and I have many letters reporting over six hundred cases of most disastrous results from that operation, results worse than the conditions which it was designed the operation should relieve. There is another point referred to in Dr. Beach's paper, having particular reference to the mechanism of the sphincter ani and of the transversus perinei—he refers to the difficulty of getting coaptation of the anterior quadrants of the sphincter when the ends are divided in surgery or torn by accidental means. These sphincter-ends may be sutured and made secure provided an additional operation is performed on the transversus perinei muscles and on the coccyx, which will take all the tension off the sphincter and give it time to unite. If an incision is made through each transversus perinei muscle, and if the tip of the coccyx—last bone—is divided from its fellows, all the muscular structures about the anus are set adrift and almost immediate union of the sphincter follows.

USE OF ACETANILID IN VARIOUS COMBINATIONS AS A SUBSTITUTE FOR MANY PROPRIETARY DRUGS AND MIXTURES.

BY LOUIS FAUGERES BISHOP, A.M., M.D.
NEW YORK CITY.

Those of us who are confused by the claims of the ever-appearing antipyretic analgesics should consider one method by which we can obtain definite knowledge of this special class of drugs. It is better to know one drug well than many partly. For a long time I have not prescribed any new drugs of this class, but have substituted acetanilid in such a combination as seemed desirable for the case. In doing this I have also returned somewhat to the custom of prescribing liquid medicines. Acetanilid is not soluble, but it is readily suspended in

syrupy mixtures so that one can write for acetanilid combined with ammonia in any of its forms—salicylic acid, nux vomica, digitalis, codein, creosote, bromid of potash, or indeed almost any drug, and obtain a prescription that can be much more readily adapted to the case than is possible where any of the ready-made combinations are used that are sold under so many registered names to such enormous profit to the alleged proprietors of the same. The fact should be known to the profession that the foundation of most of these drugs is practically acetanilid, and any particular virtue that is claimed for them is obtained by the admixture of bicarbonate of soda, caffeine, carbonate of ammonia or some other such drug. Now these may or may not enter into chemical combination with the drug. The difference between a mixture and a loose chemical combination of organic products is often so slight that it is not worth considering. Practically in the body these drugs are broken into the acetanilid radicals and the other drugs, and for that reason it is much more professional and scientific to write for the mixture that we wish to use than to be the slaves to a secret medicine fad.

This is as much a pharmaceutical as a therapeutic problem. It is for pharmacy to decide the truth of the familiar claims of the owners of proprietary medicines, that they are in possession of some magic process of combination, or some method of purifying drugs unknown to the pharmacist in general that gives them the right to control and own particular remedies. It would seem that a man who had devoted himself to a profession, such as pharmacy, would be able to discriminate promptly between true and false claims of this kind. The *bete noir* of the proprietary medicine man is the substitution, by the pharmacist, of an equivalent combination for his elaborately advertised and prettily named remedy. Nor in the long run is it judicious for physicians to countenance this habit. However, it is within the legitimate province of the physician to substitute just as much as he pleases in prescribing, and the number of mixtures written for under specific names will be in inverse proportion to his knowledge of their constitution and composition.

There is another great class of remedies that is particularly abused, namely, the preparations of iron. In time the greed of the manufacturer often transfers his remedy from the domain of professional use to that of a nostrum, chiefly employed by the public. It is hard to see how the respect of the profession can be maintained by the foras of advertising that have already been put into use. Perhaps the most generally useful combination of acetanilid when used as an analgesic is the migraine tablet. This is equivalent to at least several of the most widely used secret mixtures that are sold under a specific name. It consists of two grains of acetanilid and one-half grain, each, of caffeine citrate and monobromate of camphor. The caffeine neutralizes much of the depressing effect of the acetanilid and monobromate of camphor acts favorably on the nervous system. These tablets are convenient for office use and for the pocket case as a general and efficient analgesic. Another useful combination that can be prescribed in capsules is acetanilid and quinin. A grain of acetanilid will neutralize the disagreeable effect of four or five grains of quinin. As a general tonic, when a patient is very uncomfortable from a cold, 1 grain of acetanilid with 2 grains of quinin three times a day, makes a good adjuvant to other treatment. In rheumatic conditions and those in which there is a suspicion of

*Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

intestinal fermentation, acetanilid and salol can be prescribed in capsules. For the disagreeable disturbances of circulation and neuroses of the menopause, a useful prescription is a mixture that will give 2 grains of acetanilid, 15 grains of bromid of potash to 1 dram of simple elixir. The acetanilid does not dissolve, but is well suspended in the viscid vehicle.

Indeed, a small amount of acetanilid can form an ingredient of any one of a large number of familiar prescriptions, supplying a valuable anodyne and antiphlogistic remedy. For instance, a useful cough mixture can be composed of acetanilid, aromatic spirits of ammonia and syrup of tolu. It combines well with bromid as a hypnotic, and may be prescribed in powdered form to be mixed with water. It is a useful addition to various mixtures for acute indigestion, helping distinctly in the relief of pain; for instance, in these very severe cases of flatulence, causing tremendous distress after meals, relief is obtained by a teaspoonful of the following tincture.

Acetanilid	5iij
Tinct. nux vom.	5iij
Tinct. capsicum.....	5ss
Tinct. gentian. comp.....	5iv

M.

As a substitute for iodoform and a host of other antiseptic dusting powders acetanilid has been found to be very efficacious. It has the endorsement of successful surgeons, and there seems no reason to doubt that acetanilid in powdered form, or mixed with equal parts of boric acid, can easily replace the long list of antiseptic powders used in surgical disorders. There is a danger of toxic absorption, but this is true of all the others, and it is more likely to be understood, recognized and guarded against if one substance is habitually used than if the surgeon is constantly changing from one antiseptic to another.

In making this study of the practical therapeutics of acetanilid, it is not my desire to in any way antagonize those who deal in these preparations corresponding to these various prescriptions. My plea is rather for a better knowledge of these compounds so that the physician, if he does not wish to write his prescription, may use them intelligently. It is for the chemists to tell us what proportion of the new substances that are brought out represent important discoveries in pharmacy, and what proportions are mixtures, or such slight chemical modifications of well-known substances that they serve more to introduce mystery and confusion into therapeutics than to advance knowledge.

What is needed by the profession to-day is a better knowledge of drugs that it is using. It would be well if the new pharmacopeia could be the work of a genius, eliminating the thousands of drugs that have fallen into disuse, and enumerating only those of practical importance, so that in the next generation physicians could concentrate their attention on fewer drugs, and acquire thorough knowledge of these. It is impossible to eliminate patented drugs from use, but there should be some authority which fearlessly would give a true and impartial opinion as to their construction and therapeutic value. One hardly realizes how much the profession really stands in fear of the influence of some of these drug companies. I remember that once, at a state society, I spoke in a disparaging way of the most widely advertised secret acetanilid mixture, and was approached after the meeting with the advice that it would be better not to antagonize a company that gave so much advertising to the medical press. I noticed that my remarks were eliminated from the report in the most

prominent medical journals. It should not be the duty of any individual to lay himself open to lawsuit and possible persecution in behalf of the medical profession in exposing the true value and construction of drugs. It would seem that the time had come when there should be some central body which could be entrusted as a court to give a verdict on the true composition and value of drugs. Some foreign countries have laws prohibiting the sale of secret preparations and making it a misdemeanor to sell drugs at a greater price than a reasonable profit.

There will be a stubborn fight on the part of the owners of certain secret remedies for their introduction into the pharmacopeia, and it is almost certain that they will not be admitted. While it must be acknowledged that some patented synthetics must be admitted, still care must be exercised that under the cover of these really new drugs a great many worthless ones are not also introduced.

PROGRESS IN SERUM THERAPY*.

BY GEO. W. COX, M.D.

CHICAGO.

The gradual unrolling of the scroll which displays the evolution of serum therapy brings into view one of the most pleasing pictures to be found in the gallery of medical art. It presents to us the image of a system whose present status was attained with a suddenness bordering on abruptness; and whose steady growth gives promise of eventually placing it in line with established sciences. My definition or conception of serum therapy must not be construed to limit the practice to the administration of antitoxins; but to embrace the treatment of disease with all such substances as are the natural outgrowth of applied bacteriology, which in turn is the result of the germ theory. Strictly and technically speaking some of these would necessarily be excluded from consideration under this head, because they are not serums, as that term is popularly understood and applied. However, the principle involved is essentially the same; and inasmuch as it would be impracticable to create a separate department for each substance, I hope the general term serum therapy may, for the present, at least, be accepted in such a broadened sense as to include medication by toxins, antitoxins, all blood-serums and vaccines; and let subdivisions of the subject be determined by future study and development.

An idea may be transformed into a theory instantly, and a theory into an art with moderate precipitation; but the conversion of an art into a science is a process of deliberate growth and can only be accomplished through the media of time, of skill, of patience and of labor.

Serum therapy is an art; and while its position as such is of recent date, it is descended from an idea so ancient that no man can reckon its birth or point its origin. Even the second degree of progression, the stage of theory, is so veiled in the gloom of antiquity that history fails to record the transition. The human race seems to be endowed with one principle which is common to all peoples in all ages, namely, the intuition to worship and to heal. Even among nations that are regarded by us as wholly uncivilized, where letters are unknown and environment the most crude, some sort of deity is recognized and some sort of "medicine man" is found; and concerning these two personalities, the spark of genius has, from age to age, occasionally flashed forth to break the blackness of the general gloom.

*Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

Anxiety for present health and for future life and happiness may constitute the only beam of intelligence discernible in an entire tribe; and no matter how benighted the race or barbarous their habits, on these two points the power of reasoning has never been entirely lost. The idea of deity and the idea of physical cure are co-existent with human life; and while in each instance the idea may have stopped far short of reason, as we are able to discern and exercise it, it has usually been sufficiently progressive to crystallize into some form of theory. So it has long been with the art which we are now able to demonstrate, and the science which we hope to establish. Serum therapy, in principle, if not in name, has been a theory for many centuries, playing hide-and-go-seek with the seekers after truth, but never forgotten, never entirely lost, and constantly suggesting to inquisitive minds the possibilities of ultimate victory in the line of great achievement and of great usefulness. Before the days of Jenner, of Galen, of Celsus or even of Hippocrates, the idea of cure by inoculation had passed to the theoretic stage, and had even been put to practical test by a people whom we have been taught to regard as hereditary heathen. From this most anciently known source, then, inoculation has extended through succeeding centuries, and has at various times been practiced by the Chinese, the Hindoos, the Persians, the Arabians, the Egyptians, the Turks, the Continental Europeans, and finally by the English, who first established it on its present practical footing by the marvelous discovery of Jenner. Crude as their methods must have been; unsatisfactory and disappointing as their results, in the main, surely were; without the advantages of modern education and equipment; with no knowledge of bacteriology, of chemistry, of the microscope, the spectroscope or even of human anatomy and physiology, the ancient physicians were like a mariner in mid-ocean without compass or sextant, without rudder or sail. But even so, they did not sit down to waste and starve in idleness; they did the best they could—they looked at the stars and plied the oars.

Perhaps it is not entirely just to our ancient brethren to assume a position for them that would make their achievements look altogether like the result of accident or of instinct, for occasionally we find traces of practices that could only have been devised under the guidance of a well-balanced reasoning power. For example, in the department of serum therapy, the very latest addition to our galaxy of "new discoveries," in a very ancient Hindoo medical work entitled "Sacteya Grantham," the following remarkable description of smallpox vaccination occurs: "Take the liquid of the pustules of the cow's teat, or from the arm of a human being, between the shoulder and the elbow; place it upon the point of a lancet, and introduce it in the arm at the same place, mixing the fluid with the blood; the fever of variola (Bhadvidee) will be produced. This disease will be mild, like the animal from which it is derived; it need not cause fear, and requires no remedies; the patient may be given the food he desires. The pustule is perfect when it is of good color, filled with a clear liquid and surrounded by a red circle." Nothing short of sound reasoning, close observation and practical experience could invent such a systematic procedure as this; and it would even be difficult to more accurately describe it. Where the Hindoos received their knowledge of inoculation, or how long, or with what success they practiced it, are among the things that erratic history does not record; but notwithstanding their familiarity with the subject, as evidenced by the above

terse description, the art was permitted to become entirely lost, leaving nothing but traces of the theory, or even of the primitive idea, for succeeding generations to grasp and build upon. And so tradition and history furnish us with occasional glimpses of the medical mind during a period of two or three thousand years that prove conclusively that much originality, much ingenuity and much practical knowledge have, from time to time, been displayed throughout the centuries that are dead. This does not detract in the least from the halo that decks the brow of modern fame, for the re-discovery of a lost art by means of original research is entitled to all the glory that clusters about archetypal production. The work of Jenner and that of Pasteur are as truly original as any that was done in the long forgotten past, or ever will be done in the years to come; and it is to the genius of these two men that the world is indebted for the saving of more human lives than to that of any other score of men who ever lived. Jenner applied smallpox vaccination empirically, to be sure, for he was without bacteriologic knowledge necessary to account for his magnificent clinical results on a scientific basis; but if he had waited for the acquirement of this knowledge before applying his remedy, several decades would have rolled by and millions of helpless victims would have yielded to the relentless power of variola.

Half a century after Jenner's great triumph, the first promise of a solution of the entire vaccinal problem was given in Pasteur's discovery of the cause of fermentations. From that moment, and from that incident, bacteriology began to take form and to grow into the ever-spreading science whose branches have now extended around the globe to shed blessings on suffering humanity in every land. Pasteur not only pointed the way for others to follow, but by original discoveries and demonstrations, rendered their work of development comparatively easy. Through Pasteur's discoveries it was made possible for us to know just how and why vaccination protects against smallpox and other diseases, and thus the great work of Jenner is rounded out and made into a monument to the genius of both the beginner and the finisher. In like manner it was Pasteur's work that paved the way for the discovery of every disease-germ that has been found since his time or that shall be discovered hereafter.

The discovery and demonstration of the cause of a disease is a long stride in the direction of controlling the disease itself; and inasmuch as the science by which this is accomplished with respect to infectious maladies is founded on such a solid basis, and is in a state of such healthy growth, we have come to regard such discoveries as a matter of course, and but little surprise is expressed at the announcement of the capture of a new offender. Likewise, we are constantly expecting to hear of the discovery of new remedies along the lines of serum therapy, and our patience grows weary because they are not more rapidly forthcoming.

Between the time of the discovery of the bacillus anthracis by Pollender, and that of the vaccin which so completely controls the disease caused by it (anthrax), by Pasteur, there is a period of thirty-two years, notwithstanding the fact that a noted French physician had, in the meantime, experimented with the germ sufficiently to establish an undeniable etiologic relationship between it and the disease. In 1876 Pasteur began the methodic study of anthrax; and while he was the acknowledged leader in the line of work pertaining to micro-organisms and their effects, it was not until 1881 that he was prepared to announce and demonstrate the

discovery of a vaccin that would effectually prevent the disease. This announcement, together with the faith that had been inspired by his former discoveries, seemed to stimulate bacteriologists to greater effort; so that not a year has elapsed since that time in which something new and useful has not been recorded, either within the walls of the great laboratories founded by Pasteur, by some pupil of his or by some one who had profited by his teachings. In all, something like two hundred pathogenic micro-organisms have been discovered, many of which have yielded up their secrets and their power to the superior force of science. Nearly three-fourths of the entire number belong to the class known as bacilli, almost one-fourth to the division called microbes, while a few only are included in the group designated spirilla.

Following closely on Pasteur's discovery of anthrax vaccin came, from a pupil and co-worker of his, the announcement of the discovery and successful application of a vaccin for the prevention of symptomatic anthrax, or blackleg, as it is more familiarly known in this country. Anthrax and blackleg had become so prevalent, and their ravages so great, in many parts of the stock-raising world that financial ruin was not only threatened but actually experienced in many instances. The two vaccins just mentioned have so fully and completely fulfilled the requirements as preventives, that where vaccination is practiced at the proper time, outbreaks of anthrax and of blackleg are now simply matters of history. In no branch of medical science has the power of a remedy ever been so beautifully shown and universally successful as in the control of these two animal scourges; and if serum therapy had stopped short at this stage of its progress, its name on the escutcheon of fame would have been written in letters of living light. But it did not stop here. Forging its way by slow and tortuous steps, it has advanced until to-day we have it in a system which promises absolutely perfect and definite results in its important, if limited, sphere. Hog cholera, which has cost the American farmers multiplied millions of dollars during the present generation, seems just on the verge of losing its terrors through preventive inoculation; veterinary tetanus and purpura hemorrhagica are more amenable to serum treatment than to any other, while the certain detection of tuberculosis and of glanders in their earlier stages is made easy, and their general management greatly simplified, by the application of the principles of serum therapy. Other veterinary diseases, such as pleuropneumonia, rinderpest and a number of others of less importance, have been studied with great interest, and usually with encouraging results, but their further consideration must be left to the future.

Passing now from the veterinary field to a consideration of serum therapy as applied to the human subject, we find that the vastly increased importance of our theme is more than proportionately recognized and acknowledged by the profession. The efficacy of antitoxin in the treatment of diphtheria is no longer a debatable question, for by dint of proofs innumerable and incontestable, the remedy has gained the enthusiastic indorsement of an overwhelming majority of the medical profession. It seems to me to be particularly fortunate for the system of serum therapy that one of the most dreaded of all infectious maladies should have been the first to completely yield to its influence; for it is a reasonable argument that if diphtheria may be thus conquered, many, if not all of the others, must sooner or later fall into the line of subjugation. If the first statements of Roux and Behring had not been borne out by subsequent tests,

and their promises had not yielded such immense returns, it is quite likely that incredulity and lack of interest would have largely predominated in the public and professional estimate of the antitoxin theory, and many years might have elapsed before another impetus was given to its slow but persistently onward motion. However, as the tide of fate was favorably turned thus early, investigators all over the world at once took a renewed interest in their work, and subsequent developments have fully justified their efforts. Up to the present time, no other human disease has so completely yielded to the curative power of serotherapy as has diphtheria; but from some of the most recent investigations a number of valid reasons have been discovered and cited for this, and which have in no way discouraged the friends of the system beyond that degree which belongs to unavoidable delay. For example, it has been found that infectious diseases are frequently so complicated by the invasion of other micro-organisms that two or more distinct pathologic conditions coexist in the same subject. The complications may either intensify or mask the original malady; and in a paper I presented to this Section one year ago, I cited a number of cases of tuberculosis which presented all the classic symptoms of far-advanced pulmonary phthisis, but which, after being freed from their complicating factors proved to be mild and easy to control. The most striking of these cases is still under observation; and the tubercular element, while still in evidence, has apparently not advanced in the slightest degree for more than two years, and the patient is attending to business interests that he had wholly relinquished in the fall of 1896. Before the days of serum therapy, cases like this would have been either abandoned as hopeless or sent to some mountain or seaside resort—too late to receive any benefit from the change. Climatic changes are of great importance in properly selected cases, and I do not wish to undervalue them; but cases like the one just mentioned could receive no benefit from climatic influences alone, and having practiced for ten years in one of the most noted resorts in the United States for the climatic treatment of tuberculosis, I can recall a number of similar cases that came to us only to sink rapidly to dissolution. It is not claimed that there is an antitoxin or an antitubercle serum that can be depended on to combat tuberculosis in its various forms and phases; but it is claimed that serum therapy furnishes us with a sure means of detecting the disease in its incipency—even before its location in the organism can be made out—and far in advance of any other means of diagnosis. The importance of early diagnosis is self-evident. If no complications exist, and the general conditions are favorable, tuberculosis is quite manageable in almost any climate; but if for any reason a change becomes necessary or desirable, serum therapy enables us to advise that change at a time when benefit might reasonably be expected. Moreover, if the case has been permitted to progress until the infected area has been invaded by organisms far more destructive than the tubercle bacillus, serum therapy, while not perfect, not infallible, offers the only hope that comes within the range of our present knowledge. This hope grows brighter as the days go by and we note the advancement of this rapidly growing art; and to those of us who keep track of its progress the day of full fruition seems more than a possibility.

It is already well known to us that blood-serums act in different ways in different conditions, and that a full explanation of this variation is impossible with our present knowledge of the subject. Some of them have

a direct germicidal effect, some an antitoxic effect, while still others seem to act principally by cell stimulation or by producing phagocytosis. Sufficient time has not yet elapsed for a full investigation of all these phenomena so that explicit reasons may be given for apparent discrepancies; but when we remember that small-pox vaccination was practiced with wonderful success for fifty years before its action could be fully explained, our impatience at the present time seems just a trifle unreasonable. The very latest addition to our knowledge of smallpox infection is the discovery of the bacillus of vaccinia by Stanley Kent, of St. Thomas Hospital, London, the announcement of which was made but a few weeks ago. The discovery should forever put an end to the former dangers encountered by the use of impure vaccinia virus and thus remove the only remaining reasonable objection to vaccination.

During the past year, while no astounding revelations have been made, such as electrified the world when Roux read his famous paper at Budapest, yet a number of important advances have been made and a few important discoveries announced. The antipneumococcal serum, which was entirely new at the time of my last report, has grown in favor, not only by Pane, its originator, but also by others who have given it a trial. Pane's own experience in Naples has been quite extended and very satisfactory; while at Guy's Hospital, Eyre and Washbourne have conducted a series of experiments which have established the value of the remedy to their entire satisfaction.

Tetanus antitoxin has grown wonderfully in favor during the year, owing, no doubt, to a better understanding of its action. Its greatest field of usefulness still continues along the line of prophylaxis, and in this respect it has no superior in any branch of medicine. Surgeons and veterinarians have come to recognize this fact to such an extent that a large number of them now make a routine practice of administering one or more immunizing doses of the serum after such accidents or surgical operations as are usually followed by attacks of tetanus; and in no case, so far as I know, has the disease developed after such immunizing treatment. The curative properties of tetanus antitoxin are also better appreciated than formerly, chiefly through the improved method of administering it. I refer to the intracerebral injection devised and first practiced by Prof. Roux, of the *Institut Pasteur*, Paris. This method, while rather too formidable for the general practitioner's application, is easily within the scope of the ordinarily skilful surgeon, and many successful operations have been reported since its first introduction, a little more than a year ago.

STREPTOCOCCAL INFECTION.

It has been my good fortune to see and study a large number of cases due to the streptococcus microbe as well as to report on their treatment with Marmorek's serum. From the very first, my experience ran in pleasant lines, and the favorable impressions expressed in former papers are intensified by more recent investigations. So uniform has been the success of the remedy in my hands that in no case have I had reason to regret its use.

Now, please discriminate between the legitimate action of the serum and the recovery of a patient who, among a multiplicity of pathogenic conditions may chance to number streptococcal infection with them. All that is claimed for the Marmorek serum is that it destroys the streptococcus germ and relieves such symptoms as are caused by it. If the case is one of purely

streptococcal infection, as we see in most cases of erysipelas, one or two efficient doses of the serum will quickly destroy the germs, relieve the symptoms, cure the disease and restore the patient's health. On the other hand, if the case is one of multi-infection, so frequently noticed in advanced cases of tuberculosis, in diphtheria, in scarlatina, etc., then the Marmorek serum will simply eliminate the one factor on which it is intended to operate and leave those remaining to be combated by appropriate means. In many cases of tuberculosis with mixed infection, the complication is far more destructive, or at least more rapidly destructive, than the original malady; and in some of these the most brilliant results are obtained from the timely use of Marmorek's serum. These, of course, are cases in which streptococcal infection is the only, or at least the principal, complicating factor, as mentioned in some of my former papers.

I have mentioned on several previous occasions that the antistreptococcal serum is one of the most difficult of its class to properly prepare; that it has been poorly made by several manufacturers; that it has been indiscriminately used by many physicians without regard to appropriate indications; that it has been given for cure of the patient, and not for the cure of streptococcal invasion; and as a result of these combined causes a number of failures have been reported. It has been my purpose to point out these facts and to endeavor to correct the errors and prevent the disappointments that are sure to follow laxity in judgment and method. To this end I have advised the use of the serum made by Dr. Marmorek himself, and not to trust to those prepared by manufacturers who even express a lack of confidence in their own productions. Carrying out this idea in practice, my experience with Marmorek's serum has been eminently satisfactory, and it is with much pleasure that I can refer to a number of fellow practitioners whose enthusiasm exceeds my own. Referring to the report of the committee of the American Gynecological Society, just filed, it is precisely in line with a prediction I made six months ago¹, and should not deter one from using the Marmorek serum promptly, fearlessly and confidently in all cases where the streptococcus is found.

Two discoveries have been announced during the year, which, if they prove to be well founded, are of such importance as to command our heartiest congratulations. I refer to the germs of cancer and of scarlatina; and I am only too sorry that the time since the announcements were made is so short that full confirmation is impossible. Most of the other diseases that have been subjected to serum treatment, including a few new ones added during the year, are still undergoing investigation, and nothing of special importance can be mentioned concerning them. However, it may be said that a few of the most dreaded, such as the bubonic plague, leprosy, yellow fever and Asiatic cholera, give greater promise of yielding to treatment than do those of a milder type. With men like Sanarelli, Yersin, Koch, Haffkine, Archinard, Marx, Sternberg, Jellinek, Ashmead, Clewom and others constantly on the trail of these terrible maladies, but little surprise will be expressed when their final subjugation is announced.

Since the writer's study of serum therapy began, about four years ago, a few glaring faults have been noticed and frequently commented on in the hope of seeing them corrected. One is the permission granted by our authorities for the indiscriminate manufacture and sale of antitoxins, blood-serums and vaccins without proper supervision. These are delicate substances, delicate in struc-

¹ New York Med. Jour., Jan. 14, 1896, p. 63.

ture, in nature and action; they are perishable and changeable to a degree unknown in any other class of remedies; their preparation deals with the infinitely small; contamination and ruin may creep in all unobserved and unsuspected by the novice manufacturer; the quality and strength of the finished product can not be determined by one of limited skill and experience; and finally, special equipment and favorable surroundings are an absolute necessity for the proper prosecution of this work. Clean, pure, reliable antitoxins can not be produced in a livery stable or in a veterinary hospital, any more than linen can be cleansed and purified in a blacksmith's shop. The fad for making antitoxins began as soon as antitoxins became articles of recognized utility, and the craze extended until antitoxins and blood-serums are on tap at short notice in many a dingy barn where not a single sanitary prerequisite for their production is to be found. All this is to be deplored; for no matter how little the manufacturer may possess, either in skill or equipment, a certain amount of his product will find its way to the consumer, where its failure will be noted and charged up against the entire system.

EXPERIMENTS WITH PARALDEHYDE.*

BY C. C. HERSMAN, M.D.

Member Staff South Side Hospital, Medical Department; Lecturer on Materia Medica and Therapeutics South Side Hospital Training School for Nurses; Physician to St. Francis Hospital for In-sane; Member American Medical Association; West Virginia State (Honorary); Pennsylvania State; Allegheny County, etc.

PITTSBURG, PA.

This remedy was first introduced to the medical profession by Cervello. I think he was an Italian, as it was soon after reported by Morello and Bergesio at a meeting of the Italian Medical Association.

Paraldehyde is formed from an aldehyd or dehydrogenated alcohol by the action of an acid, either acetic, nitric, sulphuric or sulphurous. Some writers have called it an exaggerated aldehyd, as its molecular composition is a multiple of the latter by three, aldehyd being represented by the symbol C_2H_4O , and paraldehyde by $C_6H_{12}O_3$. When acted on by chlorin it is said to be converted into chloral. It is a colorless liquid, having an unpleasant taste and peculiar odor, which remains with the breath many hours after its administration. Its specific gravity is 0.998, boils at a temperature of 225 F., and is miscible in eight times its bulk of water. Some of the Italian medical profession recommend it as a sedative and hypnotic. For it are claimed all the good qualities of chloral, without its dangers; that it acts first on the cerebral hemispheres without the preceding excitement so common to hypnotics, and subsequently affects the medulla and cord; that in fatal doses it paralyzes the center of respiration, and the heart is last to act; that its hypnotic effect can be maintained by the repetition of sufficient doses; that no ill effects, no nausea, depression nor headache have been noticed after its free administration. This is in substance a quotation from the *Medical News*, on introducing the drug to the medical profession as founded on the experience of Italian reporters.

Another quality of the drug discovered by Cervello is its antagonism to strychnia, although strychnia does not antagonize paraldehyde, the antagonism not being reciprocal¹.

Of the American profession, Dr. C. L. Dana of New York, Dr. J. C. Wilson of Philadelphia, and Dr. J. R.

Uhler, have reported their experience with paraldehyde², and recently Dr. John V. Shoemaker of Philadelphia.

It has been used in sciatic and supra-orbital neuralgia, but gave only temporary relief. The dose was from .5 to 1 dram, with no bad effects. Dr. Dana thought it somewhat less sure and powerful than chloral, but that it might prove useful when that failed or was contraindicated. Dr. Wilson's observations do not seem to have been so favorable. He thinks it requires a speedy increase of the dose, and that while it may be safe, it will never supersede chloral. Dr. Uhler thinks the sleep produced by this agent is not so profound as that of chloral, but if a patient has to use a sleep-producing agent for a long time, paraldehyde is probably the best, as it does not cause excitement in the early stages of its action, nor interfere with the heart, and is probably a safer remedy. Dr. Shoemaker gives the most flattering report. It may be well to add that the taste and odor are so unpleasant that a patient would very likely not become addicted to its use except in case of necessity.

EXPERIMENT No. 1.

Six patients in the hospital were selected for the experiment.

The first patient, Mr. W., was given .5 dram, pulse 68; dose repeated in 30 minutes, pulse 65; returned in twenty minutes, found patient asleep, pulse 64; patient still asleep at 5 a. m.; on the following morning, pulse 84; no ill effects.

The second patient, Mr. T., was given .5 dram, pulse 68; dose repeated in thirty minutes, pulse 80; returned in twenty minutes, pulse 64, patient not asleep, but slept most of after part of night; bad headache next morning, pulse 72.

The third patient, Mr. K., was given .5 dram, pulse 88; dose repeated in thirty minutes, pulse 80; returned in twenty minutes, pulse still 80; patient slept very little, if any, during the night; no ill effects.

The fourth patient, Mr. C., was given .5 dram, pulse 84; dose repeated in thirty minutes, pulse 65; returned in twenty minutes, pulse 64; patient up all night and tore up his bed; no ill effects.

The fifth patient, Mr. N., received a dose of .5 dram, pulse 68; repeated in twenty minutes, pulse 64; returned in twenty minutes, patient dozed, pulse 60; he slept well during the night; no ill effects.

The sixth patient, Miss C., was given .5 dram, pulse 96; repeated in thirty minutes, pulse 100; twenty minutes later, pulse 92; patient slept two hours during the night, no ill effects.

At another time five female patients were selected, who were kept on the medicine for a number of nights in succession.

The first patient, Miss C., same as before mentioned, was given .5 dram, which was repeated in thirty minutes; only slept a few minutes during the night; the second night she was given 1 dram, but slept none; next morning she had a headache, dry mouth, and was crying and begging the nurse to give her something to relieve her misery and put her to sleep. She ever after refused to take the medicine.

The second patient was given .5 dram, repeated in thirty minutes, and slept well; the second night she was given a dram and slept after one hour. The third night she was given 2 drams and slept in half an hour; the fourth she was given 2 drams, seemed stupid, but slept very little during the night.

The third patient was given .5 dram, repeated in thirty minutes, but slept very little all night; the sec-

¹ Med. Record, November, 1883.

² *Ibid*, August 25; N.Y. Med. Jour., Dec. 15, 1883; JOURNAL, May 3, 1884.

ond night she was given 1 dram, and still slept very little; the third night she was given 2 drams, but had very little sleep, and the fourth night she was given 2 drams, but remained up all night.

The fourth was given .5 dram, repeated in thirty minutes, with no sleep; the second night she was given 1 dram and rested moderately well; the third she was given 2 drams and slept very little, and the fourth night she was given 2 drams and slept well.

The fifth patient was given .5 dram, repeated in thirty minutes, with no sleep; the second night she was given 1 dram and slept very well; the third she was given 2 drams and had very little sleep during the night, but the fourth, given 2 drams, she rested much better than on the previous night.

On the fifth night, the night-watch reported all as resting well with one exception, but to her great surprise was informed that none of the medicine had been given.

This remedy has been resorted to in a number of other cases in which it acted like a charm, but in many it has failed me altogether. I tried the remedy on myself, but with such ill effects that I did not care to repeat it. As this was tried mostly in cases of insanity, it is, probably, not a fair test either for or against it.

Alcohol, we are sure, is a violent poison in large doses. In the dose of less than an ounce it has been known to kill a medium-sized dog, and many cases are on record of fatal effects being immediately produced in the human subject after comparatively small quantities have been swallowed. As paraldehyde is a preparation from alcohol, and much more concentrated, it is proof that it is more poisonous, unless it is denatured during the process of preparation. From reports of different experimenters, a number of patients who were given large doses complained of feeling very similar to those following debauch. Judging from the opinions of others, and that of my own experience, I do not consider it a good hypnotic. I found .5 and 1 dram doses to act better than larger doses. Headache was less liable to follow. Out of eleven cases selected, I can boast of but one happy result. In other cases I had some good and some bad results, occurring with the same patients. Also, we notice in most of the cases, the increase of dose seemed to add to the bad effect. In some cases I recorded pulsations, but took no notice of respiration. It is certainly a hypnotic, and while it may be safe, given in proper doses, I fail to notice any property which makes it equal to other remedies at our command.

EXPERIMENT NO. 2.

In testing it as a germicide I used the following:

Sugar (gram.)	gr. xx
Yeast (dried) aa	gr. xx
Paraldehyde	ʒi
Distilled water	ʒi

Misce.

I let the mixture stand one week in a warm place, with no fermentation whatever. From this and further observation I believe paraldehyde to be a germicide, but do not know the minimum per cent. at which it will act as such.

Finally, the taste of the drug is very disagreeable. A large quantity of water is necessary to dilute it for use, and the fact that it does not supply the demand already met by other agents, will, in my opinion, prevent its extensive use both in private and in hospital practice.

EXPERIMENT NO. 3.

A large dog was given strychnin sulphate, gr. i, at 9:45 a. m., but on account of the very disagreeable odor and taste of the antidote—paraldehyde—its administra-

tion per ore was a failure, as only one dram was given in one and a half hours. Still the effects of the poison did not show until about 3 p. m., possibly being retarded by the antidote. At 6 p. m. I found him in tetanic spasms of a very severe type, a mere touch being sufficient to throw him into convulsions. At this time I gave hypodermatically, paraldehyde, m. xl, at 6:30; half an hour later I repeated, m. xlv, also hypodermatically, and left him for the night. On the following morning the dog was reported dead. At 4 p. m., on learning that he was alive, I proceeded to his kennel, at which time he partook of raw beef freely. He made a complete and rapid recovery.

Three weeks from the time of this experiment, at 9:30 a. m., I administered to the same dog, paraldehyde, m. xxv per ore, at the same time giving him strychnin sulphate, gr. i., immediately after followed by paraldehyde, m. xxiv, hypodermatically. In one hour, m. l, two hours later, m. l, and at this time he ate raw beef freely. At 6 p. m. I repeated, m. xxv—all hypodermatically, except the first m. xxv—and left him for the night. During this experiment he did not reach the spasmodic stage, although locomotion was very much disturbed, which possibly was partially caused by the free use of the paraldehyde. Next morning he refused to eat, but I think it was possibly on account of a sore mouth, caused by the first dose of paraldehyde, fearing that the meat was again saturated with it. At noon, however, he ate with relish, but deglutition was somewhat disturbed. On the following morning he ate again, and took water freely, deglutition still slightly disturbed. He made a perfect recovery. With this limited experience I am forced to believe that it is at least partially a physiologic antidote to strychnin. However, to establish this conclusion further observation must be made.

The experiments of Prof. Bokai confirm what I have stated. "In no case did the strychnin produce death, neither in moderate nor lethal doses, but in fatal doses of paraldehyde, strychnin had no effect in removing the poisonous symptoms, or to delay its fatal processes. Hence the antagonism is probably one-sided." The hope is not unreasonable then—and in fact, proven in my case—that if paraldehyde be given soon after symptoms of a poisonous dose of strychnin it might serve to antagonize it. Should it prove to be an antidote, its use for this purpose would be almost without risk, since it is freer from unfavorable action on the heart and respiratory center than that possessed by chloral and chloroform, which are known to have some antagonistic power to strychnin. But before these conclusions can be accepted as established, much more elaborate experimental research must be made.

The Italian observers give us the most favorable reports. I have observed, however, that in large doses we may have, in some, symptoms similar to those following a debauch. I have often used it in acute alcoholism, with very marked hypnotic effects when other hypnotics have failed to produce sleep. In properly selected cases I find it to act very well, but as a universal remedy I do not think it as good as some others at our command.

Since the cord in a dog is much larger in proportion than in a man, and the principal physiologic effect is on the cord, would not a grain dose of strychnin be greater in proportion to the relative sizes of the spinal cords of the dog and man? This so, it would require a much smaller dose to counteract the same amount of strychnin in a man.

It might be well to mention here the dangers of a con-

tinued use of paraldehyde, as a number of cases of drug habit have been published which seemed to be as serious in its nature as that of any other drug habit.

ACCIDENTAL WOUNDS OF THE FEMALE BLADDER.*

BY FREDERICK HOLME WIGGIN, M.D.
NEW YORK CITY.

Accidental opening of the bladder has, for many years, been considered one of the most serious accidents that could occur in the course of the complicated work which gynecic surgeons are often called on to do. It was not until 1886 that a successful case of intraperitoneal suture of the bladder was recorded by Sir William MacCormac and Mr. George Heaton, while White, in the course of an article in Dennis' "Surgery," states his belief that sutures placed in the wall of the bladder for the purpose of closing extraperitoneal wounds of the viscus are useless. This, coupled with the fact that there are on record comparatively few cases of injuries to the bladder successfully treated by suture, while accidents of this nature must be of common occurrence, makes it important that all individual experience bearing on this subject should be recorded.

Injuries to the inferior surfaces of the bladder generally occur in the course of the separation of the uterus from this wall, when the peritoneal cavity is entered by means of an incision made in the anterior vaginal wall. The accidental opening of the bladder in this situation is, however, less common than might be supposed, else as is the relation between the organs and the frequency of this procedure.

The following case is offered in illustration of this type of injury:

M. M., 37 years of age, was admitted to the gynecic division of the New York City Hospital, Nov. 1, 1897, suffering from ovarian disease, chronic endometritis and interstitial myomata, for which a vaginal hysterectomy was performed by means of an incision along the anterior vaginal wall, beginning about one inch below the meatus urinarius, and carrying it down to, and around the cervix. During the dissection of the right vaginal flap from the bladder, such persistent oozing of blood was encountered as to render the proceeding extremely difficult. On nearing its junction with the cervix, the bladder was opened, but the accident was immediately discovered. The wound was forthwith closed by means of three Lembert sutures of fine silk, which were introduced through the muscular coat only. The wound was disinfected, and the operation completed in the ordinary manner. The wound in the vaginal wall was brought together by means of catgut sutures; iodoform gauze was placed in the vagina, and suitable dressings were applied. The bladder was catheterized every three hours for several days, after which the patient was able to urinate naturally.

Accidents are also so likely to occur to the posterior wall of the bladder, while the operator is breaking up old adhesions to the intestine and omentum, to diseased pelvic organs or to tumors. In separating such adhesions, unless great care be taken, the bladder will often suffer injury. In cases of this kind the wound rarely extends through the mucous membrane, and a few interrupted Lembert sutures will ordinarily suffice.

The following case is an illustration of intra-abdominal bladder injuries:

M. H., a single woman, 41 years of age, was admitted to the gynecic service of the New York City Hospital, Sept. 30, 1898, suffering from a large myoma, which extended above the umbilicus. On Oct. 3, after the usual preparation, and under ether narcosis, the abdomen was opened by means of an incision six inches in length, and to the right of the median line, beginning about two inches above the pubes. The tumor, which weighed seventeen pounds, was drawn through this incision, freed from its attachments and removed, together with the body of the uterus, which was amputated at the internal os. This tumor proved to have sprung from the anterior uterine wall. During the operation hemorrhage occurred from some sinuses on the surface of the tumor, which having rigid walls could not be clamped, therefore it was necessary to remove the mass very rapidly. To accomplish this the anterior attachment of the tumor was clamped and cut, when it was discovered, from the escape of urine, that the bladder had been opened at the fundus. At the beginning of the operation, the general cavity had been shut off with gauze pads, and the parts had been thoroughly irrigated, and the bladder walls, including the wounded part, drawn well up. The irrigation of the pelvic cavity was followed by the use of hydrozone in half strength, and this, in turn, by saline solution. The gauze pads were next changed, and the opening in the bladder, which proved to be about four inches in length, was closed by means of two layers of chromicized catgut sutures. The first row was introduced from within the bladder, and included the mucous and muscular coats, the knots being in the interior of the bladder. These sutures were thus placed on account of the extensive wound, which made it impossible to get the parts properly joined together in any other way. The second row was introduced from the outer side, after the manner of the mattress sutures, and included only the muscular and peritoneal coat. The wound was disinfected, and there being a large peritoneal flap, it was attached to the bladder, and made to cover the line of sutures, thus making the bladder wound extraperitoneal. After further washing out of the abdominal cavity the abdominal wound was closed without drainage, and the usual dressings applied. As the operation was prolonged, and the patient feeble, it was not thought advisable to make a vesicovaginal fistula for the purpose of draining the bladder, but instead a self-retaining catheter was introduced. For about ten days the convalescence was uneventful, except that occasionally the catheter would become blocked by a knot of one or other of the catgut sutures, which began to come away by the end of the third day. At the end of this time tumefaction occurred over the lower angle of the abdominal wound, and, on opening it, urine began to escape. A vesicovaginal fistula was made, and the mucous lining of the bladder attached on either side to the mucous lining of the vagina, by means of silk sutures. This was done for the purpose of keeping the fistula open, and to afford adequate drainage. The sinus in the abdominal wall was curetted and, after being thoroughly disinfected with hydrozone, its walls were sutured. The abdominal sinus having closed, the sutures which kept open the vesicovaginal fistula were removed, and this fistula closed quickly without any further operative interference.

The most dangerous and least often injured portion of the bladder is in the region of the trigone. It is here, when an injury does occur, more than in any other place, in gynecic operations, that a cool head, and a good knowledge of anatomy and surgical technic are necessary, but with these requisites and a knowledge of

*Presented to the Section on Obstetrics and Diseases of Women, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

the work accomplished by Kelly, Van Hook, Krug, Penrose and others, in the management of the vesical ends of the ureters, we may almost invariably look for a successful result.

Percival¹ reports a case of ruptured bladder on which he had operated. The rent was in the middle of the posterior bladder wall, about four inches in length. It was closed by means of a double wall of Lembert silk sutures. The wound in the abdominal wall was closed, after the peritoneal cavity had been flushed out with boric acid solution and a large quantity of clots and urinous fluids had been removed. For a few days the patient did well, and then died from peritonitis. But the necropsy proved that the bladder wound had completely healed. It is the writer's opinion that had saline solution and hydrozine been used, instead of boric acid, and the wound been kept open, the patient would possibly have recovered.

Wyeth² in the course of a paper entitled "Suprapubic Cystotomy," says, in describing the operation, that when the bladder is not inflamed, as after the removal of a small tumor, stone or foreign body, the operator may close the bladder by immediate suture. This is a very desirable method of dealing with the wound, for the reason that it does away with the necessity of drainage, and of the slow healing process. Two successful cases of immediate suture of the bladder wound are also reported by the same author.

The writer of this paper believes that with the technique at present at our command, wounds of the bladder made in the course of operating, whether extra peritoneal or intraperitoneal, should be closed immediately, and the operation continued as if the accident had not occurred, and notwithstanding the fact that drainage is not used, there will be little or no danger of peritonitis, extravasation of urine, or hemorrhage. It is of great importance when breaking up adhesions and removing tumors, or separating the bladder from the anterior vaginal wall and uterus, to be certain whether or not the bladder has been injured, and it has been the writer's custom to test this by the injection of saline solution, or by the uterine sound. Catgut is undoubtedly the best material for suturing the bladder wall, and no harm will result in case the suture is passed through the mucous lining of the bladder. A large proportion of all fatal cases of rupture of the bladder that have been operated on die from faulty stitching. In injuries of the posterior wall of the bladder, the sewing process is facilitated by the use of the Trendelenburg posture. In extensive intraperitoneal wounds of the bladder, where the vaginal wall is intact, it is best in the after-treatment to drain by means of a vesicovaginal fistula, which promptly heals, in the majority of instances, without operative interference, as soon as the sutures which hold its edges apart are removed. These fistulae differ from those occurring during childbirth in that there is no loss of substance. When the damage is not extensive, or when it occurs in the inferior wall, the peritoneal cavity having been opened, the bladder wound should be sutured, and the viscus drained by means of a self-retaining catheter, or by having a catheter passed every two to three hours. The healing of the wound may also be aided by the position of the patient in the bed.

While accidental wounds of the bladder occurring in the course of operations are to be deplored and guarded against by every possible means, when they do occur, the knowledge of their existence is of the utmost importance, for, as soon as discovered, they may be treated much in

the same manner as simple incisions in any other part of the body. The fear of septic peritonitis has prevented a general appreciation of this fact, but the labors of American gynecologists in proving the safety of closure of abdominal wounds without drainage, even where infection is known to exist, has done much to establish on a firm basis immediate suture of wounds of the bladder. The operation advocated by Rydgieer, of opening the bladder for the removal of tumors and calculi from its peritoneal side, has been followed by a lower rate of mortality than the older extraperitoneal, suprapubic or perineal operations.

Before operations on the pelvic organs are begun, and after the administration of the anesthetic, the surgeon should himself empty the patient's bladder by means of the catheter, instead of, as is usually done, leaving this for the nurse to do, before placing the patient on the operating-table. Attention to this detail would not only lessen the danger of injuries to the bladder, but when they did occur would lessen the danger of septic infection.

It is the writer's belief, based on many years' experience in abdominal surgery, that where care is taken there is no more reason why a recent intra-abdominal wound of the bladder should not be sutured and the abdomen closed without drainage than in the case of a wound occurring in the bowel. We must recognize the fact that, in the course of operations on the female genital organs, injury to the bladder is occasionally inevitable, but fortunately for all concerned when this accident does happen, our patient's life is not necessarily endangered, or her recovery retarded thereby.

55 West Thirty-sixth Street.

INTESTINAL TREATMENT OF TUBERCULOUS PERITONITIS.*

BY HENRY T. BYFORD, M.D.

Professor of Gynecology, College of Physicians and Surgeons of Chicago (University of Illinois); Professor of Clinical Gynecology in the Northwestern University Woman's Medical School, etc.

-CHICAGO.

In his "Principles and Practice of Medicine," Osler uses these words: "The treatment of tubercular peritonitis has fallen largely into the hands of the surgeons." And after a long search among medical text-books I ceased to wonder at this, for I could get but little information on the medical treatment. Therefore the average practitioner who depends on his text-books would seem to have no way of learning how to treat it. He is taught to treat peritonitis by opium, rest, etc., and to send the case to the surgeon.

The fact that improvement takes place after an abdominal incision in cases of tubercular peritonitis, has led many surgeons to look on the procedure as a cure. If, however, we believe with von Winckel that five years should elapse before the patient is considered cured, and remember that only about 15 per cent. have been under observation more than two years¹, we must infer that such an opinion is premature. A case of mine may serve as a sample. I reported the young woman as teaching school eighteen months after the operation, and, according to information given me, in good health. At the end of three years I received word that she was dead.

On account of the uncertainty of the reported cures I have not taken the time to tabulate them. I have, however, been struck with the similarity, in some recent re-

*Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

¹ British Medical Journal, 1897, Vol. 1, p. 1282.

² N. Y. Polytechnic, Vol. x, No. 1.

ports, of the results of medical and surgical treatment.

E. Schroeder² reports on 24 cases treated in the medical clinic at Bonn with the following results: Deaths, 33 per cent; unimproved, 20 per cent.; discharged about cured, 41 per cent.

Parker Sims², in reviewing the subject, says that some writers claim cures in 80 per cent., others in 24 per cent., by abdominal incision. His own conclusion is that improvement occurs in about 80 per cent., and a permanent cure in about 30 per cent. Here we have 20 per cent. unimproved in the medical treatment against 80 per cent. improved in the surgical, and 41 per cent. discharged about cured by medical treatment against a permanent cure in about 30 per cent. by incision.

The treatment by abdominal incision, which is undoubtedly followed by immediate benefit, must still bear the burden of proving that the ultimate results are the better. Some cases have undoubtedly been demonstrated to be cured by a subsequent abdominal section, but, on the other hand, subsequent abdominal sections in cases that had shown improvement have demonstrated uninterrupted progress in the disease⁴.

The most suspicious fact of all, in these cases that show improvement is that no one can find out how or why the improvement takes place. It is not from the removal of fluid, because tapping does not produce the same improvement, and because cases without fluid accumulation are also benefited by it. It is not the exposure to air or light, because a quick operation works better than a long one. It is not anything that destroys the bacilli, because the introduction of germicides does not materially affect the results. To say with Tait that opening the abdomen produces a change in the physiologic character of the peritoneum, which enables it to destroy the tubercle bacillus, is contrary to our experience with the peritoneal cavity, for we know that to open the peritoneal cavity and expose it to air impairs the functions of the peritoneum from A to Z. It is said that the cure is produced by increased phagocytosis. But do not the new conditions that call for phagocytosis require all of the phagocytes and perhaps more for their own cure?

I have come to the conclusion that there is something connected with the abdominal incision that is not connected with tapping or other forms of treatment, and that it is the same thing that causes improvement in almost all cases treated by abdominal section, even when pathologic conditions in the peritoneal cavity are not removed or are not even found. Thus cases of neurasthenia, hysteria, epilepsy, pelvic pain, etc., are usually temporarily benefited by an abdominal section, although they may lose the benefit later.

This something, according to my observation, is the preparatory, and after-treatment of that belongs to abdominal section. There is no doubt that the medical treatment ordinarily used for subacute and chronic tubercular peritonitis is in some respects similar in nature to that belonging to peritoneal section, but it deviates in laying more stress on nourishment and tonics and less on intestinal rest, intestinal depletion and intestinal disinfection, i. e., it deviates in the most essential parts.

The quickest and best way of explaining the application of the treatment is to report a case in point:

Mrs. L. B. L., aged 33, married thirteen years, mother of five children, the youngest 2½ years old, and one abortion twelve years ago, was treated for pulmonary tuberculosis fifteen years ago, at which time she had severe cough that lasted about two years. For a time the cough was much worse when lying down, and she had to sleep in a chair. She has had a slight cough ever since.

In December, 1898, she complained of abdominal soreness and pains for two weeks, when the menstrual period, which had been normal, came on with an increase of pains. The flow was slight for five days and then profuse for five days. She felt some better until Jan. 20, 1899, when she menstruated with some pain, and was bloated. On February 1 she was taken down with acute peritonitis, accompanied by an increase of the abdominal distension. The highest daily temperature ranged between 102 and 103 F.

She was brought to me for an operation February 26, at which time the temperature ranged between 99.8 and 102.6 F., always from 1.5 to 3 degrees higher in the afternoon than in the morning. The pulse varied between 90 and 110, but was poor in quality. An encysted peritonitis was diagnosed, the accumulation of fluid reaching above the level of the umbilicus on the left side and not quite as high up on the right. By vaginal indagation some induration could be felt beside the uterus. She was put on strychnia, gr. 1/20, and ten minims of the tincture of the citrochlorid of iron three times daily, after meals, 5i of sulphate of magnesia twice daily, and ʒss. of brandy four times daily. Hot applications were applied to the abdomen. She was allowed a piece of broiled steak for dinner, thoroughly dried toast three times daily, and liberal quantities of fluids. At the end of a week she was allowed an egg-nog every morning.

At the end of two weeks (March 9) the temperature and abdominal enlargement were the same, although the pulse remained between 90 and 100, and the nutrition and general appearance of the patient had improved. I now considered it the best time to operate, and gave her four grains of the mild mercuric chlorid at bedtime, to be followed by salines the next morning, etc. But by the next day I had made up my mind to give the plan of treatment I have been speaking of a trial, and proceeded to carry it out. The salines were stopped after sufficient had been given to produce four bowel movements, and then continued in dram doses twice or three times daily as necessary to produce two semiliquid stools each day. All solid foods were withdrawn, and six ounces of peptonized milk alternated with one ounce of liquid peptonoids three hours apart were ordered. Six grains of salol were prescribed four times daily. The iron and strychnia and brandy were continued. After three days a small quantity of thoroughly-dried toast was allowed three times daily, and the diet was kept the same for ten days, or until March 20. After that she took Mellin's food a part of the time instead of the milk, and was allowed a little cottage cheese, butter, 40 per cent. gluten biscuit and from one to two ounces of a delicate cereal such as corn-starch or rice once daily.

From this time the improvement was steady. I marked the upper border of the fluid with ink each week, and demonstrated a steady diminution until, when she left the hospital on April 1, there was no dulness on the right side of the median line, and only a narrow border extending from Poupart's ligament over the crest of the ilium on the left side. The pains and tenderness and abdominal enlargement were gone, and she was gaining flesh. The temperature seldom reached 100, but usually marked from 99.2 to 99.6 F. in the afternoon.

I was unable to keep her under observation until cured, and am not attempting to prove that she is or will be cured. I am merely endeavoring to illustrate the effects of a certain method of treatment, as compared with abdominal section, on the progress of the disease. The progress of this case demonstrated to those of us who watched it that whenever the nourishment was pushed

during the first two weeks, the severity of the symptoms was increased. From the time that she was put on the strictly liquid diet and salol, the improvement was marked and sustained.

I am not discussing remote results, for that belongs to the future, but my experience with this and with similar cases that had been subjected to an operation has convinced me that in subacute as well as acute tuberculous peritonitis we must for the moment make the supporting treatment subservient to that of the inflammation, and that the *treatment of the alimentary canal*, in addition to the use of tonics and stimulants, is the one on which we should depend. If we destroy the sources of local irritation, Nature will often do the rest.

We should endeavor to keep the alimentary canal as aseptic as we do during and just after an abdominal section, and this applies to the prodromic stage as well. Two or three liquid stools should be produced daily, by salines. Eight or ten grains of salol, guaiacol, or an equivalent, should be given from three to four times daily to aid in disinfecting the alimentary canal, and possibly in producing some effect on the bacilli. The diet should be entirely liquid and should be such as to produce the minimum of gas or solid residuum in the intestinal canal. If it is thought wise to try to affect the disease by mercurials, calomel or blue mass would be better than inunction, because it would stimulate the action of the liver and aid in disinfecting the intestinal canal. The same rest in bed is necessary as after an abdominal section. In subacute cases the patient usually tries to be up and about, and this increases the inflammation.

In subacute and chronic cases opium should never be given under any circumstances, except to check a diarrhea that resists other medication. A proper restriction of the diet and hot fomentations, or an ice-bag, will relieve the pain, while bismuth and soda in connection with the salol and guaiacol will check a tendency to diarrhea. Ordinarily I do not give bismuth, because I do not wish to check the action of the bowels.

If the same rapid improvement can thus be obtained without the abdominal incision, then the incision will be indicated only in the severe or neglected cases in which the fluid can not be made to disappear by absorption. Even then tapping can be substituted by those who have not the facilities for an aseptic section. At least there will be no excuse for opening the abdomen early and before time for absorption has been given, and before the intestinal treatment has been thoroughly tried.

If more innocuous specific germicides shall be discovered for tuberculosis, it is possible that they can be given by mouth or per anum in sufficient quantities, and for a sufficient length of time to destroy the bacilli in the tissues. I have depended mainly on intestinal aseptics. Perhaps in the future intestinal antiseptics may add to its efficiency. I would therefore recommend the following treatment:

During the first few days of an acute attack the usual treatment for acute peritonitis would be indicated; after the first few days no opium, but the continuation of hot fomentations if necessary for pain and discomfort. Enough calomel may be administered to turn the stools to a dark green. As soon as the stomach will tolerate them, salines are to be given in divided doses to produce two or three soft or liquid stools daily.

The diet must be fluid and in regulated quantities, so as to produce no intestinal gases, until the subacute symptoms have passed, and then only such solids may be allowed as will neither leave a solid residuum, nor produce gas either in the stomach or bowels. It is the want of

strict and intelligent attention to what is taken as nourishment that leads to intestinal pain, distension, nausea, increase of the peritonitis and effusion and the necessity for an opiate. Salol, guaiacol or crocote are indicated both for their antiseptic action and for a possible effect on Koch's bacillus.

The patients must be kept quietly in bed until all abdominal tenderness is gone and the p.m. temperature is almost normal, and they must be careful to be more quiet whenever there is any rise in temperature or indications of abdominal tenderness or pain.

Tonics, stimulants and general remedies that may be found curative of tuberculous infection are not to be neglected. The patient must be kept under systematic treatment for several months, and should be cautioned to restrict her diet to food that will be easily digested and non-irritating to the bowels, for we know that nine out of ten people who are not careful in eating are almost constantly subject to more or less intestinal irritation.

RELATIVE TOXICITY OF COCAIN AND EUCAIN.*

BY A. H. PECK, M.D., D.D.S.

Professor of Materia Medica, Therapeutics and Special Pathology
in Northwestern University Dental School.
CHICAGO.

Cocain hydrochlorate is a white crystalline alkaloid obtained from the leaves of the *erthroxylon coca*, a small shrub of Peru and other western South American countries. Its extensive use as a local anesthetic is so familiar to all that repetition is here unnecessary. It is not my intention in this paper to especially refer to its anesthetic properties, only its toxic effects relatively with those of eucain, as observed in actual practice and as determined by original experimentation.

Eucain is a colorless crystalline powder of German production, and was placed on the market some years ago as an anesthetic to be used in a similar manner to cocain. It was soon observed that the first product, or that which is now called "Alpha Eucain,"¹ produced many undesirable and some very disagreeable effects, so much so that its use was soon largely discontinued. In February, 1897, Dr. Silex of Berlin brought forward a new substance, called eucain "B," that it might be distinguished from the first, or eucain "A." These substances are now termed—the first product, alpha eucain, and the second beta eucain. The use of alpha eucain has been almost entirely discontinued, and it is no longer furnished by the dealers unless especially designated in the order.

Beta eucain is said to be a chlorhydrate of benzoyl-vinylidacetonealkamid.

Were the action of these drugs as anesthetics always unattended with disagreeable, and, as is sometimes the case, alarming symptoms, both of local and systemic character, they would be to the dental and medical professions one of the greatest boons of the present century. Many minor surgical operations, both in general and dental practice could, by the aid of these drugs, be performed with greater facility—and with equally good results—than can be performed without their

*Presented to the Section on Stomatology, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

properly used, and also frequently produces poisonous symptoms, oftentimes alarming. If a certain quantity of arsenic or morphia, or almost any other known poison be used under certain circumstances, the resulting symptoms are nearly always the same; we know what to expect. It is unfortunate that the same can not be said of the action of cocain. I have often seen the most alarming symptoms of systemic poisoning result from the use of a certain quantity of cocain, while in other individuals, a like amount under seemingly the same conditions, produces no bad symptoms. There is no other drug in the whole realm of medicine, in connection with the action of which individuals vary so much in point of susceptibility. I have seen all the stereotyped symptoms of systemic cocain poisoning result from the use, in a pulp-canal, of a small quantity of a 1 per cent. solution, while again I have seen 20 minims of a 2 per cent. solution injected into individuals, and this repeated as high as four times without poisonous symptoms resulting, so varying is the susceptibility of individuals to the action of the drug.

I can not pass on without calling attention to the fact that I as firmly believe that cocain produces, in some, local as well as systemic poisoning, notwithstanding the fact that many disagree with this statement. I have seen from the subcutaneous use of cocain, for the extraction of one root of a tooth, three good teeth lost, with extensive destruction of the alveolar part of bone, together with extensive sloughing of the soft parts, and all this in the absence of any systemic symptoms. Some, no doubt, will say this is the result of infection by an unclean syringe. But how is it to be proven that this is the case? The work has been done under the most careful antiseptic precautions. I have seen so many cases of local poisoning in varying degrees result from the use of this drug, that I am forced to the belief that it possesses local toxic properties as well as systemic toxic properties.

As to eucain "B," there is much to be said in its favor as compared with cocain. During the past year I have frequently used it in practice for devitalizing pulps, for local applications, and by injection, and have as yet observed no evil effects of note. Eucain, however, is not capable of producing the same degree of anesthesia under like circumstances as is cocain. This has been proven beyond the possibility of a doubt by the experiments I have made. As this paper is to deal only with the toxic properties of these drugs, I will not here discuss their anesthetic properties.

Last year, while experimenting extensively with the essential oils, using guinea-pigs largely, I did some work with cocain, and eucain, enough to demonstrate that there was an interesting field in contrasting the two. Since then I have experimented extensively with these agents, using guinea-pigs.

How completely is the statement that cocain varies much in its action demonstrated and proven to be correct by the following experiment—the first one serving to exhibit the poisonous propensities of the drug, and this, too, in the absence of any marked anesthetic effect. A pig, weight $8\frac{1}{2}$ ounces, into which was injected 20 minims of a 2 per cent. solution of cocain, which amount represents $\frac{3}{20}$ of 1 grain, after the lapse of eight minutes showed some indications of anesthesia, but these were comparatively insignificant. For the next six minutes various symptoms of distress were exhibited, such as a general spasmodic jerky action of all the muscles of the body, accompanied with evidences of pain. At the end of fourteen minutes its hind legs were partially paralyzed, and one minute later it fell on its side

completely overcome. Its head was firmly drawn back, all the muscles of its body being rigid; this condition would, at short intervals, give way to a distressful spasmodic action, general in its scope, and thus these sets of symptoms continued to alternate for a period of five minutes. During these twenty minutes the animal was not anesthetized to any appreciable extent, responding vigorously to a prick of the needle at any portion of the body. The heart action was at first somewhat depressed, but soon recovered, and thereafter its contractions were strong and rapid, evidently being much stimulated. The respiratory organs, at first slightly stimulated, were very soon depressed, and remained so until recovery set in. After twenty minutes it began to recover and at the end of twenty-five minutes could stand on its feet; however, it could not walk without falling. At the expiration of forty minutes, recovery was far advanced. This experiment shows the toxic action of the drug with the absence of anesthetic effect, better than any other on my list. While the poisonous propensities of this drug are frequently manifested, they are usually accompanied with anesthesia.

The following experiment shows in just as interesting and decided a manner the anesthetic action of the drug to the exclusion of nearly all manifestations of poisonous symptoms: weight of pig, $8\frac{1}{2}$ ounces; 20 minims of a 2 per cent. solution of cocain were injected at 10:15:30 p.m.; at 10:25 general anesthesia was quite marked, there being little response to the prick of a needle: when placed on its back it could hardly regain its feet. The heart action was somewhat depressed. At 10:27 it fell to its side, the heart action being now about normal; respiration somewhat shallow and quick. At 10:37:30 it regained its feet and occasionally evinced a desire to run away, its heart action now being strong and rapid and respiration normal. At 10:46:30, 10 minims more were injected, this making, in all, $\frac{9}{40}$ of 1 grain. The side in which the second injection was made almost immediately became swollen, as if considerable edema was induced. This has been noted by others, and forms the basis of the claim of some that local sloughing is only due to infection of the products of edema, which have infiltrated the tissues, liquefaction or pus formation taking place and sloughing finally resulting. This is no doubt true, oftentimes. Up to 10:56 the pig remained on its feet, and for the last five minutes preceding would walk about, prick up its ears, look up and chirp, and in various other ways gave evidence of enjoying a period of that intense beatitude and inner joyousness, while a succession of visions and phantasmagoria, most brilliant in color and form, trooped rapidly before his eyes—as related in Wood in connection with the experience of Montegazza while under the influence of this drug. Occasionally it would make a sudden rush, as if impelled by a plenitude of physical power, such as also took possession of Montegazza at various times. At 10:56, symptoms of general anesthesia were quite marked, a condition of general relaxation rapidly developing. At 11 it became unconscious and sank to the table on its side. Immediately after the second injection, the heart action was noticeably depressed, but quickly revived and became exaggerated over that of the normal. The respiratory apparatus was somewhat depressed most of the time. At 11:03 there occurred a slight general spasmodic action of all the muscles, its head being slightly drawn back and accompanied with a feeble cry, as if in slight pain. Action of the heart was strong and rapid; its breathing quick and shallow; true tetanus of various muscles was observed. This endured only an in-

stant, all the muscles becoming perfectly relaxed as before. Thus the animal continued in a state of perfect general anesthesia. At 11:06 action of the heart became feeble and respiration scarcely noticeable. At 11:12:30 the animal was apparently dead; respiration and the heart action both ceased. Thus it lay for 30 seconds; at 11:13 a faint gasp was observed, followed quickly by a second and third. The heart began to beat feebly, and in another two minutes, or at 11:15, the heart was beating regularly, but not so rapidly as normal; the respiratory apparatus was working regularly, but not strongly. Thus the animal remained in a perfect state of general anesthesia for twenty-three minutes, or until 11:38, when signs of recovery were observed. It was then placed in its box, and in the morning was found to be as bright and lively as its mates.

The behavior of other pigs under the influence of cocaine has, in some instances, approached the behavior of this one, but no other has been so typical. This, in connection with the results of all my experiments in this particular, to my mind, effectually settles the question of the inconsistency of the action of cocaine.

Let us now study the action of beta eucain under similar circumstances.

Twenty minims of a 2 per cent. solution of beta eucain, or $3/20$ of 1 grain, injected into a pig of $8\frac{1}{2}$ ounces weight gave at the expiration of thirteen minutes slight evidences of anesthesia—or perhaps better said, the action was that of a mild hypnotic, the animal appearing somewhat drowsy, at the same time all reflexes responding to any interference by way of pricking. The action of the heart and respiratory apparatus was slightly depressed. Three minutes later recovery commenced, and at the expiration of twenty minutes the effects of the drug had largely passed away. Two minutes later another 20 minims, or $6/20$ of 1 grain, in all, were injected. Five minutes later slight evidence of nausea was observed; at nine minutes the hypnotic action was more marked and was accompanied with slight evidence of true anesthesia. Its hind parts were somewhat paralyzed, and the reflexes slightly blunted. The heart action and respiration were more depressed than at first. At eighteen minutes it began to recover and at the expiration of twenty-five minutes, or forty-seven minutes from the time of the first injection, was able to walk about. One minute later, or forty-eight minutes from the time of the first injection, a third injection of 20 minims, making $9/20$ of 1 grain in all, was made. Five minutes later nausea developed and the animal seemed much distressed thereby. The heart action and respiration being at first stimulated, soon became much depressed; after ten minutes, twitching of all the muscles of the body, spasmodic in character, developed; this condition increased until, at the expiration of eighteen minutes, the animal fell to the table completely exhausted. Its head was firmly drawn back, all the muscles being at high tension; rapid winking of the eyes continued, with gasping for breath and twitching of ears. For the next twenty minutes this condition continued, with violent tetanoid spasms of all muscles following one another in rapid succession, each spasm being accompanied with mournful squealing, which seemed to indicate much distress and pain. At no time were the reflexes, either plantar or cremasteric, lost; neither was there much evidence of general anesthesia; indeed, the entire action seemed to be more that of a paralyzer than of an anesthetic. The heart action and the respiratory apparatus were much depressed. At times the heart-beat was almost undiscernible, and the animal would distress-

ingly gasp for breath. At the expiration of this twenty minutes, signs of recovery developed, and at the expiration of twelve minutes more it could stand on its feet, but could not walk without toppling over. It was now very late, and the animal was placed in its box, and in the morning was found to be none the worse for its experience. This case is interesting in that it seems to prove conclusively that, at least, three times the quantity of beta eucain is required to produce virtually the same degree of toxicity as is produced by cocaine. These results, or this action of the two drugs, as related in this experiment and the first one with cocaine, I regard as bearing directly on their toxic properties.

Legrand and Joanin, like Silex and Schmidt, have demonstrated that $1\frac{1}{5}$ grains of cocaine are necessary to cause the death of a guinea-pig of $2\frac{1}{5}$ pounds weight, and that $4\frac{5}{8}$ grains of beta eucain are necessary to cause the death of a pig of same weight. I have been unable to secure pigs as heavy as this, the heaviest I have had weighing $26\frac{1}{2}$ ounces. Taking their figures as a basis, and reckoning a fatal dose for a pig of less weight, in direct ratio therewith, it would require $5/6$ of 1 grain of cocaine to cause the death of a pig weighing 24 ounces, and of beta eucain, $2\frac{4}{7}$ grains would be necessary. Let me say, in this connection, that this manner of determining a fatal dose for a pig of a given weight is not a safe one to follow in dealing with pigs of less than 24 to 25 ounces weight. My experiments seem to conclusively prove that the ratio of a fatal dose of these drugs decreases rapidly in proportion to the decrease in weight and age of the animal.

In my work $5/7$ of 1 grain of cocaine proved the limit as a fatal dose for a pig of $24\frac{1}{2}$ ounces weight. The symptoms manifested in this case were not in any essential particular different from those occasioned by a non-fatal toxic dose, which symptoms have already been described; except at times they were all exaggerated, and especially was this noticeable in connection with the heart. After the brief depression of this organ, which occurred at first, its action became greatly exaggerated, at times thumping violently, especially as the end drew near and the respiratory apparatus became more depressed. Death occurred at the expiration of nineteen minutes, by paralysis of the muscles of respiration—the heart continuing to beat feebly and irregularly for thirty seconds after breathing ceased.

This violent action of the heart above referred to seemed to be more an effort on the part of the animal economy to supply the needed oxygen to the system, through the medium of the circulation, during the period of respiratory depression, than it was the result of direct stimulation by the drug.

The difference of susceptibility of these animals to this drug is striking. In one instance $1/2$ of 1 grain proved fatal to a female pig of $25\frac{1}{2}$ ounces weight, while in another instance a male pig of $16\frac{1}{2}$ ounces weight survived the effects of a like quantity. However, on the whole, I think the sex makes very little, if any, difference in the action of these drugs. The above fatal dose for a pig of the given weight has been determined after many experiments with pigs of different weight, and with different quantities of the drug. The same also is true in connection with beta and alpha eucain.

Of beta eucain, $2\frac{2}{7}$ grains are necessary to cause the death of a pig of $24\frac{1}{2}$ ounces weight. In this experiment death occurred in $32\frac{3}{4}$ minutes from the time of injection. The symptoms were not unlike those as already described in connection with the use of this agent, except, as in the case of fatality by cocaine, they were

use. Unfortunately cocain is, in its action, one of the most inconstant and unreliable drugs in the whole pharmacopoeia. It will always produce anesthesia, if greatly exaggerated. At no time were evidences of anesthesia marked, nor were the reflexes entirely lost. The action of the heart and the respiratory apparatus was depressed after a brief period of stimulation at first. When violent spasms occurred the heart action would be temporarily stimulated. Death occurred from paralysis of the muscles of respiration and of the heart, breathing and the heart action ceasing at the same time.

Alpha eucain has proven to be virtually on a par with cocain as to toxic properties. Five-sixths of one grain is the limit as to fatal action with pigs of $2\frac{1}{4}$ ounces weight. I injected this amount of alpha eucain into a pig of this weight, and at the expiration of seven minutes trembling of all its muscles occurred; at nine minutes its head drooped with the nose to the table; at $11\frac{1}{2}$ minutes the animal suddenly fell to its side, and was seized with violent spasms; its heart action and respiration were temporarily increased, being much depressed very soon thereafter; nausea and some vomiting occurred; the drug also acted as a diuretic, renal discharge occurring quite freely; severe spasmodic contraction of all muscles followed one another in rapid succession, and were invariably accompanied with evidences of pain more or less severe. Death occurred at the expiration of eighteen minutes, by paralysis of the muscles of respiration and of the heart, breathing and the heart action ceasing at the same time.

It is also stated that cocain can not be sterilized by boiling, and if subjected to a temperature of 176° F., is transformed into egonin, a substance devoid of all analgesic power; also that boiling does not in any degree affect the efficiency of eucain. I have demonstrated this statement regarding eucain to be true, but if it be true regarding cocain, my experiments in this connection are in error. According to them it is conclusively shown that boiling does not destroy the potency of this drug, but does modify it somewhat. I prepared a 2 per cent. solution of cocain and also of eucain. These I subjected to a bath of boiling water for five minutes. These solutions were allowed to cool gradually, after which 20 minims of the cocain solution were injected into a pig of $3\frac{1}{2}$ ounces weight, with the following result: At the expiration of seven minutes all its muscles were in a tremor, and at ten minutes control of its hind parts was lost; at eleven minutes it fell to the table completely overcome. The symptoms which followed were the same as in other cases, except that they were less violent. At the expiration of thirty minutes the animal had apparently recovered.

Into another pig of $3\frac{1}{2}$ ounces weight were injected 20 minims of the boiled 2 per cent. solution of beta eucain. No symptoms of note followed this injection, with the exception that its hind parts were for a time somewhat paralyzed. At the expiration of 22 minutes a second injection of 20 minims was made. The symptoms following this injection were virtually the same as those which followed the second injection of the other case as related above. At the expiration of forty-five minutes after the second injection, recovery was well advanced. A third injection of 20 minims was now made: the symptoms which followed were identical with, and somewhat intensified over, those of the other case related above. At the expiration of forty-six minutes after the third injection, the animal had nearly recovered.

By way of recapitulation, my experiments lead me to conclude as follows:

1. The action of cocain is inconstant; one never knows whether the symptoms occasioned by like quantities of the drug, in animals or individuals, under like circumstances, will be similar or dissimilar.

2. The action of eucain is constant. The symptoms occasioned by the use of like quantities in animals under like circumstances, and so far as my experiments have gone, in different individuals also, are the same.

3. The first action of cocain on the heart is that of a depressant, and on the respiration it is that of a mild stimulant, the after-effects being, on the heart, that of a decided stimulant, and on the respiration, that of a decided depressant.

4. The first action of eucain on both the heart and respiration is that of a stimulant, the after-effects being that of a decided depressant.

5. Cocain causes death in animals by paralyzing the muscles of the respiratory apparatus, the heart's action continuing in a feeble way for a brief period after breathing ceases.

6. Eucain causes death in animals by paralyzing the muscles of the heart and of the respiratory apparatus, they ceasing to operate simultaneously.

7. Eucain in toxic doses nearly always causes nausea, and occasionally vomiting.

8. Cocain is much less nauseating and scarcely ever causes vomiting.

9. Eucain is decidedly a diuretic, causing renal discharge in a majority of instances in which a toxic dose is used.

10. Cocain is not a diuretic to any appreciable extent, renal discharge having occurred in only one instance in connection with all my experiments.

11. The pupils of the eyes, in nearly all cases of cocain poisoning, do not respond to light and are more or less bulging from their sockets.

12. The pupils of the eyes in most cases of eucain poisoning do respond feebly to light, and rarely ever bulge from their sockets.

13. The action of toxic doses of eucain is more like that of a paralyzing, tetanoiding, convulsion-producing agent, than it is like an anestheticizing one, the plantar and cremasteric reflexes nearly always responding.

14. Toxic doses of cocain cause general anesthesia in connection with the other symptoms in the majority of cases.

15. True tetanus, of all striped muscles of the limbs, and Cheyne-Stokes' breathing nearly always occur with the use of cocain, but seldom does either occur when eucain is used.

16. Cocain is at least three times more toxic than beta eucain, and alpha eucain is as toxic as cocain.

17. Boiling does not destroy the efficacy of cocain, but it does modify it, and boiling in no degree lessens the efficacy of eucain.

The above deductions have been made only after many experiments in connection with each individual point. I have observed many interesting features in connection with the relative worth of these drugs as local anesthetics, but this paper is not to treat of this phase of the work. There is much experimental work yet to be done in this connection, the results of which I shall be pleased to present at some future meeting¹.

Dr. JOSEPH B. HAVEN, of Chicago, has been appointed consul to St. Kitts Island, W. I. Dr. Haven was graduated from Rush College in 1880, and had built up a good practice. He left for his new field September 1.

DISEASE OF THE PANCREAS*.

BY FRANKLIN E. WALLACE, M.D.

MONMOUTH, ILL.

The infrequency with which post-mortem examinations are made probably accounts for the apparent rarity of diseases of the pancreas. This organ belongs to the important system of secreting glands, and I feel that their relationship to the human economy is but imperfectly known. We know that there is a bond of some extent between these glands, through the sympathetic nervous system and the lymphatics, but is there not some bond existing which has control over the power whereby one gland assumes a function laid down by another? Does such a power exist in the human organism, or is the function, once destroyed, lost forever? Does the organism adjust itself to the loss of an organ through other organs, or does it live without this function being restored? There seems to be a close relationship between the pancreas and the central nervous system also, for microscopic examinations of the tissues of the pons, medulla and cerebrum in some cases of pancreatic disease, show colloid degeneration. "In diagnosing affections of the pancreas, special stress should be laid upon incomplete digestion of fat and starches and the existence of diabetes and fatty stools, and for this reason the feces and urine are to be carefully examined. The urine also contains fat in some cases!" It is, therefore, essential to make a very careful examination of the feces and urine, in these cases in which we are undecided, as to diagnosis of pancreatic diseases.

Cyst.—Cystic degeneration seems to be the most common disease of the pancreas. One reason for this is because of the more conspicuous signs and symptoms present, making an early diagnosis of this condition easier, while other cases go unrecognized. The history of a case sometimes gives us an insight into the diagnosis, for in the majority of cases of cyst, injury is given as the cause. In the reaction following an injury to any tissue there is always swelling and congestion in the parts injured. Following contusion of the pancreas, therefore, we would expect these effects to follow and we have the essential conditions present for a cystic formation, viz., a closure of the duct, with retention of the secretions. The injury may be severe enough to set up permanent changes, and through cicatricial contracture we get partial or total closure of the duct and the cyst becomes evident, by an increasing sized tumor. Cancer, calculi and abscess may all act as obstructions.

The diagnosis of cyst is not always an easy matter, and the statement is made that it has been correctly made in a minority of cases. The lack of all symptoms of local or general inflammation, its fluctuating character and its position, in the region of the pancreas, behind the stomach, are its chief diagnostic points. Some very high authorities advocate tapping through the abdominal wall with an exploratory needle, withdrawal of contents and examination, chemically and microscopically. The question arises, is this a safe procedure? Being a retro-peritoneal organ, and lying, as it does, behind the colon and stomach, a surgeon certainly adds danger to an already dangerous condition, for he runs a risk of puncturing either of these overlying organs, and is very apt to infect the peritoneum. Cyst of the pancreas must be diagnosed from ovarian cyst, hydrops of the gall-bladder, hydronephrosis, hemorrhagic effusion, etc. I can not take time in this paper to give the points of differential diagnosis, nor to even mention all of the diseases of the pancreas, but I call attention to the inflation of the colon

as a valuable procedure in arriving at a diagnosis. "This is done by means of air, hydrogen or carbonic acid gas. In tumors of the pancreas, kidneys and spleen, or in aneurysms, the inflated colon comes between them and the abdominal wall." "Tumors of the ovaries and the uterus enlarge from below upward, push the intestines to one side and are not covered with them?" In summing up this disease the following conclusions have been arrived at: 1. That contusions of the upper part of the abdomen may be followed by the development of a tumor in the epigastric, umbilical and left hypochondriac region. 2. That such tumors may be due to fluid accumulations in the lesser peritoneal cavity. 3. That when the contents of such tumors are found to have the property of rapidly converting starch into sugar, we may assume that the pancreas has been injured. 4. That many such tumors have been regarded as true retention cysts of the pancreas and that this opinion has been formed upon insufficient evidence*.

Hemorrhage.—Hemorrhages are divided into three classes. The most common form is passive hemorrhage, as a result of diseases of the heart, lungs or liver. The second class comprises those rare cases resulting from rupture of a large blood-vessel, due to some change in the vessel wall. The third class constitutes those cases in which the whole organ becomes hemorrhagic, the blood infiltrating the interstitial tissues, after which disintegration of the whole organ occurs. "The first form of hemorrhage is unattended by special symptoms. In the second a pulsating tumor may suddenly appear in the epigastrium and the ordinary indications of hemorrhage, viz., vomiting, fainting fits, cold extremities, feeble pulse, and general exhaustion, are present. Death may occur suddenly or the patient may linger for months. In the third condition death usually occurs very suddenly, probably from pressure on the sympathetic ganglia. There are no symptoms and the rapid termination prevents the development of general peritonitis, which would otherwise occur from the sloughing of the peritoneum. There are no indications for treatment*."

Acute Suppuration.—Next to acute hemorrhage, the most rapidly fatal disease of this organ is acute suppuration. Pain may be sudden and severe, nausea and vomiting as a rule persistent, fecal vomiting occurs in a large number of cases, tenderness more or less constant, great prostration, pulse rapid and weak, temperature may be normal, subnormal or but slightly elevated, constipation and tympany generally present, tumor rare, jaundice may or may not develop. The septic infection arises through traumatism, ulcers of the intestines, stomach, or bile tract, from peripancreatic abscesses, or it may take place, primarily, through the blood or lymph channels. In exceptionally rare cases it runs into a chronic condition. Nature is very kind and may protect herself, if she has time enough, to build up a wall. The offending material may be discharged through the bowel or stomach and recovery take place. In most cases the microbic invasion is so rapid that Nature is overpowered and death is the result. In other cases, abscesses have formed in the lumbar region and recovery has been brought about by simple incision and drainage. This condition must be diagnosed from intestinal obstruction, abscess of the liver, gangrenous cholecystitis, empyema of gall-bladder, perforative ulcer of stomach or bowel. The following case, which came under my observation while on the house staff of St. Elizabeth Hospital, Chicago, serves as a type of this disease. It has already been placed on record, as I presented the history of the case and showed a specimen of the omentum, presenting fat

*Read before the Illinois State Medical Society, Cairo, May 16, 1899.

necrosis, before the Chicago Pathological Society in 1896.

Mrs. F., aged 26, Irish, housewife, was admitted to St. Elizabeth Hospital, Oct. 26, 1896, as a private patient; family history negative; mother of two children, one miscarriage; has always been well up to two years ago, when she had pain in the epigastrium, with slight icterus, but made good recovery. Since that time she has had three or four such attacks. Her present history is of five weeks' standing. She was taken with pain in the region of the gall-bladder, nausea, vomiting and fever. These symptoms continued more or less severely for three weeks, and then gradually abated under treatment. For the next ten days she was considerably better, but five days ago was taken with the former symptoms.

She was admitted to the Hospital for an operation, a probable diagnosis of gall-stones having been made. On admittance her condition was found to be as follows: Able to walk, restless, face flushed, hurried respiration, pulse 114, temperature 100.4, pain in epigastrium, nausea and vomiting, tongue slightly coated, tenderness over abdomen, rapid heart action and pulsations strong, constipated and urine scant; liver, lungs and spleen normal. Urinalysis showed biliary coloring matter and one-fifth by bulk, of albumin. Postponement of the operation was advised by her physician. Medicines to relieve her incessant vomiting were in vain, and anything taken into the stomach was immediately rejected. Her condition remained about the same for the next two days. The urine became more scant and enemas did not relieve the bowels. October 28: Voided but sixteen ounces of urine the previous twenty-four hours; more restless and anxious looking; seemed weaker; slight fecal movement; vomiting still continued, and temperature was the same as on admittance. October 29: Heart weaker; fecal vomiting; previous symptoms unabated; semidelirious and extremely restless; at 7 p. m. she passed into coma, and died at 11 p. m.

Post-mortem.—The autopsy was held by Dr. E. R. Lecount, attending pathologist, assisted by the writer, and it showed an intensely interesting state of affairs. A brief synopsis of the findings is as follows: The heart and lungs were normal to a casual examination, the spleen small, the gall-bladder small and contracted from connective-tissue bands in the walls, gall-stones numerous, acute parenchymatous nephritis in both kidneys; the body and tail of the pancreas consisted simply of shreds of necrotic tissue, extending across and lying free in a cavity, possessing for walls, the stomach, retroperitoneal, and perirenal adipose tissue, the transverse mesentery, duodenum, and tissue of lesser omental cavity, as well as some loops of small intestines and colon. The walls of this cavity were necrotic, dark gray and slaty in color. The cavity communicated with the stomach and bowels through perforations, and contained fecal matter. The head of the pancreas was the least involved. We found disseminated fat necrosis throughout the omentum, mesentery and fatty tissue. This necrosis of Balsar may be found in the interlobular pancreatic tissue and in the abdominal fatty tissue generally. It consists of small, opaque, yellowish white spots, from pinhead-size to that of a split pea, distributed more or less thickly throughout the tissues involved. In this case these areas could be plainly seen in the omentum, when held up to the light. I examined the contents of these areas under the microscope, and fat crystals were easily visible.

Primary cancer of this organ is a most insidious disease, developing gradually and without much pain. The patients are usually past middle life. Temperature is generally subnormal, and the patients may, later in the

disease, have a tumor, and like cancer of any part of the body, may have cachexia and emaciation. It is accompanied by various digestive disturbances, liver small and hard; jaundice sets in gradually and once present never disappears. With the accumulation of bile in the gall-bladder, a tumor can oftentimes be made out and might lead one to a diagnosis of cholelithiasis; therefore, if we have a case presenting jaundice, with or without pain or a tumor in a person past middle life, and it can not be relieved by active medication in a few days, operate. One diagnostic point is this: Cancer of the pancreas nearly always produces jaundice, because of the frequency with which the head is involved, while cancer of the liver rarely does, for its growth generally occurs in parts of the liver distant from the gall-duct.

It is only within the past few years that any systematic effort at investigating the surgery of this organ has been attempted. Billroth, Kocher, Gould and others have placed cases of interest on record, but much of the honor of placing surgery of the pancreas on a solid footing belongs to Senn. He has made extensive experimental investigations, and has collected illustrative cases and placed them on record. Although the results of laparotomy so far have not been encouraging, I think it apparent that only through an early diagnosis and operative procedure can we hope to decrease the large percentage of mortality from diseases of this organ. Several cases are on record in which the pancreas has been removed entire, and its function apparently taken up by other organs, however, in some cases, more or less imperfectly, for glycosuria has been noted. There are some authors who claim that total extirpation of the pancreas is invariably followed by diabetes, and probably an equal number deny this, but it is true nevertheless, that in a majority of cases this operation is followed by glycosuria. Complete removal may easily prove fatal, so it should be avoided if possible. I advocate an exploratory incision and after a thorough investigation, a decision can be reached as to the best method of procedure. With our advanced knowledge of antiseptics and improved methods of operating we certainly are justifiable in making an exploratory incision for diagnosis. If an obstruction should be present from gall-stones, stricture and the like, we are in a position to remedy it. If found to be cancer, an operation may be indicated, depending on the involvement. Should our examination reveal a cyst or abscess without involvement of the peritoneum, then a posterior incision below the twelfth rib should be made, the tumor pushed backward, incised and drained and the anterior incision closed. I favor this route, because: 1. It permits of better drainage. 2. We run no risk of infecting the peritoneal cavity with the tumor contents. 3. "The permanent adhesion of the left end of the pancreas to the abdominal wall, in this situation, is less likely to lead to subsequent mischief than is an anterior adhesion between the stomach and transverse colon⁵." The cure of cancer of the breast by the administration of thyroid extracts is reported and we know of the favorable results in other diseases from its use. We know, also, of favorable results from the administration of extracts and secretions of other glands. If, as I have suggested, there is a peculiar relationship existing between all glands, is it unreasonable to expect that in diseases of the pancreas or other glands, we might not have a beneficial effect by giving the combined extracts or secretions from all the glands?

MEDICINE.

ITS PROGRESS, PROBLEMS, AND PROSPECTS.*

BY J. BRUYERE, M.S., M.D.

SURGEON TO MERCER HOSPITAL.

TRENTON, N. J.

(Concluded from Page 591.)

Etiology thus becomes of prime importance and gives to us many problems for future solution. For example, can a micro-organism, under different circumstances, produce different diseases and the variations in the virulence of different epidemics? We know that micro-organisms are greatly influenced and modified, in form and activity, according to their food-supply, temperature, moisture, the presence of oxygen, light and other organisms. Can not the same germ have the conditions of its development so changed by environment as to undergo progressive modifications sufficient to account for the variations in the virulence of different epidemics, and to produce various symptoms and diseases? Does not the pneumococcus, when subject to different environments, produce numerous infectious processes, such as pneumonia, pleurisy, endocarditis, pericarditis, peritonitis, cerebrospinal meningitis, arthritis, and general septicemia? May not the same specific cause give rise to different diseases in different patients? Can the same micro-organism produce erysipelas in one person, and puerperal fever in another? Are all infectious diseases due to individual or specific germs and their modification by environment, or are most infectious diseases due to a combination of germs and of circumstances? Can a disease like croupous pneumonia or diphtheria be the result of two or more micro-organisms acting alone or in combination? Is pneumonia, cystitis, meningitis, hepatitis, tonsillitis, carditis, gastritis, nephritis or enteritis always the same in kind, or are there many kinds of these diseases, corresponding to the combination of germs and circumstances present? Do suppuration, erysipelas, septicemia, pyemia and pneumonia depend upon their own specific germs, or are they produced by various germs, or a mixed infection? If numerous microbes can, and do, develop in the same organ at the same time, is not their resultant effect often responsible for the varieties of diseased conditions? Are the symptoms at the beginning and termination of a microbial disease always due to the same kind of germs? Why is it that various organisms may produce the same pathologic, anatomical and clinical symptoms? Why does not a specific bacterium always produce the same effects—the same symptomatology and pathologic phenomena? For example, why is it, as Mikulicz tells us, that “all forms of peritonitis run the same clinical course, regardless of the bacteria that cause it?” May we not have phthisis pulmonalis without the presence of the tubercle bacillus, and with streptothrix instead? Can not pneumonia be produced by the tubercle bacillus and also by the microbes of diphtheria, typhoid fever, anthrax, erysipelas and influenza? Is not epidemic cerebrospinal meningitis often due to a variety of organisms, such as the meningococcus, pneumococcus, streptococcus, tubercle bacilli, anthrax and typhoid germs? May mumps, orchitis, meningitis, pleurisy, goiter, hepatitis and melancholia be due to typhoid infections, and may not other things than typhoid germs give rise to typhoid symptoms while typhoid germs may give rise to other than typhoid symptoms? Are the meningococcus and the gonococcus identical organisms, or are they only closely related? As there is no individual germ peculiar to each

disease; as environment modifies the nutritive and reproductive activities of germs, thus causing a great diversity in their virulence, and in the symptoms and diseases they produce, as many germs in combination may produce a given disease, and as many diseases may be produced by a variety of germs, it follows that the problems in etiology are the most difficult. In fact, in every department of medicine the problems that confront us are very numerous.

There are many problems in tuberculosis. Why do dogs, goats, rats, white mice, and all cold-blooded animals, possess immunity, while cats, rabbits, field mice, pigs and fowls are susceptible? Why is tuberculosis common in cattle, and rare in sheep and horses? Why are rabbits and guinea-pigs very susceptible to inoculation and yet rarely have tuberculosis; and why do apes and monkeys contract tuberculosis so readily in confinement and never in their native wilds? On the contrary, the wild Indian is very prone to consumption, even when occupying one of the finest climates in the world. The death-rate among them is about twice that of the white race. Why is an Indian, who lives an outdoor life, in a beautiful climate and free from the effeminating effects of civilization, more prone to consumption than his white brother? Why is the negro, in this country and the West Indies, more prone to this disease than in Africa; and why are the Jews far less susceptible than any other race? If tuberculosis can not be directly transmitted, can not the virus be transmitted that gives rise to infantile tuberculosis, or is this always the result of infection? Is not congenital tuberculosis more common than we imagine? What is the peculiar character of the tissue-soil that allows the seeds or germs of tuberculosis to develop? All weak and delicate people are not predisposed to consumption. Lowered vitality does not always favor infection. Is tissue-resistance, therefore, always greatest in those of the greatest vitality or physical strength? It is said that immunity depends on tissue-resistance, and that tissue-resistance depends largely on healthy tissues and favoring circumstances. It is also known that tissue-resistance may be inherited or acquired, independent of strong vitality. A sick infant can resist some germs better than a strong man, and some people are easily inoculated or infected, others not. Do the bacilli of tuberculosis, or their products induce suppuration or is this due to a mixed infection? Is the virus which produces scrofula, tuberculous adenitis, or tuberculosis of the lymph-glands, the same as the virus that produces tuberculosis in other parts of the body? Does it differ in kind, or is it only milder in form? Why do measles, whooping-cough and diabetes so strongly predispose to tuberculosis? Why are the lungs most susceptible in adults, and the lymph-glands in children? Why does scrofula in childhood furnish a partial immunity to tuberculosis in adult life? Is pneumonia, resulting from tuberculosis, due to the tubercle bacillus and its toxins, or is it due to secondary infection with other germs? Is secondary infection frequent? Are the cavities in the lungs produced by the tubercle bacilli, or are the pus-germs—the streptococcus, etc.—responsible for all cavities? Why does a free incision into a tuberculous tissue so often set up healthy action in the parts? For example, why does an abdominal incision often cure peritoneal tuberculosis, or an incision into tubercular bones and joints so often have a curative effect? Why does suppuration at once cease, when we open an abscess antiseptically, although pyogenic organisms are present in vast numbers? Why do tubercle bacilli sometimes cause tuberculous tissue, sometimes a

* Read before the Mercer County (N. J.) Medical Society, at its Fiftieth Anniversary, May 23, 1898, and subsequently revised.

cheesy mass, and sometimes a chronic abscess? Is the bovine tubercle bacillus identical with the tubercle bacillus of man? Theobald Smith has shown that these bacilli are not identical, and casts discredit upon the opinion that tuberculosis can be spread from dairy products, while Dr. Busch believes that "all the tuberculosis affecting the human race comes from the dairy cow." Obermuller finds Koch's bacilli in butter, while Rabinowitch fails to find any. Is a large percentage of infant tuberculosis due to milk infected by the tubercle bacilli, or its toxins? Many believe that most milk is filled with tubercle bacilli, and, regarding the infant stomach as a germ incubator instead of a sterilizing chamber, they sterilize and pasteurize the milk, and thus impair digestion and nutrition. Is consumption of vegetable origin, and is the bacillus a vegetable parasite and to be found on certain grasses, as affirmed by M. Moeller and Rabinowitch? Can artificial immunity to the tubercle bacillus be produced by inoculating with the tubercle bacilli in the early stages of tuberculosis, before the vital forces have been reduced by the disease?

It is estimated that there are over 150,000 deaths annually from consumption, and that about one in every sixty is infected, nevertheless Parker of London tells us that the mortality for consumption has diminished 46 per cent. As the germs of tuberculosis are so widely disseminated—revealing their presence in about one-half of all cases of autopsy, from whatever cause, and thus showing that possibly the majority of mankind are infected, although in only a minority is the germ able to overcome vital resistance and produce fatal effects—does it not follow that mankind should, in the course of time, acquire a partial, or a total immunity to this disease? Should not better sanitation, better hygienic laws, and acquired immunity, eventually stamp out this terrible disease? In India there is an acquired immunity to cholera, which in this country is very deadly. Measles have almost depopulated the Pacific Islands, but here it is mild. Wherever a disease has been long prevalent there seems to be eventually developed an acquired immunity. Landerer declares that cinnaamic acid "cures all cases in the early stages, and many others." Murphy of Chicago claims to have secured excellent results by compression of the lungs by nitrogen gas, and others, with the serum and climatic treatment, claim excellent results; but is not the decrease of the death-rate from tuberculosis due far more to improvement in sanitation and gradually acquired immunity than to all medical treatments combined?

We will next briefly consider some of the problems in diphtheria and typhoid fever. The true bacillus of diphtheria can only be identified by its cultural peculiarities and its pathogenic activity. Being irregular in outline, especially in cultures, and closely resembling other organisms found in the mouth, particularly in those having decayed teeth, mistakes are easily made, when only a microscopic examination is made. We can not always, from the form of a bacillus, determine the class to which it belongs, for its form depends largely on the nature of its environment, or the media employed in its development. There have been found bacilli identical in form to the bacilli of true diphtheria, and yet these were harmless when inoculated. Why does the bacillus of diphtheria sometimes entirely or partially lose its virulence and become incapable of producing death? Does it lose its virulence as the disease progresses toward recovery, and is this difference in virulence due to difference in species, or difference in circumstances or environment? We do not know why the bacillus of diphtheria

may be harmless at one time, cause true diphtheria at another, or membranous rhinitis at still another. The New York Board of Health found the germ of diphtheria present in 80 per cent. of the reported cases of membranous croup. Is membranous croup, therefore, simply laryngeal diphtheria?

Why is it that susceptibility to the typhoid bacillus can be artificially induced in the lower animals, that are scarcely susceptible to this germ, by the injection of the products of certain saprophytes? Alessi tells us that rats, guinea-pigs, and rabbits, when compelled to inhale the emanations from decomposing products in cess-pools become susceptible to typhoid infection. Is resistance to the typhoid bacillus weakened by the toxic action of the saprophytes? If not, what are the things, or conditions, that diminish natural resistance to infection in the various zymotic diseases? Why are enteric lesions present in some cases and absent in others, although infection may have taken place through the intestine in both cases? Why may typhoid infection at one time produce a septicemia—a severe intoxication—without local manifestations, and at another time attack, either alone or in combination, various organs, such as the lungs, kidneys, spleen, or cerebrospinal meninges, without affecting the intestines? Does the effect of the typhoid germ predispose to a mixed infection, and is this not responsible for many of the symptoms that are present in typhoid? Is the bacillus coli communis, of which, according to Rahlff, there are sixty-two different kinds, capable of becoming pathogenic and producing typhoid symptoms? As it is now known that the urine of typhoid cases may contain the germs for many months, is not the public health greatly endangered by this fact, and should not the urine be disinfected as a sanitary precaution, while any germs remain in the system?

Much yet remains to be known of the life and internal structure of bacteria. As by nature, they are usually colorless, it is quite probable that they are greatly altered in structure by the staining process. At present our text-books teach that the bacterium is devoid of a nucleus, still Gruber, Klebs, Nussbaum, Balbini, and others have shown that "the nucleus is an element essential to the life of the cell," or is the "focal seat of life in all its forms." Butschli believes that the bacterium consists almost entirely of a nucleus. From this we observe that much still remains to be known about the structure of the bacteria.

There still remain many problems in infection, immunity, etc. We have yet to learn how infection may lead to structural complications, and how normal bacteria become abnormal in growth and character. We know that healthy tissues resist microbe attacks, while enfeebled tissues are predisposed to microbic action. The want of vital energy or defective nutrition makes the tissues a receptive soil for bacilli and causes infection. Infection depends largely upon the pathogenic power of the germ, and upon the amount of cell resistance. The condition of the vital forces, therefore, largely decides the action or effect of the germ. For example, a person of strong constitution, and in good health, can meet disease on a war footing, and nine times out of ten repulse it. It is said that "the microbe trembles when he sees a body cheerful and at ease."

It would seem, therefore, that immunity was due to increased vital force; but such is not the fact in all cases. The very nature of immunity is still an unsolved riddle, for no general or satisfactory law of immunity has as yet been formulated. For example, why are infectious diseases mild in some cases and virulent in others, and why

are the warm-blooded animals immune to most of these diseases? Why are children immune to certain diseases of adult life, and adults immune to certain diseases of childhood? Why is natural immunity peculiar to some species, races, or individuals? We know that artificial immunity is secured by attacks of disease ending in recovery, by vaccination, by treatment with sterilized cultures of germs, and by treating a susceptible animal with the blood-serum of immune animals, but we do not know how the immunizing effect is produced. Are artificial immunity and the cure of infectious diseases due to the combination of enzymes with organic albuminoids? Ehrlich believes that the specific diseases, caused by toxins, are produced in those individuals whose living cells or tissue possess a substance which has a chemical affinity for the toxin, and when this substance passes from the tissues into the blood, it becomes a protecting and curing substance. Buchner says that immunity is caused by "reactive changes" in the fixed tissue cells, after which they are not again susceptible to the action of the same organisms. There seems to be a retention of some bacterial products in the tissues. Others attribute immunity to phagocytosis; to the germicidal powers of the blood-serum; to the bactericidal properties of the proteids; to the exhaustion of the pabulum by the germs. Metschnikoff claims that immunity is due to phagocytosis. Dr. William Carter, in 1893, showed that normal blood-serum is a powerful and active therapeutic force, with globulicidal and germicidal properties. Vaughn, Hankin, and others, believe that the nuclei in the blood, which is derived from the white corpuscles, has decided germicidal and immunizing properties. Others believe that the first attack of an infectious disease exhausts the pabulum or nourishment in the blood or tissues on which the germ feeds; or produces such cellular, or chemical changes that the germs die, and the disease terminates. This pabulum having once been exhausted, and the cells of the organisms having adapted themselves to this change, or been modified by it, is the supposed cause of future immunity. Vaccination, with a migrated virus, seems to habituate the phagocytes, or tissue cells, to the poison, and thus produce immunity; but according to the recent reports of the British Royal Commission, protection is relative, not absolute; temporary, not permanent. How sterilized cultures of germs and antitoxins produce immunity we do not know. The antitoxins seem to be secreted by the cells of the organism, and to combat the toxins secreted by the germs. Whether the antitoxic serum acts biologically or chemically we do not know. It may stimulate cellular resistance, or it may act chemically by checking germ growth or by neutralizing their action on the toxin. According to Behring and Kitasato the antitoxins aid the tissue-cells in resisting the action of the germs and its poison, and do not neutralize or destroy them. The germs that produce alcoholic fermentation give rise to chemical products, which ultimately check fermentation. Is self-limitation, in certain diseases, due to chemical products that have been produced by the germs of the disease? Disease is not limited by any period of the life history of the germ, for with suitable pabulum and proper conditions, germs will multiply and reproduce themselves indefinitely. Is self-limitation to disease due, therefore, to exhaustion of the elements on which the germs feed, to modification of the tissues, or to chemical products? In some infectious diseases, like diphtheria, erysipelas and tetanus, the germs may develop in only a small portion of the body—hence, the nourishment for the germs has not been exhausted, and one attack does

not immunize against another. There is a distinction, therefore, between self-limitation and immunity. Why is it that in some infectious diseases, like scarlatina, typhoid fever, smallpox, and measles, there is self-limitation and immunity to subsequent attacks, while in others, like pneumonia, erysipelas, and diphtheria there is self-limitation, but practically no immunity? How can we produce artificial immunity to diseases where the natural processes of disease do not afford immunity? For example, tuberculosis, in its natural process, does not seem to furnish the agents for self-limitation or immunity—hence how can we ever establish these artificially, except possibly by injecting antagonistic germs, or the serum of animals naturally immune, or by some other process yet undiscovered? As one disease may prevent the contraction of another by means of the antagonism of germs, it may be possible by injecting antagonistic germs to cure many diseases, as anthrax is cured by injecting the micrococcus prodigiosus. Natural immunity seems to be due to the condition of the blood. Can we, therefore, transfuse the nature of an immune animal, by blood transfusion, to the individual? A greater and more accurate knowledge of the cause, or causes of immunity, will enable us the better to secure artificial immunity. When we know how the tissues themselves combat infection, we may be able to aid them in their work. When we know more about the chemical and physical changes that go on in the cells during elimination and absorption, we will have far greater powers of combating disease. Along this line many great discoveries still undoubtedly await us. If the germ products that cause toxic symptoms also cause self-limitation and immunity by isolating the various chemical elements produced by the germs, could we not ascertain which of the chemical elements produce the harm, which self-limitation, and which immunity? If we could ascertain this, we might then secure from artificial cultures, or the serum, only the immunizing elements, and thus ascertain the relative merits of the chemical product, and the living virus. We know but little about immunity, and there remains much to be learned about the biochemistry, the poison, etc., of micro-organisms, and their products.

We do not know why it is that in people of apparent health we so often find the diphtheria bacilli in the throat, the pneumococci in the blood; the tubercle bacilli in the lungs, and many other pathogenic species almost constantly distributed throughout the organism, without producing disease. Montesano tells us that the tetanus bacilli and toxin have been found in large numbers in the nerve-centers, without producing their characteristic lethal effects. It appears that microbes, *per se*, are usually inoffensive. It is the condition of the germ, aided by physical condition that makes it virulent rather than the germ itself. Even the so-called pathogenic bacteria are not always guilty of homicidal intent. The diphtheria, typhoid, cholera and other pathogenic bacilli are widely spread in nature, are almost universal, but it is only when they become diseased or virulent that they become dangerous. What causes the diseased or virulent condition of the germ, or what makes them at one time pathogenic, and at another time not, we do not know. The contact of the germ with an organism of lowered vitality seems to cause the germ to become pathogenic or diseased. The virulence of a germ depends upon its nutritive and reproductive activities, and these are greatly increased when the germ is developed in a highly susceptible individual, and usually diminished when the germ is artificially cultivated. While in a patho-

genic condition it seems to secrete, or excrete, poisonous products which are most harmful to the organisms. How to prevent germs, therefore, from becoming virulent is one of the problems that now confront bacteriologists. We must more thoroughly understand the natural history of bacteria. We must study them individually and not in groups. When we more fully understand the structure and life history of the pathogenic bacteria we will undoubtedly be able to prevent bacteria from becoming pathogenic. Then antiseptics and serum-therapy will have vanished and become a landmark of the past. As we, through observation and research, more and more understand the objects and forces of nature, we will preside over them, while fate and limitation recede into the dim past. We will then, possibly, be able to convert the parasites—the degenerates of microbial society—to a better mode of life, and of activity, and we will more thoroughly understand and appreciate the beneficial effects of the saprophytes. We observe, therefore, that microbes have power for good or for evil, the same as all forces in nature. The good may become bad, and the bad may become good. How to civilize and Christianize the microbes so that they become harmless, if not beneficial, to humanity is a problem for the future. Many microbes are benefactors to humanity, and when rightly understood and managed, they become our friends, and life itself depends largely upon them. Schulze, Schwann, Pasteur, and many others believed that the fermentation that gives rise to bread, vinegar, wine, beer, etc., was due to micro-organisms. Recently Professor Buchner has declared that "fermentation is not a physiologic process, but is caused by the substance called *zymose*," which is a chemical product of the growth of yeast-cells. Most germ diseases are caused by the poisons generated by the cells. Is it not most probable, therefore, that fermentation is due to yeast juice rather than to yeast-cells. Some germs convert starch into cellulose, and some germs in the soil greatly aid plant life by forming nitrous and nitric acid, ammonia and phosphorus. Some color milk blue, and others transform the white snow of the Alps into scarlet. The phosphorescence of sea water is due to microbes. Many colors, aromas and flavors, are due to bacteria, as in butter and cheese. Dr. Johann Olsen of Norway; by bacteriologic methods, has produced the various textures and flavors of the different varieties of cheese. Certain microbes and combinations of microbes produce certain flavors. With the microbe corresponding to the flavor desired he inoculated a sterilized cheese, and thus secured the texture and flavor desired. Kahn has made a science out of butter making, and Hansen produces the various kinds of beer from various yeasts of his own production. Many industrial processes depend for their success on bacterial fermentation. Alzares has discovered a bacillus that "converts a sterilized decoction of indigo plant into indigo sugar and indigo white," the latter then oxidizing to form the valuable blue-dye. The proper preparation of tobacco leaves and of tea depends on the right amount of fermentation—the same is true of ensilage. Flax and hemp are steeped in a water containing a certain bacteria, which so acts on the plant as to aid in separating the choicest fibers. Bacteria also aid in the tanning process, and are in many ways useful in the arts. We observe, therefore, that although bacteria are essential factors in many diseases, they nevertheless are for the most part harmless, and may render a beneficent and important service to mankind. They are highly useful as scavengers and ferments, and do much toward keeping the world sweet and clean. Kijanizin, of the

University of Kieff, says that many kinds of intestinal bacteria, by acting as ferments, aid digestion. They decompose and peptonize the nitrogenous matter, and thus aid in the absorption of food. From Schottelin's experiments upon chickens it appears that microbes are, at an early period of life, essential to digestion, and at a later period an aid to digestion. It is also true that other intestinal bacteria cause disorders of digestion, by causing decomposition of food, and the production of various poisonous substances, which irritate the stomach, poison the system, and give rise to numerous symptoms. Some microbes are poisoners, murderers, vandals, and even incendiaries. According to M. Jean de Loverdo, there are incendiary microbes—the thermophiles—which are responsible for the so-called cases of spontaneous combustion. Microbes are thus beneficial and harmful, useful and useless. It is the problem of the future to ascertain the exact structure, composition and nature of microbes, so as to convert them to the highest use. The pathogenic microbial savages, with homicidal intent, must have their environments and nature modified or changed, so as to become harmless if not beneficent.

The microbe, it is true, is a great factor in evolution, and more thoroughly respects the doctrine of the survival of the fittest than any other agency or cause. It selects the weak and unfit, and as it is not in harmony or sympathy with altruistic sentiments, it usually destroys them. The simplest form of living matters—the cell, microbe, or micro-organism—is endowed, we are told, with psychic life. Can we, therefore, bring psychological influences to bear upon micro-organisms, so as to modify their nature, and make them more humane and altruistic in their sentiments toward humanity. This suggestion may seem like pleasantry, and is undoubtedly impracticable, still Bunge, Gruber, Verworm, Moebius, Balbiani, Binet and others, believe that in both vegetable and animal organisms, we find manifestations of an intelligence which greatly transcends the phenomena of cellular irritability. They believe that "psychologic life begins with living protoplasm," for the phenomena of life obey much more complicated laws than any merely physico-chemical phenomena, or phenomena due to cellular irritability. Life emanates but from one source, and wherever there is life there is design, intelligence, the power of choice, and other psychic manifestations. "The same desires," says Montaigne, "stir mite and elephant alike. The psychic life of the bee is as complex as that of the whale." The varied movements, caprices, and frolics of micro-organisms, their selection, and method of seizing and appropriating food, all indicate psychic faculties. According to Ehrenberg, Pouchet, Kunstler, Lachmann, and others, some micro-organisms possess organs of sight, hearing, and of touch, and manifest surprise and fear. Some micro-organisms are herbivorous, and others carnivorous. There is not only selection of the food, but there is sexual selection. We observe, therefore, that all psychic and vital phenomena are present in micro-organisms; but if such were not the case, we would have to assume that they were "superadded in the course of evolution, in proportion as an organism grows more perfect and complex." All life originates from a minute point of matter called a cell. Human life first starts from the union of a sperm-cell with a germ-cell. These cells live as minute organisms, independent of the individual from which they originate. They possess vitality and psychic life. The sperm-cell, or spermatozoid, has organs of locomotion, and in obedience to a kind of innate instinct that is intelligent and volitional, it seeks the ovule, and accord-

ing to Binet "is animated by the same sexual instincts that direct the parent organism toward its female." The ovule throws out a minute protuberance, called the cone of attraction, on which the head of the spermatozoid fastens itself, and is then drawn into the interior of the ovule, and by the union or fusion a more complicated cell is formed which begins that strange process of evolution, or development, by which cell is added to cell, and part to part, until a most wonderful and complex organism is produced. If the sperm-cell does not possess psychic life how could a father transmit his form, features, disposition and peculiarities to his child? The same is true also of the germ-cell, which represents the psychic life of the mother. Is it not plain, therefore, that psychic life can and does exist in a single cell or micro-organism? The whole possibilities of man—his form, features, and every faculty and endowment—exist as a latent potential in the original germ. A study of the life, habits, and peculiarities of the individual germ, its psychic life, may lead us to discover the cause of its virulence or pathogenic condition and enable us to convert a bad germ into a good one, or a useless into a useful one. In this age of psychic research, may this not be a problem for the future? Dr. Baraduc of France claims to have succeeded in photographing certain emanations from the human body, and of having caught the human soul itself on his sensitive plates. At Munich he exhibited no less than four hundred photographs of this kind. He also claims to have secured "photographs of familiar spirits, and the like," and in the near future will undoubtedly discover the shape of an odor, the length of an emotion, and the color of thought. When all this is accomplished, some psychologic genius may be able to hold communion with the lower organisms, and interpret aright their psychic life. If there is to be progress and new discoveries in the future, there must be, as in the past, scientific daring and the spirit of adventure. This spirit of inquiry, research and daring has given us in the last ten years many new and sensational discoveries in mechanics and physics, such as the modern bicycle, horseless carriages, electric railways, polyphase currents, the Laval steam-turbine, the interior combustion motor, calcium carbide, the cinematograph, the Roentgen rays, liquid air, hydrogen and other gases, color-photography, wireless telegraphy, cold light, high-frequency currents, etc. There seems to be no limit to future possibilities; hence the prospect for the future is the brightest. The skiagraph may foreshadow the invention of a dolor-meter to measure the amount of pain, and other similar inventions. We may then have some delicate instruments to measure thought and emotion. We may then use liquid air to furnish pure air for our hospitals; to reduce the temperature in fever wards in the tropics. We may then convert bacteria to some useful purpose. M. P. Melnikoff has already constructed an engine which depends for its motive power upon the fermentation of bacteria and the presence of the gas generated. In the future we may regulate sex by the quality and quantity of the food digested. In the future, hypnotism and more useful. Scientific investigation has done much to clear hypnotism of its mysticism, and the explanation of the duality of mind has given to hypnotic suggestion a therapeutic application. Through physical and psychic research all forms of occultism are being placed on a more rational basis, and in the future the relation of mind and body will be more thoroughly understood.

At the present time it is believed that the germs of certain diseases are too small to be revealed by even the

compound microscope, with the best immersion objective—for any germ much smaller than the influenza bacillus could not be recognized by the microscope. An improvement in our microscopes might reveal to us the germs of all our infectious diseases and teach us the etiologic importance of germs as a factor in disease. The limitations of the microscope may prevent us from ascertaining many mysteries that reside in the living cell and germ. Can we ever so increase the powers of the microscope as to determine the mysteries of life and the secrets of death? Will we not, in the future, so strengthen the cell that it can withstand the invasion of pathogenic bacteria? A greater knowledge of the pabulum on which bacteria feed may cause such an improvement in the living culture-media as to enable us to cultivate the pathogenic bacteria, and to isolate and study them more effectively. The normal blood-serum, especially in the naturally immune, holds in solution chemical substances or specific antitoxins, which are manufactured by the cells of the organisms. In the future the art of serum-therapeutics will be to obtain this immunizing product. Possibly chemistry may yet discover the antidote for the poisons generated within the human system—some drug that is innocuous to the patient and destructive to the germ. It is highly probable that in the near future the effective serums and antitoxins may ultimately banish infection. With a fuller knowledge of natural and acquired immunity we will undoubtedly be able to prevent all contagious diseases, as we are now able to prevent a few by inoculation. "By a process of vaccination or immunization it may soon be possible," says Pasteur, "for man to eradicate every contagious disease from off the face of the earth." At present, therefore, clinical medicine should seek protection from all toxic agents, and immunity from diseases. May we not, in the future, so understand the secrets of life and the cause of disease as to secure to each individual a limited immortality? Then the patient may beseech the doctor to let him die instead of keeping him so long in this vale of tears. We will then quarantine the mosquitoes and flies so that they will not spread disease. The scientific spirit will eventually overcome the commercial and mercenary spirit of the age, which foists upon us germ juices and specifics *ad nauseam*, and the mad rush after every fad and fancy, every novelty, will cease. Commercial houses will no longer lord it over the medical profession. They will supply the demand, and no longer create it. Honest seekers after truth, observers, experimenters, will then advance the science of medicine. There will then be less credulity and more judgment, and the bewildering and disgusting multiplications of so-called remedies, which like the Dutchman's razor, are made to sell, will no longer depend upon the testimonials of the credulous and ignorant. Dr. Elmer Lee says that "in some future day it is certain that drugs and chemicals will form no part of a scientific therapy." No one will then enter the medical profession except from a pure love of humanity, a love of science, and self-abnegation. The medical prospects for the future are inspiring, for the doctor is becoming more and more a self-sacrificing altruist, and seeks prevention rather than cure. Increased knowledge of the cause of disease has so greatly increased our powers of prevention that the future for humanity promises to be far more free from disease, far healthier, and far happier.

DR. MARK A. BROWN has been elected professor of materia medica and therapeutics in the Cincinnati College of Medicine and Surgery.

Therapeutics.

Internal Treatment of Lupus with Fluorin.

A. Philippson has been testing sodium fluorid in the treatment of lupus since 1895, and now announces that we have in it a most effective means of favorably influencing lupus, applied in a 10 per cent. plaster, but most active taken internally. His report in the *Dermatologische Zeitschrift* for July, of several cases followed for a couple of years, more or less, emphatically demonstrates the value of this new medication. Unfortunately it causes gastric disturbances in time, requiring suspension of its use before the cure can be completely realized. To obviate this he resorted to an organic preparation—natr. parafluorbenzoicum—and found this equally effective, readily taken and free from after-effects. The prompt and marked improvement constantly attained suggests its application to other tuberculous processes. The dose is $7\frac{1}{2}$ grains three times a day.

Methyl Salicylate in Pruritus.

In a number of cases the effect has been immediate and abnormally remarkable. It has been found effective in pruritus, prurigo and lichen simplex. The following is the formula:

- R. Methyl salicylate.....gr. xxx
Zinc oxid
Vaselin aa.....5v

M. Apply in a thick salve, so that it will adhere closely to the skin.

—Lercôdt.

Soluble Metallic Mercury in Syphilis.

From an experience of eighty-two cases of syphilis in various stages, all promptly and thoroughly cured with inunctions of the new soluble preparation of mercury—similar to Credé's soluble metallic silver—O. Werler recommends it as the easiest, simplest and most effective means of curing all syphilitic processes, in a communication in the *Derm. Ztft.* for July. Very much less of the mercury is required than in any other form. It is more rapid, non-toxic, non-irritating and an improvement in every respect over other methods of mercurial treatment, internal or external, according to his experience. The formula for the salve is:

- R. Hydrargyri colloidalis.....5iiss
Aque destil.....3iiss
Adipis suilli et ceree albae (4-1).....5xviiss
Ether sulph.....gr. xxviiss
Ether benzoati.....gr. liiss

For Insect Bites.

- R. Flexible collodion.....5iiss
Salicylic acid.....gr. xv
R. Collodion.....5iiss
Mercuric chlorid.....gr. vii
M. Apply locally to arrest pain and abort inflammation.

—Beinbeck.

Acute Gastritis.

For the vomiting of acute gastritis Pepper frequently prescribed one of the following formulae:

- R. Hydrag. chor. mit.....gr. i
Bismuth subnitrat.....gr. xxxvi

M. Ft. powders xii. Take one powder dry upon the tongue every three hours until four or five have been taken.

- R. Acid. carbol.....gtt. iv
Sodi bicarb.....3iiss
Elix. aurant.....5ss
Aque q. s. ad.....5iv

M. Sig. A teaspoonful every three hours.

Myalgia.

This affection is unusually trivial as to duration and consequences, but often is such a source of discomfort to the patient that a ready remedy is a definite addition to the physician's armamentarium.

- R. Ext. cimicifuga fl.
Ext. erythroxylon fl.
Tr. guaiac. ammon., aa.....f3i
M. Sig. A teaspoonful three times a day.

Cardiac Dropsy.

The following diuretic pill, suggested by H. C. Wood, will be found of great value in cases of cardiac dropsy.

- R. Pulv. scilla
Pulv. digitalis
Cafein citrat, aa.....5ss
Hydrag. chol. mit.....gr. v
M. Ft pil xxx. Sig. One pill three times daily.

To Keep the Hands White and Soft.

In these days of asepsis the hands of the physician, and especially of the surgeon suffer greatly from frequent scrubbing and immersions in antiseptic solutions. A preparation that will keep the hands white and soft and that will not at the same time be inelegant to use, is always in demand. The following formula will be found to be one of the very best ever proposed for this purpose:

- R. Ol. rose.....gtt. xv
Glycerin.....3i
Spts. myrcia.....3iiss
Ol. cajuput.....gtt. xx

M. Apply at night before retiring, first washing the hands thoroughly in hot water. In cold weather this can also be applied to the hands before going out.

Fatulent Dyspepsia.

While the following formula is not pharmaceutically elegant, it is at times exceedingly efficient in the treatment of gastric fermentation.

- R. Bismuth salicyl.....3ii
Magnes. carb.....3ii
Carbo pulv.....3iiss
Ol. menth. pip.....gtt. xx

Of this powder give a small teaspoonful one-half to one hour after meals.

Atropin in Bronchial Asthma.

Von Noorden recommended Trousseau's method of treating asthma, e. g., by atropin (*Journal of Med. and Science*). The treatment lasts from four to six weeks, commencing with half a milligram per dose, increasing every two or three days by half a milligram, until a dose of four milligrams has been reached. After having reached this amount, the dose is again gradually diminished. If the dose is increased so gradually, no injurious by-effects will be noticed, but nevertheless the patient must be under the physician's supervision. On the attack abate, the atropin has no effect, but it prevents further attacks for a long time. Where no permanent cure is achieved by the atropin there is at least a long-lasting improvement; provided the asthma is not complicated by emphysema and chronic bronchitis.

Malarial Cachexia.

Dr. Lockwood recommends the following for the anemia following malarial attacks.

- R. Ferri redacti.....gr. ii
Pulveris ipecac.....gr. ¼
Acidi arseniosi.....gr. 1/40
Ext. colocynth Co.....gr. ii
M. Ft. pil. Sig. Take one three times daily.

—Louisville Med. Mon.

Suprarenal Gland in Chloroform Accidents.

In the *Revue de Therap. Medico-Chir.*, we are told that Minkowsky has repeated the experiments of Biede and of Gottlieb, and has found that the use of suprarenal gland in the lower animals does much toward preventing accidents during the administration of chloroform, probably through its powerful influence on the vascular system.—*Therap. Gascite*.

Treatment of Gonorrhœal Ophthalmia.

Dr. D. T. Vail of Cincinnati summarizes an excellent paper on this subject as follows:

1. The general practitioner should always warn his gonorrhœa and leucorrhœa patients of the danger of inoculating their eyes.
2. As the family physician is usually the first consulted,

he has the golden opportunity which the first hours afford. He should seal the unaffected eye at once.

3. It is well to bear in mind that all cases of purulent ophthalmia are not gonorrhœal; on the contrary, only a very small percentage are.

4. For diagnostic and scientific reasons microscopic examination of the discharge should be made.

5. For the cornea to escape involvement is the great exception.

6. The best early treatment in my judgment is: *a*, leeching; *b*, continuous iced applications day and night; *c*, nitrate of silver, 2 to 4 per cent. solution, applied to the everted eyelids once or twice a day; *d*, non-irritating gentle flushing of the eye every few minutes; *e*, canthotomy downward and outward to liberate the lower lid.

Subcutaneous Injection for Hemoptysis.

- R. Ergotin ʒiv
 - Morphine hydrochloratis gr. 1/12
 - Antipyrini gr. xxiiiss
 - Sparteina sulphatis gr. 1/30
 - Atropina sulphatis gr. 1/32
 - Aque destil., q. s. ad ʒiiss
- M. Sig. One hypodermatic (n. x to xv) every half or quarter hour, not exceeding five in all.

—*Capitan, Med. Rec.*

Gargling in Hiccough.

Dr. Laura M. Plantz, of Putney, Vt., calls attention to the value of gargling the throat in cases of hiccough. She has tried this treatment in several cases, says the *Jour. of Med. and Science*, and in no case did it fail. It seems to make no especial difference whether cold water is used or some medicated solution, the act of gargling being the one essential thing. The relief of the spasm is probably to be explained by the fact that the gargling sets up a reflex action in a new direction, and the spasmodic action of the diaphragm ceases. Mr. Morrill Macenzie long ago called attention to the fact that in dangerous spasm of the glottis the one thing to do is to set up reflex sneezing by tickling the nose with a feather or by use of snuff. The act of gargling must relieve spasms of the diaphragm in a similar way.

To Check Hemorrhage.

Chlorid of calcium, in doses of eight to sixteen grains, every two to four hours, should be tried in all forms of persistent hemorrhage, especially hemoptysis, hematuria, and intestinal hemorrhage of typhoid fever, for this salt increases the coagulability of the blood. It should be remembered, however, that this drug should not be used more than three days continuously, for its prolonged use decreases the coagulability of the blood.

For Sweating Feet.

- B. Formaldehyde gr. x
 - Thymol gr. x
 - Zinc oxid. ʒiiss
 - Powdered starch ʒiiss
- M. Sig. Apply as a dusting powder.

Pepsin in Burns of the Third Degree.

O. Waterman of New York gives a history of a case, reported in *Merek's Archives*, of a machinist, 46 years of age, who received a burn of the third degree, caused by some boiling pea-soup which was spilled over his left forearm. This was at first treated with carron-oil, and next day with iodoform gauze. At the end of three or four days the wound had a raised edge and was covered with a dirty-whitish purulent secretion. Some places were curetted. Pepsin was then sprinkled over the arm and the whole surrounded by a gauze bandage. At the end of four days this was removed and the wound surface was studded over with healthy granulations, and here and there new patches of epidermis had commenced in this short time to develop. The wound was then again cleansed with antiseptics and another sprinkling of pepsin applied. At the end of about twelve or

thirteen days the whole arm was healed and there was no scar tissue. It is also to be noted that the patient was anemic and suffering from tabes dorsalis.

Antiemetic Mixtures.

The *Gazetta degli ospedale e dell clinica* attributes the following to Wighesworth, says the *N. Y. Med. Jour.*:

- R. Mentholi gr. xv
 - Alcoholis ʒi
 - Syrupi, aa ʒss
 - Aque chloroform. ʒviiiiss
- M. Sig. A dessertspoonful every half hour.

Vomiting of Pregnancy.

For the vomiting of pregnancy and bilious vomiting the following are given:

- R. Acidi carbolic. gr. 9/10 to 4½
- Chloroformi ʒt. v
- Syrupi ʒi
- Aque destillate, aa ʒssxx
- Tinct. aurantii cort. q. s.

M. Sig. A dessertspoonful every two hours. Some spoonfuls of water should then be administered from time to time.

Treatment of Burns.

In a communication from Paris in *The Therapeutic Gazette* the following formula employed by Dr. Lucas Championnière in the treatment of burns is given:

- R. Vaseline ʒviii
- Essence of thyme.
- Essence of organum.
- Essence of verbenæ.
- Essence of geranium gr. iiss
- Naphtholate of soda gr. xv-lxxv

Quinin Sulphate in Exophthalmic Goiter.

Paulesco, in collaboration with Raynier, has made certain studies in regard to the pathogenesis of exophthalmic goiter. He believes that the principal trouble in this affection is the vasodilatation which affect the blood-vessels of the neck and head. As the result of this distension we have tremor, the goitrous swelling and active congestion of the thyroid body which produces in its turn a hypersecretion of the gland, and which has a distinct physiologic action. Paulesco claims that he has employed the sulphate of quinin with remarkable results, arising from its influence in producing vasoconstriction of the vessels of the head and neck. He gives fifteen grains of it at night after supper, and again a quarter of an hour later. He states that this treatment decreases the tachycardia, diminishes the exophthalmus and the size of the goitrous swelling. —*Revue de Therap. Med. Chir.*

For Irritating Cough of Phthisis.

When not accompanied by much expectoration the following mixture is recommended:

- R. Codeinæ gr. iv
- Acidi hydrochlorici dil. ʒss
- Spiritus chloroformi ʒiiss
- Syrupi limonis ʒi
- Aque destil., q. s. ad ʒiv

M. Ft. emulsiõ. Sig. One teaspoonful at short intervals when cough is troublesome.

—*Murrell.*

Treatment of Early Morning Diarrhea.

Lemoine (*Nord Med., Med. News*) thinks that the morning diarrhea, occurring especially in nervous individuals with an excess of hydrochloric acid, can be favorably affected by a suitable diet. Toast or broiled meat should be taken at supper time, and no vegetables. He gives his patients ½ to 1 dram (2 to 4 grams) of bicarbonate of soda before the evening meal, and at bedtime 2½ drams (10 grams) of gelatinized phosphate of chalk, either in milk or in syrup.

Diarrhea after meals occurs also in hyperchlorhydric persons. They should be put on a correct diet, and should lie down after eating. Each meal should be followed by 2 or 3 drops of acetum opii in a little water.

AMERICAN.

1. See JOURNAL, April 29 and May 6.
 2. **Carcinoma of the Ovary.**—Henretin and Herzog report two cases of the comparatively rare condition of the development of carcinoma on a primary non-malignant cystadenoma of the ovary. Both cases were demonstrated pathologically, after removal. In the first case perfect cure was apparently obtained; in the second, a recurrence of the malignant disease carried off the patient in a comparatively few months. The authors remark on the frequency of the primary condition and its lasting for many years, and in many cases without developing malignancy as in these cases.
 3. **Congenital Obliteration of Bile Duct.**—According to Walls, the so-called congenital obliteration of the bile-duct is a misnomer. In the great majority of cases, if not in all, an inflammatory infection of the larger bile-passages initiates the disorder, and as the tendency does not seem to be toward spontaneous cure, unless speedily relieved, the condition passes into an adhesive or obliterating angiocholitis, with or without cystic dilatation, terminating fatally within a few months. The indications for treatment are, he states: 1. Prophylactic: Aim to prevent, especially during the first few weeks of life,

all irritation of the gastro-intestinal canal. 2. Medical: Remove or counteract any condition that may have occurred, lessen the intensity of the inflammation; stimulate intestinal, hepatic and pancreatic activity. 3. Surgical: When medicine is of no avail, at the earliest moment consistent with the exclusion of possible error in diagnosis, inspect the bile passages and endeavor to establish bile-flow by probing the bile-duct, dislodging the foreign mass, dilating if necessary or in the event of organic obstruction establish an anastomosis between intestinal and biliary tracts.

4. See abstract in JOURNAL, August 26, '97, p. 599.

5. This paper was printed in the JOURNAL of February 18.

6. **Some Interesting Surgical Cases.**—Eiscendath reports a case of surgical kidney in a woman aged 27 years, relieved by the operation of nephrectomy, with good recovery, showing that the prognosis of this condition is not necessarily unfavorable. Another case is reported, of traumatic rupture of the urethra requiring suprapubic cystostomy and retrograde catheterizing, also attended with success. The paper discusses the literature of these conditions.

8. **Cystitis.**—The summary of Dudley's paper is as follows:

1. The conditions which were formerly considered the prime causes of cystitis have receded to their proper place and must be estimated only as predisposing causes. 2. The recognition and appreciation of pathogenic bacteria as the exciting causes of cystitis is essential to a scientific understanding of its pathology, etiology and treatment. 3. Alkalinity of urine depends on the action of certain bacteria, notably the proteus vulgaris, in the decomposition of urea. The bacillus coli communis, which is one of the most frequent causes of cystitis, is one of a class which does not decompose urea and therefore does not produce ammoniacal urine. Contrary to the older opinion, alkalinity is not the rule; on the contrary, in the majority of cases the urine remains acid. Alkalinity, if present, is often the work of microbes secondarily introduced. 4. The classic symptoms of vesical pain, frequent urination and pus in the urine are wholly inadequate as a basis of the diagnosis of cystitis. Moreover, the condition called cystitis has receded from the rank of a distinct disease to that of a symptom, and should be so regarded. The mere recognition of the fact that cystitis exists is not a diagnosis. A fact is not a diagnosis, and the recognition of cystitis may by contrast with that of its complications be of very minor importance. 5. The diagnosis must comprehend not only the presence of infection in the bladder but, what is more important, it must embrace the source, routes, type and complications and the variety of the inflammatory reaction. Simply uncomplicated inflammation of the bladder is rare. 6. The endoscope and cystoscope can alone open the way to efficient exploration and diagnosis, can alone define the indication for topical or surgical treatment, but, more essential, can alone prepare the way for the examiner to distinguish between cystitis and a wide variety of other urinary affections of the bladder, urethra, ureter and kidney. One is astounded at the revelations of the cystoscope in the recognition of most important lesions which must otherwise have passed unobserved. 7. The washing out of the bladder as a routine measure is not approved. The injection of disinfectants is indicated only in general or nearly general cystitis. For localized cystitis direct applications to the part affected should be made through the endoscope. 8. Dilatation of the urethra is indicated for localized cystitis at or near the neck of the bladder. The efficiency of the procedure for such localized cystitis has given it an undesired recognition in the treatment of general cystitis, which under cystoscopy it can not now retain. 9. The most valuable disinfecting topical application in cystitis is the nitrate of silver.

9. **Surgery of Bladder.**—Fisher reports over a dozen cases of surgery of the bladder, classified according as they were performed by peripheral section with or without guide, or suprapubic cystostomy, or by combination of suprapubic and perineal operation with retrograde catheterization. He sums up his conclusions as follows: 1. The surgeon's duty is not done when he gains an entrance into the bladder, but it should be supplemented by proper after-treatment. 2. A small perineal incision is preferable, but, if large, the excess should be sutured. 3. Without a proper drain, chills, fever and uremia, with closure of cut surfaces will cause a fetal issue. 4. When a proper

drain is employed Nature will usually render cut surfaces impervious to the absorption of urine. 5. As an aid gauze should be packed around the catheter till this is effected. 6. In packing be careful that the compression does not create an adhesive inflammation, uniting the distal end of the urethra and necessitating a second operation. 7. To prevent this cohesion of raw surfaces, begin instrumentation on the third day unless contraindicated. 8. The bladder should be flushed daily with mild antiseptic solutions, and when toxic symptoms develop, the whole tract, often. 9. An impermeable coarctation of the deep urethra, resisting a perineal section, demands a suprapubic cystostomy. 10. In the combined method, the prevesical space should be opened and the bladder incision should be made of but sufficient length to admit the passage of a small sound. 11. When collapse of the bladder prevents immediate suturing, the through-and-through drain should be used for four to eight days, followed by the perineal drain. By this method a fistula is prevented. 12. In obstructive cases operate immediately, thereby preventing destructive changes that militate against recovery. 13. In retention from stricture, if instruments, baths, opium, belladonna, enema and aspirations fail, do not delay operation beyond the third day. 14. After an operation, the urethra should be kept pervious by daily instrumentation, gradually lessening the same to once a month.

11.—See abstract in JOURNAL, May 20, p. 1115.

12. **Appendicitis.**—Crile asks the question whether appendicitis should be treated as a medical disease from the beginning to the end of the attack, and, if not, at what time should surgery share the responsibility? He argues that it should be considered a disease for both medical and surgical treatment from the beginning. Observation should be made at very short intervals, every two or four hours during the development of the disease, so that the opportune moment for surgical interference may not be lost.

14. **Hydrophthalmos.**—Dr. Pyle notices the extraordinary state of confusion in the nomenclature, classification, etiology and treatment of these cases. The proper name is hydrophthalmos, as indicating a general condition, which is present at birth, or appears in early infancy, the beginning being generally prenatal. The diagnostic symptoms are uniformly enlarged and protruding eyeball, insufficient lid action, increased tension, sluggish and dilated pupil, atrophic iris, which appears tremulous if the lens is luxated, peculiar bluish sclera, corneal opacity and anesthesia, deep anterior chambers, restlessness, ill temper, rubbing of the eyes and signs of local pain. While the causes may be various, there is evidence of the following: 1, an intrauterine iridokeratitis, causing closure of the periphery of the anterior chamber; 2, congenital lack of development, either in separation of the iris from the cornea or by a deficiency of the filtration angles in the neighborhood of the iridic angle; 3, a fetal serous cyclitis or uveitis, causing excessive secretion and contraction of the veins of Leber's plexus and obstruction of the spaces of Fontana; 4, vascular disturbances causing arterial over-tension and tropic disorders. He divides these cases into two classes: 1. True hydrophthalmos, depending on congenital defective development of the cornea, iris, or filtration channels. 2. Hydrophthalmos secondary to fetal intraocular inflammation, usually in the form given under the heads 1 and 2 above. The prognosis is better than the text-books give. If a case is early recognized and not relieved by iodids, mercurials, and myotics, repeated paracentesis should be tried. These failing, a broad iridectomy should be performed on the worse eye unless the eyeball is very large, when repeated sclerectomies should be tried. The earlier the operation the better. Late operations are dangerous because of the looseness of the lens, thinness of the membranes and disorganization of the vitreous. Prolapse of the vitreous and intraocular hemorrhage are the chief dangers. The more open the filtration canals, the better the prospects. Myotics should invariably be used as adjuncts to operation. The increase of the anteroposterior diameter in hydrophthalmos produces myopia, and the associate corneal disease is likely to cause irregular curvature. In cases giving evidence of useful near vision, whether operated on or not, correction of the refraction by retinoscopy or ophthalmometry with confirmation by test lenses is strongly advised.

17. **The Crisis in Binocular Vision.**—Barnes insists on the

importance of endeavoring to secure binocular vision in all cases of strabismus, and that this can, contrary to the common notion, be accomplished in a surprisingly large number of cases. To restore or create binocular vision, he would first correct all errors of refraction, which he thinks will continue to have an etiologic relation. He would, then, before resorting to surgery, use every possible means to produce binocular vision by orthoptic exercises. When, however, the patient shows no sign of recognition of double images, surgery should be resorted to, not merely for its cosmetic but also for its economic effect, and he would have as little disturbance as possible, in the operation of the muscular insertion. Finally, he would refine the vision by orthoptic exercises.

22. **Eclampsia.**—Recognizing toxemia as the principal cause of eclampsia, DeLee lays down the course of treatment before, during and after the attack. In case of threatened eclampsia he advises close attention to the renal functions, and when the toxemia seems aggravated, it is well to place the patient on an absolutely milk diet at once. As the condition improves, starch, and gradually proteid vegetables and the vegetable oils and butter, may be added. The return to a meat diet should be when recovery is almost or quite complete, and then it should be white meat and fish, beef, veal, pork and nutton being forbidden as well as stimulants and spices. The emunctories should be kept active. The patient should have an abundance of fresh air and should rest a good part of the day. In severe cases absolute rest in bed and daily hot packs may have to be ordered. When the attack has occurred the indications are to protect the patient from the violence of the convulsions, and to narcotize her with hypodermics of morphin and chloral per rectum if necessary. Chloroform is only advisable when the attacks succeed each other rapidly. As to bleeding, he thinks it has a place in the treatment, but careful discrimination is necessary. To aid elimination, subcutaneous injection of normal salt solution is an excellent method. Its effect on the kidneys is remarkable. If labor has not commenced when the convulsions occur, it should be induced unless it takes place spontaneously, and should be ended as soon as possible. The treatment during the puerperal period is much the same as that advised for threatened cases.

23. **Labor in Pelvic Deformities.**—The conclusions of Dobbin's paper are as follows: 1. In 131 cases of contracted pelvis there was necessity for operative delivery 46 times—35.11 per cent. 2. The pelvis most frequently requiring operation are the rachitic and irregular forms. The generally contracted pelvis, though very common in the negro race, is comparatively rarely sufficiently deformed to seriously obstruct labor. 3. Pelves in which the degree of contraction is slight, and those in which the contraction is very marked, are the easiest for treatment, as in both cases the indications are definite, and should give the operator little trouble in deciding on the treatment to be pursued. 4. On the other hand, the pelves possessing a medium degree of contraction are the most perplexing, and call for the exercise of the greater skill and judgment. When proper appliances are at hand, such cases are best treated by tentative application of forceps, and this failing, immediate Cesarean section. 5. In general, forceps give a lower fetal mortality than version, but version done as a primary operation on a movable head, in a slightly contracted pelvis, is a safer operation for the child than a difficult high forceps operation. 6. Except in very exceptional cases, symphysiotomy is not to be compared with Cesarean section, for the former operation, besides causing greater injury to the mother, is always an uncertain procedure. 7. Operations on contracted pelvis are rarely uncomplicated. Among the commonest accidents may be mentioned premature rupture of the membranes and prolapse of the umbilical cord. 8. The only rational and scientific method of obtaining "corrected morbidity" statistics is by the bacteriologic examination of the uterine lochia, for only in this way can we say definitely which infections are the result of operation.

27. **Two Unusual Cases.**—Rogers describes the case of a boy who, on the disappearance of the eruption in measles, was allowed to go out and sit in the sun for some length of time. This was followed by a condition in which he was unconscious, with Cheyne-Stokes respiration, low temperature, blue and cold skin and complete anesthesia. At times the respiration

became so feeble that artificial methods were apparently required. He was in this condition for four days, then began to take nourishment and on the sixth day sat up some, though still in a confused mental condition. From this time on convalescence was normal, but there was for quite a period a very peculiar alteration of his disposition. From being quiet and orderly he became noisy, troublesome and vulgar, and at one time had a paroxysm of spitting and other erratic symptoms. Three months later, however, he seemed perfectly normal. The second case was that of a young woman who was run away with by a horse, which she finally succeeded in controlling. There was no shock, though she was badly bruised. The peculiar feature of the case, however, was the complete alteration of her vision. She had been wearing glasses for hyperopia and astigmatism, but the day after the accident her vision was apparently perfectly normal and continued so for about a month. At the end of that time, under the strain of school work, she noticed the return of her old trouble, and at the end of two months she resumed her glasses as before. The Doctor makes no attempt to explain the pathology or nature of these cases.

28.—This address was presented before the Iowa State Medical Society.

29. **The Curette in Gynecology.**—The general trend of Tucker's article is opposed to the common use of curettement in gynecologic conditions. He thinks the uterine mucosa can not be compared with other mucous membrane; that its circulation is derived directly from the uterine substance, with which it shares its disorders. Of course, as to new growths, when they require removal, the curette is indicated as well as in certain other special conditions, but he does not find in his own experience the necessity for curettement that he would expect to find from the reports of others, and he says that if he is losing a chance of making an honest dollar he wants to find it out.

30. **Hysterectomy or Myomectomy.**—Mackenzie reports 8 cases, 5 of myomectomy and 3 of complete hysterectomy, and draws the following inferences as to the advantages and disadvantages of the operations: 1. For pedunculated myomata, whether single or multiple, myomectomy should be done in preference to hysterectomy. 2. In cases of uterine fibromyoma, where the tumors are of moderate size and capsulated, not exceeding in size a small orange, whether single or multiple, not exceeding say five in number, enucleation should be done under careful precautions. 3. In moderate-sized, single, interstitial fibromyoma of the uterus, size that of an orange, where the outlines on palpation plainly suggest encapsulation, enucleation should be done even if in enucleating the uterine cavity be exposed, but in all such cases where the size of the tumor and situation suggest that the uterine canal will be involved in the operation, previous curettement and antiseptic treatment of the uterine canal should be a defensive measure. 4. In small, hard tumors of slow growth, enucleation is indicated if operation is done at all. 5. Subserous fibromyomata, sessile, or pedunculated, unless of great size, should be removed by enucleation. 6. Small fibromyomata, whether subserous or interstitial, should be enucleated. 7. In cases where the uterus is infiltrated with small myomata of symmetric size and growth, whether subserous, interstitial or both, enucleation should be done, but careful examination and palpation should be made to determine that all are removed. 8. In all cases of submucous fibromyoma, enucleation should be performed.

Indications for hysterectomy, supravaginal or total, are outlined as follows: 1. Large tumors, tumors weighing say five to eight pounds and upward, unless pedunculated. 2. When the uterus is the seat of disseminated myomatous formations where distribution and arrangement suggest great variations in size and numbers, and when the uterus is large and of rapid growth. 3. When the tumor in uterus is large and of rapid growth. 4. When the tumor is intraligamentous. 5. In all cases where, on account of the situation of the tumor, projection of the growth takes place, impinging on important organs, such as the bladder, rectum, etc. 6. Soft, edematous tumors which are of rapid growth and which tend to cystic degeneration. 7. Menorrhagia co-existent with large tumor of the uterus.

23. **Cannabis Indica.**—Shoemaker points out the thera-

peutic indications and physiologic action of *cannabis indica*. It is an efficient anodyne in functional and organic diseases, and he reports cases of its use in gastralgia, enteralgia, gastric ulcer, endometritis with metrorrhagia, dental neuralgia, headache from tumors, neuritis, zoster, tabes, migraine, in which it has special value, and chorea. He also speaks of its usefulness in some cases of epilepsy, in paresthesias and insomnia. 35.—This article appeared in the JOURNAL of July 15, and is here reprinted without credit.

36. **Protargol.**—Stubbs reports his experience and observations as to the value of protargol, of which he speaks rather highly. He has found it especially useful and effective in diseases of the lachrymal apparatus, and has frequently used it as a collyrium in chronic conjunctival catarrh, in 1 to 3 per cent. solution. Its advantages over nitrate of silver are that it keeps well in solution, is not affected by heat, and does not irritate the mucous membrane. He hopes that it will stand the test of time, but regrets that its manufacture is controlled by a single firm.

39. **Perineal Lacerations.**—This address in obstetrics, before the Medical Society of Pennsylvania by Ball, treats especially of the lacerations of the perineum and their treatment. He insists on the prompt relief of this condition. The laceration of the cervix is also mentioned and its immediate repair is recommended.

40. **Injury of Brain.**—The key-note of Anderson's paper is that the pathology of the symptoms of cerebral compression is anemia of the encephalon. The danger in concussion is from the anemia or engorgement of the pial veins during the stage of reaction. He explains these ideas in detail, and while he does not wish to have it understood that he thinks the whole pathology of cerebral injury consists of pial engorgement, he believes it to be the key to the treatment of intracranial pressure.

41. **Nephrectomy.**—Noble remarks that the common estimate of nephrectomy is that it is a very dangerous operation. This is not according to his experience. He believes that if it is done promptly, under circumstances that require it before the general health of the patient becomes too much broken down, it will be followed by a very low mortality. The object of his paper is to insist on a more careful study of kidney disorders, so that this operation may be done when called for. He reports eight cases where it was performed for tuberculosis, stone, cancer and accidental destruction of the ureter, and he insists on the importance of catheterizing the ureters separately to determine the condition.

44. **The State and Antitoxin.**—Davis believes that the state should supply free antitoxin for the poor suffering from diphtheria, from stations at easily accessible points. It should also see that a strict quarantine is established, that all cases are isolated, and that those coming in contact with them are treated with immunizing antitoxin.

46.—This paper appeared in the JOURNAL of June 17.

48.—See abstract in JOURNAL, May 13, p. 1054.

49.—Ibid, p. 1052.

52, 54, 55 and 56. **Specialism in Medicine.**—Benedict calls attention to the fact that specialism implies a certain superiority in special lines, or a formal promise to acquire such skill by experimenting on patients, or a mere subterfuge to gain practice. The last requires no discussion, the second refers to the fact that occasionally a physician passes into special practice immediately after graduation, and he does not think that he deserves special censure if he does this under the guidance of and in immediate association with an expert, though he will probably go lame through life for lack of knowledge of general medicine. The ideal specialist is not born or made, but grows. In passing from general to special practice there must be a transition period, which he estimates at from two to three years. The specialist should limit his practice rigidly enough, to be fair to himself, his patients and the general profession, but not so much as to refuse relief in case of emergency. He calls attention to certain objections that have been made to the distribution of reprints, which he thinks is a perfectly legitimate and dignified method of presenting one's self before the profession.

Bulky asks the question: How far has specialism benefited the ordinary practice of medicine? and answers that it has advanced the science and art. It has classified diseases more thor-

oughly and simplified nomenclature; obscure conditions have been discovered and elucidated; clearer descriptions of disease have been given in every branch of medicine; treatment has been generally simplified and crystallized, and multitudes of new methods have been introduced, and all these advantages have been open and free to the general practitioner. It has also advanced the ordinary practice of medicine by relieving conditions which the general practitioner could never have accomplished alone, and incidentally has benefited it by a certain education of the public to the pecuniary value of professional services.

Makuen speaks of certain obstructions to the progress of specialism in medicine from lack of ethical considerations on the part of physicians toward each other.

Morris takes up the side against specialism, holding that it is disastrous alike to the medical profession and the public. The system of specialism can not give rise to broad men. It narrows one down to a limited field, and cuts him off from what is around him. It has led to a want of confidence in ability to treat the ordinary diseases. The all-round physician has become too rare. He would like to have a law on the statute books prohibiting any man becoming a specialist until he had spent at least three years in general practice, and then only allow such as had shown special ability or fitness.

58-63. **Medical Advertising.**—Babeock deprecates the tendency to advertise in medicine and points out the direction in which the remedy is to be obtained.

Goldspohn points out the advantage of the ethical rules against advertising on the part of the profession to the laity. That they may better appreciate this, he suggests that all honorable physicians themselves recognize this as an important practical reason for this time-honored rule in our ethics. They should explain to the laity, individually and collectively, the practical meaning of this rule in medical conduct, whenever occasion is presented. There should be more frequent discussions of this general subject in medical societies, so that the practical basis of this feature of medical ethics may become current in the medical mind, and that the public should have come authentic and conveniently accessible register of all physicians who strictly abide by the spirit and letter of our code of ethics in this and all other important points. In the preface to such a directory it should be modestly but plainly stated that this is a list of physicians who depend for employment on a spontaneous recognition by the public of their general qualifications and results in actual practice, and that they should shun commercial advertising in order to enable laymen to recognize and escape the frauds of medical impostors.

McClintock speaks of the method of advertising by reprints, college professorships, and various unethical though rather intangible methods. He thinks that we should have some legitimate way in which the man of ability could make known his qualifications.

The point in Lichty's communication is that medical literature is dominated by advertising methods. Medical periodicals are gradually coming to the level of ordinary newspapers, while medical books are being lowered in standard to the ideas of the publishing companies and the laity.

Havegill believes that there would be no harm in stating on the card the name of the specialty to which practice is limited. As for the cards in daily papers, they are really of little value and only a matter of expense to the physician. He also deprecates the advising of proprietary remedies or those of unknown composition as an evil and lending one's self to the mercenary methods of others.

Stuver concludes his paper with the following: 1. All physicians, from the most eminent to the most obscure, should be accorded equal advertising privileges. 2. Professional advertising should be limited to the insertion of plain cards in the local papers or a sign pointing out the location and office hours of the physician. 3. All local notices in which the name of the physician is mentioned in connection with the treatment of cases or the performance of operations should be absolutely interdicted. 4. The public should be educated to regard active participation in promoting the organization of the medical profession and assisting to build up and strengthen medical sciences as a criterion of greater professional eminence and distinction than merely local notoriety.

85.—See abstract in JOURNAL, August 12, '39, p. 405.

110. **Case of Abdominal Pregnancy.**—Bolton reports a case of a young negro woman who suffered from symptoms interpreted as malaria threatening abortion, when she was apparently four or five months pregnant. These symptoms disappeared under treatment, but her husband came several times afterward for further medicine. Some weeks after her expected period she came to the office somewhat reduced in size but seemed to be in perfect health. She then passed into the hands of a quack and was not again seen until nineteen or twenty months after the first visit, when she was found moribund. Post-mortem revealed a complete skeleton with soft parts entirely putrified.

112. **Nerve Stimulants in Pregnancy.**—Should nerve stimulants be administered to pregnant women is asked by Perkins, and answered in the negative, on the ground that they have a bad effect on the fetus.

113. **Lung Gymnastics.**—Abrams recommends, as methods for forcible lung distension, holding the breath after full inspiration, and also irritation of the skin of the thorax. His experiments have shown that any skin irritation, mechanical, chemical or electrical, will produce dilatation of the lungs, always greatest in the immediate vicinity of the irritation. This lung reflex will prove useful in diagnosis, as resonance can be increased by friction of the skin over the lung percussed.

120. **The American Voice.**—Farlow's paper discusses the assumed prevalence of a nasal twang in the American voice, and he comes to the conclusion that it is merely a bad habit, and not due to climate or racial conditions. The disorders incident to our climate do not specially favor the nasal tone, at least in the adult. (See editorial in JOURNAL, p. 295.)

121. **Hay-Fever.**—After some general remarks as to the nature and causes of hay-fever, Douglass considers the treatment under four heads, viz.: 1. Treatment of the cause *a*, local irritation by pollen, etc., relieved by change of locality to where such irritants are absent, also by respirators, etc.; *b*, vicarious elimination of autotoxic irritants via the nasal mucosa being a possible cause, other organs of excretion must be stimulated into action; *c*, if vasomotor disturbances, shown by blueness, pallor, readiness to take cold, etc., are a cause, cold baths, spongings, spinal douches, and regulation of the circulation by small doses of quinin and digitalis are indicated; *d*, neurasthenic conditions are to be combated by exercise, rest, change of occupation, tonics, etc., and if the uric acid diathesis exists, proper eliminative treatment must be adopted. 2. Treatment of the attack, *a*, local, by cleansing away the irritants, relieving the hypersensitiveness of the overirritated nerves. For the first of these warm nasal douches of weak saline solution, after gentle spraying with a watery 1 per cent. cocaine solution. After this, treatment with a 4 to 6 per cent. cocaine solution cautiously applied, followed later if necessary by mild cautery with silver nitrate, phenol canphor, or preferably Clark's solution, composed of mercury bichlorid, 1 gr., quinin hydrochlorid 1 dram, glycerole of carbolic acid (B.P.), 1 oz. For home use milder applications of menthol, etc., may be used. For the general treatment he recommends acetanilid, digitalis and quinin, the first used cautiously, the other in full doses to tone up the vessels and relieve the constitutional symptoms. The internal administration of dried suprarenal glands is also very highly recommended by Douglass. He believes it almost specific. He also uses the remedy locally in solution as a spray, but trusts more to its internal administration. Between the attacks, the existing nasal lesions should be treated and all pathologic conditions relieved.

123. **The Therapeutic Value of Oxygen.**—Conklin insists on the therapeutic value of oxygen inhalations, claiming that facts show that when it is needed by the blood it is thus readily absorbed. He has used it in a variety of conditions accompanied with dyspnea, bronchopneumonia, acute lobar pneumonia, and advanced valvular cardiac disease—with great advantage.

124. **Intramuscular Injections of Mercury.**—After reporting a case in detail treated by intramuscular injection of salicylate of mercury and of calomel, with success, Stinson describes his method as follows: 1. Sterilize by boiling four ounces of oil of sweet almonds, which is kept in a sealed ster-

lized bottle. 2. Use pure salicylate of mercury that has been put up in a sealed half-ounce bottle and prepared by some reliable firm—e. g., Merck. 3. Weigh out accurately the amount to be used for one injection on a clean paper. 4. Put the powder in an aseptic small mortar and pour in about half a dram of the sterilized oil; triturate well. 5. Place the patient flat on his stomach, legs extended; disinfect area of injection with 1-to-500 bichlorid of mercury solution. 6. Sterilize the needle (two inches long) by syringing with alcohol and bichlorid solutions or by boiling or some other method. If bichlorid is used, wipe the needle off at once with dry cotton, which removes the bichlorid, prevents tarnishing, and, in fact, makes the surface of the needle shine better than before. 7. Draw the fluid into the syringe, stirring while doing so with the end of the syringe; fit or screw on the needle and force the fluid along the needle till it appears at the point, which is wiped dry with cotton. 8. Plunge the needle vertically into the tissues the full two inches of the needle, introducing the point about a quarter to half an inch above the junction of the inner and middle thirds of a line carried from the upper border of the great trochanter to meet the cleft of the buttock at right angles. 9. Inject the oil slowly, and when the syringe is empty withdraw the needle slowly. This prevents any of the fluid being deposited in the fatty tissues, which is a source of some pain. Dust on a little aristol or other mild antiseptic and pour on a few drops of collodion, which is allowed to dry. I have often used, and have frequently seen, intramuscular injections of the salicylate of mercury used, in the treatment of syphilis, and have yet to see the first case wherein an abscess formed. Absorption of mercury begins very soon after the injection, as shown by the symptoms and by testing the urine for mercury, which does not disappear from this excretion for four or seven days if two grains have been injected. Subsequent doses are repeated about twice a week so as to obtain a thorough systemic effect. By this means mercury is continuously in the system.

Points in Technique, etc.—In tertiary syphilis, as in other stages, a thorough course of treatment should be followed if one wishes to cure. Four series of injections should be given each year for three years or longer. If the salicylate of mercury is used, and two grains can be tolerated at each injection, two injections should be given a week, and this treatment continued for about five weeks—i. e., till nine or ten injections are given. Forty per cent. of patients take two grains without any inconvenience. Forty per cent. more can not stand two grains, as it produces too many movements of the bowels, quite painful colic, sometimes considerable pain in and around the region of the buttock, and exceptionally a few bloody stools. These patients can be given about a grain and a third of the salicylate at an injection with little discomfort, which is therefore given three times a week; while the remainder, about 20 per cent.—hyperesthetic individuals—will not take intramuscular injections of two grains, as they cause pains and lameness, on account of which they will not submit to them. Between the series of injections ten minims of saturated solution of potassium iodid in water should be given three times daily. If there are urgent symptoms, increase two minims daily until coryza and a few other symptoms of iodism appear, when the original dose may be resumed.

By using injections the functions of the digestive tract, the skin and liver, etc., are not interfered with. The doses are certain of absorption and can be regularly regulated according to the susceptibility of the individual; with aseptic and antiseptic precautions the treatment is perfectly safe and the resulting improvement is certain and rapid. Under ordinary conditions the practice of adding morphia or cocaine or both to an injection, is not necessary, and should be condemned. In cases of syphilis with dyspnea, cocaine can be added with advantage, as it rapidly overcomes this distressed condition. I know of a case with marked cardiac dyspnea (in the practice of my colleague, Dr. G. Gross), in which cocaine was added to an injection. The dyspnea ceased immediately, and it was not necessary to repeat the cocaine subsequently.

It is of vast importance before beginning intramuscular injections to ascertain that the teeth are in excellent condition and that the kidneys are not diseased. Patients with nephritis should not receive large doses of mercury by injection, as even

small doses are not well tolerated. In all cases the urine should be examined once in a while during the course of treatment.

126. **The Effects of Training.**—Darling's article is not concluded in this issue but will be noticed when completed.

127. **Joint and Bone Fixation.**—The chief point in this paper is the use of "splint-blanks" or pieces of wood-liner splint material reinforced with gauze, cut in such fashion from a paper pattern that when moistened it can be molded over the limb or fracture and bandaged, thus producing fixation of the part. The author gives details for the application of these "splint-blanks" to each joint or region and points out their advantages. They allow of ready inspection, are quickly and easily applied, and light and comfortable and reliably fixative.

132. **Medicine.**—Spiers deprecates the lack of literary culture in some medical writers; the too ready assumption of the effects on medicines on man from those animals; the dropping of old tried remedies to take up new ones, etc.

133. **Typhoid Pneumonia.**—Smith's paper is an argument against the use of the term "typhoid pneumonia." His conclusions are as follows: In view of the fact, 1, that the majority of pneumonias occurring in the course of typhoid fever are not caused by Eberth's bacillus, but by the pneumococcus, and 2, that asthenic pneumonias with so-called typhoid symptoms have nothing in common, so far as etiology is concerned, with typhoid fever, it would seem advisable, with our present knowledge, to discard the term "typhoid-pneumonia" asavoring too much of inaccuracy, especially as we are reminded by it of the wholly indefensible term "typho-malaria." For these rare cases in which it can be proved beyond doubt that the pneumonic process as well as the general typhoid infection are both due to the bacillus of Eberth we still have the term "pneumo-typhoid," the use of which, however, should be subject to these strict limitations. Accuracy in terminology is the first step toward a reasonable therapy, and the ill results of calling conditions by wrong names must inevitably lead to a less clear-sighted management of them.

134. **Ethyl Bromid.**—Kempter advocates a more general use of ethyl bromid in minor surgery, claiming that its dangers have been overestimated, and its convenience and advantages not duly appreciated.

135. **Psychotherapy.**—The condition of mental impressibility affecting the bodily states is noticed at some length by Seelye, who reports at more or less length seven cases where mental suggestion produced striking effects and cures. He thinks that it is not necessary after detailing these to strengthen his cause by referring to other ailments, such as headache, insomnia, neuralgia, etc., that may be similarly relieved by this means as an adjunct to drugs and other recognized therapeutic methods. While cases where suggestion alone is sufficient from beginning to end are comparatively rare, it can, nevertheless, be advantageously employed to some extent in almost every case.

136. **The Etiology of Scarlet Fever.**—This is practically the same article as published in *Medicine*, June, 1899. (See *JOURNAL*, April 8, p. 765, and June 24, p. 1432.)

137. **Carbolic Acid in Mastoid Wounds and Ear Diseases.**—After noticing that Dr. S. D. Powell has reported the use of pure carbolic acid followed by alcohol in surgery, and that Dr. Roosa has also employed it, Phillips reports six cases in which he himself used it in this manner with good advantage. He has prepared the carbolic acid by simply adding enough water to the crystals to hold them in solution, and later he has used this in a very finely drained spraying-tube which can be introduced into the aural canal and spray the acid into the attic and middle ear. It well to avoid any excess of carbolic acid, so as not to have to use too much alcohol. Up to this time he has observed no ill effects, no inflammatory reaction, and no extension of disease from its use.

138. **International Scientific Language.**—Ellis discusses the subject of an international language for scientific purposes, and asks whether it is a possibility. National feeling and jealousy have hitherto prevented the use of any one of the leading modern tongues, and this will probably be the case hereafter. As regards dead languages, and especially Greek, which has been so strongly recommended, he refers to the difficulties of

learning a tongue of this kind, and points out that it would give the advantage to mere linguists while men of real scientific merit would be precluded from publishing their results. He believes that the old way will have to be followed, but the time will come when by some arrangement, a translation of every paper presented at the international meetings can be provided for.

144. Difficult Points in Gynecologic Diagnosis.—After alluding to the difficulties of gynecologic examinations in many cases, Krusen discusses the subject of the diagnosis of uterine carcinoma, and to aid, suggests the following points which will be found useful though they may not be applicable to every case:

1. The usual friability and vascularity of the tissue, which, if not detected by the finger, may easily be made apparent by hooking a tenaculum into the suspected area. The tenaculum will immediately tear out and cause abundant bleeding from the carcinomatous tissue.

2. A close adhesion of the mucous membrane of the portio to the parenchyma.

3. The difficulty in cervical dilatation as evidenced by the introduction of a tent. In a cancerous process there is, as a rule, a continuance of the hardness after dilatation.

4. Bleeding is easily provoked by an examination or by any unusual exertion or manipulation.

5. The characteristic induration of the cervix is almost imperceptible at first, but increases as the disease progresses.

6. Puncture of any suspected nodules or follicles will differentiate carcinoma from cystic follicles or distended glands.

7. Ulcerated or eroded areas which are not speedily amenable to treatment should be regarded with suspicion.

8. Any enlargement of the uterus occurring after the menopause, is usually due to malignant disease. (Fisher.)

9. An early diagnosis can only be made with absolute certainty by microscopic examination of either an excised wedge from the suspected cervix, or, in cancer of the body, of portions of the endometrium removed by curettage. The value of the examination will depend upon the experience and competency of the pathologist.

Epithelioma is less frequent but it is liable to be confused with: 1, simple vegetations; 2, lupus of the vulva; 3, syphilitic affections; but the first, the simple vegetations, secrete a virulent fluid unlike the ichor of cancer, they readily yield to an energetic caustic which prevents their reproduction, and they have no hardened base, being remarkable for their softness. In the case of lupus, the vulva is red and presents scattered fungous ulcerations which are without any indurated base; while the syphilitic chancre is more limited and has a little circle of characteristic indurations. Other points of difficult diagnosis referred to are ectopic pregnancy, the differentiation of appendicitis from pyosalpinx or ovarian disease; ovarian cysts from ascites, and the perplexing problems of pregnancy complicated with typhoid.

145. Rupture of the Intestines.—The first part of this paper is largely a review of opinions of this accident and a brief analysis of the symptoms in some 70 cases observed since 1893. As regards the technic of the operation when it is required, the following points are specified:

1. To cut down over the point of impact of the force, and then gently lift the loops of intestine going toward the spine, Fovrier and Adam having shown that the laceration will be found in this situation; 2, after finding one tear to search for others, avoiding, however, evisceration; 3, to regard any discolored spots with great suspicion and treat them as ruptures. Seven cases are briefly stated.

146. Symptomatic Treatment of Consumption.—The treatment of pulmonary tuberculosis, according to Lyle, is hygienic and dietetic and whatever we may do for the disease in other directions must not compromise our efforts in this line. For the toxemia of the early stage, creosote alone has the confidence of the profession. It has no effect on the tubercle bacillus but seems to diminish its toxins and probably has some effect on the associated germs. It also stimulates the metabolism. Sunlight, fresh air and nutritious food are the next essentials and on the functional ability of the stomach our efforts will largely depend, hence, the necessity of attention to the condition of this organ. A urine analysis should be made

occasionally to show the condition of the assimilative functions, decrease of urea being a warning symptom. Lyle thinks that cod-liver oil and alcohol are over used. He believes in the local treatment of the cough, intratracheal injection if necessary. In the advanced stages, opium may be required, but bromids may often enable us to dispense with it if the cough is purely nervous. The night sweats he considers as conservative and their treatment is seldom necessary. Fever is the result mainly of sepsis. Rest and the open-air treatment must be principally relied upon to combat it though quinin may be useful sometimes. Latterly he has used hypodermic injections of 10 to 30 minims of guaiacol to modify the fever, with good results. Hemorrhage in the early stages is usually salutary and requires no special treatment other than increased nutrition. The later hemorrhages due to rupture of large vessels should be treated by enabling a thrombus to form in the artery. The patient should be placed in a reclining position with plenty of fresh air, and if the bleeding is persistent, the chest movements may be limited by adhesive strips and the return flow of blood from the lower extremities withheld by constricting the thighs. Ice bags, he thinks, are likely to be harmful.

147. Intrauterine Epidemic Cerebrospinal Meningitis.—Gradwohl reports a case of a woman who died of cerebrospinal meningitis in the seventh or eighth month of pregnancy. The brain of the fetus presented the same appearance as the maternal brain and contained the characteristic bacilli. The only reported case bearing any resemblance to this that he is aware of is one of Herwerden of a sporadic meningitis due to pneumococcus.

FOREIGN.

British Medical Journal, August 19.

Ununited Fracture in Childhood. EDMUND OWEN.—Owen's presidential address raises certain questions as to the causes of lack of union in fractured bones in childhood, and as far as he can answer it, it is by the influence of trophic nerves. He suggests that there is a subtle disturbance of the anterior horn of the cord inhibiting nutrition of the bone, rendering it weak and friable and hindering its repair.

Discussion on Pleuritic Effusion in Childhood.—Robert McGuire discusses the pathology, treatment, etc., of pleurisy and pleuritic exudates in children, and Betham Robinson treats of it in its surgical aspects. He discusses whether free incision and drainage are of any value in tuberculosis of the pleura, where we should make the incision, and should we resect the ribs or not in empyema, and lastly, should we use irrigation? He always resects the ribs, as it adds no risk to the operation, and as regards irrigation, he thinks its value counterbalances its attendant risk in cases of septic collections in the pleura. In the discussion that follows, Tubby considers irrigation a very dangerous proceeding.

Observations on Morbid Anatomy of Tuberculosis in Childhood, with Special Reference to Its Primary Channels of Infection. GEORGE F. STILL.—The morbid anatomy of tuberculosis in childhood, and especially the methods of its infection, are discussed at some length by Dr. Still. He concludes that the commonest channel of infection is through the lungs. That by way of the intestines is less common in infancy than in later childhood. Milk is, therefore, not the usual source of tuberculosis in infancy, and he suggests that this is due to precautions taken in boiling, sterilizing, care-taking, etc. Inhalation is much the commonest mode and the overcrowding of the poor population in the large towns is probably responsible for much of the tuberculosis of childhood. Prophylaxis must be directed to the prevention of this overcrowding, improvement of ventilation, etc.

Discussion on Convulsions in Infancy. A. M. GOSSAGE AND J. A. COUTTS.—The authors lay most stress in the causal factors of convulsions in childhood on a neurotic predisposition, and local irritation of the digestive tract and elsewhere is probably less effective than supposed without this predisposition. They conclude that the frequency of convulsions in infants has been greatly overrated, that the immediate danger of fits has been overrated, while that as regards future neurotic manifestations has been underestimated. The predisposing causes are of more importance than the exciting causes.

Hugh R. Jones believes that convulsions must be regarded as causally related to digestive disorders or other organic disease,

and indirectly, also, to social conditions tending to produce disease. It is important to reduce the complexity of medical statistics, which are more than usually intricate, because they very frequently involve more than one factor. It is desirable to reduce to a minimum the obstacles which tend to prevent the recognition of the ultimate origin of disease, for progress in the improvement of public health is retarded through want of accurate knowledge.

Causation of Night Terrors. E. GRAHAM LITTLE.—After discussing the theory of these disorders, Little analyzes some thirty cases that he has observed and offers the following deductions: 1. Night terrors are in the great majority of cases caused by disorders productive of moderate but prolonged dyspnea. 2. A preponderating number of cases are found in rheumatic subjects with early heart disease. 3. A considerable proportion of cases are due to obstruction of nasal cavities and fauces. 4. Digestive disturbances do not play the important part in causation that is often assigned to them. 5. The evidence of their causal connection with epilepsy or allied neuroses is scanty. 6. The attacks occur in the subconscious stage of early sleep, and are confined to young children under puberty.

Lancet, August 10.

Albuminuric Retinitis. SAMUEL WEST.—The author divides albuminuric retinitis into two types, the exudative and the degenerative forms. The first of these is similar to what is met with in other forms of neuroretinitis. The degenerative form consists in white patches and hemorrhages, the former being the most characteristic. This degenerative form is associated with granular kidney, the exudative especially with parenchymatous nephritis. The exudative is probably toxic in its origin, the degenerative follows vascular changes and is more or less mechanical. The exudative may recover with little impairment of sight. In the other, however, if there is any impairment of sight it is usually progressive. As to their diagnostic value, the exudative form is an interesting accompaniment of parenchymatous nephritis, otherwise manifest, while the degenerative often makes the diagnosis certain in cases which have hitherto been obscure, while both indicate a grave form of renal disease. The degenerative type also indicates the dangers due to arterial disease.

Journal des Sciences Médicales de Lille, August 15.

Subconjunctival Injections of Atropin. L. THILLIEZ.—By this method minute amounts produce the desired effect and cure even when all other measures have failed, as is evidenced again by a number of observations reported in this communication: ulceration and phlyctenular keratitis, acute and painful iritis, etc. Two drops of a 1/200 solution injected under the conjunctiva proved promptly effective without causing any phenomena in the other eye, not even the slightest paresis of accommodation. Subconjunctival injections are usually reserved for mercurial salts, etc., but this method is indicated in all cases in which the conjunctive absorbs defectively, or not at all, also, in cases requiring prompt action or in which the action of other medication requires to be reinforced or completed.

Presse Médicale (Paris), August 9.

Mobility of the Pelvic Articulations and Influence of Posture on the Size of the Pelvis. E. BONNAIRE AND V. BUÉ.—The attitudes instinctively assumed by the parturient woman modify the dimensions of the pelvis, and Bonnaire and Bué have established that an exaggeration of the natural attitudes has a decided influence in favoring delivery, enlarging the diameters of the inlet and outlet, assisted by the relaxation of the pelvic symphyses induced by the pregnancy. The play of the various pelvic articulations in the different positions is described in detail as they observed it on 500 maternity patients examined, and the practical conclusions are drawn that hyperextension of the entire body, the trunk braced against a resisting plane at the sacral region, enlarges the inlet by 3 mm. in the sagittal direction, as the sacrum is thrown back and the pubis lowered. The attitude produced by rolling up the pelvic members on the trunk, the knees opposite the shoulders, avoiding both abduction and adduction—the perineal incision position—reduces the diameter of the inlet but enlarges the bi-ischial diameter of the outlet to an average of 16 to 18 mm. The hyperextension position is indicated to favor the spontaneous engagement of the head in the various

forms of rachitic malformation of the pelvis. Sufficient enlargement can not be counted on, however, unless first assured of a marked relaxation of the pelvic articulations, appreciable by the degree of mobility of the two pubes on each other. Hyperextension is also indicated to effect the engagement of the head with the aid of forceps, or to extract the back of the head retained by the small inlet, but this attitude hinders obstetric maneuvers to such an extent as to counterbalance the advantages derived from the slight enlargement, in most cases. It is impossible also to determine in this position in the usual way the minimum promonto-pubic diameter as the proportions are altered. The perineal incision position is much more profitable; it favors obstetric interventions by exposing the field of operation to the accoucheur, but is less frequently indicated than hyperextension. It will be found especially beneficial in cases with narrow inlet—cyphot pelvic—or when the head is locked in frontal presentation in the small pelvis and must be extracted with forceps, or when the head has been extracted, but the shoulders are caught on the floor of the pelvis owing to the size of the trunk.

Deutsche Medicinische Wochenschrift (Berlin), August 17.

Fatal Acute Dilatation of the Stomach. R. KIRCH.—A young man, rather anemic, but who had never suffered from gastric disturbances, was suddenly affected with syndrome resembling the symptoms of perforation of an abdominal organ; intense pain, vomiting and large fluctuating area of dullness but no fever. A splashing sound when the patient was shaken confirmed the diagnosis of dilatation of the stomach, and emptying and rinsing the stomach cleared up the symptoms at once, but too late to relieve the compromised heart action. At the autopsy the stomach was found like an enormous bag resting on the floor of the pelvis, the pyloric end reaching up to join the duodenum, and the pylorus permeable for two fingers. The stomach was normal except for its size and the evidence of gastritis that had followed the fatal supper of two plates of "brodsuppe" and a glass of beer. In the course of the gastritis the stomach had suddenly renounced its motor functions and all absorption by the mucous membrane had ceased, inducing intense thirst, while the quantities of water ingested and not absorbed only served to increase the dilatation further.

Deutsche Zeitschrift f. Chirurgie, I, 1 and 2.

Cancer of the Lip. FRICKE.—An experience with 137 cases, at Bonn, has convinced Fricke that neither tobacco nor alcohol is a factor in the pathogenesis of cancer of the lip, but that vices prompt extirpation of any warty excrescence on either lip, is twelve times, and of the upper lip three times, more frequent in men than in women. Invasion of the jawbone may occur within three months of the first appearance of the neoplasm, and, with or without ganglion metastases, renders the prognosis very grave. The only treatment is early removal, and he advises prompt extirpation of any warty excrescence on either lip. Nine of the patients died; there has been recurrence in forty-one; the rest are all well to date, in most cases over three years. He advocates removing the ganglia before touching the primary neoplasm, and rejects extensive resections of the jaw as dangerous and useless. All the deaths occurred in patients thus treated.

Wiener Klinische Wochenschrift, July 20.

Clinical Pathology of the Peripheral Nervous System in Pulmonary Tuberculosis. R. SCHMIDT.—This communication, concluded from the two preceding numbers, describes the valuable information to be derived from certain nervous symptoms in the early diagnosis of tuberculosis, at a period when other indications are negative or conflicting. These disturbances in the peripheral nervous system are either the result of local, chiefly mechanical, seldom toxic, action of the tuberculous process in the lung on the adjacent nerve routes—the brachial plexus, recurrent and intercostal nerves, etc.—or the result of the generalized action of toxic and especially dyscrasic injurious influences. Among the former the most important are the phenomenon of unilateral pain on pressure of the brachial plexus, and the frequently associated homolateral acroparesthesia, usually located in the ulnar region, which have a special diagnostic significance in the early stages of pulmonary tuberculosis and initial hemoptysis. Tuberculosis must be considered as a possible factor, direct or indirect, in all the various causes of

acroparesthesia, especially in the young. Symptomatic acroparesthesia in phthisic subjects is distinguished from the acroparesthesia due to organic or functional lesions of the nervous system proper, by its frequency in male subjects; its frequent coincidence with acute catarrhal pulmonary processes—influenza bronchitis—its limitation to one side; its parallelism with typical tuberculous symptoms, night sweats, evening fever, etc., and the frequent coexistence of unilateral and homolateral pain when the brachial plexus is compressed. In the 162 cases of acroparesthesia on record, due more or less totally to vasomotor, trophic, gastric, etc., disturbances, there are only twelve males and no cases under 20 years of age: almost all were women about 40. Schmidt considers the statements of tuberculous subjects in regard to their symptoms seldom reliable, and hence does not attract attention to his brachial examination nor inquire whether pain follows compression. The expression of the face is usually sufficient indication and the shrinking from a repetition of the pressure which he controls several times, standing in front of the subject, laying his right hand in his left and applying the latter to the right supraclavicular fossa with the finger tips on the upper margin of the trapezius muscle, sliding them along perpendicularly to the direction of the plexus. Darting pains into the fingers and neck are occasionally encountered, which possibly suggests circumscribed perineuritic alterations in the plexus. Bilateral pain possibly indicates general intoxication from mixed infection. The left side, in his experience, was a little more frequently affected than the right. If the plexus test is positive, inquiry will usually elicit anamnestic data in respect to the acroparesthesia.

Zeitschrift f. Orthopädische Chirurgie (Stuttgart), vii, 1.

Tendon Implantation. H. GOCHT.—Nineteen observations are described in detail from Hoffa's private clinic, emphasizing the value and benefits to be derived from implanting the tendon of an active muscle in the tendon of a paralyzed muscle, restoring the function and neutralizing the paralysis or deformity. (See JOURNAL, xxxii, p. 1109, May 20, 1899.) One of the cases was a traumatic typical radial paralysis of the right hand, of four years' standing, in a child of 12. Narcosis followed 25 grams of chloroform. The operation required forty minutes. After expelling the blood with an Esmarch, the tendon of the extensor carpi radialis longus was exposed with a 5 cm. incision. The hand and forearm were then placed on the radial side and an incision carried from the processus styloideus ulnae upward to the ulna, and the tendon of the flexor carpi ulnaris isolated and detached by slipping a sound under it. Then returning to the extensor carpi radialis, the tendon was cut between clamps and with the hand in extreme dorsal flexion, the stumps of the tendon were pushed up 2.5 cm. on each other and sutured with six fine silk stitches. The crushed ends were cut off and sutured with six fine stitches. The hand had now assumed the radial elastic dorsal flexed position. After closing the skin wound, the tendon of the flexor carpi ulnaris was detached from the os pisiformis, taken up with a silk thread and passed through the tendon of the extensor carpi radialis longus, the skin pulled as far as possible toward the radialis to expose the tendon of the extensor digitorum communis. At the point where it spreads out into a fan, the well-pulped central end of the flexor carpi ulnaris was inserted in it, bringing the fingers into a passive hyperstretched position. The cutaneous incision was then closed, and after wrapping the arm in a sterile compress and a little padding, a circular plaster cast was applied, reaching to the elbow, and holding hand and fingers in a hyperstretched, radially flexed position. A plaster splint was also applied extending beyond the fingers on the side of the flexion, and a metal ring, cast in the plaster on the upper radial side, held the thumb with a rubber band passing through this ring and around the abducted thumb, well stretched. The cast and stitches were removed in ten days and another similar cast applied. Two weeks later this was changed for a volar plaster splint reaching from the elbow to the finger tips, and holding the hand stretched and in slight radial flexion. After three days this splint was removed twice a day for massage, electrization and passive and active exercises of fingers and hand. At the end of the tenth week the patient was writing and taking zither lessons, with normal conditions restored in every respect. Gocht observes that the

results in this one case alone would insure a dominant place for tendon implantation in the treatment of paralytic deformities. The technic above described is identical with that of another case of deformity from spinal paralysis in a child of 7, equally successful in its results.

Societies.

COMING MEETINGS.

- American Association of Military Surgeons of the United States, Kansas City, Mo., September 27-29.
- American Association of Obstetricians and Gynecologists, Indianapolis, Ind., September 19-21.
- American Electro-Therapeutic Association, Washington, D. C., September 19.
- Medical Society of the State of Pennsylvania, Wilkesbarre, September 18-20.
- Medical Society of the Missouri Valley, Council Bluffs, Iowa, September 21.

Nova Scotia Medical Society.—The election of officers of this Society, at its last meeting, resulted as follows: President, D. McIntosh, Pugwash; First Vice-President, C. A. Webster, Yarmouth; Second Vice-President, F. S. Yerston, Truro; Secretary-Treasurer, W. S. Muir, Truro.

New Brunswick Medical Society.—The following is the roll of officers of this Society, elected for the ensuing year: President, William Bayard, St. John; Vice-President, R. L. Botsford; Second Vice-President, T. F. Sprague, Woodstock; Treasurer, Foster MacFarlane; Corresponding Secretary, B. M. Mullin, St. Mary's; Recording Secretary, W. E. Ellis, St. John.

Maritime Medical Association.—At the last meeting of this Association, the following officers were elected for the term of 1899-1900: President, James Christie, St. John, N. B.; Vice-President for Nova Scotia, N. E. McKay, Halifax; Vice-President for New Brunswick, Geo. A. Hetherington, St. John; Vice-President for Prince Edward Island, H. D. Johnson, Charlottetown; Secretary, G. M. Campbell, Halifax; Treasurer, T. D. Walker, St. John.

British Medical Association.

Annual Meeting, Portsmouth, Eng., August, 1899.

(Concluded from Page 606.)

RECENT ADVANCES IN PRACTICAL MEDICINE.

SIR RICHARD DOUGLAS POWELL, Bart., M.D., F.R.C.P., presented the address in medicine, on this topic. He briefly considered the clinical thermometer, anomalous fevers, and the combination of surgery with medicine.

Bacteriology.—He pointed out that bacteriology in its application to diagnosis and treatment in practical medicine is yet in its infancy; but it is a very robust infancy, full of promise, the complete fulfillment of which none of us will live to see. The bacterial origin of tubercle, anthrax, diphtheria, erysipelas, septicemia, typhoid, malaria, influenza, has been revealed to us almost within the memory of the youngest, yet has already been, in many instances, fruitful in suggesting measures of prevention and treatment. Bacteriology, in all its departments, is and must ever remain subject to expert investigation. It is impossible for the busy practitioner to find the time or to maintain the technical skill and apparatus necessary for trustworthy investigation. The various research associations have hitherto in part fulfilled the want and the bacteriologic departments of our hospitals are steadily growing in importance and value; but it is to be hoped that the time will soon come when in every district throughout the country there will be in connection with the public health department a bacteriologic laboratory, where the ordinary, and even the extraordinary, clinical tests will be at the command of every practitioner at a moderate scale of fees.

Susceptibility and Immunity.—It has long been clear to every observant physician who has on the one hand even superficially kept in view the results of bacteriologic inquiry and who has thought on the incidences of such infective diseases as he happens to meet, that we carry about with us in our accessible mucous tracts, and especially in our naso-oral and respiratory passages, amidst other unconsidered trifles and as yet

unclassified germs, samples of the organisms specific to many diseases. We are tenanted by these varied organisms in small colonies or singly, rendered inert only through want of opportunity. The very careful observations of Drs. St. Clair Thomson and Hewlett, recorded in the "Medico-Chirurgical Transactions for 1895, show that there is a natural cleansing if not antiseptic secretion from the healthy nasal membrane which preserves it from contamination by the numerous organisms which abound in the nasal avenues, so that mucus taken from the central membrane of the nose in health contains few or no organisms. Other bacteria surround us on all sides, and from time to time obtain a temporary but abortive lodgment within us; virulent catarrh, diphtheria, pneumonia, influenza, tuberculosis, erysipelas, perhaps rheumatism, and probably in epidemic times most of the other infective diseases would be represented in one or other category among our domesticated or casual occupants. It is not, however, enough to have the poison germ on the one hand to acquire the disease on the other: there are intermediate or antecedent circumstances of dosage, acquired susceptibility or that subtle malformation of tissue in certain organs which is inherited, and renders them weak in resistance to certain forms of attack. Let a period of depression come over us, involving some slight change in our blood or tissues, some local or general alteration in our chemical or vital functions, and one or other of these organisms may receive the opportunity for aggressive cultivation. We virtually know that this is so in the case of a common cold. Acquired by a momentary chill at an open door, or through wet boots, such a catarrh becomes at once a highly contagious disease, and will "run through the house." There can be no doubt that the catarrh is associated with the cultivation of an organism; it is equally probable that that organism must have pre-existed in some part of the nasal surface. Does some vasomotor disturbance bring about the local conditions of increased heat and moisture needful for that particular form of microbe cultivation, or is it merely depressed vitality that makes the host susceptible? No one, so far as I am aware, has yet descended to work out the bacteriology of a common cold. Yet it is the type of a large number of more important diseases, and carefully investigated it would be fruitful in side-lights on their etiology and prophylactic treatment.

Serumtherapy.—It is already an immense achievement if we have acquired the knowledge that every infection requires a separately-prepared serum for its treatment. It explains many of our failures, and gives promise of adding to our successes. It has for some time been recognized that infective endocarditis has a manifold microbial pathology—streptococcus, staphylococcus, pneumococcus, gonococcus, are some of the organisms concerned. It is useless to employ an antistreptococcus serum for a pneumococcus infection, and even the two organisms, streptococcus and staphylococcus, which seem to work most cordially in couples, require a separate treatment. This in part accounted for the very poor success as yet achieved by the serum treatment of this and of some other maladies more or less allied to it. From the clinical side one would judge that very frequently more than one poison was in association. This is certainly the case in many diseases, for example, in the third and often in the first stage of enteric fever, in the suppurative stages of tuberculosis, in scarlatina, and perhaps in gonorrhoeal rheumatism. In pneumonia again it is remarkable that in every variety of the disease, the sthenic, the asthenic, the typhnoidal, the septic pneumonia, and the influenza catarrhal forms, the characteristic pneumococcus is invariably to be found, and this coccus may be the micro-organism conspicuously present in those secondary lesions with which pneumonia is often complicated, and which are attributed to it, such as empyema, infective endocarditis, etc. Yet there are good reasons to doubt whether the pneumococcus organism alone, unassisted by some of its pyrogenic *confreres*, is ever able to bring about these secondary lesions which are usually attributed to it. We must push our diagnosis further, to include a recognition of the precise organism or organisms which have obtained lodgment in any given case. Unfortunately, in the earlier stages at least of ulcerative endocarditis, bacteriologic investigation is by no means always successful in identifying the organisms or, indeed, in recognizing any organism, for with well-marked clinical features the specimen of blood exam-

ined must be sterile. We may yet for some time to come, therefore, as in complex cases of enteric fever, with which these cases are often confounded, have to rely on the general clinical phenomena presented by the case and its history of attack in our attempt to identify the poison and in our endeavor to select the antidote. We are indeed only at the dawn of serumtherapeutics, and many mistakes will have to be retrieved, many apparent steps forward retraced, in the sure but slow advance in this new departure of therapeutics.

Whilst the possibility of neutralizing by appropriate treatment, the specific poison in certain diseases, will relieve the practitioners of some anxiety, it can not fall on the other hand to add much to the tension of their labors by requiring an earlier diagnosis, and by the great care needed to avoid accidents in the use of delicate organic fluids prone to contamination and decomposition. It is impossible that the treatment can be much developed in general use until abundant local centers are secured for the provision of materials of guaranteed purity.

It is curious and instructive to note that in the two diseases in which antitoxins are of most approved value, namely, diphtheria, and tetanus, the bacillary cultivation is declared (Behring) to be limited to the seat of inoculation, the blood only being charged with their toxins. Whereas the mortality from diphtheria but a few years ago varied from 25 to 50 per cent., according to the severity of the epidemic, it has been reduced by the serum treatment to from 25 per cent to 8 per cent., according to the severity of the case and the date of infection.

Concerning serumtherapy in pneumonia, he said, in part: Unfortunately, we have not yet been supplied with any reliable antidote for the serum treatment of pneumonia, and to-day, although Pane's antipneumococcus serum will protect a donkey or a rabbit from the evil consequences of a strong dose of pneumococcus infection, it has not as yet come into practical use in the human disease. I have recently tried it in two cases without result. This may be due to three causes: 1. It is difficult to use the serum early enough in the disease. 2. The most severe cases in which alone at present one feels disposed to try the remedy are most generally complicated with some other infection, so that the pneumococcus in the sputum does not signify the sole—perhaps not the most important—element of danger in the case. 3. The doses employed by Dr. Pane have been very large, so large that one shrinks from introducing in such bulk an unknown or imperfectly accredited element into any case not already desperate. In the use of these very large doses, my friend Dr. Charles of Rome has suggested to me the introduction of the serum *per rectum* as a method which he has known to prove efficacious with other serums, the absorption being rapid and the serum unchanged. As yet, however, the serum can not be obtained in sufficient quantity for use in such large doses. In all probability the want of success in the antitoxin treatment of erysipelas, puerperal fever, and allied affections, including infective endocarditis, may be similarly accounted for by the presence of more than one organic infection, thus requiring, as pointed out by Behring, Pfeiffer, and Kant-hack, more than one antidote.

Soil and Disease.—It is difficult to recognize the striking testimony of such reliable observers as Middleton, Bowditch and Buchanan as to the influence of a wet subsoil on the prevalence of consumption with the present view of the transmission of the disease only by human and bovine infection. We must recall, too, to mind the enormous prevalence of bovine tuberculosis, not to be observed only among stall-fed, crowded, and insanitary cattle communities, but amongst those animals under good open-air conditions. Do we not find in this prevalence of tubercle among pasture-fed cattle, and in the fact of the prevalence of the disease in localities with wet subsoils and dulcified sunlight, some probability that the tuberculous organism, like those of actinomycosis, tetanus and anthrax may have an independent and parasitic existence, and that, like malaria, tuberculosis will probably be found to have a double origin from purely microphytic as well as from parasitic infection?

It is remarkable that two at least of the most deadly of disease microbes, tetanus and anthrax, should be normal inhabitants of the soil, and yet how comparatively scarce these diseases are, and, having arisen, how communicable. It would seem that, as is the case also probably with malaria, while the

ultimate source of the disease is vegetation in the soil, yet a greater virulence and activity is attained, and for a short time maintained by cultivation in the human body, or in that of certain other warm-blooded animals. With regard to tuberculosis I would make this final remark: that while we may hope on the one hand by further careful sanitation, "by destroying and diminishing the careless distribution of bacillary dust, foods, that a considerable inroad on the remaining 14 per 1000 deaths from consumption may happily still be made. But if on the other hand we withdraw or relax precautions dictated by observations sound in themselves, although in some regards capable of amended explanation, our efforts will be less fruitful; for there will be some deductions to be made from the 20 per cent. reduction in mortality already achieved. In my belief there is a mephitic laboratory beyond our special control, yielding organisms ever ready to attack the unwary, and cleanliness is our first line of defense against them all. Where-ever the conditions of insanitation, dampness, deficient sunlight, and the prevalence of favoring diseases are present there aggressive activity may be again looked for.

San Francisco County Medical Society.

August Meeting.

EXTRAUTERINE PREGNANCY.

DR. E. E. KELLY pointed out that recent results in the operative treatment of this condition have aroused general interest. Formerly the doctor waited in anxious expectancy till rupture occurred and the patient fortunately lived, or died from the hemorrhage; or he endeavored to destroy the fetus in some one of many ways, trusting for subsequent absorption of the fetal mass. In 1597 Israel Spach described this condition and reported a case of calcified fetus. Regner de Graaf voiced a theory as to the place of impregnation, which closely corresponds with the modern and widely accepted theory. He believed the ova to be normally fertilized in the ovaries, and that the arrest of the fertilized ovum at any point along its path to the uterus caused extrauterine pregnancy. Many theories have been advanced as to the etiology of the condition; they differ as the advocates of the theories differ in their opinion as to the place of impregnation of the ovum. It is claimed that the ovum is fertilized in the Fallopian tubes; in the abdominal cavity; in the ovary; and in the uterus itself.

Kelly classifies the causes of ectopic gestation as follows: Obstacles in the lumen of the tube; disease of the tubal walls or anatomic peculiarity; factors acting externally to the tube, reducing its lumen. All these conditions imply a reduction in the internal diameter of the tube; they simply indicate the cause of the reduction. He evidently holds impregnation to take place in the tube or in the abdominal cavity. The pregnancy may be primarily tubal, ovarian or interstitial; secondary forms may develop from a dislocation of the fetus. Ovarian and abdominal pregnancy are extremely rare.

The clinical history of extrauterine pregnancy does not differ from normal pregnancy during the early weeks. A tumor forms on one side of the uterus, which is elastic and painful to touch. Both the uterus and this tumor grow from month to month. Obscure pains in the pelvis and down the legs may be noticed, and sometimes one sees all the signs of pelvic inflammation. After a few weeks there is usually an irregular bloody discharge from the uterus, more profuse than normal menstruation and more irregular as to time. The uterus often casts a decidua vera, which may be a perfect cast of the uterine cavity. This is a most important symptom; if it occurs with a known ovarian tumor, it is almost diagnostic of extrauterine pregnancy. The condition may go on to full term, spurious labor take place, and the fetus die. Generally the walls of the tube become thinned and rupture; this may occur at any time from a few weeks to nine months. The symptoms are quite characteristic of the condition. The patient, previously in good health, or but slightly indisposed, pregnancy known or suspected, is suddenly seized with severe lancinating pains in the pelvis and abdomen, which may be agonizing; pulse becomes rapid and feeble, and there are generally symptoms of more or less profound shock.

Hemorrhage may be between the layers of the broad ligament, in which case the symptoms of shock are less marked. The amount of hemorrhage into the abdominal cavity depends on the

point of rupture and the size of the vessels involved. If a large artery in the placental site is ruptured, death results before any operative interference can be undertaken. The hemorrhage may be slight, cease spontaneously, and recur from time to time as the fetus grows. The ovum may escape into the abdominal cavity, and death of the fetus result. If the ovum is near to the end of the tube, it may be expelled into the abdomen and there become encysted, producing adhesions, but perhaps doing little harm. This expulsion is known as tubal abortion. Suppuration may, on the other hand, occur, with discharge through perforation, into the rectum, vagina, bladder, or through the abdominal walls. Simultaneous uterine pregnancy may obscure the diagnosis of extrauterine pregnancy. Dr. Wilson of Baltimore has reported the occurrence of this condition, both fetuses going to full term and being saved, the mother subsequently dying from septic infection.

If the diagnosis is not made at the time of rupture it may be very difficult to make later. The fetus undergoes calcification and remains, often, as a hard mass in the pelvis, and may so remain for many years without causing any serious trouble.

The treatment has become of late years, almost exclusively surgical. Some of the methods for destroying the life of the fetus may be mentioned. The induced, or "faradic," current may be used for five to ten minutes daily for one or two weeks. Atropin or morphin may be injected into the tumor by means of a long syringe needle, two or three times a week. Whatever method is employed, it should be used till the shrinking of the tumor shows the life of the fetus to be destroyed. The electric treatment may cause rupture of the sac; it should be used only during the first three months, and in the intraligamentous form of gestation. It is best to operate and remove the entire mass. Immediate operation should be performed as soon as the diagnosis can be made; it is perfectly safe, and should the mass prove to be a hydrosalpinx or pyosalpinx no harm is done, for operation is indicated in these conditions. After rupture, if the case is first seen then, a mass may be found connected with the uterus, fluctuating in character, circumscribed and not occupying the cul-de-sac. Here the hemorrhage has taken place into the ligament, and some surgeons do not advise immediate operation. I think this dangerous advice, and always recommend operation. With rupture into the peritoneal cavity immediate operation is imperative.

He then reported a case illustrating some of the difficulties of the surgeon in making a correct diagnosis after rupture has taken place, and also one unusual in that a second extrauterine pregnancy occurred six weeks after operation for the first one.

CASE 1.—Mrs. T., aged 38, first seen July 19, 1898. Emergency call, she having been under the care of a homeopathic physician. Suffering very severe pain, only relieved by a hypodermic injection of morphin. Seen again July 22, suffering from a similar attack. August 4, called again and asked to take charge of the patient. The history was then obtained for the first time. Had been treated by former medical attendant since May 1, 1898. He assured her she was pregnant. About May 20, excruciating pains in the pelvis, with marked prostration. From this time had recurrences of the pain every few days, but not so severe as at first. Patient said her former attendant had not made an examination per vaginam since the commencement of her trouble. Examination showed uterus enlarged to size of three months' pregnancy; ordinary signs of pregnancy not present; uterus fixed in the pelvis; large nonfluctuating mass on the right, not clearly separable from the uterus. Diagnosis agreed within consultation, was uterine pregnancy, death of the fetus without expulsion, and it was thought septic infection had caused the pelvic pain. August 8, operated upon at the Waldce Hospital; uterus excised and mass resembling placenta removed. Left hospital August 18, much better and with temperature normal. October 28, exploratory incision determined on; tumor thought to be multiple fibroid, because of firm and unyielding character of the growth. November 5, abdomen opened. Mass in right side of pelvis, walled off by tissue. Right tube found to have ruptured, placenta remaining *in situ*, and the fetus located in Douglas' pouch. The cord was intact. Patient made uninterrupted recovery. At time of operation left tube and ovary found to be normal. Four weeks later complained of pain in left side of pelvis. Enlargement found in left tube. Increased in size and diagnosed as a probable tubal

pregnancy of the left tube. Operation on January 12, at the Waldeck Hospital. Left tubal pregnancy, with rupture from the fimbriated extremity; so-called tubal abortion. Large blood clot found in the pelvis. Patient has now entirely recovered and remains well. Fetus not found at second operation, but chorionic villi found on microscopic examination of the tube removed. Ovaries not removed; patient now menstruates normally and without pain.

CASE 2.—Mrs. L., age 28, in good health. Sudden, severe pain in right side of pelvis. Consulted Dr. A. G. Meyer, who made correct diagnosis and ordered her to the hospital. Pelvic tumor clearly made out on right side of pelvis, disconnected with the uterus. A complete decidua vera was passed, which did not show clearly the villi; diagnosis was made, nevertheless, of extrauterine pregnancy with rupture. Operation May 31. The right tube found enlarged and ruptured at extremity, with presence of a hematoma. Hemorrhage had ceased; abdomen closed without drainage. No fetus found, but chorionic villi clearly observable in portion of tube removed.

In conclusion he insisted on early operation when diagnosis can be made. The operation is not more difficult and is less dangerous than the operation for pyosalpinx. The mortality, when left to nature, is 68.8 per cent, according to Schauta, based on 249 cases. In 515 cases of operative treatment, the mortality, according to Martin, was 23.3 per cent. The great value of the uterine decidua membrane in diagnosis can not be overestimated.

He expressed his belief that hematoma of the pelvis is always due to ectopic gestation.

DR. J. HENRY BARBAT also urged immediate operation, performed as soon as diagnosis could be made. He exhibited two specimens recently removed. One was a tube, ruptured at about its center, with the placenta still *in situ*, the fetus having been expelled. Considerable hemorrhage followed but the case terminated in favorable recovery, after operation. Gestation had progressed to about the fourth week. The other tube and the appendix were removed at the one operation. A second specimen showed the smallest fetus he had ever seen. It could not have been more than two weeks from the time of fetation, and its true nature was only revealed by looking at the tiny mass of tissue with a magnifying glass. The diagnosis in the second case had been made by Dr. Barbat while he was himself in bed recovering from an operation for appendicitis which had been performed on him three days before. On the eighteenth day after his own operation he removed the tube and specimen shown. The husband of the patient called on Dr. Barbat while in the hospital, and from the husband's recounting of the symptoms extrauterine pregnancy was diagnosed, subsequent operation demonstrating the correctness of the diagnosis. He mentioned this phase of the case, simply to illustrate the fact that in the average case the symptoms were so clear that a mistake in the diagnosis should not be made, when the patient is seen before and at the time of rupture. The presence of a history of what seems to be pregnancy, with sudden severe lancinating pain, with more or less shock, and a tumor in the pelvis, make a picture that should lead to no mistake in the diagnosis. In his opinion, no question can exist about anything connected with this condition, save the one factor of diagnosis when the patient is not seen till some time after the rupture has occurred. As to the method of dealing with the trouble, one thing alone is to be done; operate and remove the tube, and also the ovary if the latter is found to be diseased. The appearance of the decidua vera, noticed by Dr. Kelly, is a very valuable factor in the diagnosis. The macroscopic appearance of the decidua is generally characteristic enough to confirm or make the diagnosis, without waiting for a microscopic examination.

DR. MAX STEVANSKY asked Dr. Kelly if immediate operation was advisable in all cases, as soon as the diagnosis was made, and without regard to the question of rupture. He had recently seen a report of forty-three cases in which the fetus was killed by means of the interrupted current and in all but one of these the patient made a good recovery; one patient died from rupture of the sac and subsequent hemorrhage.

DR. F. B. CARPENTER indorsed what had been said as to the value of the decidua in the matter of making a diagnosis. Curetting would often bring to light the decidua, if it were not cast out spontaneously. The gross appearance he also thought

quite significant of the condition, as the decidua did not at all resemble the decidua of uterine pregnancy. The operation he thought justified on the symptoms, the presence of a tumor in the pelvis, and the finding of the decidua vera as indicated. The operation is simple and the danger is not greater than in any abdominal section, save from the hemorrhage, which, in fact, does not in any way pertain to the operation, but rather to the cause for which the operation is undertaken.

DR. H. D. ROBERTSON said that the treatment of this condition was much easier than formerly, for the reason that we now knew more regarding it, could more readily make the diagnosis, and aseptic surgery had removed the dangers of operating. He recalled many cases, seen years ago, in which the patients could have been in all likelihood saved by operation which would at the present day be undertaken without much discussion. He cited, as a case in which much doubt and confusion had occurred through the patient not having been seen at the time of rupture, the case of a negro woman, a widow of 35, who had consulted him, as well as several others, for an obscure abdominal trouble. The early history could not be obtained, for the reason that the woman, a widow of three years, disclaimed all possibility of pregnancy and did not really give her history. The uterus was found enlarged, when first seen by the Doctor, and the temperature was 104 to 105 degrees. The tumor in the pelvis, which could be easily felt, had the appearance of an infiltrated cellular tissue. The os was slightly dilated, and the diagnosis made was that of abortion. Subsequently the uterus was curetted and decidua tissue found, which convinced all the doctors interested in the case, that it was one of abortion. There remained a mass behind the uterus, which was hard and not fluctuating. Two days after curetting he was hastily called and found the bed almost flooded with a very thick and foul-smelling pus; 40 to 50 ounces had escaped. Examination showed that the pus had perforated through the tumor wall into the rectum, and the finger, when introduced, encountered sundry masses of tissue that felt like bone. These were dug out and proved to be portions of a decomposed fetus. Operation was refused and the tumor scraped out as well as possible, through the rectal opening. The pus continued to discharge for some time, but the woman recovered and is now up and working, though there is still some discharge.

DR. HAROLD BRUNN said that while the diagnosis was often easy, there were times when it was difficult to make. Cases are encountered, however, in which the amount of the hemorrhage is small, the pain is not excessive, and examination shows the os somewhat dilated and the uterus enlarged; there has been a good history of pregnancy, and every indication is that the case is one of threatened abortion. Here it is not wise to curette, for it is not certain that the abortion may not be stopped. Such cases are exceedingly difficult to diagnose and not easy to handle certainly until the lapse of some days and the condition reveals itself more clearly.

DR. ZEMACH LEVIN asked in what manner the diagnosis could be made in the early stages of the trouble and before rupture of the sac had occurred. He thought it certainly wise to operate early, when the diagnosis could be made, but knew of no way in which the diagnosis could be surely made in the very early weeks and before rupture had taken place. He asked Dr. Barbat how he could make the diagnosis of extrauterine pregnancy in the cases he had reported, before rupture occurred.

DR. J. HENRY BARBAT said, in reply, that he knew of no way of making the diagnosis as a certainty in the early weeks and before rupture. In the cases he reported the diagnosis had been made for the reason that the sac had ruptured and the accompanying symptoms were clearly those of extrauterine pregnancy with rupture.

DR. KELLY, in closing the discussion, said that operation was the only method of treatment that could be safely recommended. He recalled a report of sixteen cases treated by electricity in order to kill the fetus, and of these three of the patients died. The operation is especially free from dangers, as we know that pregnant women will take an anesthetic better, and resist shock better, than those not pregnant. He agreed in the belief that the gross appearance of the decidua was often enough to indicate the condition, without resorting to the microscopic examination of the tissue. When the whole cast of the uterus is thrown out, it does not at all resemble the cast in membran-

ous dysmenorrhea, and confusion ought not to arise between these conditions.

CANCER OF STOMACH.

DR. F. B. CARPENTER reported an operation for cancer of the stomach, and said that he did not report the case as cured, nor make the statement that the man would live forever. He thought it well, however, to record the operation as successful so far as the time elapsed allowed. The man had now been quite well for three months. The history was clear, all the classic symptoms and signs of cancer of the stomach being present. Operation was recommended and refused. Later the patient returned and agreed to the operation. The pylorus was somewhat to the right, and the incision was made vertically, through the right rectus muscle. The mass was very easily reached, was movable, and there were no nodules in either the lesser or the greater omentum; there were, however, some in the tissue of the stomach away from the mass itself. For this reason the chance of relief after operation was thought good. Two clamps were placed on the stomach and one on the duodenum; the lesser and the two anterior layers of the great omentum were ligated. Great effort was made to preserve all the blood-supply possible. The value of this had been demonstrated by the experiments which he and Dr. Barbat had made on dogs, and the results he thought were uniformly better when ample blood-supply was assured. The omentum for about one-third of the length of the stomach was tied off. The entire cut end of the stomach was sewed with three layers of sutures. The first lot of sutures was through the mucosa, and was a continuous suture; the second was an interrupted suture line which approximated the cut ends perfectly; these sutures passed through all layers. The approximation seemed to be perfect, but for safety a line of interrupted Lembert sutures was introduced. The duodenum was anastomosed with the posterior wall of the stomach very easily, by the aid of a Murphy button. No temperature over 99 was observed, and that occurred on the following day. For four days rectal feeding was employed, but after that liquid diet by the mouth was allowed. The man made a good recovery and has since the operation gained thirty pounds in weight. Mortality was formerly from 15 to 50 per cent. in these cases, following operation; it has been reduced by recent mechanical aids and is now probably about 20 per cent.

DR. J. HENRY BARBAT said in the matter of connecting the intestine, it would sometimes be found that the duodenum could not be brought up to the stomach without too great tension. When this was the case he thought it better to cut the jejunum and anastomose it with the stomach, closing the lower end; then to anastomose the duodenum to this portion of jejunum, five or six inches below the stomach. In this way the bile is led to the intestine at about the normal point, and is not allowed to enter the stomach and do harm by producing irritation.

Canadian Medical Association.

(Thirty-Second Annual Meeting, held in Toronto, Ont., Aug. 30, 31 and Sept. 1, 1899.)

(Concluded from p. 622.)

SECOND DAY—MORNING SESSION.

ERYSIPELAS, WITH TREATMENT BY MARMOREK'S SERUM.

DR. A. DE MARTIGNY, Montreal, recited his experience during the last fifteen months with this serum in cases of erysipelas of the face. Although the result of the ordinary treatment in these cases is very good, he thought that the results that he had achieved in several cases treated after the manner commended the employment of the serum to the profession. One case in particular reported, where the temperature registered 105 degrees and the pulse 148, patient very weak and the face very much swollen and no improvement after ichthyol and ordinary tonic treatment, one injection (20 c. c.) of the antitoxin, with the application of a solution of bichlorid 1-4000 brought the temperature next morning down to normal and the pulse to 96; and the next day pulse normal. Five days thereafter, the patient, a female, went back to work. Other cases were mentioned in which the results were equally good. It exerted a prohibitive action also on relapses.

DR. POWELL, Ottawa, asked re the dose of this particular

serum, whether the standard dose was 20 c. c. and whether the dose is altered by the severity of the case or by the age of the patient and other necessary rules for the guidance of the practitioner.

THE PRESIDENT stated he had employed this plan of treatment recently in half a dozen cases with very prompt results and instanced a case where seven attacks or relapses had occurred in fourteen months, but after using this serum, no relapses had occurred in that particular patient.

SIR JAMES GRANT, OTTAWA, hoped Dr. de Martigny would pursue further his observations on this plan of treatment for erysipelas and stated that as far back as 1863, he himself had been subjected to the influence of the serum from ordinary vaccin for a very severe blood-poisoning from which he was suffering at the time. He had employed serum therapy then in the treatment of cases of skin disease, particularly severe forms of psoriasis that he had met.

DR. IRWIN, Weston, related a case of scarlet fever in a child which after two weeks developed erysipelas and in twenty-four hours was in a very bad state. He injected 10 c.c. on the second day without any result and the child died.

DR. DE MARTIGNY, in reply, stated that either 10 or 20 c.c. can be used, but the streptococci are not all of the same kind. He spoke of the different families of these, and if we are sure of the particular variety we have to deal with in a specified case, the serum corresponding, then 10 c.c. would be a sufficient quantity; but as we do not always possess this information, he considered it wise to inject the larger dose at once. He concluded by asking the members to try this treatment on any cases they might meet with in the next twelve months and report progress at the next general meeting of the Association.

COMPLICATIONS AND TREATMENT OF FRACTURE OF THE SKULL.

DR. J. M. ELDER, Montreal, read this paper. At the outset he stated that his paper had more especially to deal with fractures at the base. During this past summer, he had had under his care in the Montreal General Hospital, no less than seven cases, five being there at the same time, and the whole seven recovered. He thought the profession too prone to think that this was a form of fracture in which treatment was useless. The history of one of these cases in particular was related, the form and nature and location of the injury with the symptoms. He quoted from one of Shepherd's cases where he had assisted that surgeon several years back in tying the common carotid artery after such an injury and stated that in this case he ligated the left common carotid artery, the injury being on the left side, put the patient to bed and she regained consciousness on the third day. Complications ensued in the way of thromboses in different sinuses, but the patient left the hospital twenty-six days after the accident, perfectly well and continues well up to the present time. The other six cases were very much of the same nature. The doctor then outlined the general form of treatment pursued in these cases, giving attention to keeping nose, ears and mouth in proper condition, and having controlled the hemorrhage we should render the parts as aseptic as possible, giving special attention to the external ear. The patient should be kept free from all excitement either of sight, sound or mental agitation.

DR. LETT, Guelph, Ont., brought up the question of the development of mental symptoms after these injuries and also after the tying of the carotid artery.

DR. ERNEST HALL asked the surgeon what led him to select the left side and where there are symptoms of internal without external hemorrhage, what are the surgical indications.

DR. HARRISON, Salkirk, Ont., also asked as to the development of mental symptoms following these cases. He had had injuries of the brain in which there was no ligation of the carotid, in which there was perfect restoration and then a year after these symptoms supervened.

MR. CAMERON stated that he had tied the common carotid on both sides and no mental symptoms followed and thought that these symptoms were due to the traumatism.

DR. SHEPHERD, Montreal, said, in reference to the case Dr. Elder had mentioned, that he had operated several years ago on one of these patients and found a clot at the base of the skull, and because the hemorrhage was so profuse, he tied the carotid immediately. So far as he knew, up to a year ago, no mental symptoms had developed.

DR. ELDER in reply thought that he had heard that this case of Dr. Shepherd had within the last two or three months gone insane; Dr. Shepherd had no knowledge of this and thought it could not be the fact. He was of the opinion, however, that mental symptoms did not develop by reason of tying the cord.

DRS. ATHERTON, Fredericton, N. B., and BELL, Montreal, contributed further to the discussion of the paper and the cases cited therein.

OBSERVATIONS ON ADENOIDS AND ENLARGED TONSILS AND THEIR REMOVAL, WITH NOTES.

DR. D. J. GIBB-WISHART, Toronto, contributed a paper with this title. The paper was based on the results obtained in a service of four years in the Sick Children's Hospital. His table showed that in all 103 operations had been performed, 47 males and 56 females. Twenty-four per cent. were under 5 years, 21 per cent. over 10 years, and 52 per cent. between 5 and 10 years. Two deaths resulted, both from the anesthetic. Sixteen of these cases were examined one or two or three years after the operations and only four showed any return of the disease. He spoke of the diagnosis of adenoids, the treatment after operative measures had been practiced and the healthy mental improvement which followed operation for this condition. A description of the operation for removal of diseased tonsils followed and he stated that in his opinion the operation was too frequently performed. He also discussed the choice of anesthetic, favoring chloroform.

SIR WILLIAM HINGSTON deprecated the employment of the spray in the nasal passages and the frequency of the operation of tonsillotomy. He had seen many members of different families, all having enlarged tonsils in their youth, grow up, and in adult life the tonsil returned to its normal condition. Powders are the proper applications to the nares.

TUBERCULOSIS AND INSURANCE.

DR. JOHN HUNTER, Toronto, spoke of the imperative duty of the examining physician furnishing true and accurate reports to the medical directors of life insurance companies, and at the same time strongly asserted the position that it was the duty of these companies to see that the applicants should receive the benefit of the advances of medical science of the day. The whole burden and purport of the paper was to invoke discussion that could be used to define more clearly where we are at with reference to the relationship between tuberculosis and insurance and to what degree does the presence of tuberculosis in the individual or family history justify the rejection of applicants. Hereditarily counted for naught, physical condition and environment much. Too much stress was put upon family history nowadays, whereas the applicant did not receive the right benefit from his own good physical condition.

DR. BENEDICT, Buffalo, spoke of heredity as very much like the heredity of scarlet fever, the difference between a longer period of incubation.

SIR WILLIAM HINGSTON said that this question has done an enormous evil to society. A beautiful young girl is about to be married; a whisper goes round that the disease may be transmitted; she comes of tuberculous stock; the nuptials are declared off and in this way society suffers.

SIR JAMES GRANT advocated the formation of a national society such as the Prince of Wales presides over in England for the spread of information concerning tuberculosis and the means to employ to effect its eradication.

DR. P. H. BRYCE thought that if this Association could form an association to assist the government of the country in this matter, it would be accomplishing much. He advocated inspectors for schools and institutions and if a solitary case be found, to have that individual removed.

CYST OF BROAD LIGAMENT.

DR. CHAS. SMITH, Orangeville, Ont., outlined some of the features we have to deal with in operating on intraligamentous cysts of the broad ligament. The patient, who was 53 years of age, enjoyed good health after operation for a period of five years, when death resulted from an attack of apoplexy.

AFTERNOON SESSION--SECOND DAY.

IMPLANTATION OF THE URETERS IN THE RECTUM IN A CASE OF EXTROPHY OF THE BLADDER, WITH PATIENT.

PROF. GEORGE A. PETERS, Toronto University, exhibited the

patient, a boy aged 4½ years. At the age of 2½ years he first came under the surgeon's notice, with the condition described in the title and also proclivita recti. These cases are very troublesome, disgusting and loathsome to friends and an operation ought to be performed for their relief. The surgeon first described the cause of these conditions, then took up the operation for the restoration of the rectum, which was done two years ago and now shows it to have been a skillful and beneficial operation to the patient. The scrotum was present and the testicles descended; and a groove descended along the broad and shortened penis down to its tip. At the lower part of the bladder wall, the openings of the ureters could be detected; and the surface when dried would remain dry only from 15 seconds to 1 minute. He proceeded further in the description of the case and then detailed the different steps of the operation. The operation was done entirely extraperitoneally; the incisions in the rectum were made on either side thereof; and the little patient has good control over his sphincter ani, to the extent, that on the day he was shown to the Association, he had passed his urine at 8 a.m., then at 11:30, and again at 2:30 p.m. At night, he will go for four or five hours, without passing anything from the bowels at all. Almost immediately, the rectum manifested a tolerance of the urine. It is now five weeks since the operation was performed, and the bladder is all gone.

MR. CAMERON, the president, thought that this operation was bound to become the operation of the future. Heretofore a good many of these operations have proved failures.

PROF. JAMES BELL, McGill University, congratulated Dr. Peters on the result of this case. He considered it a surgical triumph. The operation for replantation of the ureters has been done for a good many different things; and the question of tolerance of urine in the rectum is still much discussed; but the results shown in this operation are good.

DR. SHEPHERD, Montreal, thought that the operation was an ideal one and congratulated Dr. Peters on the great success he has obtained in this case.

DR. PETERS, in reply, said that we must not lose sight of one point, that there is danger of death from ascending pyelonephritis. That has been the cause of death, when the operation has been done in animals.

CO-OPERATION OF SURGEON AND PHYSICIAN IN ABDOMINAL CASES.

DR. A. L. BENEDICT, Buffalo, took this as his theme and made an interesting presentation of the subject. He cited in illustration thereof several instructive cases in which the surgeon and physician should conjointly treat the patient. He thought it would be infinitely to the advantage of both and also to the patient if many of these cases were handed over for after-treatment to the physician.

The President spoke of the difference between the two callings and thought that every surgeon should serve a considerable apprenticeship in general medicine before reverting to purely surgical work.

SIR WILLIAM HINGSTON said that the surgeon should not make his diagnosis at the time of the operation. Some surgeons when in doubt, cut in. That, to his mind, is almost criminal. He generally finds that men in relation to their youth and experience, diagnose their cases in this way. They often, so to speak, "jump at the diagnosis." The proper way is to go over your case thoroughly, write down what it may be, then eliminate what it is not and by this process of exclusion, you ought always to be able to arrive in the end at a correct diagnosis. Sir William always diagnoses his cases before he operates. He expressed amazement at the rapidity with which some men rush to operate.

GALL-BLADDER SURGERY.

DR. J. F. W. ROSS, Toronto, first exhibited to the meeting a cabinet of gall-stones he had removed in operations and a specimen of a fistulous gall-bladder. He then took up the surgery of the gall-bladder, described the technic of the distinct operations, gave records of his cases and percentages of recoveries and demonstrated many important facts of interest in connection therewith. He also presented for examination an instrument he had recently devised and had prepared in London for the removal of stones from the common bile-duct. In regard to a remark from Sir William Hingston, he took issue with

that gentleman, and stated positively that he did not hesitate, when in doubt, to "cut in."

DR. T. K. HOLMES, Chatham, Ont., spoke of the interest and instruction conveyed in Dr. Ross' paper. When the gall-bladder is enlarged and adherent and the abdominal wall thin, the operation for the removal of gall-stones becomes an apparently easy operation; but if thick or under the edge of the liver far, he knows of fewer operations that will tax the surgeon's strength, than an operation of this kind. He commended Sir William Kingston's plan of exclusion in the diagnosis of abdominal tumors and illustrated on the black-board, an operation he had performed six weeks ago for gall-stones, on a woman with a thick abdominal wall.

PROFESSOR BELL entirely agreed with most of the conclusions of Dr. Ross; but when we come to deal with stones in the common bile-duct, he holds widely different views from Dr. Ross. It is not such a very difficult and serious operation as Dr. Ross seems to think. He reported eight cases twelve months ago and since then he has removed stones in four cases. Two of these have died: one from ether and the other from iodoform poisoning. In no case has he failed to remove the stone and in three of these cases the stone has been lodged in the ampulla. He does not attempt to break the stones.

ADDRESS IN SURGERY—THE RADICAL CURE OF HERNIA.

DR. W. B. COLEY, New York, gave an admirable historical review of this subject. He traced its origin from earliest times, giving dates and names of those concerned in its development, describing *en passant* in detail the different operations performed by the pioneers in this particular branch of operative surgery. Coming down to more recent times, the work of Macwren, Bassini, Kocher, Halsted, and others received detailed attention. The respective operations and improvements of these gentlemen were described and the honor accruing therefrom apportioned. Errors of technic were then dwelt with. Incision of sufficient length both in skin and also in aponeurosis came in for notice. Sutures and suturing and suppuration and the splendid advances which the radical cure has made in the last decade were not forgotten. Instead of a mortality of 6 per cent., we have now one of less than 1 per cent. amongst the leading operators. Five to 10 per cent. now suffer from suppuration. The reader closed his able paper with a concise reference to the operation as applied to femoral hernia, and thought most umbilical hernia got along better without any operative interference.

A vote of thanks was moved by Dr. Shepherd, seconded by Dr. Peters, to Dr. Coley for having given the Association the opportunity of hearing such an important paper. This was carried unanimously. Mr. Cameron presenting this to Dr. Coley in his usual happy manner and Dr. Coley making a felicitous reply.

THIRD DAY—MORNING SESSION.

ANESTHESIA BY CHLOROFORM AND ETHER.

DR. W. B. JONES, Rochester, delivered a practical paper with his title. He described minutely the preparation of the patient beforehand for the administration of the anesthetic, deprecating smearing the face and nose all over with vaselin. The information regarding the heart did not so much take cognizance of heart murmurs as it did of the muscular tone of the heart and the condition of the arteries. The quality of the blood was of importance. One should know something of the capacity of the chest and the total solids excreted in the twenty-four hours in the urine. Deformities and any partial paralysis should not escape notice and attention. The quantity of the anesthetic employed was dwelt upon. The usual quantity of chloroform is from eight to twelve drops per minute although he has kept up the anesthesia with only four drops per minute or half an hour. Strict attention must be paid by the administrator to his work, particularly following the pupils, respiration and the color of the face. The position of the patient must be such that respiration will not be impeded, the arms not hanging over the edges of the tables and all proper instruments at hand ready for emergencies. The particular juncture at which ether might be successfully changed for chloroform and vice versa received minute description. The surgeon was to understand that the anesthetist "was boss of the job," and neither needed nor should tolerate any interference. The time was ripe for

the appearance of the specialist in this branch of medical science; and every large city should have specialists in this line. He further dwelt on the symptoms of impending dissolution and the necessary means to be employed to avert such an accident. The responsibility of the anesthetist is equal with that of the surgeon and he should have a complete knowledge of the operation to be performed and the length of time that ought to be taken to complete every operation.

SOME OBSERVATIONS ON THE TREATMENT OF CANCER.

DR. A. R. ROBINSON, New York, illustrated his subject with a diagrammatic drawing. The paper which he contributed was in support of two papers which he had already delivered in Canada on the same subject, one in Toronto and the other in Kingston. He stated that after a pretty extensive experience in drugs, experimenting for a cure for cancer, there was no single drug known to the medical profession, internally administered, that would exert any influence on one of these growths in any part of the body. Too many cases go on with medicinal treatment when an early application of surgical measures would bring about more beneficial results. There were one or two places where the speaker thought a paste preferable to the knife, i. e., where you can not employ a knife to cut down deep, such as in the region of the nose and on the scalp. Arsenious acid paste is supposed to have more or less of a selective action in epithelioma. Equal parts of this with gum acacia of the consistency of butter should be applied and left on for 16 to 18 hours so as to get the right effect. From this you will get a complete necrosis *en masse* and an inflammatory process, but not an inflammation sufficient to destroy the tissues. Then you get the simple process of granulation. He protested strongly against a remark of Mr. Watson Cheyne that all epitheliomata should be treated with the knife and that alone. In his opinion, the assertion was too sweeping and his statements erroneous. He quoted Marsden in support of his conclusions.

DR. SHEPHERD thinks that in the majority of instances, the knife is the proper instrument. He has not employed escharotics except in a very small number of cases. Cancer in the first place is local and ought to be treated immediately by removal. Nitrate of silver is no use at all. In some cases the knife is not as good as the escharotic, but these cases are very few and chiefly on the face and scalp.

DOMINION REGISTRATION.

DR. RODDICK, who had the subject in hand delivered at some length a detailed plan of the scheme and was followed by Dr. Williams, Ingersoll, Ont., representing the Ontario Medical Council, who moved a strong resolution committing the Association to the carrying out of the plan, seconded by Dr. McNeill, Charlottetown, P. E. I. which was put to the meeting and unanimously adopted amidst great enthusiasm. Dr. Roddick was further commissioned to introduce a bill into parliament at the next meeting of that body.

NOTES OF VARIOUS EUROPEAN CONVENTIONS IN 1899.

DR. R. A. REEVE, Toronto, recited his observations whilst attending the International Otolological Convention, the International Ophthalmologic Convention and the British Medical Association's section on ophthalmology. He quoted from four sets of addresses delivered at these meetings and reviewed the discussions that had arisen on different subjects, paying attention to recent advances in these specialties and the newer remedies employed.

SURGERY AMONG THE INSANE.

DR. A. T. HOBBS, Asylum for the Insane, London, Ont., first pointed out the differences in operating on the sane and the insane and the difficulties to be met with in practicing upon the latter. After dwelling on the peculiarities and the maneuvers necessary before an examination will be submitted to on the part of these people, he spoke of the exceptional obstacles which had to be surmounted in order to study gynecology in these unfortunates. The best results were achieved in pelvic inflammations. In anesthetizing at first, chloroform had been employed, but it was found to be invariably weakening for the patient, so that it was abandoned and ether is now altogether given.

DR. ERNEST HALL, Toronto, instanced several operations in his own practice in British Columbia, in which out of 29 cases operated on, 7 were restored to reason. He contended that 92.5 per cent. of insane women have pelvic disease.

CRANIOTOMY FOR MICROCEPHALUS.

DR. W. J. WILSON, Toronto, reviewed the history on this subject and then proceeded to state his own case. The patient, a boy of 4 years, was presented to the members present. The patient was first brought to him in April last. He had then been taking thyroid extract for nine months in 5-grain doses per day and gradually increased until he was taking 20 grains per day. When the doctor saw him he walked bent over almost at a right angle, very excitable, nervous and always "on the go," restless, sleepless and could only say one word, "mamma." It was "mamma" for everything. Operations were done on him in four stages, with the object of preventing shock. Since operation five months ago, he has learned quite a number of words. He can stand erect and shows quite an improvement in every way. This, the doctor thinks is entirely due to the operation, as before, the mother had frequently tried to teach and train him but without perceptible result.

Place of meeting in 1900, Ottawa, Ont.

ELECTION OF OFFICERS.

President, Dr. R. W. Powell, Ottawa.
 Vice-President for Ontario, Dr. A. J. Johnson, Toronto.
 Vice-President for Quebec, Dr. A. R. Marsallais, Montreal.
 Vice-President for New Brunswick, Dr. Meyers, Monckton.
 Vice-President for Nova Scotia, Dr. W. G. Putnam, Yarmouth.
 Vice-President for Prince Edward Island, Dr. S. P. Jenkins, Charlottetown.
 Vice-President for Manitoba, Dr. W. J. Neilson, Winnipeg.
 Vice-President for Northwest Territories, Dr. Hugh Bain, Prince Albert.
 Vice-President for British Columbia, Dr. O. M. Jones, Victoria.
 Treasurer, Dr. H. B. Small, Ottawa, Ont.
 General Secretary, Dr. F. N. G. Starr, Toronto.

Orleans Parish Medical Society.

Meeting held Aug. 26, 1899.

UNILATERAL HYPERIDROSIS.

DR. L. G. LEBEUF related a case of unilateral hyperidrosis occurring in a man aged 60 years, suffering from spinal sclerosis. After exertion of any kind the left side of the body is dry, while the right perspires excessively. This is particularly well marked above the level of the fifth cervical vertebra, below which the hyperidrosis is not so noticeable. The trouble dates back thirteen years, to an attack of la grippe, of three weeks' duration, followed by hemiplegia, recovery from which was tardy. There is no history of syphilis.

DR. ISADORE DYER said this was the most extensive case of hyperidrosis he had ever seen. It is not uncommon to see localized disorders of the kind, as for instance excessive perspiration on one side of the lip, so intense as to cause inflammation of the sweat glands, hydradinites.

CARBOLIC ACID IN TETANUS.

DR. HERMAN B. GESSNER called attention to the treatment of tetanus, with carbolic acid, injected hypodermically. He had received a letter from Dr. E. F. Newell of St. Joseph, La., detailing a case treated successfully by this method. This was a negro boy aged 12 years, to whom he gave 25 m. of a 2 per cent. solution of carbolic acid on the second day. There was immediate relief from chronic convulsions, and a diminution of the tonic muscular contraction. The treatment was repeated twice daily for a week, when the boy was entirely well. Chloral and bromid, which had been in use at first, were discarded on the second day of the carbolic acid treatment. This treatment was brought to the attention of the profession by Prof. H. C. Wood, Jr., in an article published in the May number of *Mercer's Archives*.

DR. T. S. DABNEY spoke of the treatment of tetanus with the brains of animals, reciting three cases reported as cured by the use of emulsion of rabbit brain.

DR. C. H. TEBALUT, JR., had recently treated three cases of tetanus with serum, all without benefit. In one of these, that of an infant, the injection had been intracerebral. He condemned the use of eserin, which he had seen used in the surgical wards of the Charity Hospital. Of peculiar interest was a case lately seen by him, which ended fatally within twenty-

four hours, with subnormal temperature throughout—this was a case of intracerebral infection through unskilled douching.

DR. M. J. MAGRUDER had used serum in one case only; in this the effect seemed to be harmful rather than beneficial. He was interested in determining the cause of the frequency of tetanus neonatorum in midwives' cases. In his own obstetric practice he had delivered two hundred infants without having a case, while he had treated twenty-five or thirty cases in infants delivered by midwives.

DR. H. A. VEAZIE had treated seven cases by plying them freely with liquor, keeping them fully under the influence; all had recovered. Chloral and bromid had also been administered, as well as salicylate of sodium in some cases.

DR. E. M. DUPAQUIER stated that credit for the introduction of carbolic acid in the treatment of tetanus should be given Baccelli, an Italian physician; solution as strong as 10 per cent. had been used by him.

DR. F. PETTIT had not met with success in the use of anti-tetanic serum as a curative means, but he made it a practice to use it as a preventive in all punctured wounds likely to be followed by tetanus. He believed that the serum had been efficient in this application.

DR. GESSNER read from Lewis Smith's work on Children, a passage describing the great reduction of the mortality from tetanus neonatorum in the Dublin Lying-in Asylum after thorough ventilation had been provided for. Possibly this is not a true tetanus after all, but, as had been suggested to him by Dr. Dupaquier, some other cerebral affection.

Referring to Dr. Magruder's statement about the relative frequency of this disease in midwives' practice, he regretted to say that he had once had a case, in the infant of a cleanly woman whom he had delivered. In this case, however, the stump of the cord had been meddled with by a relative of the patient, who had probably been the infecting agent.

DR. F. W. PARHAM spoke of papers by Drs. Halliday and Sims, attributing the disease to pressure on the head in faulty modes of carrying infants.

DR. DUPAQUIER, referring to the suggestion that the disease in the new-born may not truly be a tetanus, said this had been put forth by a French author, who dwelt on the traumatism to the head of the fetus in its passage through the pelvis, and thought a resultant meningitis might explain the symptoms observed in these cases. As to serum treatment, it had been established that serum injected into the subcutaneous tissues can not be expected to reach and affect toxins fixed by the cerebral tissues. Intracerebral injection must be resorted to for this purpose.

Value of Patient's Estate Not to Be Considered.—The supreme court of Alabama holds that the trial court erred, in the case of *Morrisette* against *Wood*, in admitting testimony as to the value of the patient's estate against the objection of the defendant, who was executor thereof. And for this it reverses a judgment recovered for medical services rendered defendant's testator, remanding the case for a new trial. The supreme court says that the inquiry was as to the value of the professional services rendered by the plaintiff, and that the amount or value of the patient's estate could shed no legitimate light upon this issue, nor aid in its elucidation, as the case was presented in the trial court, there being no hint in the evidence that there was any recognized usage obtaining to graduate professional charges with reference to the financial condition of the person for whom such services were rendered, which had been so long established and so universally acted upon as to have ripened into a custom of such character that it might be considered that these services were rendered and accepted in contemplation of it. The cure or amelioration of disease, the court goes on to say, is as important to a poor man as it is to a rich one, and, *prima facie* at least, the services rendered the one are of the same value as the same services rendered to the other. The statement of the plaintiff as a witness that he knew the defendant's testator, and that he had a certain disease for several years before his death, and that he died of that disease complicated with another, which witness named, the supreme court further holds, involved no transaction with the deceased, and was not within any exception to the competency of parties as witnesses under section 1794 of the code, prohibiting a party from testifying as to transactions with a decedent in an action against his executor.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

These new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, SEPTEMBER 9, 1899.

THE MICROBE OF YELLOW FEVER.

When Sanarelli announced his discovery of the bacillus icteroides, which he held to be the specific cause of yellow fever, upon rather weak grounds, Sternberg drew attention to the similarity between his bacillus X, isolated from yellow-fever cases, and Sanarelli's organism. Since then evidence has accumulated to show that these two microbes are distinct; this is now Sternberg's opinion¹.

Sanarelli's claims in regard to his bacillus have been confirmed by numerous Italian investigators, including such names as Foà². Most of these confirmatory studies were made in the laboratory and far removed from infected districts. Novy advanced the claim that inasmuch as Sanarelli's organism proved itself very resistant to low temperature, it could not well be the cause of yellow fever, which is a disease of warm countries and warm seasons. Sanarelli³ ridicules this statement and calls attention to the well-known fact that pathogenic bacteria in general withstand cold well without losing vitality, although no growth generally occurs while so exposed. Certain observations in epidemiology also show that the agent of yellow fever does not lose its vitality in cold, e. g., the occurrence of yellow fever in midwinter and the transportation of the disease by means of ships which pass through severe exposure to cold.

In thirty-two out of thirty-nine autopsies on yellow-fever cases, P. E. Archinard⁴ found a bacillus practi-

cally identical with the bacillus icteroides, but the agglutination reactions, obtained with the serum of convalescing yellow-fever cases and other diseases, did not, it seems to us, produce as prompt, decisive and constant results, as might be expected and desired, neither in the case of Sanarelli's organism nor that of Archinard.

Then Reed and Carroll⁵ published a preliminary note concerning the marked resemblances of the bacillus icteroides to the bacillus of hog cholera in cultural, morphologic and biologic respects. They expressed the opinion that Sanarelli's organism is a variety of the hog-cholera bacillus, and that it should be regarded only as a secondary invader in yellow fever. It is impossible now to go into the details of Reed and Carroll's experiments, but one observation strikes us as very significant, and that is the marked agglutinative reaction shown toward the hog-cholera bacillus by the serum, very highly diluted indeed, of an animal immunized with bacillus icteroides, and vice versa.

In his answer to some of these criticisms, Sanarelli can do nothing but emphasize the great differences between his observations and Reed and Carroll's, especially as to cultural peculiarities and to certain lesions following experimental inoculations; Reed and Carroll obtained typical focal necrosis in the liver by injecting bacillus icteroides, a lesion which Sanarelli had not met with in all his work—if we mistake not, Foà observed the production of necrotic foci in the spleen by the bacillus icteroides—Sanarelli ascribes Reed and Carroll's startling results to some deplorable fault or accident in bacteriologic technique—a point which will no doubt be effectively and completely disposed of.

Sternberg⁶ refused to yield to whatever evidence there may be in favor of the specific iteroide rôle of Sanarelli's bacillus because he—Sternberg—did not find it in his researches, employing, as he did, media upon which the bacillus grows readily, because of the similarity between Sanarelli's bacillus and the hog-cholera bacillus, especially with respect to pathogenic action and agglutination, and because serum of yellow-fever patients does not markedly agglutinate Sanarelli's bacillus while serum of immunized animals does in very high dilutions. Sternberg expresses perfect willingness to revise his opinion if Reed and Carroll's observations are shown to be faulty. There is another possible contingency which, perhaps, ought to be taken into account in connection with this, namely, that Sanarelli's bacillus might be the cause of yellow fever even though its resemblance to the hog-cholera bacillus is so pronounced as to apparently amount to absolute identity except possibly in respect to the pathogenic effects on man. However, this is not supported by analogy, and it does not satisfactorily explain the failure of yellow-fever serum to agglutinate the bacillus icteroides as promptly as that of immunized animals. For the present, and as the matter now stands, Sternberg's view that the colon bacillus, bacillus X and bacillus icteroides are

pathogenic saprophytes occasionally and accidentally present in the blood and tissues of yellow fever would therefore seem a reasonable one. To what extent the results of the work in Havana and elsewhere of the Commission of Medical Officers, U. S. Marine-Hospital Service, of which a preliminary report has appeared¹, will change matters remains to be seen. The preliminary report is very favorable to Sanarelli. The bacillus *icteroides* was isolated from all the cases of yellow fever which were studied in Havana. While a large number of different animals were found susceptible in the same general manner to experimental inoculation with bacillus *icteroides*, bacillus X, colon bacillus and Havelberg's bacillus, and their toxins, the commission claims to have established the "natural specificity" of Sanarelli's organism because it proves to be the only microbe which was infectious under natural conditions. The primary infection takes place through the respiratory tract; the infection may remain local in the lungs or it may invade the blood and give rise to a septicemia, the invasion of the blood corresponding clinically to the "secondary paroxysm" of yellow fever heretofore regarded as the result of secondary, mixed infections which, of course, may take place. The commission differs from Sanarelli, who regards yellow fever as a septicemic disease from the start, and from Sternberg, who regarded the gastrointestinal tract as the point of first attack. Theoretically, the primary infection of the respiratory tract may explain the failure of Sanarelli and others to find the bacillus in every case of yellow fever on the assumption that the lungs were not examined carefully enough. The full report of this commission will be read with great interest. In the meantime the relations of the bacillus *icteroides* to the hog-cholera bacillus should be definitely settled, as much which now seems strange will then become clear.

NAGGING WIVES AND NERVOUS HUSBANDS.

Some years ago one of the health officers of New York City stirred up self-appointed representatives of the "new woman" by his remarks on the production of nervous prostration in husbands by the nagging of wives. The novelists devote much attention to the self-sacrifice of the wife to the hypochondriac husband, but the reverse of the picture is too well known to physicians. The hysteric nagging wife of the insane or neurasthenic husband is a familiar acquaintance. Such women are usually regarded as *fin-de-siècle* products. The puritan matron, like her descendants, however, was often a hysteric. The eighteenth century statutes anent the use of the ducking-stool—which still survive in Delaware—demonstrate the recognition of nagging as an antisocial vice by the fathers of the republic. In the late sixteenth and early seventeenth century, hysterics were far more frequent than is usually supposed, and that minor form of hysteria which takes the direction of motor restlessness was peculiarly apt to voice itself in nagging. In-

deed, in the "Comedy of Errors," which appeared in 1593, Shakespeare indicates that, according to popular opinion of that time, husband nagging produced not only nervous prostration but even insanity. In Act V, Scene i. the Abbess endeavors to ascertain the cause of the alleged insanity of Dromio of Syracuse, in the dialogue with Adriana.

Ben Jonson also indicates the popular belief in the nerve-destroying effects of nagging in his "The Silent Women." (Taine's English Literature.) Morose is an old paranoiac who has a horror of noise but loves to speak. He inhabits a street so narrow that the carriage can not enter it. He drives off, with his stick, the bear leaders and sword players who venture to pass under his windows. He sends away his servant, whose shoes creak. The new one wears slippers with wool soles, and only speaks in a whisper. Morose forbids the whisper and makes him reply by signs. His nephew, whom he ill-treats, finds for him a supposed silent woman for a wife. Morose, enchanted by her brief replies and her voice, which he can hardly hear, marries her. As soon as she is married she speaks, scolds, argues, as loud and as long as a dozen women. She orders the valet to speak louder and opens the doors wide to her friends, who arrive in crowds, overwhelming Morose by their noisy congratulations. Morose drives them out, gnashing his teeth and looking dreadfully. Afterward physicians who are called pronounce him mad and discuss his insanity before him in an interesting illustration of psychiatric phraseology of the seventeenth century.

The disease in Greek is called *mania*, in Latin *insania furor*, *vel, ecstasis melancholica*, that is *egressio*, when a man *ex-melancholico erudit fanaticus*. But he may be but *phreneticus* yet, mistress; and phrenitis is only delirium or so.

While the play is intended to depict a paranoiac with suspicious ideas, it also illustrates the influence which medical and popular opinion ascribed to nagging as a factor in nervous disorder. The Elizabethan dramatists, Jonson, Shakespeare and the rest were very fond of drawing dramatic allusions from current medical science, especially as related to psychiatry.

The most ludicrous appearance of the nagging wife in the literature of the first half of the present century was that of Mrs. Caudle of the famous "Mrs. Caudle's Curtain Lectures," by Douglass Jerrold. Of his hero Jerrold remarks: "Mr. Caudle was blessed with an indomitable constitution. One fact will prove the truth of this. He lived thirty years with Mrs. Caudle, surviving her. The nagging, however, had one serious result. When Mr. Job Caudle was left in this briery world without his daily guide and nocturnal monitor, he was in the ripe fullness of fifty-two. For three hours at least after he went to bed—such slaves are we to habit—he could not close an eye. His wife still talked at his side. True it was she was dead and decently interred. His mind—it was a comfort to know it—could not wander on this point; this he knew. Nevertheless his wife

was with him. The Ghost of her tongue still talked as in the life, and again and again did Job Caudle hear the mienitions of by-gone years. At times so loud, so lively, so real were the sounds that Job with a cold chill doubted if he were really widowed. And then, with the movement of an arm, a foot, he would assure himself that he was alone in his holland. Nevertheless the talk continued. It was terrible to be thus haunted by a voice, to have advice, commands, remonstrance, all sorts of saws and adages still poured upon him, and no visible wife. Now did the voice speak from the curtains; now from the fester, and now did it whisper to Job from the very pillow that he pressed. "It's a terrible thing that her tongue should walk in this manner," said Job, and then he thought confusedly of exorcism or at least of a counsel from the parish priest.

The "common scold" of the seventeenth and eighteenth centuries, and the nagger of to-day were expressions of an ill-regulated and ill-balanced nervous system which led to motor restlessness and egotistic inability to see the rights of others. Nagging is far from rare as an occupation disease of school teachers and adds to the school strain of children. It also occurs among the occupation diseases of regular army officers and others in authority. Its worst effects are, however, seen in the domestic circle.

THE PATHOGENESIS OF ACROMEGALIA.

Since Marie, in 1886, first described acromegalia as a morbid entity, it has continued to awaken interest and its literature has steadily increased. Marie's first account, based on two cases in Chareot's wards at the Salpêtrière, was exhaustive and left little to be added by later investigators except explanation of its pathogenesis. Under other names the disease was recognized long before Marie's day, for Sternberg has gathered several undoubted cases from literature as far back as 1552. One of Carl von Langer's two classes of gigantism, first announced in 1872, is clearly acromegalia. In 1884 Fritsche and Klebs described a characteristic case, but as an unknown disease. Since Marie's first systematic and accurate description, many reports of cases and explanations regarding its nature have been made.

Of the etiology or its predisposing causes practically nothing is known up to the present time. Its symptomatology is, on the other hand, so well known that nothing further need be said of it here. Its treatment offers little that has hitherto proved satisfactory.

The special interest in the affection at the present moment centers in its pathogenesis. The question, together with a masterly consideration of the whole subject, is discussed by Harlow Brooks of the Pathological Institute of the New York State Hospitals, in an elaborate monograph published in the *Archives of Neurology and Psychopathology*, vol. i, No. 4, 1898, issued in July, 1899.

Many theories have been elaborated to account for the phenomena of acromegalia. Of these the author discusses seven, but clearly shows that none of these explanations cover all of the phenomena of a typical case, or are sufficiently constant to warrant their acceptance, except these which have to do with the pituitary gland.

After elaborately considering the comparative anatomy, embryology, histology and physiology of this gland, the writer passes at once in *medias res* in the sentence: "it is manifest that the only reliable key to the unraveling of this rather chaotic mass of morphological alterations in the hypophysis obscuring the pathogenesis of acromegalia is on the basis of function." This is because the great variety of lesions found in the hypophysis can bring about the acromegalic condition only by coincident changes in the gland's functions. If the quantitative changes in the secretion be the basis of consideration, the lesions fall naturally into two groups. The first are those which cause, or are associated with, diminution or suppression of its functions; and the second, those which cause or are associated with its increase. The former include various tumors tending to replace the parenchyma of the prehypophysis as well as degenerative and distinctive lesions of all sorts. The latter include the hyperplasias and adenomas of the prehypophysis.

Rogowitsch, Marinesco and Marie seem to have adopted the theory of atrophy and suppression of the prehypophyseal function, using the thyroid gland and the rôle it plays in myxedema as an analogy. Brooks declares that such an explanation is "flatly contradicted by definite and reliable facts;" for as in a case cited by McAlpin, the entire pituitary body was completely destroyed by a sarcomatous growth, without an approach to any characteristic acromegalic phenomena. The testimony afforded by Boyce and Beadles, as well as the experimental evidences of Vassale and Sacchi, of Horsley and of others, all tend to disprove the atrophic theory. The "error lies in the fact that these instances of sarcoma of the hypophysis in acromegalia are not sarcomata at all. In such cases hyperplasia has been mistaken for sarcoma."

This leaves, then, as the only tenable explanation of acromegalia, hyperplasia including adenoma of the prehypophysis, with an increase of its function and of its functioning cells. The hypersecretion theory was first brought forward by Tamburini, and is not in the least weakened by reason of the so-called compensatory hypertrophy of the pituitary gland occasionally observed in myxedema. In myxedema the increased function of the prehypophysis is only relative, supplying a deficiency of the thyroid secretion, whereas in acromegalia there is an actual increase of prehypophyseal secretion. The relation of this increased pituitary function to the connective-tissue growth, to parenchymatous degeneration, and to the nervous system, is most interestingly and minutely discussed.

THE JOURNAL AND THE CANADIAN MEDICAL ASSOCIATION.

Those in attendance at the meeting of the Canadian Medical Association, held in Toronto, Ont., last week, were profuse in their praise of the enterprise displayed by the JOURNAL in the early publication of the proceedings. They also expressed astonishment at the short period of time which elapsed between the close of the first day's session and the receipt of the printed report. The Association assembled on Wednesday, August 30, and early on Friday morning, September 1, a copy of the JOURNAL containing a complete report of the day's proceedings was handed to each member in attendance.

A CORRECTION.

Dr. Ira Von Geison, of the New York State Laboratory, has repudiated the statements attributed to him in a New York paper, which were editorially noticed in this JOURNAL some weeks ago. His disclaimer, which we are glad to see, is printed in the July issue of the *American Journal of Insanity*, which has just appeared. It is not always safe to treat statements made with the circumstantiality of that of the New York journal as beneath notice, and if Dr. Von Geison had not made this correction the world would have been justified in thinking that the interview was authentic. It would have been better all around if the correction had been made more promptly after the publication.

AN ENFORCED ANTI-SPITTING LAW.

The anti-expectorator ordinance in San Francisco seems likely to hold its own and to be enforced without fear or favor. One offender, who is reported to be a millionaire, has had to undergo his punishment, and the repetition of the offense only made it more severe. If this is not merely an indication of a "sand lots" prejudice against millionaires, and if like even justice is dealt out to the hoodlum who deserves it, as well as to every grade between, San Francisco is to be congratulated. The prohibition of indiscriminate expectoration is one of the most reasonable hygienic regulations, and has, moreover, the advantage of being cosmetic as well as sanitary. It is to be hoped that this pervasive nuisance can be legally checked elsewhere as well as in San Francisco.

THE CENTURY'S ADVANCE IN PHYSIOLOGIC PSYCHOLOGY.

The September issue of *Harper's Monthly* contains an article by Dr. H. S. Williams, on "The Century's Progress in Physiological Psychology." There is certainly a large amount of material for such a review, and Dr. Williams appears to have fairly utilized it. We know vastly more than formerly about the functions of the brain, and the latest developments of our knowledge of its anatomy are suggestive in many ways. We have also become able to measure and register our sensations and have reduced some facts thus obtained to their mathematical expression; methods have been improved and a vast store of facts obtained, but after all we are not so very much nearer an understanding of the real nature of our mental action than before. In fact, as Dr. Williams shows, some of our advances are really only experimental verifications of ideas theoretically

advanced many years prior to the beginning of the present century. The quality of mind does not necessarily appear to have improved, though we may know more of its correlated mechanisms. As a popularizer of scientific subjects Dr. Williams is a success, and his paper will open up to a large section of the reading laity a wide range of scientific thought.

EXTRAIESTINAL INFLAMMATORY LESIONS CAUSED BY TYPHOID BACILLUS.

W. T. Howard, Jr.,¹ points out that among the many typhoidal and post-typhoidal inflammatory lesions in various extraintestinal organs, a considerable number are now known to be caused by the bacillus typhosus, either alone or mixed with other bacteria. He reports three cases of this sort, and states that he has been able to collect 144 cases from the literature, in which the typhoid germ was present in inflammatory foci outside of the intestines; in 20 other cases mixed infections were present, making a total of 164. While some of the older cases are open to doubt, in all the recent ones the Widal test was applied, and in consequence the diagnosis is conclusive. The typhoid bacillus is, therefore, a frequent and important cause of the complications and sequelæ of typhoid fever; in some cases it also causes infectious processes without the necessary presence of typical lesions.

THE TESTIMONIAL AND THE MEDICAL PRESS.

A fine line lies between the testimonial to the effectiveness of a remedy that the manufacturer obtains from the physician to aid in selling the product, and the honest report on the utility of a new agent, derived from the painstaking observation of the clinician whose only aim is to assist his fellow-practitioners in arriving at a correct estimate of the remedy. The line of demarcation can not always be discerned in the face of the testimonial, but can invariably be discovered in the professional reputation and standing of the giver. Unhappily the latter can not often be generally known among the 125,000 physicians of the United States. There remains then as a guide for the reader only the character of the medical journal in which the testimonial appears. Unfortunately there are too many journals which sin in this respect, and still more unfortunately the profession in most cases does not closely discriminate between the wheat and the chaff among its periodicals. We should, however, invariably eschew those journals that devote much space to testimonials of whatever kind as to the effectiveness of proprietary remedies. The clean medical journal does not admit to its columns laudatory articles concerning proprietary remedies, and there is no temptation to laud unduly preparations the making of which is open to all pharmacists. If one cares to read such testimonials, he may be sure that the manufacturer will not cease to keep his desk full of reprints of them.

THE ETIOLOGY OF CIRRHOSIS OF THE LIVER.

Hyperplasia of the interstitial connective tissue of the liver, with secondary contraction, results essentially through the agency of irritating influences conveyed

¹ Philadelphia Medical Journal, July, 1899.

to the organ through the portal vein or the hepatic artery, possibly also through the bile-duct. These influences are principally either toxic or bacterial. Of the former, some are derived from without, as alcohol, cad and highly irritating foods. Bacteria may cause cirrhosis in part directly and in part indirectly, through the poisons they generate. Other toxic substances, generated in the intestines as a result of fermentative processes, or resulting from deficient functional activity of certain organs such as the liver, the kidneys, the skin, may also contribute to the development of hepatic cirrhosis. Sometimes no etiologic factor can be determined. As the irritating cause reaches the liver either through the portal vein or through the hepatic artery, the type of the resulting diseases will vary accordingly, with the development on the one hand of the lesions and symptoms of ordinary portal or atrophic cirrhosis, or on the other of biliary or hypertrophic cirrhosis. Cirrhosis of the liver may also arise in consequence of circulatory or biliary stasis, or of the presence in the blood of particles of dust. The most commonly accepted cause of hepatic cirrhosis is alcoholism, but in a discussion of this subject Rolleston¹ contends that alcohol does not induce cirrhosis directly, but rather by leading to the production of sclerogenic poisons or by enabling such poisons to exert their pernicious activity on the liver.

YELLOW FEVER.

No sooner have we realized that the yellow fever is under control at Hampton, Va., than the news is flashed over the United States that it has developed in at least three other localities. And these cases can in no wise be traced to Hampton. One suspected case, fatal, is reported from Knox County, Ind.; others are at Key West and New Orleans. The probability is that all these cases can be traced to Cuba, although but little of the disease seems to be prevailing there. It has been expected, and we have so claimed in these columns, that hereafter hygienic laws would be enforced, and the disease kept out, or at least would be kept under control. We have no reason to change our views. A complete sanitary inspection of the islands can not be made in one season, nor can the requisite hygienic measures be carried out in a few short months. The rigid measures which have been adopted, and which are being extended throughout the islands, will, it may be expected, completely wipe out the disease. The result of the work already done is so evident that still more energetic measures will do the rest. As far as the present outbreak in this country is concerned no fear need be felt. The active measures put forth so quickly after the appearance of the disease, together with the lateness of the season, remove all possibility of its spread. The marine-hospital service, by its action in its management of the outbreak at the Soldiers' Home, and by its energetic work at the present time, shows that this bureau is always on the alert, and prepared to do active work when required. This is necessary so long as there is any disease in any part of Cuba, for, with the greatly increased intercommunication, a rigid quarantine against all the ports is almost an impossibility. It must not be forgotten, also, that the

present epidemic, especially as far as New Orleans is concerned, may have had its origin on the Isthmus of Tehuantepec or at Vera Cruz, where the disease is prevailing.

MICROBES IN MILK.

The question of milk infection has been prominently to the front of late, especially in connection with tuberculosis. It is a matter of some little interest, perhaps, to know that bacteria are pretty generally present in milk, even before it is drawn from healthy cows. Some of the earlier observers who recognized this fact maintained, nevertheless, that these organisms only existed in the lower milk-ducts, the teats and the lower part of the cistern, and that the last milk drawn was sterile; in other words, that the infection was probably from without, in the normal condition. Later observers have not confirmed this view and in the last volume of the "Transactions of the American Microscopical Society," Mr. Archibald Ward reports some tests that appear to be conclusive. Not satisfied with making cultures from the milk drawn under antiseptic precautions, he, in connection with Dr. V. A. Moore, made bacteriologic examinations of the milk from the remoter glandular tissues of the udder, the samples being taken under due precautions immediately after slaughtering the animals. Bits of tissue were also detached with flamed scissors, and transferred to culture-media by the aid of a flamed platinum loop. In the cultures thus obtained it was found that the same organisms frequently occurred in the fore milk and in each of the three parts of the udder, and that in all of the six apparently healthy cows thus examined there were found bacteria in the depths of the milk-secreting tissue. Most of the pure cultures were found to belong to some one of three species of micrococci, and Holmes concludes that these organisms are pretty constant inhabitants, and if reduced in number by one milking, enough are left to produce the original abundance before another. The practical bearing of these findings is obvious. If normal milk is never sterile, it is quite possible that it may not always contain only innocuous species. Indeed, in one cow Ward found a streptococcus rather persistently present, and in another a culture of bacillus prodigious introduced into the milk cistern was detectable for six days. The chances of udder infection from without are numerous, and further study of milk bacteriology at its source is very desirable.

THE ASSOCIATION BUTTON.

After considerable delay, the ASSOCIATION button is now ready. It is in every way attractive, handsome, and above all, appropriate, and for the reason that a large number were ordered at one time, can be sold at the low price of one dollar. It is hoped that every member of the ASSOCIATION will place one of these adornments on the lapel of his coat before the snow flies, and to assist in bringing about this much desired result, an offer is made in our advertising columns. We refer those who are anxious to help build up the ASSOCIATION to the offer there made. It will not be inappropriate to quote from the report regarding this button, made to the ASSOCIATION at Denver a year ago by

¹ Quarterly Medical Journal, 1896, p. 239.

Dr. Richard French Stone. Dr. Stone obtained letters patent for the leading features of the design, which patent he has turned over to the ASSOCIATION. The following is from his report: "We can readily see how the wearing of such means of permanent identification might be of much service in arousing a spirit of fellowship that would be helpful in bringing the members of the ASSOCIATION closer together. It would serve to fix attention and direct thought to the interest of the ASSOCIATION during the intervals between the annual meetings, and would prove suggestive of matters pertaining to its growth and development. To meet this requirement I herewith send you for consideration and adoption what is believed to be an appropriate gold and enamel finished emblem. Please observe that the device is in the form of a circular shield, having for its central feature a spear-pointed cross, opposite to the arms of which are the initial letters of 'Member of the American Medical Association.' The circular shield and spear-pointed cross typify the protective armor of the period in which medicine had its origin. The cruciform center not only typifies the great advancement of the profession during the Christian era, but was also the ideographic sign or symbol of life and of the 'Healing Art' in ancient Egypt, Greece, Rome and other nations of the greatest antiquity. The initial letters and the enameled national colors (red, white and blue), sufficiently symbolize the nationality of our ASSOCIATION. For these reasons it is believed that the design represents the origin, history, traditions and province of our profession, as well as the national character of our organization in the fullest sense, and that the emblem constantly worn as an ornate coat-lapel button (or scarf-pin), will serve at all times and on all occasions throughout the world as a distinctive method of social and professional recognition, thus securing the many advantages resulting from this identity."

SANARELLI'S AUTOBIOGRAPHY.

One of the enterprising New York dailies had in its last Sunday's edition a history of the alleged discovery of the yellow-fever bacillus, written by the discoverer himself, Sanarelli. While it is hard to believe that any one, much less a true scientist, would write in such a self-laudatory style, still we are compelled to believe this in this instance, for the article is introduced with an editorial statement to the effect that it "was written by Prof. Giuseppe Sanarelli, and it may be considered the first authentic autobiographic statement made by the discoverer of the bacillus of yellow fever." The writer states that he was born at Monte, Sept. 20, 1865, and that after preparatory studies, he entered the University of Siena, that his graduation thesis had for its subject the etiology and pathogenesis of morose infection, "which thesis I am proud to say was afterward printed and published at the expense of the government." Sanarelli then tells us that after his graduation in 1889 he went to Pavia to study under the "famous Professor Golgi," then to Munich, and from there to Paris. During this time he published many valuable monographs "which are well known to all students of bacteriology." He tells us that his rise was now rapid, for at 29 he was called to the chair of hygiene in the University of Siena, and soon afterward, in 1895, he was

invited to the University of Montevideo, Uruguay." "And let me here say that, if I left a brilliant position and still more brilliant career in my mother country to accept the invitation of the Montevideo University, it was because I hoped in the new world to face and grapple the great problem of exotic pathology, which had occupied and tormented me for a long time—the problem of yellow fever." He then refers in a half sneering way to Drs. Sternberg and Friere's long-continued efforts to discover the germ of yellow fever. Speaking of the former, he says: "At the end of ten years of labor he declared his mission accomplished and published a minute and detailed report, which resulted in showing failure and insuccess." Of Friere's labors he says: "he was compelled to publish a report devoid of all scientific interest or importance." Then the writer tells the world what brilliant work he did in a short time: how in June, 1897, he communicated his discovery to the scientific world, and how his success created great surprise, and caused many to be incredulous. And so on. He closes his communication by stating that he rejoices to learn that the United States, after an excessive period of inactivity, is commencing to do something toward emancipating itself from that dread scourge. "My personal satisfaction is great, for this awakening and consequent acting will save me from the fate of the majority of the scientists of my country—the fate of recognition and justice after death." The whole article reads so much like the writings of a quack that we feel loath to believe that it is really printed as Sanarelli wrote it. The great big "I" and little "u," the self-praise, the conceited references to his own work, not only in the investigation of yellow fever—for he claims to have revolutionized the views held as to the etiology and pathogenesis of other diseases, especially typhoid—and the sneering supercilious manner in which he alludes to others, make one feel like pitying him. If a young man only 34 years old had accomplished all and more than Sanarelli claims to have accomplished he could only lower his reputation by such self-praise. Allowing for a certain foreign ignorance of American ideas of propriety, this effusion still leaves behind it a rather unpleasant impression of his personality.

Medical News.

DR. JOHN T. MANGE of Baltimore has been elected chief of the gynecologic clinic of the Baltimore University School of Medicine.

THE GOVERNMENT hospital ship *Relief* has been condemned by the local inspector of steam vessels at San Francisco. The vessel was pronounced unsafe for ocean travel.

THE APPEARANCE of yellow fever in New Orleans, it is said, is reviving the rigid quarantine regulations which have caused in the past so much disturbance of business and other matters in the South. However, only two cases have thus far been definitely reported, with one death.

MRS. MARY SANSONI, a leper, who has offered those interested in leprosy a chance to study the disease, died in Baltimore last Tuesday, aged 32. She had been isolated in a hospital in Baltimore for two years.

LATEST reports are to the effect that yellow fever is spreading at Key West. Five deaths have occurred.

DR. A. T. HAIGHT, Chicago, has just returned from Europe. He attended the International Otological Congress and read a paper before that body.

MUNCIE, IND., has no hospital, but the physicians and the public-spirited citizens there are agitating the question of building one, and it is hoped that the city council will act in the matter and either build or assist in building one.

NEWS by way of Madrid states that one case of the plague has developed in the prison at Oporto. Much uneasiness exists at the infected place relative to the sanitary cordon maintained, and already one of the guards has been shot from ambush.

ON SATURDAY, September 2, the Chicago Lying-In Hospital, 294 Ashland Ave., opened its doors to the public. Emergency cases from any part of the city are received there at any time. The president of the Association, having the institution in charge, is Mrs. E. C. Dudley, 1619 Indiana Ave.

THE PORTUGUESE steamer *Oceunum*, from Oporto, Lisbon and St. Michaels arrived in New York on September 1, having on board ten cabin and fourteen steerage passengers. Owing to the existence of the bubonic plague at Oporto the vessel was ordered to the quarantine station for disinfection.

THE FOUNDATIONS are being laid for the construction of a new annex to the Isabella McCosh Infirmary of Princeton College. The building will be three stories high, and constructed of limestone and brick. It will be used for contagious diseases. When completed the additions will have cost about \$20,000.

PROF. WILLIAM F. SMITH has resigned the chair of anatomy in the College of Physicians and Surgeons, Baltimore, on account of ill-health. Dr. Isaac R. Trimble has been elected to fill the vacancy. For some years Dr. Trimble has held the chair of anatomy and clinical surgery at the Woman's Medical College.

ANOTHER death attributed to Christian Science treatment has occurred in Seranton, Pa. Death is said to be due to cholera infantum, and the mother, being a Christian Scientist, refused to call a physician. The funeral was announced to have taken place on August 27, but the services were prevented by the coroner, who ordered an investigation made.

It is reported that Dr. Andrew von Grimm, adjunct professor of diseases of children at the Post-Graduate Hospital of New York, while recently performing an operation on a child suffering from diphtheria had the misfortune to be severely bitten on the finger, from which septicemia subsequently developed, and at last accounts his condition was pronounced serious.

THE MEMBERS of the Andrew G. Curtin Association of Army Nurses held a meeting in Philadelphia on August 28, to take some action relative to the entertainment to be given the members of the National Association of Army Nurses of the Civil War, and who were to be in attendance at the G. A. R. encampment held in that city. A tablet will be erected at Fernwood Cemetery in memory of deceased members.

JUDGE GAMBLE of Iowa who recently delivered a decision in the case of a traveling practitioner, that the Medical Practice Act of the State was unconstitutional, has sent his opinion to the State Board of Health. He bases his opinion on certain New Hampshire cases, and declares the law class legislation. The attorney-gen-

eral, it is said, maintains the validity of the act and the supreme court will have to make the final decision.

ALTHOUGH the city of Philadelphia and other cities of Pennsylvania have dispatched a vessel laden with supplies to the distressed of Porto Rico, which has been fitted out at a cost of thousands of dollars, it is now proposed that another similar one be sent to that country. Already contributions are pouring in, the latest being a gift of \$1000 by the citizens of Erie. The sum now on hand amounts to \$30,243.21.

IT IS SAID that the Illinois Society for the Prevention of Consumption is preparing plans for the establishment of a state sanatorium for the treatment of this disease, and a bill will be introduced into the next legislature for an appropriation for this purpose. The movement, it is said, has the support of Governor Tanner, and the forthcoming report of the State Board of Health will give the facts of the needs of the State of Illinois in this direction.

ACCORDING to the *San Francisco Examiner*, Dr. Alonzo Taylor of the University of Pennsylvania, will become the head of the Department of Medicine in the Affiliated Colleges of the California State University. Dr. Taylor, it is said, will make a special study of the requirements of the medical department as to equipments, etc., and will then go to Europe and spend some time in gaining ideas and facts from the best German universities.

JOSEPH FUNK, a resident of Philadelphia, has secured a writ of habeas corpus against the attending physician to the Municipal Hospital of that city to show cause why his two children, suffering with scarlet fever, who he avers were removed from his house without his consent and against his will, should not be taken away from that institution. Judge Pennypacker, who granted the writ, made it returnable on Friday, September 8, when the complaint was to be heard in open court.

BY ORDER of Surgeon Anita N. McGee, in charge of the army nurses, instructions have been issued regarding the kind of uniform to be worn by them. The uniform consists of a waist with adjustable cuffs, and an apron of white linen, worn with a skirt and necktie of army blue galatea. A jacket of the galatea style is also provided. Caps are not to be worn. Chief nurses are entitled to wear in place of the apron a sash of red silk, knotted around the waist. The badge of the nurses' corps consists of a modified form of Greek cross.

ON AUGUST 29 the coroner's jury in the inquest into the death of James McGuire, a paretic patient in the Manhattan State Hospital for the Insane, on Ward's Island, rendered a verdict to the effect that his death was caused by undue violence at the hands of three attendants. The coroner committed the three men to the Tombs, to await the action of the grand jury, while another attendant was sent to the House of Detention as a witness. In view of the medical testimony presented at the inquest this action certainly seems unnecessarily harsh, but at the same time it is only proper that every case of this kind shall receive a very thorough investigation.

A SLIGHT epidemic of anthrax among cattle has appeared in southern Chester County, Pa. In one herd five cattle have died. The disease has also appeared in the region of Chambersburg, four cattle and two horses having died within the past few days. It is now feared that one of the owners of the cattle may have been inoculated with anthrax while burying an animal affected

with the disease, for at present he manifests symptoms of the disease and his condition is serious. An epidemic disease, the cause of which is as yet unknown, also exists near Allentown, Pa. Among a herd of 200 Jersey cattle belonging to one farmer, 70 afflicted animals have died. In some respects the affection is said to resemble anthrax.

AN INSTITUTION peculiar to Philadelphia is The Philadelphia Medical Corps. Organized in 1887, it did excellent service in connection with the centennial celebration of the constitution. It has its volunteer surgeons on hand at every great gathering to do gratuitous service when called on in an emergency. During the Peace parades last year its services were especially noticed. At the Grand Army Reunion, held during the past week, the value of this organization was to be again tested. It is a purely philanthropic organization, receives no rewards and asks no aid except occasionally calling on a bystander for help in special cases. It is, therefore, a credit to the city and one that should be duly appreciated.

THE "CHRISTIAN SCIENTISTS" held a meeting in Jersey City recently and, according to the *Buffalo Medical Journal*, some remarkable cures were reported. One of these was vouched for by an old woman, who, prefacing her remarks with a statement of her undying belief in the efficacy of prayer, said she knew a man in Texas who had spilled acid in his eyes. The eyeballs were so badly injured that both were removed by surgeons. The owner of the eyeless sockets became a believer and by means of prayer new eyeballs grew, and now the man can see as well as anyone. No wonder these people get patients, when they can perform such remarkable feats. We are patiently waiting for the raising-of-the-dead report.

A CURIOUS fact is reported by the *Medical Press and Circular* in regard to the assault on M. Labori, Dreyfus' counsel. He was in charge of Dr. Réclus, a distinguished French surgeon, who was called by the family. Among those who shared in the excitement on the night of the attempted assassination was M. Doyen, another prominent French surgeon, who immediately seized his instruments and took the next train for Rennes and succeeded in obtaining an interview with the patient, which, it is said, was not allowed to take a professional turn, though in taking leave "he placed himself at the patient's disposal." The action has stirred up an ethical controversy in which, it is said, Dr. Réclus very emphatically expressed his opinion.

ACCORDING to the official report of Surgeon-General Wyman, pilgrims returning from Mecca have been attacked by bubonic plague, which is said to have been due to inexcusable negligence of taking even the ordinary precautions against the disease. It is said that the danger of the spread of contagion is especially great at the second annual pilgrimage, because those who return must first undergo examination at the quarantine stations. In order to evade these requirements many of them escape into the surrounding countries, thus conveying the disease in all directions. It is further stated that on board a vessel loaded with 1200 pilgrims there recently occurred four deaths, which were unmistakably due to bubonic plague. The Turkish health authorities are much afraid that the disease will be carried to many districts by rats and vermin, hordes of which swarm around the vessels of the carrying trade. The plague now exists in the following different countries: Japan, China, Egypt, India, Persia, Turkey and Portugal.

MEDICAL STUDENTS ACCUSED OF PRACTICING FRAUD.—*The Philadelphia Press*, in its issue of September 3, contains an accusation which if proved to be true will react very unfavorably on the candidates who recently passed the examination prescribed by the Board of Medical Examiners of Pennsylvania. This paper charges on information furnished it that the students of at least two of the medical colleges of Philadelphia had been provided with all the questions asked by the Board previous to the examinations. It is not definitely known as to how the questions were obtained, but the idea is hinted at that the sum of \$500 was placed in the hands of the printer at Harrisburg, and that the questions were then transferred to probably one of the students, representing a clique, to be subsequently sold to the candidates intending to present themselves before the State Board of Medical Examiners. It is charged further that these questions were circulated widely. A recent graduate in medicine—whose name is not given—stated that papers containing the whole set of questions were offered him for \$2.50.

Correspondence.

Inebriety a Disease.

HARTFORD, CONN., Aug. 26, 1899.

To the Editor:—The question of vice and disease in inebriety was first agitated in this country by Dr. Rush of Philadelphia, in 1809. He asserted that all inebriety should be regarded and treated as disease. This was called a wild, infidel theory. In 1829, Dr. Todd secured the passage of a resolution in the Connecticut State Medical Society, declaring inebriety a disease requiring medical treatment. This was termed rank heresy and so bitterly denounced that nothing more was heard of it. In 1854, Dr. Turner's project of an asylum for the medical treatment of inebriates as diseased, roused a more severe criticism. This continued with varying intensity until 1870. At this time the Association for the Study and Cure of Inebriety was organized, and its declaration of principles pronounced inebriety a disease, and curable. The religious press denied this with great bitterness, and denounced the Association and its members as enemies of truth. The medical press followed with sneers and contemptuous silence. Even the temperance advocates joined in denying the disease theory. These extreme criticisms and denials of disease finally reacted into a half vice and half disease theory, which is urged by many persons up to the present.

The publication of the *Journal of Inebriety*, in 1876, was the occasion for a new outbreak of most acrimonious criticism. For several years the *Journal* and its writers received, with each issue, what was intended to be a destructive criticism and condemnation of its purpose and work. As chairman of a committee appointed by the Association I personally urged the leading opponents of the disease theory to present the evidence of the vice origin of inebriety in a scientific form for publication in the *Journal*. Beyond a few dogmatic statements of opinions, nothing was offered, while on the other side over fifty physicians presented the history of cases and studies of the various physical conditions and causes of the disease of inebriety. For over twelve years many facts were grouped and examined in the issues of the *Journal*, and in other publications. The conclusions were so unanimous that further discussion was useless. Hence, from 1890, little attention has been given to the former denials and assertions of the vice origin of inebriety. Yet moralists, clergymen, and occasionally a sadly belated physician, refer to the topic again as if it was new, and the advocates of the disease of inebriety were all ignorant extremists. They are unaware that all these theories and opinions

have been settled by an appeal to the facts, and the question is, what are the teachings of these facts, not the opinions of the advocate? This is a curious repetition of the same criticism which has followed the recognition of the disease of insanity. Six years ago a noted divine denounced the physical origin of insanity, and declared that vice and wickedness were the most common causes. Less than three years ago a physician urged that the insane were pampered and made worse by luxuries, and that insanity was more vice than disease, and that harsh remedies were the true means of treatment. By some persons inebriety is regarded, in the same way, as a vicious indulgence of the appetites, which can be checked at any time. Fortunately the questions of acts and conduct are not settled by theories and opinions. The study of the inebriate is a question of facts and their meaning, which every year is clearer and can be determined with more exactness. If there is a case of vice origin in any inebriate it can be proven with a great degree of certainty, and the *Journal of Inebriety* will gladly publish all such records. They will be new to the scientific world.

T. D. CROTHERS, M.D.

The Neurotic's Diet.

NEW YORK CITY, Aug. 31, 1899.

To the Editor:—The article entitled, "The Neurotic's Diet," by Henry C. Eyman, M.D., is good reading, and I shall reproduce it with due credit in the *Dietetic and Hygienic Gazette*. Dr. Eyman says: "There is no doubt of the efficacy of raw meat, dry bread and hot water, exclusively in the very common acid dyspeptic states, while plethoric individuals with irritated kidneys and the neuralgic twinges of the uric acid condition, will just as surely obtain relief by the use of farinaceous food and nuts."

Who uses raw beef when he can obtain it cooked? What physician is foolish enough to prescribe a food uncooked, unpalatable, not in a condition for digestion and liable to provoke the presence of tapeworm in the body? Occasionally I come across this statement of the use of raw beef; physicians also ask, "how do you get your patients to eat raw beef?" The reply is that I never ask them to, but, when it is necessary to feed a patient closely on beef preparations, I have them broiled and palatable. I understand that in some of the European sanatoria inmates are stuffed with raw beef; this is hard treatment and unnecessary. Are any American physicians doing it?

As to "plethoric individuals with irritated kidneys and the neuralgic twinges of the uric acid condition," I have found such to do better on beef foods with the careful admixture of other foods, watching the blood and urine under the microscope.

Yours fraternally,

JOHN A. CUTTER, M.D.

London.

(From Our Regular Correspondent.)

LONDON, Aug. 22, 1899.

THE OTOLOGICAL CONGRESS.—This congress held in London the past week, under the presidency of Dr. Urban Prichard, had a most successful meeting, 300 aurists from all over the world, having been in attendance. Such names as Politzer Knapp, Hartman, Luc, Macewen, Malherbe, adorned the program, and so great was the pressure of papers that extra sessions had to be held to accommodate them all. Many of the foreign delegates came the week before and attended the British Medical Association at Portsmouth. The social side of the gathering was most elaborate; congratulations were sent to the Queen, and the festivities closed with a visit to Windsor and an entertainment on the prettiest part of the River Thames, by Dr. Field.

One of the most amusing things about the Congress was the frank and outspoken astonishment of the lay press that such

a large body of scientists could assemble from such remote distances, merely to discuss such a limited subject as diseases of the ear. The newspapers were never tired of referring to "Specialism Ultraspecialized," and wondering more or less openly and naively how the members were going to fill up their time in session. As the frank and innocent *Daily Chronicle* expressed it: "To the mere layman it is almost incredible that diseases of the ear should command the minute attention of a holiday-making crowd of highly cultured gentlemen addressing each other in all the languages of Europe for six hours a day during an entire week!" The superbly sesquipedalian terminology of the science impressed them hugely, chiefly because it was hopeless to attempt to understand it, and they noted with awe that all this prodigious accumulation of learning has been created within the past fifty years. Perhaps there was some show of reason for their astonishment, as it must be confessed that this new branch of the medical art, hopeful and valuable as its work has been, has so far not yet made itself illustrious to the popular eye by its practical triumphs.

There was a singular dearth of specially striking papers read on new discoveries announced during the session although the general standard of the communications was high and the discussions were most animated. The chief advances noted by the president in his address were in prophylaxis of chronic middle-ear trouble and greater mastering of suppurative otitis, especially with reference to preventing cranial complications. Hartman, at Berlin, reported two interesting cases of congenital absence of the external meatus and one acquired atresia of the meatus resulting from post-scarlatinal suppuration. The entire morning was given up to a discussion on the always exciting and somewhat venerable question of when to open the mastoid in chronic suppurative otitis media; an operation which is claimed by the general surgeon nowadays as belonging to his sphere. The museum was superb, the British section alone containing over 2000 preparations.

CONTROL OF OYSTER BEDS.—The failure of Mr. Chaplin's excellent bill for the control of oyster beds is a source of much regret to the English profession and to sanitarians generally. It came by its death in that belated survival of the Middle Ages, analogous to our intelligent and disinterested Senate, the House of Lords. The report of the now famous commission on oysters as a cause of disease was clear and urgent enough to secure for the bill a large majority in the House of Commons, but of course had little weight. It was killed by an amendment which referred its carrying out to a board of fisheries which has no jurisdiction over nearly half the areas in which beds are laid in the kingdom and these areas the most liable of all to pollution by sewage.

PROFESSOR OGSTON'S INDICTMENT OF THE ARMY AND NAVY.—The bold and vigorous indictment of the army and navy authorities for their contemptuous treatment and inadequate provision for the medical staff, by Professor Ogston, in his address in Surgery at Portsmouth, is still being widely commented on. Indeed, the unfavorable impression produced by it is both widening and deepening as the controversy goes on, and it really looks as if the sluggish authorities would have to take action in the matter and that speedily.

UN SOUND TEETH AND THE ARMY RECRUIT.—The announcement that over seventeen hundred English recruits were rejected on account of the condition of their teeth sounds appalling, until we discover upon inquiry that this apparently large number was the residuum of nearly 80,000 examinations, or barely 2 per cent. of the men examined. And as it only takes three badly decayed or missing teeth to disqualify a recruit, the bubble of physical degeneracy, so far as this proof of it goes, collapses into its constituent thin air and froth. We have long been most suspicious of the popularly accepted dictum, that our modern teeth are degenerate and degenerating. It is one of those pseudoscientific conclusions which sound well, harmonize with all our traditional nonsense—dating from the glacial epoch—about "these degenerate days" and man's fallen estate, and hence appeal powerfully to the popular mind.

Canada.

(From Our Regular Correspondent.)

TORONTO, Sept. 3, 1899.

CANADIAN MEDICAL ASSOCIATION.—The largest, the most enthusiastic, and the most profitable meeting ever held in the history of this organization was that which after "three days of solid enjoyment" closed its final session at 1 o'clock on Saturday morning. Contrasting the numerical representation with that assembled in the city of Quebec last year, over three times as many delegates were present at this year's meeting as at the last annual assemblage. From the moment Dr. A. J. Johnson, chairman of the committee on arrangements, announced the entertainments that the committee under charge of Dr. Bruce L. Riordan had arranged for the enjoyment of out-of-town members, the visitors completely abandoned themselves to a pleasurable participation in the several functions. On the evening of the first day, the beautiful halls and apartments of the museum of the Normal School were thrown open; a fashionable company soon surged and thronged through its magnificently spacious compartments, invitations having been extended to many of the city's best-known families. A musicale and reception was held in the theater, presided over by the chairman of the committee on arrangements. In his usual eloquent and brilliant style, Dr. G. W. Ross, Minister of Education of Ontario, welcomed the members and their friends to those time-honored and classic halls; in the name also of the Ontario Government, of which he is an acknowledged leader, he welcomed the representatives from the other provinces of the confederation and spoke of the mighty factor for good the physician was in the community. Mr. Cameron, president of the Association, made a particularly happy acknowledgement.

The afternoon of the second day was close and oppressive, which proved a decided incentive to a pleasant sail across Toronto Bay to the island home of the Royal Canadian Yacht Club. On one of their extensive lawns, a marquee had been erected, within whose shady bower, seats and tables were tastefully arranged, for the enjoyment of those good things, cool and nice and dainty. The city's "society" physicians and their ladies contributed to making this function very successful. The city fathers also showed their hospitality and good cheer. The steamer *Chippewa* was chartered by the City Council and an enjoyable sail around the island and out into the lake on the evening of Thursday was greatly appreciated by members from a distance. About 9:30 the vessel stood off at anchor from the grounds of the Industrial Exposition, where a magnificent view was afforded of the nightly fireworks and the battle of Omdurman. On the afternoon of Friday, the directors of the exhibition invited the various committees and the officers and visiting members from the other provinces and the United States to luncheon; and all the members of the Association and their wives and lady friends, together with the delegates from abroad were given free passes to the grounds, with reserved seats on the grand-stand, where a delightful performance in the ring, with both running and trotting races, caused the profession to forget sorrow and the heavy work of the morning session. The Toronto Golf Club also extended its hospitality to the members.

The splendid array of pathologic specimens reflected deserved credit on the chairman of that department, Dr. A. Primrose, Toronto. Trinity Medical College, the Medical Department of Toronto University, McGill University and private members loaned specimens which proved instructing and interesting.

JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION.—On all sides were heard expressions of pleased surprise at the commendable enterprise displayed on the part of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION in having a copy of its issue of Saturday, September 2, containing a telegraphic report of the first day's proceedings, placed in the hands of each member of the Association present at the beginning of the morning session of the third day, September 1.

DOMINION REGISTRATION.—On the third day Dr. Roddick dealt in detail with a Dominion federated council. Each province is to be represented on the central board by three members. The committee recommended this plan of giving equal representation rather than the plan of representation by population. All the provinces are to retain their present systems, their respective medical councils not being interfered with in any way whatsoever. Should a physician become licensed to practice, for instance, in the Province of Ontario, he needs no other license so long as he desires to continue in that province; but should he desire to have the privilege of practicing in any other province of the Dominion, he must obtain his authority to do so from the central licensing board, to be situated presumably at Ottawa, the capital of the Dominion of Canada. All practitioners in any province of the Dominion, who have held their licenses to practice for at least ten years, may at any time after the adoption of this scheme by the Parliament of Canada, present themselves before this board and obtain licenses to practice in any province of the Dominion; but should a physician only be in practice, say for seven years, he will have to wait three more years before he can obtain such a license. This seemingly retroactive clause applies to present licentiates. The bugbear in the whole matter seems to be the standard of the preliminary education, delegates from some of the provinces being afraid that the standard of the central body might not be high enough.

THE BRAIN OF MURDERER PARBOTT.—Before giving the notes on the examination of the brain of this matricide, a short resumé of the case may be in order. Aged 32, by occupation a carter, this man was tried at the last assizes in Hamilton for the murder of his mother, who had been dispatched with an axe in the hands of the accused. At the trial, the plea of insanity was set up and Dr. Russell and Dr. Daniel Clark, of the Hamilton and Toronto Asylums, respectively, were summoned to examine the patient and report, on behalf of the defense. Dr. Russell states that he found the prisoner of a low intellectual order, his normal sense being of a still baser grade. At first he denied all recollection of the deed, but subsequently confessed and told the two experts all about it. He said he should have done the deed long ago, and spoke brutally of his mother. He said he had been a hard drinker for years and was drunk the day the murder was committed. On June 23 last, he was hanged, and his body was given over to the jail surgeons, Dr. Balfe and Dr. Wallace of the Hamilton Asylum for the purpose of a post-mortem. He weighed 160 pounds and was 5 feet 8 inches in height. The tips of the fingers could be thrust into the interval in the broken neck. The scalp was abnormally thick; calvaria also thicker than the average, being slightly asymmetrical in the occipital region. There was no difficulty in separating it from the dura. The Pacchionian bodies were very numerous and very adherent. Over the parietal regions, the pia was noticeably milky in appearance and when the brain was being lifted from its position, posteriorly, the medulla and the pons and adjacent parts were seen to be of a deep red color, there being quite an extensive extravasation of blood. The spinal cord was torn through about two inches below the lower margin of the pons, being attached to the nether portion by the pia mater alone. On passing the finger through the foramen magnum, the atlas was in its proper position, while the axis was with the lower part of the column and the odontoid process intact upon it. With the finger still in the foramen, no fracture of bone could be detected, the gap being due to the separation of the vertebrae. The brain weighed fifty ounces, and the convolutions were broader than the average. Section of the brain was perfectly normal and healthy in every respect macroscopically. The pupils were equal, about half way between extreme dilatation and contraction.

SKIN CLINIC AT ST. MICHAEL'S HOSPITAL.—The skin clinic at St. Michael's Hospital at 9 o'clock on the morning of the sec-

and day, was an important feature of the meeting, and was well attended. Refreshments were served, and the members of the Association present spent a very pleasant and profitable hour examining the patients. There were about thirty cases shown, and among them were several rare skin diseases, such as dermatitis herpetiformis, larva migrans, articular pigmentosa, hydrocystoma, hydradenitis, favus, molluscum contagiosum, exfoliative dermatitis following psoriasis. Drs. A. R. Robinson of New York, Shepherd of Montreal, and Graham Chambers and A. McPheeran of Toronto took part in the discussion of the cases.

TUBERCULOSIS CONTINUED.—Supplementing the information already given in the *JOURNAL* of August 26, p. 560, regarding the attention the profession in Canada is bestowing on this subject, some mention ought to be made of two able articles emanating from the respective pens of Dr. A. D. Blackader, Montreal, and Dr. H. McL. Kinghorn, Saranac Lake, N. Y., both published in a recent issue of the *Montreal Medical Journal*. The article by the first-named gentleman, "On the Treatment of Tuberculosis," gives a historic account of the open-air method of treatment, deals with tuberculin and specific immunity, and mentions experiments of Maragliano of Genoa, Paquin of St. Louis and Stubbert, at the Loomis Sanitarium, with serumtherapy. And further, diet, cod-liver oil, hydrotherapeutic measures, strychnin, creosote and ichthol in keratin coated pills, in daily doses of from 6 to 10 grs., all receive ample attention. Reverting to chest protectors, the essayist quotes Ransome, who asserts that the best procedure in this direction is douching the chest well, night and morning, with cold salt water. "The Results of Sanatoria and Special Hospital Treatment in Pulmonary Tuberculosis," are dealt with by Dr. Kinghorn for the special benefit of Canadian readers. After dwelling for some length on the cases denominated "cured," "apparently cured," "disease arrested," and "improved," the writer gives in tabulated form, the statistics of nine sanatoria for the treatment of pulmonary tuberculosis. In this table, the Gravenhurst Institution, Muskoka, where up to that time the mortality had been *nil* or not given, the "cured" is represented by 14.45 per cent, the "disease arrested" by 27.7 per cent., the "improved" by 34.93 per cent., and the "unimproved" not given. The article concludes with a table, on "Two Hundred and Three Patients who Remained in the Adirondack Cottage Sanitarium, an Average Time of Nine Months." In the August number of the *Dominion Medical Monthly*, three important points are mentioned in an editorial article on this subject: 1, the employment of a rubber "sanitary" pocket, so constructed as to fit into the inside pocket of the patient's coat, serving as a receptacle for handkerchiefs, used for the sputum of the afflicted; 2, the formation of a national society, for the propagation of information concerning tuberculosis and the necessary means to employ to stay its ravages—with provincial and county branches, on the lines of that promulgated by Sir William Broadbent in England, and presided over by H.R.H. the Prince of Wales; and 3, trephining in tubercular meningitis, incising the dura mater, admitting air to the subdural space—and, if need be, the employment of medicated injections therein. Just to hand is the July report of the Provincial Board of Health of Ontario. This shows a slight increase in death-rate over the average of the last three or four years. The total number of deaths reported is 1643 and the death-rate is 9.3 per 1000. For June the number was 1521, the death-rate, 9 per 1000. The total number of deaths from contagious diseases was 230, 6 more than in July, 1898, and 17 more than in June of this year. Scarlatina registers 7, diphtheria 20, measles 4, whooping-cough 6, typhoid 15, while consumption shows a marked increase; 178 deaths were registered from the "white plague" alone, which is the rate of 1 per 1000. In July, 1898, deaths from consumption were 143, 0.9 per 1000.

NOTES.

Dr. N. E. McKay, Halifax, N. S., has received an appoint-

ment on the faculty of the Halifax Medical College. He will be lecturer on surgery and professor of clinical and operative surgery. . . . Surgeon-Lieut.-Col. J. L. H. Neilson has been appointed director-general of the Canadian militia army medical services. . . . Dr. Oronhyatekha, Supreme Chief Ranger, I. O. F. Toronto, and Dr. Thomas Millman, medical officer of the same institution, have been elected to the positions of president of the National Fraternal Congress and vice-chairman of the medical section thereof, respectively. . . . Dr. P. H. Bryce, Secretary of the Provincial Board of Health for Ontario has just returned from a trip to Muskoka. He states the hotels up there are now in fine sanitary shape and that not a single case of typhoid fever has been reported there this season, which is altogether unusual.

Book Notices.

TREATMENT OF PELVIC INFLAMMATION THROUGH THE VAGINA. By WM. R. PRYOR, M.D. Professor of Gynecology, New York Polytechnic; Consulting Surgeon, City Charity Hospital; Visiting Surgeon St. Elizabeth Hospital, New York City. With 110 illustrations. Price, \$2.00, net. Philadelphia, W. B. Saunders, 1899.

As the title indicates, the author has not attempted to cover even a small part of the gynecologic field, but that which is covered is done thoroughly. The inflammatory diseases of the pelvis are the cause of the major portion of the suffering of women, and the importance of right treatment can not be too much emphasized. The spirit predominant throughout the work, as the author acknowledges, is that of an aggressive interference, yet the radicalism does not go beyond what is dictated by sound reasoning. The ultraconservative gynecologist even will find much to aid him in his methods of treatment, for while the author is emphatic in urging radical treatment when indicated, the milder methods are fully given. The book is distinctly original, and is intended to reflect the author's views, and his only. "The views and methods of others can readily be procured from the medical press," as the author informs us. The book is well illustrated and will be found of great practical value, not only to the operator, but also to those who confine themselves to the more simple or palliative measures.

TWENTIETH CENTURY PRACTICE. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In Twenty Volumes. Volume XVI. Infectious Diseases. New York: William Wood & Co. 1899.

This slightly belated volume of this valuable series contains a number of important articles by authors whose names alone are a guarantee of the worth of their contributions. Chief among these may be noticed: "Lobar Pneumonia," by Dr. Andrew H. Smith; "Cerebrospinal Meningitis," by Dr. Netter of Paris; "Inflammation," by Prof. Ziegler of Freiburg; "Relapsing Fever," by Prof. Popoff of St. Petersburg, and the two on "Typhoid Fever," by Drs. Thacher and Brauman of New York. Tropical medicine is represented in the articles on "Yaws," by Dr. Nicholls of Dominica, W. I., and that on "Dysentery" is by Dr. Sodré of Rio Janeiro. All the articles are monographic and give the latest accepted views on their respective subjects, of course, in some cases tinged by the author's own predilections on certain disputed points. This, however, does not detract from their general value, and the volume is one that will rank well in the series.

LES POSSES VISCERALES (ESTOMAC-INTESTIN-REIN-FOIE-RATE) DIAGNOSTIC ET NOSOGRAPHIE (ENTEROPOSES-HEPATITES). Par FRANTZ GLENARD, (The Visceral Poses, Etc.). Avec 224 figures et 30 tableaux synoptiques. Paris: F. Alcan. 1899.

The theme of this bulky volume is the derangements characterized by displacement of the abdominal viscera, which the author remotely attributes to hepatic derangement and creates a new diathesis, that of "hepatitis," a condition in his opin-

ion responsible for a large number of nutritional disorders. The arguments in favor of the author's views are given at great length, and are based, as he claims, on the study of over ten thousand cases, all of the same pathologic family.

THE MECHANICS OF SURGERY, comprising Detailed Descriptions, Illustrations and Lists of the Instruments, Appliances and Furniture necessary in Modern Surgical Art. By Charles Truax. Chicago: 1899. Price \$4.50.

Mr. Truax has attempted something in this book that is unique, to say the least, and he has done his work well. The task of giving us such a work as is attempted in this volume is a very hard one, for the reason that the author does not pretend to be a surgeon, and yet has quite often to give advice which is not supposed to come from any one but a surgeon. The position which he occupies, and from which he writes, is that of a manufacturer of instruments, and he lays no claim to anything further. He has carefully avoided, therefore, stepping over the boundary, although at times he seems to have gotten very close to the edge.

Each branch is taken up and instruments are grouped under the particular department to which each belongs. The opening chapter is on the history of instruments, which is followed by one on the construction of surgical instruments, and in this the subject is treated in a general manner. Then follows a chapter of the care of instruments, in which he is given advice that is serviceable as far as it goes, but it is disappointing in that so little is said about the minor details in the care of instruments. However, this omission is met in different places in the book where hints are given for the care of special instruments.

Not only are hints given as to the care but also how to select the right instrument for the purpose in hand, and in this part of the work comes its great value. Taking up the subject of thermometers, for instance, the physician will find in paragraphs devoted to this instrument some very practical information that will be found useful. He calls attention to the advantage of knowing how long it takes the thermometer to register, so that time may not be unnecessarily wasted in securing the proper temperature. Different instruments take different lengths of time. An instrument that will register the maximum degree of heat in one minute is preferable to one requiring five minutes. The author calls attention, however, to the fact that in getting these thermometers that register in a minute it requires that the bulb be very thin and consequently more breakable. The time required for a thermometer to register the maximum temperature must depend on the shape of the bulb, the quantity of mercury and the thickness of the glass forming its walls. It is, he says, very important that physicians should know the time requisite for each thermometer to register, and to obtain this he makes a suggestion. This is that on receiving a thermometer, it be tested by immersion in water at about the normal body temperature—say for five minutes. After shaking down the mercury, it should be tested for four minutes. If the temperature is found the same after this test, it should be again tested for three minutes. If this reaches the same result, it may be tested for two minutes, and so on until a test is made in which the maximum temperature is not reached. The shortest time, then, in which the proper temperature is secured should be selected for each registration, and if accurately timed in all cases the physician will be content to secure perfect results.

Such hints as he gives in reference to thermometers may be found in reference to other instruments in various chapters of the book; and those who want to know how to select good instruments and how to take care of them when they have them, will find many helpful hints.

The chapter on "Prosthetic Surgery," which comes at the end of the book, is one of the most valuable, and is a subject that has been well handled by the author, who speaks from experience.

We can not help but congratulate the author on the success he has made, and we are sure that those who procure the volume will feel that they are well repaid in the amount of information contained therein.

Deaths and Obituaries.

WALTER T. ADAIR, M.D., for fifteen years superintendent of the Cherokee Orphan Asylum and the Cherokee High School, died at his home, near the asylum, August 15, aged 65 years. He was staff surgeon of Stand Watie's command and chief surgeon of the First Indian Division, on the staff of General Douglas H. Cooper, during the Civil War.

WILLIAM H. CAEMMERER, M.D., Univ. of Jena, Germany, 1847, died at his home in Brooklyn, N. Y., aged 78 years. He was born near Madras, India, and soon after his graduation came to this country. During the Civil War and for some time previously he was an examining physician at Castle Garden, N.Y. In 1870 he removed to Brooklyn, N. Y., where he established himself in a large family practice.

WILLIAM H. DALLAM, M.D., Univ. of Md., 1845, died at his home, near Creswell, Md., August 31, aged 77 years. He was for many years connected with the management of the Chesapeake Furnace Association.

JAMES FITZGERALD FEELY, M.D., N. Y. Univ., 1865, visiting surgeon of St. Catharine's Hospital, Brooklyn, N. Y., died at his home in that city, August 30. He was born in London, Eng., in 1841, but came to this country with his parents when a child and completed his scholastic course at the Brooklyn Polytechnic Institute. He was a member of the AMERICAN MEDICAL ASSOCIATION, the N. Y. State Medical Association and other scientific bodies.

DR. ROBERT W. HASLETT, for forty-five years a practitioner of medicine in Wheeling, W. Va., died at his home September 2, aged 71 years. He had been president of the State Medical Society, of the Ohio County Medical Association, and had held other responsible positions. The Ohio County Medical Association, at a special meeting called for the purpose, passed resolutions of condolence, and these, with other proceedings, show the high esteem in which he was held by the profession and the citizens.

JOHN M. GRAY, M.D., of Noblesville, Ind., died at the home of his daughter, in that city, August 29. Through the Civil War he was surgeon of the Thirty-ninth Indiana. During his late years he had been in failing health, and was almost blind.

J. B. HARRISON, M.D., died at his home, in Union City, Tenn., August 27, aged 70 years. He was an old landmark of the city, and did a large charity practice for years.

JOHN J. LYNSON, M.D., died at his home, in Tarrytown, N. Y., August 26, aged 73 years. He was an assistant surgeon in the Sixth N. Y. Heavy Artillery during the Civil War, later being surgeon of the provost-marshal's office at Tarrytown.

HAMILTON MAILLY, M.D., died at his home in Bridgeton, N.J., August 30, aged 32 years. Dr. Mailly was a victim of tuberculosis, and spent six months in Colorado, returning about one year ago apparently benefited in health. He was born in Delaware in 1867, graduated from the University of Pennsylvania in 1891, and has since been practicing his profession in Bridgeton. He has for a number of years held the office of Secretary of the Cumberland County Medical Society, and was also a member of the Medical Staff of the Bridgeton Hospital Association. Dr. Mailly was held in the highest esteem by the medical profession in general.

CORNELIUS HANFORD SCHAPPS, M.D., formerly of Brooklyn, N. Y., died in New York City, September 1, aged 82 years. He became a licentiate of the N. Y. State Medical Society in 1840.

George S. Pohls, M.D., died in Philadelphia, August 30, aged 49 years. . . . William Tuby, M.D., Macon, Mo., August 29. . . . George H. Trumbo, M. D., at Linden, Va., August 26, aged 59 years.

Miscellany.

Pharmacy in Germany.—The drug store in Germany must have, besides the store and separate prescription room, a room for dry storage, a cellar, a laboratory and a compounding room, and he accepted as suitable by the Regierungspresident. It is inspected once in three years by a commission consisting of a physician, a druggist, government official and a policeman. Poisons have to be kept locked up in a special compartment with special scales.

Death After Zinc Chlorid Injection Into Uterus.—M. Schmid recommends applying zinc chlorid on a cotton wad, instead of using the Braun syringe, as the solution may penetrate into the tube and cause fatal perimetritis, as has recently occurred in his experience. Three injections of 1 c.c. of a 50 per cent. solution were uneventful, but the fourth caused death within eight hours, although the fluid had not reached the fimbriated extremity.—*Monats. f. Geb. u. Gyn.*, June.

Peace Propositions.—The three propositions advanced at the Peace Conference, prohibiting the throwing of explosives from balloons, the use of projectiles destined solely to disseminate asphyxiating or toxic gases and of projectiles that spread after entering the body, were all signed by Russia, France, Sweden and Norway among the more important of the twenty-six powers represented. All were rejected by Austria, China, Germany, Great Britain, Italy, Japan, Luxemburg, Servia and Switzerland. The United States also refused to sign the gas and bullet ordinances, and Portugal the latter. The same powers also all refused to sign the ordinance applying the principles of the Geneva Convention to maritime warfare, with the addition of Turkey.

Can Block off Streets.—In the case of George V. Anderson against the mayor and council of the city of Wilmington, the superior court of Delaware holds that the city had a right to block off a street for the comfort and well-being of sick residents thereon, in its discretion, and to use for that purpose such instrumentalities as it deemed proper. Inasmuch, however, as the street was a public highway of the city, to the proper use of which all the citizens were entitled, the court adds that it was the duty of the city, in placing such obstruction, as for example a wire, there, to so place and mark the same as to properly guard the public safety, and to give such notice of the obstruction as would reasonably notify all persons having occasion to use the street that the danger was there.

Infiltration Anesthesia.—This method of inducing anesthesia, according to the Berlin correspondent of the *Medical Press and Circular*, seems much more cultivated in Germany than in other countries, and a recent article by H. Braun in *Volkmann's Archiv*, brings it still further to the front. The best medium for producing the anesthesia in the eucain B solution (eucain B 0.1, sod. chlorid 0.8, aq. dist. 100.0). This solution admits of sterilization, while cocain does not. Before the operation Braun always gives a morphia injection, but not in the region to be operated on. The method of injection is that adopted by Schleich himself. He has performed both minor and major operations under this form of infiltration anesthesia—tracheotomies, empyo-thoracentsis, abdominal sections (twenty cases). The solution is said to be very suitable for hydrocele operations. After removal of the fluid, the sac is filled tensely with the fluid, and in a quarter of an hour the tissue to be removed is infiltrated with the solution. The regionary anesthesia recommended by Oberst is most suitable for phlegmons and diffuse inflammations.

Entitled to Sick Benefits.—The word "sickness," as used in the by-laws of beneficial societies, the supreme court of Rhode Island states, in the case of Robillard against the

Societe St. Jean Baptiste, is construed to include insanity, so as to entitle a member becoming insane to sick benefits, where the by-laws provide for sickness and do not especially exclude insanity. Nor is it a defense, where the allegation is that the member was sick and unable to work, on account of nervous trouble, the supreme court of Michigan holds, in the case of Wuerthner against Workingmen's Benevolent Society, that his condition might be due to immoral practices, where there is no specific exclusion on that account under the by-laws. It says that a claim that such is the case has force, by reason of the repulsive nature of the vice; but, it adds, had the sickness resulted from overexertion in sport, or over-eating, or the liquor habit, the same defense might be made, if this one was permissible.

Nursing Consultations.—Seven years ago Prof. P. Budin established a weekly consultation for the infants, born in his service at the Charité, who are brought back by the mothers every Friday morning for inspection and advice after they leave the hospital. It is impossible to overestimate the benefits of these conferences, with the weight and progress of the infants recorded from week to week, advice to the mothers and gratuitous distribution of sterilized milk in bottles only containing enough for one meal for the baby. There has not been a single case of rhachitis, milk dyspepsia, "big belly" nor scorbutus among the 435 thus supervised for one month to two years, and only one death from bowel trouble, and in this instance his advice was disregarded. Similar consultations have since been established elsewhere in France. Some, like the "Drop of Milk" at Fecamp, where the mortality from enteritis has fallen to 1.28 per cent., supply all the sterilized milk needed by the infants, free or not according to circumstances.

Medical Department, University of California.—Many changes have been made in this institution since the closing of the last term. The anatomic and pathologic departments have been entirely reorganized and will be placed under salaried heads, the men in these departments have nothing to do outside of the college work of their own departments. Fifty microscopes have been given to the department by a regent of the university, the same regent also having agreed to be responsible for the full equipment of a pathologic laboratory on the best and most complete scale. It is expected that all the laboratories will be fully equipped by the end of another year. Very extensive facilities are to be provided for original research and for animal investigation, and as there is considerable research work already in progress, this part of the college work may soon be expected to be heard from. The library of the department is being catalogued as rapidly as possible, considering the fact that no catalogue of any kind has previously existed. There are about 3000 bound volumes in the library, including complete sets of many journals, among them being *Virchow's Archives*, Schmidt's *Jarbuch*, the *Lancet*, the *British Medical Journal*, and others. There are also about 2000 German monographs and as many English and American pamphlets. When fully catalogued and indexed the library will be very valuable.

Fifty Dollars a Day Not too High.—In the case of the City of Walla Walla vs. Ferdon, the supreme court of Washington holds that an ordinance imposing a license fee of \$50 per day for the sale by public outcry of drugs, medicines, nostrums or any other substance for the cure of, or pretended cure of, any disease or ailment, is not invalid, as being unreasonable, in demanding an extortionate sum for the license. The court recognizes that a municipal corporation may not arbitrarily declare a lawful trade or business a nuisance. Yet it says that the manner of conducting it may be regulated, and that it may be licensed when so regulated. Nay more, it declares that it can not be said that the sale of drugs and nostrums by public outcry, and accompanied, say by a concert, comes within the class of useful trades or employments.

It thinks it rather falls within another class, where, under the authority to regulate and license, a substantial revenue may be incidental to the license. Nor does it consider that it made any difference that the defendant held a license as auctioneer and also for a show or exhibition, although the contention was that therefore as a showman he could attract people, and as auctioneer he could vend drugs and nostrums which were claimed to cure ailments. Neither does it accede to the contention that because there was no license required for the sale of drugs in the usual manner by drug stores there was discrimination in the terms of the ordinance in question. It insists that there is a material difference between the ordinary dispensation of drugs through the drug store, and noisy sales by public outcry. It further asserts that it can not be said that the public welfare of a city requires the sales of nostrums in the latter manner.

New York Medical Items.—The monthly report of the New York State Board of Health of the mortality in the State in July, just issued, places the total number of deaths at 11,291. Of these 7324 were in the maritime district, a showing that compares favorably with the mortality in past summer seasons. The total number of deaths in New York City was 6808, of which 3571 were in the Borough of Manhattan, 2381 in Brooklyn, 397 in Bronx, 285 in Queens, and 164 in Richmond. Of the deaths in the city, 101 were from old age, and 836 from accident or violence. In the maritime district in general the mortality represented an annual death-rate of 22.5 per 1000 of the estimated population; in the city of New York, a death-rate of 22.5; in the Borough of Manhattan, a death-rate of 21; in the Borough of the Bronx—increased by the number of the large institutions there—25.5; in the Borough of Brooklyn, 22.5; in the Borough of Queens, 25.8, and in the Borough of Richmond, 28.7. The percentage of deaths of children under 5 years of age to the total number of deaths was 51.3 in the maritime district in general; 52.2 in New York City as a whole; 49.1 in the Borough of Manhattan; 50 in the Bronx; 53.1 in Brooklyn; 55.2 in Queens, and 49.4 in Richmond. Some rather curious contrasts are presented by the mortality records of some of the towns in the maritime district outside of New York City. Thus, in Sag Harbor, at the eastern extremity of Long Island, while the total number of deaths represents an annual death rate of 32, or one-third more than New York City and the district in general, the percentage of deaths under 5 years is only 12.5. On the other hand, in White Plains, Westchester County, a rural community, the percentage of deaths under 5 years is 62.5, or more than 10 per cent. greater than in the city of New York. The proportion of deaths from zymotic diseases per thousand deaths from all causes was 265.3 in the district in general; 267.6 in the City of New York as a whole; 228.2 in the Borough of Manhattan; 245 in the Bronx; 312.6 in Brooklyn; 302.5 in Queens, and 250 in Richmond. In the towns outside New York City the largest proportion per 1000 of total deaths, 555.5, was in North Hempstead, on Long Island, and the smallest, 103.8, in Brookhaven, also on Long Island.

Good Will.—Lord Eldon said that good will was simply "the possibility that the old customers will resort to the old place." In that sense, in which he used the term "good will of the premises," the supreme court of Tennessee says there may be an advantage of pecuniary value in occupying premises which have been occupied by skilled professional men, and to which the public has resorted, or has been attracted by advertisements, or prior visits, or general reputation of prior occupants. It reasons that many persons, attracted to the place by the reputation of former occupants, might remain, no matter who might be in occupancy, while others might leave so soon as it was ascertained that they were not occupied by the persons in whom they had professional and personal confidence. But whatever else may be said about it, or done to such good will as arises out of location, the court holds, in

Slack vs. Suddoth, that there can be no forced sale or transfer in invitum of such good will, so far as it is based upon business connections or professional reputation and standing, such as arises from the skill of physicians, dentists, etc. More particularly, the court holds that where two dentists had been talking of dissolving partnership, and one of them went out of the firm, rented a room adjoining the old offices, and offered his former partner \$500 to let him have the lease and use of those offices, the court holds that this offer was no criterion of the value of the use of those rooms, and would be no justification for an award to him of \$500 or any other sum for the good will so-called acquired by the remaining partner. In other words, it holds that the partner that left was entitled to nothing on the account of good will, under the above-stated principles.

Not Responsible for Amputated Parts.—A case apparently without a parallel, is that of *Doxtator vs. Chicago and West Michigan Railway Company*. The plaintiff sued to recover damages on account of having been deprived of the right to give the remains of her deceased husband a Christian burial, alleging that she had been deprived of that right by the wrongful act of the defendant. The theory of the plaintiff was that, when the railway company lifted her husband from the ground, after he had been run over while in its employ, it took on its shoulders a duty, and that duty was to care for him while he should live, and at his death deliver his remains, and the whole of them, over to his wife for burial; that the company did not do this, but, instead, negligently allowed the cremation of the dismembered lower limbs, and was, therefore, liable to the widow in damages. She obtained a judgment in her favor. But the supreme court of Michigan reverses this, holding that the defendant was entitled to a directed verdict. At the outset, it states that at the common law there was said to be no property in a dead body, and that in one sense this may still be deemed an accurate technical statement; but that it has been held in a number of well-considered American cases that the one whose duty it is to care for the body of the deceased is entitled to possession of the body, as it is when death comes, and that it is an actionable wrong for another to interfere with that right by withholding the body or mutilating it in any way. This right was conceded here. Taking up the question of the duty of the company, and how far it assumed control over the injured man, the court holds that, by the yard foreman calling another to hold his head, and notifying the surgeon of the road and calling the police ambulance, neither the foreman nor the railway company could be said to have become bailees, or to have assumed such a control over the injured man as to preclude the relatives from assuming charge of the ministrations to him. At his own request he was not taken home, though the policeman who came with the ambulance took him to a different hospital from the one he requested. Now, if its surgeon had not appeared, the court thinks that the company would not have been liable for any further neglect of, or injury to, the unfortunate man. Nor does it consider that, finding the patient in an appropriate hospital, with another surgeon in attendance, by assuming charge of the case, the company's surgeon took upon himself, as the agent of the railway company, the duty of seeing to it that, when death ensued, the body should be delivered to the widow. It holds that the duty he assumed consisted merely of performing such operations as the nature of the case required, leaving it to the attendants at the hospital to make such disposition of the parts amputated as custom warranted, and that neither in purpose nor in fact did he assume to take charge of the dismembered parts. The assumption of the charge of the case, it holds, was simply assuming charge of the operation. The surgeon had no knowledge of any direction as to the disposition of the amputated parts, and the court maintains, was not in fault in not assuming and guarding against an unwarranted disposition of them.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including August 31, 1899.

Daniel M. Appel, major and surgeon U. S. A., from the general hospital, Savannah, Ga., to Fort Bayard, N. M., as commanding officer of the general hospital for pulmonary tuberculosis to be there established.

Edward J. Barrett, appointed lieutenant and asst.-surgeon, Vols., August 17, 1899, and assigned to the 41st Inf. Vols., at Camp Meade, Pa.

William J. Boyd, acting asst. surgeon, from Pavillon, N. Y., to duty at Fort Leavenworth, Kan., appointed member of a board at that post to examine persons designated for appointment as second lieutenants in the army.

Walter Cox, lieutenant and asst.-surgeon, U. S. A., sick leave extended.

Thomas Earle Evans, acting asst.-surgeon, from Fort Crook, Neb., to Fort Riley, Kan., to accompany troop G, 8th Cav., to San Francisco, Cal. Charles M. Galbraith, major and surgeon, Vols., leave of absence granted.

Henry Lippincott, lieutenant-colonel, deputy surgeon-general, U. S. A., to represent the medical department of the army at the eighth annual meeting of the Military Surgeons of the U. S., at Kansas City, Mo., Sept. 27-29, 1899.

James E. Pilcher, captain and asst.-surgeon, U. S. A., to report for examination to the president of an army retiring board in New York City.

Junius L. Powell, major and surgeon, U. S. A., relieved from the operation of former orders requiring him to represent the medical department at the meeting of the U. S. Military Surgeons at Kansas City, Mo., Sept. 27-29, 1899.

Charles Richard, major and surgeon, U. S. A., member of a board at Fort Leavenworth, Kan., to examine persons designated for appointment as second lieutenants in the army.

Robert P. Robbins, appointed captain and asst.-surgeon, Vols., Aug. 17, 1899, assigned to the 47th Inf. Vols.; he will join this regiment on its arrival in Manila, P. I.

Joseph L. Santoro, appointed lieutenant and asst.-surgeon, Vols., August 18, 1899, and assigned to the 29th Inf. Vols., at Fort McPherson, Ga.

Dwight B. Taylor, acting asst.-surgeon, to accompany recruits from Columbus Barracks, Ohio, to San Francisco, Cal., and thereafter return to his station.

Walter D. Webb, appointed captain and asst.-surgeon Vols., August 17, 1899, and assigned to the 43d Inf. Vols., at Fort Ethan Allen, Vt.

James S. Wilson, lieutenant and asst.-surgeon, U. S. A., orders relieving him from duty to the hospital ship *Missioni* on his arrival at Manila, P. I., amended so as to relieve him at once; he is directed to proceed to Manila on that ship.

Nelson W. Wilson, acting asst.-surgeon, to post duty at Fort Porter and as examiner of recruits at Buffalo, N. Y.

GENERAL ORDERS, No. 159.

WASHINGTON, August 29, 1899.

By direction of the Secretary of War, the Surgeon-General of the Army is authorized to establish a general hospital at Fort Bayard, N. M., as a sanatorium for the treatment of officers and enlisted men of the army suffering from pulmonary tuberculosis and hereafter transfers of enlisted men suffering from this disease may be made to this hospital on the recommendation of medical officers of the army—to be forwarded through military channels.

Such buildings pertaining to the post of Fort Bayard as may be necessary to carry this order into effect will be designated by the Surgeon-General of the Army. Fort Bayard will be put in good state of repair by the Quartermaster's Department.

The Surgeon-General is also authorized to provide for the care and treatment of discharged soldiers entitled to the benefits of the U. S. Soldiers' Home, Washington, D. C., who may be sent to the sanatorium by the Board of Commissioners of the Home. The expense of the maintenance of such discharged soldiers to be paid from the Soldiers' Home funds. By command of Major General Miles.

H. C. COBBIN, Adjutant General.

BOARD CONVENED.

The following order for a board of medical officers to be convened at Manila, P. I., for the examination of candidates for admission into the medical department of the army was issued from the War Department, August 29, 1899:

By direction of the Secretary of War, a board of medical officers, to consist of—

Major William R. Hall, surgeon, U. S. Army;

Major William H. Artlund, surgeon, U. S. Army;

Captain William L. Kneidel, asst.-surgeon, U. S. Army;

First Lieutenant Douglas L. Duval, asst.-surgeon, U. S. Army;

First Lieutenant Clarence J. Manley, asst.-surgeon, U. S. Army,

is appointed to meet on board the hospital ship *Missioni*, as soon as practicable after the arrival of that ship at Manila, Philippine Islands, for the examination of candidates for admission into the medical department of the army. The board will be governed in its proceedings by such instructions as may be communicated to it by the surgeon-general of the army.

Movements of Navy Medical Officers.—Changes in the medical corps of the U. S. Navy for the week ending Sept. 2, 1899:

P. A. Surgeon E. R. Stitt, detached from the hrean of medicine and surgery, September 25, and ordered to the *Warford*.

Asst.-Surgeon W. M. Garton, detached from the *Annapolis*, when placed out of commission, and ordered to the naval academy.

Asst.-Surgeon W. M. Garton, order of August 28 modified, when

detached from the *Annapolis*, ordered to the Norfolk navy yard for duty on the *Franklin*, instead of to the naval academy.

Pharmacist J. N. Hurd, detached from treatment at the naval hospital, Mare Island, Cal., and granted sick leave for three months.

P. A. Surgeon J. C. Rosenbluth, detached from the *Nashville* and ordered to the naval hospital, Chelsea, Mass., for treatment.

P. A. Surgeon M. S. Guest, detached from the Boston navy yard and ordered to the *Wabash*.

Asst.-Surgeon H. B. Dunn, detached from the Washington navy yard, September 2, and ordered to the Fort Royal naval station.

Asst.-Surgeon A. Stuart, detached from the Fort Royal naval station, and ordered to the *Yankee*.

Asst.-Surgeon D. B. Kerr, detached from the *Yankee* and ordered to the *Marietta*, upon reporting of relief.

Asst.-Surgeon M. K. Johnson, detached from the *Marietta* and ordered to the *Amelia*.

Pharmacist R. Wagener, ordered to the Army and Navy General Hospital, Hot Springs, Ark., for treatment.

Marine-Hospital Changes.—Official List of Changes of Stations and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended August 24, 1899.

Surgeon D. A. Carmichael, granted leave of absence for 30 days.

Surgeon Eugene Wasdin, to proceed to Marshall, Va., on special temporary duty; detailed as delegate to the International Medical Congress to meet at Brussels, Belgium, Sept. 4, 1899.

Surgeon W. J. Pettus, granted leave of absence for one day.

P. A. Surgeon W. G. Stimpson, granted leave of absence for 30 days from August 18, 1899.

P. A. Surgeon J. H. Oakley, to proceed to Paducah, Ky., on special temporary duty.

P. A. Surgeon H. W. Wickes, granted leave of absence for 10 days.

Asst.-Surgeon L. D. Fricks, detailed as inspector of unseaworthy property at Norfolk, Va.

Acting Asst.-Surgeon H. S. Caminero, detailed as quarantine officer for the port of Guantanamo, Cuba.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended Sept. 1, 1899:

SMALLPOX—UNITED STATES.

Florida: Jacksonville, August 26, 1 case.

Louisiana: New Orleans, August 26, 1 case.

Massachusetts: Boston, August 26, 1 death; Fall River, August 26, 1 case.

Michigan: Sault Creek, August 26, reported present.

Ohio: Cleveland, August 26, 2 cases.

Pennsylvania: Philadelphia, August 26, 1 case.

Washington: Spokane, August 26, 1 case.

SMALLPOX—FOREIGN.

Argentine Republic: Buenos Ayres, June 1 to 30, 1 death.

Austria: Budapest, August 6 to 10, 1 case.

Belgium: Antwerp, August 5, 5 cases, 1 death.

Brazil: Rio de Janeiro, July 14 to 27, 11 deaths.

Egypt: Cairo, July 23 to August 2, 7 deaths.

England: Hull, August 19, 3 deaths; London, August 5, 1 death.

Greece: Athens, August 1 to 11, 5 cases, 2 deaths.

India: Bombay, July 25 to August 1, 22 deaths; Madras, August 15 to 21, 1 death.

Mexico: Chihuahua, August 20, 1 death; Mexico, August 13 to 22, 6 cases, 3 deaths; Navejo Luereco, August 12 to 18, 1 death.

Russia: Moscow, July 29 to August 14, 6 cases, 1 death; Odessa, August 5, 1 case, 2 deaths; St. Petersburg, July 29 to August 12, 15 cases, 2 deaths.

Turkey: Erzerum, August 5, 2 cases.

YELLOW FEVER.

Argentine Republic: Buenos Ayres, June 1 to 30, 3 cases, 3 deaths.

Brazil: Rio de Janeiro, July 14 to 27, 6 deaths.

Colombia: Barranquilla, August 6 to 13, 2 deaths.

Cuba: Havana, August 14 to 27, 7 deaths; Matanzas, August 21, 1 case; Santiago, July 30 to August 12 to 19, 5 cases, 4 deaths.

Mexico: Tuxpan, August 14, 5 deaths; Vera Cruz, August 17 to 24, 22 deaths.

CHOLERA.

India: Bombay, July 25 to August 1, 7 deaths; Calcutta, July 15 to August 3, 73 deaths.

Japan: Yokohama, July 29, 1 death.

PLAGUE.

Egypt: Alexandria, July 30, 4 cases, 3 deaths.

India: Bombay, July 25 to August 1, 132 deaths; Calcutta, July 15, to August 3, 7 deaths.

Straits Settlements: Penang, July 7 to 14, 71 deaths; Singapore, July 2 to 15, 7 cases, 4 deaths.

CHANGE OF ADDRESS.

Akins, W. T., from 1122 Southport Ave. to 1042 Addison St., Chicago.

Bond, L. L., from West Side to Denison, Iowa.

Best, S. R., from Brandon to Centerburg, Ohio.

Bennett, A. L., from 1463 Pearl St. to Steel Blk., Denver, Colo.

Bellamy, R., from 210 W. 57th St., New York City to Newport, R. I.

Childers, R. A., from Gainesville to Abilene, Texas.

Felt, R. A., from Galesburg to Knoxville, Ill.

Gilman, J. P., from Fond du Lac, to 725 Chestnut St., Louisville, Ky.

Gilmore, G. H., from Murray, Neb., to Stanberry, Mo.

Kelly, William, from Nashville, Tenn., to Care C. I. M. Hawkwood, Hunan St., Changteh, China.

McClintock, J. T., from Sioux City to Box 1804, Iowa City, Iowa.

Neilson, T. H., from Philadelphia, Pa., to Box 188, Cape May, N. J.

Stotts, A. F., from 137 Vine St., Philadelphia to Soldier, Pa.

Ullrich, A. M., from Grove Beach, Conn., to Lancaster, Pa.

Wilson, J. B., from Canon City, Colo., to Laramie, Wyo.

Whittaker, J. T., from Lakewood, N. Y., to 32 Garfield Pl., Cincinnati, Ohio.

Woodward, R. M., from Reedy Island Quar., Port Penn, Del., to U. S. Marine-Hospit. Bureau, Washington, D. C.

Address.

A PROFITABLE MEDICAL EDUCATION.*

BY HENRY O. WALKER, M.D.

SECRETARY DETROIT COLLEGE OF MEDICINE.
DETROIT, MICH.

In the following remarks, which it is now my pleasant duty to make, I shall bear in mind that I am addressing a select body of medical gentlemen on a most familiar topic; one that is uppermost in our minds on the occasions of these annual meetings; of the utmost importance to us as teachers as well as our students, and a subject concerning which there are honest differences of opinion. It is not my intention at this time to elaborate a complete system of medical education, but rather to bring forward again some of the main elements in what constitutes for the now-a-day average graduate in medicine a profitable training. In doing this I am aware that you may recognize some old straw being re-threshed, but I am put to it by the conviction that they are worthy of frequent repetition.

The most conspicuous fact relative to medical education is its continual change. From the crude ideas on anatomy, which the early Egyptians must have had, through their practice of the healing art and the embalming of dead bodies, and from the rules in hygiene with which the book of Leviticus abounds, through the mysticism, fanaticism and reforms of the several intervening periods up to the present, medicine has been an ever-changing art, a constantly-growing science. Within our own memory, with the progressive development of the older correlated branches of medicine proper, such as physiology, physiologic chemistry, hygiene and pathology, and by the birth of histology, bacteriology, electrotherapy and other newer sciences, the curricula of medicine have of necessity been greatly modified and expanded. Prescribed schedules of study have from time to time been lengthened to admit of additional courses, and at the same time a system of compression has been practiced in all of them in order that new matter might be introduced. In calling attention to these incidents no thought of destructive criticism is indulged in. They are the inevitable results and evidences of the growth of knowledge. They are, in fact, evolutionary changes. As we have observed them in the recent past so may they be looked for in the future.

While these modifications are entirely consistent with real progress, it is nevertheless profitable for us as teachers to be frequently reminded of the true purpose of medical education and of what it should consist. As the mariner in pursuing his journey over the trackless deep, turns ever and anon to the compass and by it shapes his course, so we, in guiding our pupils through the maze of useful and curious knowledge, need now

and then to get our bearings, lest we unwittingly stray from the proper path.

In considering the various uses of knowledge it is pertinent to ask whether the accumulation of medical and correlated science, and whether mental discipline in medical lore do in themselves fulfil the most desirable intent of our instruction. Again, is the chief end of our college work to develop Harveys and Huxleys and Grays and men like Agassiz, scientists who unravel bits of Nature, but doctors who do not practice? Even were we capable of doing this, something beyond the most of us, suppose we were to pick from off the benches those who have promise of scientific discoveries, how rarely would future years demonstrate the wisdom of our choice. I feel confident that you will agree with me that the product of our medical schools should be first and always men of action; men whose professional ability depends upon perfection, not so much in the science as in the art of healing. Such are they whom the world most needs and demands and to whom it gives a substantial reward. Ideals are as noble and as attractive in our profession presumably as in any other, but the bread-and-butter motive will always be with most of us the more determinate force.

Equally as important as a proper appreciation of the ends of study is the administration of the needed training. There is involved in this an understanding of both the character of our raw material and the management of the machinery at our command. Some persons have regarded it of sufficient importance to declare the advisability of laying the foundation for technical study in early childhood if possible, or in youth. This would seem to be an ideal and most desirable plan, but unfortunately for the bulk of those who come under our care it is only a dream of a lost opportunity. They come to us from the cities and from the farms, with limited literary attainments as well as after prolonged preparation. We hold entrance examinations, and during the successive terms also weed out the incompetent and unfit. There is left, we are wont to say, a lot of picked young men; but if we think them to have more than fair average capacities we are most truly mistaken. This fact should be borne in mind as we gradually raise the standard of admissions to our schools. I would in no wise curtail the requirements which the Association has already fixed. I do not forget the part which I feebly played in putting the standard to its present height. We shall doubtless learn that further advancement in this direction will be with difficulty made and at some cost in some of the schools. It is nevertheless most desirable, must come, and will most easily follow a rigid adherence to the rules we are now pledged to obey.

On the improved qualifications of our applicants will depend the solution of some of the problems now pressing their attention on us. Our curricula have been taking on new, yet essential branches, and in some respects need revising. Our laboratory work, so promising in its results, has been wonderfully increased in both breadth

*President's address, delivered before the Association of American Medical Colleges, Columbus, June 5, 1899.

and depth, and, unless due caution is observed, is apt to crowd out other equally important training. To meet the exigencies we have lengthened the term* of study and still the work is crowded. In our enthusiasm for diversified knowledge and special training for our students we should not forget the object in view. However patient and persevering our young Lydgate may be, his fellows will not be content with dry crumbs and long years of waiting, and we have no right to expect it of them. They are not destined to be martyrs to science, nor to be secluded by a cloistered wall. They are to be working doctors; men of affairs and of the world, partaking of its joys as well as soothing its sorrows.

There is no doubt as to the value of the fundamental branches of medicine. A fair elementary knowledge of physics, botany, general chemistry, biology and embryology is essential to a proper understanding of the super-structural branches and should, without exception, be insisted on. Preliminary preparation in physics and botany is already very generally required for admission, and there is no sufficient reason why all the other subjects named above should not also be relegated to the preparatory schools. Gradually this list might be extended to include elementary physiology and general bacteriology, including a limited amount of laboratory instruction. In this direction there may be afforded a degree of relief and provision made for desirable changes affecting the more technical branches.

As to the instruction itself, what I have to say appertains perhaps less to the Association than to the faculties and teachers whom we severally represent. Its important bearing upon the subject in hand is my excuse for bringing it in here. It has reference first to the modes of teaching, and secondly to the subject matter in which we deal. The modes of instruction which we have adopted are, in the order of their probable origin: the clinical, the lecture or quiz, and the laboratory methods. They are distinctive in style and function. No one of them can be made to serve as a satisfactory substitute for either of the others. Each one has its place. Their comparative value for our present purposes is however the important matter. The question is: To what extent shall each be employed? For an answer to this inquiry we have only to consider the end in view. On this point Dr. Holmes has so pertinently expressed an opinion with which I fully agree that I quote his words: "I myself have nothing to do with the clinical teaching, yet I do not hesitate to say it is more essential than all the rest put together, so far as the ordinary practice of medicine is concerned; and this is by far the most important thing to be learned, because it deals with so many more lives than any other branch of the profession." For the great majority of our graduates the clinical features of their college work will have been found to have served them best. When time shall have erased the theories and details of the lecture-room, and effaced from the mind the laborious distinctions of the laboratory desk, the pictures of diseased yet living forms will still remain as a perennial spring of knowledge and advice. As far as the subjects are adapted and our facilities will allow, the clinical mode should predominate, and neither of the others should be permitted to encroach upon it. By reason of its objective and tangible style, the laboratory method will be found preferable to the scholastic whenever a choice is possible.

Concerning the matter of instruction, distinctions should be made between the essentials and non-essentials of knowledge. At best facts are only scintillations of truth. We see one here and another there, with a blank

between. As Holmes has also remarked: "Science is the topography of ignorance. From a few elevated points we triangulate spaces inclosing infinite unknown details." While it is true that related knowledge is more easily taught and remembered than isolated facts, it is folly to unnecessarily consume our time and cumber our minds with useless non-essentials.

There is one more reform which appeals to me as worthy of our attention. For many years we have had laid before us the desirability of adopting the metric system of weights and measures. I need not go into details regarding the bungle and inexactness of the system we use and the obvious advantages of the other. Most of us have a working knowledge of the newer method, but habit and the want of unanimous action delay its exclusive use. We advise the teaching of it, and many of the schools have followed our instruction. Its general adoption is, however, too long delayed. Progressive men in other lines have very generally discarded the older modes as obsolete, and we have the authority of their national association that the pharmacists are only awaiting our consent before doing the same. They have suggested a plan of action which commends itself as both feasible and promising in its results. It is that in our schools of medicine the metric system *only* shall be taught. As I am aware of no serious objections to this plan, I heartily recommend to this Association the grant of its influence and authority in promoting its success. It is in the line of progress, will have an incalculable effect upon the science we love and by which we live, and should receive our serious consideration and approval.

GALL-STONES.

CONSIDERATION OF THEIR ETIOLOGY, DIAGNOSIS AND OPERATIVE TREATMENT.*

BY JOSEPH RANSOHOFF, M.D., F.R.C.S. (Eng.).

Professor of Anatomy and Clinical Surgery, Medical College of Ohio (University of Cincinnati).

CINCINNATI.

Cholecystotomy was first performed by Boggs in 1868. It was not made a formal operation until ten years later, by Marion Sims. In less than a score of years, therefore, it may be said that the surgery of the gall-bladder and ducts has been developed until it would seem that little can be added to what is already known, or that greater success can be obtained in the future than the past has yielded. Nevertheless, there are many points in the etiology and diagnosis of gall-stones, their concomitants and sequelæ, that are mooted, and the elucidation of which may eventually make more successful the results to be obtained from operation. To some of these points I wish to direct your attention, and, as far as possible, to illustrate them with appropriate case reports and specimens.

Concerning the etiology of gall-stones comparatively little is known. Certain it is that the experiments made to produce them around foreign bodies introduced into a normal gall-bladder have almost always failed. Homans and Kehr have each reported a case in which a stone formed about a ligature.

The changes in the urine which lead to crystallization within the kidney or the secondary calculus formation

*Presented to the Section on Surgery and Anatomy, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

in the bladder, which can be recognized by urinalysis, present no analogies in the origin of gall-stones. This seems to depend on crystallization of an excess of cholesterolin, possibly due to stagnation within the gall-bladder and the absorption of water, probably the result of a transient infection of the mucosa and desquamation of its epithelium.

Naunyn has shown that the cells lining the gall-bladder exude a substance which, by the addition of acetic acid is formed into cholesterolin. It is now generally conceded that with few exceptions gall-stones only originate in the gall-bladder, and that the nucleus about which crystallization takes place is of hemic or bacterial origin.

Gall-stones present but few varieties, the vast majority being formed either of pure cholesterolin or of bile pigments. Either of these may secondarily be encrusted with lime salts when retained for any length of time within a suppurating nidus. In size, in color, and in shape they vary much, even more in numbers; still, the gall-stones found in an individual case, as a rule, resemble each other as much as do peas in a pod. Not the least interesting cases are those in which nothing is found within the gall-bladder or its ducts save a few calculi not larger than millet-seeds, or a little biliary sand, black in color, as hard as emery, and so insignificant in quantity as often to be isolated only with great difficulty.

When we regard a gall-bladder containing anywhere from two or three to as many as a thousand gall-stones, we involuntarily ask ourselves: When did these gall-stones develop; what, in point of age, is their relation to each other, and is it possible that they were formed at about the same time and from a common cause?

I believe this to be the case, but gladly admit it to be beyond my ability to prove. The similarity in color, size, shape and identity in a few of the specimens, examined chemically, of stones removed from the same gall-bladder forms the foundation for this view. Furthermore, recurrence of symptoms after gall-stone operations is uncommon. Since my first operation, in 1879, I have had no instance in which a second operation was necessary, and only two in which there was a recurrence of symptoms. A cholecystotomy in one of them was followed by the voiding of a stone two years later. Kehr has operated eight times in the same patient. Hermann of Carlsbad claims to have seen 15 patients who had been operated on; of these 7 had recurrence. When a stone is discharged soon after operation, through a fistula or by natural ways, it is reasonable to assume that it was overlooked at the first operation. On the other hand, there are exceptional cases in which it seems evident from the appearance of the calculi that they are chronologically far removed from each other, although contained within the same bladder. In looking over my specimens of gall-stones removed by operation, I find only three in which it seems self-evident that there is a marked difference in the respective ages of the gall-stones removed. In the prognosis as to the recurrence of gall-stones after operation, a solution of this question would manifestly be of first importance.

In the point of diagnosis it is ordinarily not difficult to come to the conclusion that gall-stones are present, although cholelithiasis, as has been shown time and again by autopsies, is one of the most frequently overlooked of all disorders. Certainly the diagnosis of gall-stones is not made in any community in every tenth or even every thirtieth individual. Yet in from 3 to 10

per cent. of adults—according to Paulsen and Naunyn—varying with different countries, gall-stones are found. Quite recently I had occasion to remove gall-stones from a deaf-mute, 45 years of age, who had previously had her ovaries removed for supposed ovarian disease, and later been treated, a short time before the diagnosis of gall-stones was made, for stricture of the right ureter and consequent renal distension. The attack of colic itself is apt to be mistaken for biliousness, dyspepsia, cardialgia, kidney colic, appendicitis, intermittent fever, intestinal obstruction, pleurodynia, and most frequently of all for gastric catarrh. The variety of affections for which gall-stone may be mistaken gives evidence of the lamentable fact that, with the exception of a passed stone, there is no reliable sign of the presence of a gall-stone or of disease within the biliary passages. Even the Roentgen ray has failed of its first promise. Notwithstanding this defect, it is my belief that where an operation is made for the relief of gall-stones a failure to find one is far less likely to meet the operator than in similar exploratory operations on the kidney. In the cases that have come under my care I have but once failed to find a gall-stone or disease of the gall-bladder. This was a case referred to me by Dr. J. A. Brown of Germantown, of a man of 30 years of age, who had passed eight or ten characteristically faceted stones. On the day fixed for the operation at the Good Samaritan Hospital, he was seized with a colic, which necessitated its postponement. The stone passed and was found in the stool. Three days after the attack was over a cholecystotomy done before the class revealed an absolutely empty gall-bladder and gall-ducts. The last stone had passed.

From an enormous experience, Riedel has come to the conclusion that the biliary colic is not due to the passage of a stone but is the result of an inflammation of the biliary ways. He substantiates this by the frequency with which the attack of colic is ineffectual, so far as the expulsion of a stone is concerned. When by the use of alkaline waters this inflammation is reduced, the transit of a stone is not usually associated with pain. It is the experience of every operator, furthermore, that the mere presence of a foreign body, like a probe or drainage-tube, in the biliary ways is not always productive of colicky pain. In a general way the diagnosis of cholelithiasis is easily made. That as to the location of the stones is far more difficult and often impossible, nevertheless there are certain features which permit one to come very near the truth.

Mr. Jordon Lloyd has very properly grouped gall-stone cases into those in which the gall-bladder walls are yielding and allow of its distension, and those in which the walls are contracted, thickened and indistensible. In either of these groups the stone may lie in the gall-bladder, in the cystic duct or in the common duct. When stones occupy a distended or distensible gall-bladder alone there may be no symptoms except the attack of colic, with a mild jaundice a day or two following it. When the stone occupies the cystic duct, jaundice is not usually present; there are attacks of colic and considerable distension of the gall-bladder. Frerichs had already shown that in these cases the stone within the cystic duct may act as a ball-valve, permitting the entrance of bile into the gall-bladder and preventing its egress. It is in these cases in which the gall-bladder is often very largely distended that we find what Hippocrates already called white bile, which is nothing more than the accumulated secretion of the glands of the

vesical mucosa. Jaundice is not a common evidence of stone in the cystic duct, although in one of my cases a large stone imbedded within it near its confluence with the hepatic duct had so occluded the latter as to produce a very deep jaundice. When there is a stone in the common duct, with a distensible gall-bladder, there is usually present more or less deep jaundice, pyrexia, a distended gall-bladder, and moderate enlargement of the liver from distension of the finer biliary ways.

Stones limited to a shrunken and indistensible gall-bladder are not easily located with precision. They may be suspected where there are frequently recurring paroxysms of pain and where there is tenderness in the region of the gall-bladder, without the presence of a tumor. A stone within the common duct, with dilatation of it and the cystic duct, and a shrunken state of the gall-bladder, probably presents evidences of its location with greater certainty than any hitherto considered. It is in this class of cases particularly that the hepatic intermittent fever of Charcot and of Osler manifests itself. In one of my cases, recently operated upon, these intermittent attacks had lasted for nearly ten years. The attacks invariably began with an intense paroxysm of pain, which was associated with a rigor, followed by temperatures of 103 and 104, and profuse perspiration. While the patient always presented during the entire period of his gall-stone history a sallow appearance, the jaundice became very deep after each attack. Nowhere in the biliary passages is the ball-valve action of a gall-stone so perfectly manifested in the clinical history as in those contained within the common duct. Paroxysmal pains and jaundice, varying in degree, are almost invariable evidences of gall-stones located within the common duct. When gall-stones are contained within the gall-bladder as well as within the common duct, no symptoms exist from which the presence of stones within the gall-bladder could be recognized. From a clinical as well as from the standpoint of operation, the stones within the gall-bladder then play a very subordinate rôle. This applies equally to the rather rare cases in which stones are found within the hepatic as well as the common duct. The condition is uncommon. It has been my privilege to see but two cases, one in an operation, the other in the autopsy of a case seen with Dr. Withrow. The patient, a male nearly 70 years of age, refused an operation, which was not particularly urged, since malignant disease was strongly suspected. Three large stones were found, one in the gall-bladder, one in the hepatic and one in the common duct.

Cholecystitis from other causes than stone can not be distinguished from that due to stone. In three cases I have met this distension of the gall-bladder from obstruction of the cystic duct without the presence of a stone. In each of these cases a tumor was manifest. In only one of the cases had the infection led to pus formation; in two of the cases there was found a thick, ropy, black bile and biliary sand or small calculi. It is interesting to note that in three of my cases of choledochus stone, with the fever curve indicating the presence of pus, pus was not found. The cause of the febrile elevations in these cases of cholecystitis and of choledochus stone, where there is no suppuration, is utterly unknown. It is ascribed to some ptomain poisoning, but it is interesting, in view of the fact that cholemia from obstruction, as in malignant disease, is, as a rule, associated with a reduction, rather than an elevation, of temperature.

Among the diagnostic features of lesions of the biliary ways there is one that merits special attention. I re-

fer to icterus. Until Lawson Tait pointed out that it was rather an evidence of malignant disease than of lithiasis, persistent jaundice was held to be an almost unailing sign of the presence of gall-stones. Latterly its import has been overrated in the diagnosis of cancer. Per se, icterus is a most unreliable symptom, both as to the nature and location of an obstruction. In two cases of men over 70 years of age—one of my own and one of Dr. Evans—in whom persistent icterus, with pain, vomiting and progressive emaciation might have pointed to the existence of pancreatic carcinoma—the operation revealed large stones in the gall-bladder alone. In regard to the importance of this symptom in localization, on theoretical grounds its persistence could only mean obstruction by stone in either the common or hepatic duct. Yet in three cases of empyema of the gall-bladder from stone and in one without stone, which I have operated on, jaundice was both pronounced and persistent without the presence of a stone in the common duct. In all these cases the icterus was of an inflammatory nature, and depended on an extension of the swelling from the mucosa of the bladder to that of the common duct. Riedel has rightly called this condition "inflammatory concomitant or allied jaundice." These cases, and those in which stones are not found, furthermore establish a fact often disregarded. It is that the severest biliary colic does not necessarily depend on the transit of a stone, but on the expulsive efforts of the gall-bladder to force its secretion through a duct largely reduced in its lumen by infiltration of its walls.

The effort of Riedel to ascribe every biliary colic to an inflammatory process rather than to the passage of a stone is futile. I have seen time and again the probing of a healthy cystic duct produce pain very like that of a biliary colic.

Empyema of the gall-bladder is ordinarily recognized with ease, yet are there cases where it has been mistaken for periappendiceal abscess or for a floating kidney. In one case I removed from an incision made for appendicitis four gall-stones. The clinical history was not that of an acute appendicitis. The patient, a very fleshy woman, 40 years of age, had suffered repeatedly from gall-stone colic. For seven weeks before the operation was performed she had been confined to bed with the general evidence of intra-abdominal suppuration. At the time of the operation the abscess was limited anteriorly by the omentum, which had become adherent to the colon and cecum. It could be traced upward toward the region of the gall-bladder, although its upper limit was not accessible. Had it not been for the presence of the gall-stones a differential diagnosis could not have been made even at the time of the operation, since the density of adhesions precluded the search for the appendix.

In a case operated on by me for Dr. Little of Cambridge City, there was a clear history of appendicitis. The operation revealed the presence of four faceted stones that looked at the first glance like biliary calculi, but section showed that they were but calcareous incrustations of small fecal masses—enteroliths. The possibility of mistaking a gall-bladder for a distended kidney exists, since in not a few cases an incision in the loin for the supposed renal disease revealed the presence of gall-stones. Such a case was reported to the Academy of Medicine of Cincinnati a few years ago by Dr. Jones. The error in diagnosis is the more readily made since Riedel has shown that the prolonged existence of gall-stones will often, by traction of a distended gall-bladder, more or less separate from the

under surface of the liver a tongue-shaped lobe, which, being in front of the gall-bladder, gives semblance to the form of renal tumor.

It does not seem probable that any perihaptic suppuration could be mistaken for empyema of the gall-bladder. Nevertheless, a case recently came under my observation in which a differential diagnosis could not be made until the abdomen was opened. The case was that of a lad of 15 years of age, who repeatedly had attacks of pain in the hepatic region. According to the clinical history, these pains were never associated with elevations of temperature. Three weeks before the patient was subjected to operation he had sustained a slight blow upon the abdomen. For a week he did not complain. He was then seized with violent pain in the region of the gall-bladder, which projected itself toward the back. When seen, twelve days after the inception of the disease, by myself and Professor Nickles, all the evidences of intra-abdominal suppuration were present. There was no enlargement of the liver, although an indistinct tumor could be found below the costal arch on the right side, which was exquisitely sensitive to touch. There was a slight sallowness of the skin. The diagnosis lay between empyema of the gall-bladder and subphrenic abscess.

The operation, performed February 28, revealed a normal gall-bladder and appendix; between the liver and the diaphragm adhesions were found. The wound in the peritoneum having been closed, search through the adhesions revealed a small subphrenic abscess, containing not more than two ounces of pus. It was evidently one of the rare cases which have recently been described, of subphrenic abscess, the result of a trauma, and independent of the gall-bladder and the appendix.

Given the diagnosis of gall-stones, the question of treatment interests, besides the patient, medical men and surgeons alike. What are the prospects from internal medication: what the dangers of operation? When is the time for surgical intervention? What form shall it take? The fact that gall-stones are so often found in autopsies without having ever made themselves manifest, so far as can be known, during life, does not argue so much for nonintervention as one would think. These are the cases in which the gall-stones did no harm, their presence was not suspected, and they could, therefore, not have been made the object of an operation. When gall-stones do make themselves manifest by symptoms more or less violent and pronounced, it is well known that they may be entirely expelled or be retained within the gall-bladder without doing further mischief. The period during which a patient may suffer is often measured by decades.

What internal medication can accomplish in cholelithiasis must be left for the consideration of the internists. I have had personal experience in numerous cases in which it, together with restriction of diet, and possibly a trip to Carlsbad or to French Lick, has seemingly put an end to the attacks of hepatic colic. I do not believe, therefore, that every case in which the diagnosis of cholelithiasis has been made is a fit subject for an operation. Furthermore, I am convinced that no complication of cholelithiasis short of secondary malignant disease is so grave but that it may be recovered from. I have twice seen gall-bladder empyema relieved spontaneously when the local and the systemic conditions seemed to make an operation imperative. I have once seen a ruptured gall-bladder terminate in recovery after an abscess of the liver

which it produced was opened. Courvoisier tells us that out of 135 cases of intestinal obstruction by biliary calculus, 70 ended in spontaneous recovery. I beg to present a specimen so recovered, and another specimen removed by operation. In view of these facts, unless indications that are vital exist, the suffering of the patient and the frequency of the attack must determine whether or not an operation is to be done. In every case in which the gall-bladder becomes distended, or in which the signs of empyema are made out, or if any obstruction of the common duct be present, or if only for a short time, an operation should not be delayed. Furthermore, where the diagnosis of gall-stones can not be made with accuracy, and where, from the symptoms, one might suspect the existence of adhesions, such as were mentioned above, and to which Lauenstein particularly called attention, an indication for an exploratory operation may be said to exist.

As in so many other fields of surgery, the early intervention is the least dangerous. When patients afflicted with gall-stones are informed of the dangers that may arise, of the relative mortality of simple cholecystotomy during the interval, and of choledochotomy in subjects reduced by high fever and by jaundice, it is certain that consent to an operation will not often be withheld.

What shall be the usual operation in uncomplicated cases of gall-stones within the gall-bladder? Notwithstanding the objections that have been made to it, I believe cholecystotomy, with the establishment of a biliary fistula at one sitting, best suited to the average case. The mortality from it is very small. Out of forty-seven cases I have had three deaths. One, my first case, was in a man of 76 years of age, who had been intensely jaundiced for six months. The hemorrhage was very severe. I believe that in this case life might have been saved by resorting to Riedel's favorite operation of cholecystotomy in two sittings. The other fatal one was one of empyema of the gall-bladder, with high sepsis and jaundice. No stones were found in the gall-bladder or ducts. The patient died twenty-one days after the operation, with uremic symptoms. Acute desquamative nephritis was found in the kidneys by Dr. Topmuller, who made the autopsy. It was probably the result of prolonged ether narcosis. No peritonitis was found, nor was there anything in the condition of the wound or gall-ducts to account for the fatal issue. The third death occurred in a case of gangrenous cholecystitis, referred to me by Dr. Curry of Lebanon, in which the existing profound sepsis was not relieved by operation.

In another case recently operated upon death followed. forty hours *post operationem*, from intestinal obstruction. My patient was a male, 40 years of age, who had suffered during twenty years with severe biliary colic. In recent years it required from two to three grains of morphia as a first injection to relieve the pain. In the intervals there was a continuous dull ache in the region of the gall-bladder. Light attacks of jaundice had been noticed. The patient had passed what was supposed to be a gall-stone three years before. An examination of the powder showed it to be of some lime salt and devoid of cholesterolin. Operation under chloroform narcosis, was performed Dec. 30, 1897, at Christ's Hospital. The abdomen was very thick and muscular. The incision parallel to the costal-arch was made six inches long. Unfortunately the thorax was a very long one, with the free hepatic margin two inches above the costal arch. The intestine was kept out of the way only with great difficulty, and the gall-bladder, covered by the lingual appendix of Riedel, could be felt, but by no operative technic brought

into view. Within it a single stone could be felt. Cholecystotomy, cholecystectomy and cholecystenterostomy were to me technically unfeasible. In the hope of establishing a ventral biliary fistula along a track limited by adhesions, the fundus of the gall-bladder was caught in the bite of a long forceps and the wound packed about the latter with gauze. The greater portion of the abdominal incision was finally closed. Eight hours *post operationem* vomiting of bile occurred, and during the night the vomiting assumed the regurgitant type. Twenty-four hours after the operation the gauze packing was removed without affecting the symptoms of obstruction. *Exitus lethalis* followed in forty hours. Although in this case I had expected to encounter no operative difficulties, it proved to be the most embarrassing of all my gall-stone cases. It is more than probable that the lamentable result was due to the tight gauze packing, which was made necessary by the tendency of the intestine to prolapse.

The chief objection to the method of cholecystotomy under consideration is the long continuance of the biliary fistula. In most cases the fistula closes in from two weeks to two months. It is very rare for much of the bile to escape from the fistula after the second month. I have the records of only two cases; in one the fistula continued to run for six months and then closed spontaneously; in the other a second operation had to be done, with division of a stricture of the cystic duct, more than a year after the first operation. It is wrong to call the fistulas remaining after cholecystotomy biliary fistulae, for the most part it is not bile that escapes from the wound, but a little glairy mucus slightly tinged with bile. There are two things, in my judgment, that have a tendency to keep the fistula open when the obstruction is not in the common duct. One is the suturing of the gall-bladder too far into the abdominal wound or even to the skin, as is not infrequently done. In my later operations I attach the gall-bladder only to the parietal peritoneum and the fascia over it. The other is the use of the silk ligatures, which I have supplanted altogether by the use of animal sutures in anchoring the gall-bladder.

Ideal cystotomy, an operation first performed by Meredith and highly indorsed by Bernays, Courvoisier and many of the French surgeons, would be the operation if it were devoid of danger. I have performed it twice, once with success, and in one case, which appeared to me an ideal one for the procedure, death resulted from peritonitis. In this case I thought I had sufficiently anchored the sutured gall-bladder to the abdominal parietes to prevent infection of the peritoneum, even if the sutured gall-bladder should not hold. I think I have performed my last cystostomy. Aside from the apparently greater danger of the operation, other objections can be justly brought against it. The drainage of the gall-bladder and the consequent relief of its swollen mucosa can not, of course, be accomplished through it. If a single stone has been overlooked—and that is possible, even probable—the object of the operation has failed of accomplishment. In not a few of my cases, although I had believed I had removed all the stones, small calculi would be repeatedly found in the dressings.

A method of cholecystotomy that must not be entirely overlooked is that originally performed by Boggs, and still advocated by Riedel and many other operators. It is the cholecystotomy in two sittings. Its advantages are that it can be quickly performed, if need be under cocaine, and that the danger of infecting the peritoneum

is nil. I have never performed it, but believe that in one of my cystectomies, fatal from hemorrhage, this method of operation might have been followed by a different result. In deeply jaundiced individuals, when cholemia has existed for a long time, and hemorrhages from the mucosæ show what is to be expected in an extensive operation, and when there is a distended gall-bladder, I think that cholecystotomy in two sittings has its proper place. For the ordinary cases of gall-stones it should be discarded. It prevents absolutely the examination of the deeper biliary ways and makes one helpless in the event of an adherent or fixed stone within them. In probably one-third of all cases of biliary lithiasis one of more stones are impacted within the cystic duct. This is at once made manifest by the hydrops of the gall-bladder. It is difficult enough to remove these with one finger in the gall-bladder and the other without. After cholecystotomy in two sittings a second laparotomy must at times be made to remove these deep-seated stones. No operation or wound of the gall-bladder should be closed until the operator has reasonably satisfied himself that there is no obstruction beyond its neck. Exploration of the cystic duct is ordinarily associated with little or no difficulty, nor is the digital examination from without of the upper two-thirds of the common duct difficult in ordinary cases. With the finger in the foramen of Winslow the free border of the lesser omentum can be palpated without any difficulty, as low as the duodenal terminus.

The difficulty in the way of this palpation, however, may be almost insurmountable. Hartman has called attention to an enlarged lymphatic gland, which I have met in one or two cases, which might very readily impress one as being a soft stone. To the management of the stone in the common duct I shall refer later. No operation of cholecystotomy is complete without an effort likewise to establish the patency of the bile passages by catheterization. In a very large majority of cases this fails. It has been shown that, even in normal subjects, catheterization is not always feasible. In some cases the soft bougie passes without any difficulty as far as the Vaterian ampulla, showing that the ducts are free. In most cases, however, owing to an inflammatory thickening of the mucosæ or to the catching of the bougie in some fold, or from some tortuosity of the neck of the gall-bladder and its ducts, the progress of the bougie is suddenly checked. The meeting of an obstacle does not mean either a stricture or an obstruction. It is a common experience after cholecystotomy to find that bile does not flow through the cystic duct during the first twelve or twenty-four hours. At the time of the operation catheterization necessarily failed. What was an apparent stricture was relieved with the subsidence of the swelling of the neck and duct of the gall-bladder. With this flow of bile through the fistula the surgeon has cause to feel relieved of his anxieties in the individual case.

Since Langenbuch, in 1882, first extirpated the gall-bladder, cholecystectomy has found many followers, particularly among French surgeons, among whom Péan, Terrier and Thiriar may be mentioned. Cholecystectomy has been held up as the only radical operation for biliary lithiasis. Were it impossible for stones to be formed elsewhere than in the gall-bladder this claim could not be questioned, but it has been established beyond doubt that they can form in the common, the hepatic, and even the smaller ducts. Recurrence after cholecystectomy has been observed, and a number of cases have been recorded in which the overlooking of a

stone in the common duct during the extirpation of the gall-bladder has caused the death of a patient. In yet other cases the lethal end was averted by the spontaneous establishment of biliary fistula after the operation. I have twice performed cholecystectomy, not through choice, but through necessity. In the one case a small shrunken bladder suffered in the efforts to liberate it, as I believe, beyond the possibility of repair. In the second case a large and soft bladder was torn into during the manipulation in such a way that a fistula could not be established. Both patients recovered, but the operation proved very much more difficult than cholecystotomy. I believe that cholecystectomy should be reserved for cases in which the position and shrunken state of the gall-bladder and the friability of its walls make cholecystotomy impracticable.

What shall be done with stones in the cystic duct? It has already been stated that in nearly one-third of all cases stones will be found more or less firmly wedged here. As a rule they can be easily pressed back into the gall-bladder by the finger from without, or forced from their position by irrigation. In the case of soft stones they may be crushed between the fingers or by forceps, after the manner suggested by Tate. In the event of these measures failing, the impacted stone should be directly cut down upon and removed. Primary cysticolithotomy is the proper procedure. When the stone has been removed, the closure of the wound with a continuous catgut suture completes the operation. I have thrice opened the cystic duct in this way, without any untoward complication. To prevent possible infection of the peritoneum I have always resorted to drainage and gauze packing in these cases. I believe a cholecystotomy an essential to success when the cystic duct is thus opened. When a fistula has been established no tension whatever can be placed on the sutured wound in the cystic duct, and union goes on unretarded. Kehr has quite recently reported five successful cases to the German Surgical Association. (1894.)

The acme of difficulties in gall-stone surgery is reached when a stone becomes firmly lodged within the common duct, from which only in exceptional cases it can be dislodged into the duodenum, or brought backward into the cystic duct or gall-bladder. When any great dilatation of the biliary ways exists behind the stone, the removal of the stone, from within the cystic duct may be practicable. Unfortunately, in most cases the stone is firmly held within the duct, giving at times the impression of a neoplasm. In two cases at least an inoperable neoplasm was supposed to have been found during the operation, and an autopsy later revealed an impacted stone. The question at once arises whether a stone within the common duct should be left to take care of itself and an anastomosis established between the gall-bladder and the duodenum and colon.

I believe cystenterostomy is so advocated in every case by Murphy, the offending body being left to take care of itself. In my judgment this does not appear good surgery. Wherever feasible the foreign body should be removed by choledochotomy. As a factor in the causation of cancer, its importance is of the first order. Cystenterostomy should be reserved for impermeable stricture of the common duct, as shown by the continuance of a biliary fistula, and for malignant disease. If operations on the gall-bladder were more often performed as soon as the diagnosis of cholelithiasis had been made, it is certain that operations on the common duct for removal of impacted stones would be relatively less frequent than now. As it is, about 6 per cent. of the

operations for cholelithiasis must be made on the common duct.

My personal experience had been limited to 7 cases out of a total of 62 operations on the biliary ways. Two succumbed to hemorrhage from the post-operative oozing so common when jaundice is present. In a third the stones were a part of carcinoma of the common duct. In removing them the vena porta was lacerated. Although the tear was successfully sutured the patient succumbed twelve hours after operation. The mortality of choledochotomy in 1890 was 40 per cent. Kehr has recently reported 32 cases with only 4 deaths. In all my cases, the choledochotomy was followed by immediate suture and drainage. Cystotomy was likewise performed in every case, except one where the shrunken condition of the gall-bladder made it unfeasible.

In conclusion, it might not be amiss to present a short résumé of my operations on the bile passages from my first operation in 1879. There have been altogether 62 operations on 54 patients, 47 being cystotomies for gall-stones, hydrups, empyema or gangrenous cholecystitis; of these 4 died. In 3 cases cysticotomy was added without a death. In 6 cases cystotomy was followed by choledochotomy and in one the latter alone was performed. All these cases have continued well except one; she passed a gall-stone two years after she was operated on, and has since continued well. Of the fatal cases 2 died from hemorrhage; the third was associated with carcinoma of the common duct. Cystendesis was performed twice, with one fatal issue. Rupture of the gall-bladder, I have observed twice. In the one case a retroperitoneal abscess was opened, with recovery. In the second case general peritonitis existed at the time of the operation, which failed to avert death. In one case a laparotomy was done for intestinal obstruction. The stone was found in the ileum about three feet from the cecum. Although operated on within sixty hours of the outset of symptoms, the intestinal paralysis was not recovered from. In one case of a common-duct obstruction from carcinoma of the pancreas, the jaundice was relieved by a cholecystenterostomy by Murphy's button. The patient lived nine months, and the button was buried with him.

While my experience in the surgery of the biliary ways is far from large, I feel warranted in submitting the following propositions for your consideration:

1. The gall-stones found in a gall-bladder are generally formed together, that is about one and the same time. Their removal will not be followed by recurrence unless a reinfection of the biliary ways occurs.
2. Cholecystotomy with drainage should be regarded as the normal operation.
3. Save in exceptional cases, the operation should be done at one time.
4. Ideal cholecystotomy or cholecystendesis is not to be recommended.
5. Cholecystectomy is rarely indicated in acute processes. It is more dangerous than cholecystotomy. Since most stones are formed in the gall-bladder, cholecystectomy is the more radical operation. It should be reserved for chronic cases in which a restitution of the gall-bladder to the normal cannot be expected.
6. Cystotomy is a safe supplement to incision of the gall-bladder for stones of the cystic duct.
7. Choledochotomy with suture and drainage should be considered the routine procedure in common-duct stones. Incision of the duct through the duodenum or from an incision in the loin (Tuftier) will rarely be needed.

8. Cholecystenterostomy has a limited but distinct field of application, i. e., obstruction jaundice from malignant disease or impermeable cicatricial common-duct stenosis.

GALL-STONES.

OBSERVATIONS ON THEIR TREATMENT.*

BY ANDREW J. MCCOSH, M.D.

NEW YORK CITY.

During the past decade it has become generally recognized that the treatment, if not the diagnosis, of certain diseased conditions demands from the moment of their onset the joint attention of both physician and surgeon. Among such diseases may be mentioned appendicitis, pyelitis, and, in its various forms, cholelithiasis. In the first mentioned of these diseases surgical observation is considered of so much importance that the case is generally transferred to the surgeon, or he at least is summoned by the family physician to see the patient in consultation, as soon as a probable diagnosis of appendicitis has been made.

In cases of cholelithiasis the drift of opinion is in the same direction, though for manifest reasons the importance of early surgical observation is less urgent. In the diseases just mentioned, as in all others, it is but natural and right that the family physician should first be summoned, but he owes it to his patient as well as to his own reputation, that a surgeon should be called early in the course of the disease, for it is only thus that a just estimate of the progress of the case can be formed whether it be toward permanent recovery, toward operative interference or—what is most common in such cases—toward a temporary stage of recovery. It is not alone the immediate outcome of the attack which is to be considered, but an important observation can thus be made and a definite opinion formed on the nature and severity of the disease should similar attacks occur in the future.

The decision as to the propriety of operation or as to the most favorable moment for such interference is often difficult and requires the nicest judgment, which must generally be based upon a large experience. The personal equation, and perhaps the training of the practitioner, will very often influence him in the decision of this question. Many of us who see such cases in consultation with physicians can frequently tell before visiting the patient whether it be wise to at once order preparations to be made for operation. When summoned by certain physicians I often feel so certain of the probability that immediate operation will be needed that all necessary arrangements are made before leaving my office.

The remarks just made apply of course only to large medical centers. The country practitioner judges his case from the standpoint of both physician and surgeon and we surgeons from the cities are often surprised by the keenness of observation, by the excellence of the judgment, and by the broad grasp of the essential characteristics of the case which are so often shown by our colleagues in the country.

Turning now our attention more particularly to the subject of this paper, cholelithiasis, we are confronted with a number of questions of the greatest importance, some of which have yet to be solved. Among these may be mentioned: What period of time is necessary for the formation of a gall-stone? Much difference of opinion

exists on the subject, and the limits of the answer seem to be from a few days to many months. Another question is the influence of medical treatment on gall-stones. Prophylaxis is of the greatest importance, but the general consensus of opinion seems to be that gall-stones when once formed can not be materially influenced by internal medication. The character of the bile and the state of the lining membrane of the biliary passages may be favorably modified by medical and hygienic treatment, but a stone once formed can not be changed by any such treatment. If not too large, conditions for its passage into the intestine may be made more favorable, or the biliary passages may be brought into a condition where they do not resent the presence of a calculus, but more than this can not be expected from treatment by diet, drugs, or exercise.

It is now believed by many that so-called biliary colic is not produced so much by the passage through or impaction of a calculus in the bile passages as it is by inflammation of the gall-bladder and ducts. As long as the bile and the biliary passages remain normal a gall-stone will as a rule produce but few symptoms. It was formerly believed that gall-stones produced colic only when they began to move along toward the duodenum, thus causing an irritation of the ducts, and that reflexly vomiting and often fever would accompany the attack, but that jaundice and distension of the gall-bladder supervened only when the stone became impacted. We now know that this view is not entirely correct. It is true that a calculus is generally the cause of the inflammation in the bile passages—probably about 90 per cent. of the cases—but it is the inflammatory process and its complications rather than the stone which produce the severe symptoms. Distension of the gall-bladder will often take place when the cystic and common ducts are entirely free from stones, and not only will the usual symptoms which are generally attributed to the passage of a stone, such as colicky pain and vomiting, be thus produced, but also those of graver character, such as chills, fever, and jaundice, and death even may result without the impaction of a stone. It is sometimes forgotten that jaundice may thus be produced, and I find it to be a not uncommon error to suppose that the cause of jaundice occurring in an attack of cholelithiasis must be the downward passage of a calculus and its impaction in the common duct. In this connection let me narrate the following case:

CASE 1.—Mrs. A., aged 29 years, had been a vigorous girl, but since the age of 15 years had been subject to attacks of colicky pain in the abdomen several times a year. These attacks lasted from twelve to thirty-six hours, and were not often severe enough to confine the patient to bed. She had an attack of typhoid fever in the spring of 1898. On Feb. 19, 1899, the patient was seized with sharp pain over the region of the gall-bladder, and until February 26 she suffered from several severe attacks of pain, occurring daily, generally accompanied by vomiting. On account of the severity of the pain she had to be kept almost constantly under the influence of morphia. On February 25 slight jaundice appeared and her temperature rose to 101. Her physician, Dr. Bradshaw, wisely decided that operation was necessary. She was admitted to the Presbyterian Hospital on Feb. 26, 1899. Her temperature was 103, pulse 114 and she looked sick, the abdomen was moderately distended and there was tenderness over the region of the gall-bladder. She was distinctly jaundiced.

Operation was performed Feb. 26, 1899, under chloroform anesthesia. A 4-inch vertical incision was made through the right rectus muscle. The transverse colon was found adherent to the liver. On separating the adhesions a small, much thickened and adherent gall-bladder was found, about the size of a small walnut, there were also numerous adhesions about the cystic duct in which were felt two small calculi. The gall-bladder was opened, and through it the stones were extracted: they were three in number, with very sharp angles, and each

*Presented to the Section on Surgery and Anatomy, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 9, 1899.

one not much larger than a millet-seed. The opening into the gall-bladder was sutured to the parietal peritoneum. The discharge of bile was very profuse during the next two or three weeks and caused a severe irritation of the skin, which produced more or less vomiting, which was probably nervous in its origin, but which for a few days in the second week was quite serious. The bile ceased to flow on March 24—the twentieth day. Up to the present time the patient has remained in perfect health.

Another stumbling-block which is often found in the path toward a correct diagnosis is the idea that if a stone be impacted in the common duct, the result will be a distended gall-bladder. The physician will sometimes argue that a stone can not be lodged in the common duct, because the gall-bladder is not distended, and he, therefore, decides against operative interference because the gall-bladder is not palpable. With a recent impaction, such distension is not uncommon, but with impaction which has persisted for any length of time a shriveled, thickened gall-bladder is the rule rather than the exception. In the case, the narration of which follows, the gall-bladder, which was opened on the twentieth day after impaction, was found markedly distended.

CASE 2.—R. F., married, aged 33 years, had always been healthy, having had three children. There was no history of previous abdominal pain. About Sept. 20, 1898, she felt rather miserable and on October 6 she experienced some vague abdominal pain, located at first near the umbilicus and later in the right hypogastric region. There was no nausea nor vomiting. The bowels moved after a dose of salts; the pain continued to increase until the date of her admission to the hospital, October 8.

On admission her temperature was 103 and pulse 90. She was a fairly well-nourished woman. There was no jaundice. The edge of the liver was felt an inch and a half below the costal margin; the abdomen was somewhat tympanitic; there was considerable tenderness in the right hypochondriac region, and there was felt, extending from the costal margin as far down as the umbilicus, a mass which seemed as large as a large coconut. It was very tender, and moved slightly with respiration. October 9 and 10 there was but little change; temperature 100.5 to 101.5. The mass was slightly tender but there was no diminution in its size or tension.

Operation was performed October 11, under chloroform anesthesia. A four-inch vertical incision was made through the right rectus muscle; the liver edge extended two inches below the costal margin; the gall-bladder was much distended and very tense. The patient was turned on the right side, gauze pads being packed around the gall-bladder; a trocar was plunged into it and gave exit to about six ounces of fluid, which at first was thin and clear bile, and then it became thicker and finally consisted of pus and mucus. The finger inserted into the gall-bladder felt a stone, oval, non-faceted, about 1½ inches in length. It was extracted. The edge of the cut gall-bladder, whose wall was much thickened, was sutured with catgut to the parietal peritoneum and the remainder of the wound closed by suture. The patient made a good recovery. There was considerable discharge of bile, which, however, steadily diminished until November 2—22 days—when it ceased. The maximum temperature was 100.5 on the second and third days. The wound was entirely healed on November 8, on which day she was discharged from the hospital. She reported on May 20 that she had enjoyed perfect health since the operation.

In the next case which I will narrate the impaction had existed for four months and the gall-bladder was found shrunken and much thickened.

CASE 3.—R. H., aged 50 years, married, had enjoyed fair health, though she had occasionally suffered from attacks of so-called indigestion. In February, 1897, she suffered for ten days from a short attack of what was called biliary colic; she remained well for two weeks and then came another severe attack. Since then until May 24, 1897, when she was admitted to the hospital, she had suffered from similar attacks once or twice each week. The attacks generally lasted about two days, and began with severe pain over the region of the gall-bladder, with vomiting. This was followed by chills and sweating. From May 10 to 12 she was slightly jaundiced. During most of this time the urine had been of a dark mahogany color.

On admission, May 24, she was found to be a well-nourished

woman; the abdomen, which was very fat, was somewhat tympanitic, and just below the free border of the right ribs there was slight tenderness, but no resistance and no tumor could be felt.

Operation was performed May 26, under chloroform anesthesia. A four-inch oblique incision was made an inch below the right costal margin, and the omentum was found adherent to the under surface of the liver, which was small in size. Under its edge was felt the shrunken and much thickened gall-bladder, adherent to the neighboring structures. After considerable search, which was difficult on account of the adipose tissue and numerous adhesions, a calculus was felt at the junction of the common and cystic ducts and another in the common duct close to its entrance into the duodenum. As it was impossible to move either stone, the common duct was therefore hooked up with the left index finger and its wall incised and a three-faceted stone, the size of a hickory nut extracted. The other stone, somewhat smaller in size, was pushed through the same opening. The opening in the duct was closed by continuous catgut suture. A gauze drain was inserted and the remainder of the abdomen closed. The patient made a good recovery, there being a slight leakage of bile until June 27. She was discharged from the hospital July 2, and since that time has enjoyed good health.

In this connection it may be of interest to state that there are reported in this paper nine cases where cholecystotomy was done for stones impacted in the common duct. In six of these a thickened, contracted gall-bladder was found, in one a thickened but moderate-sized gall-bladder, and in two a thickened and distended gall-bladder containing pus.

CASE 4.—E. J., aged 52 years, married, for eight or ten years had been subject to bilious attacks consisting of pain in the upper right side of the abdomen and accompanied by vomiting; the attack lasted usually from one to three days; she had been jaundiced but once. The present illness began on May 8, 1898, when she was seized with severe paroxysmal pain below the right costal margin. There was no fever nor vomiting and no jaundice. On May 15 she had another attack of severe pain and vomited persistently for twenty-four hours. There was marked local tenderness in the right hypogastric region. On May 17 slight jaundice appeared.

She was admitted to the hospital on May 18. The abdomen was slightly distended; she was tender over the right hypogastric and lumbar regions; there was marked jaundice; temperature 102; she was very drowsy.

Operation was performed May 19 under chloroform. A mass could be felt in the epigastric region just to the right of the vertebral column. A four-inch vertical incision was made through the right rectus muscle. The edge of the liver was hard, irregular and much engorged, and was slightly adherent to neighboring structures. The gall-bladder was not visible. There was felt, just to the right of the bodies of the vertebrae, a hard mass the size of a duck's egg, to which were firmly adherent omentum and intestines. The mass was at first supposed to be a carcinoma, but after separating adhesions it was found to be an enormous stone, occupying the entire length of the common duct, which had become enormously distended to contain such a large mass. It was with considerable difficulty that the duct could be exposed so that a three-inch incision could be made through its wall, which was very much thickened.

The stone, however, was too large to emerge from such an opening. It was, therefore, broken into several pieces with the points of a strong pair of scissors and was extracted piecemeal. It was then found that the mass consisted of an amalgamation of a number of stones, the two largest being about the size of a walnut. These were so firmly agglutinated that considerable force was required to separate them. The mass was four inches in length and the maximum circumference was six inches. A large amount of bile escaped after the extraction of the stone. The cystic duct was shortened and was apparently empty, but the finger passed on toward the gall-bladder. At its neck was found a constriction, and beyond this in the bladder itself were found thirty or forty smaller stones, the largest being the size of a hickory nut. The gall-bladder was contracted around these stones and was much thickened. It was not opened. The opening in the common duct was partially sutured with catgut. To facilitate drainage a counter-opening was made in the right lumbar region, through which a strip of gauze was passed, as was also another which was led out through the abdominal opening. Considerable shock followed, but she soon rallied. Her mental state improved daily, though it was two days before it became normal. There was a free discharge of bile until June 20—32 days—when it ceased. The maximum temperature was 101 on the second day. The

patient was discharged cured on June 30, and up to April, 1899, had remained in good health.

It should also be borne in mind that cholecystitis is generally infectious. Normal bile is sterile, but it is easily infected, and the proof is rapidly accumulating that in the majority of cases of cholecystitis the colon bacillus and often other pyogenic germs will be found in the gall-bladder, and that even before the secretion becomes purulent the general infection may be so severe as to seriously endanger the life of the patient. Case 1 illustrates this point.

That the gall-bladder and passages are easily infected is shown by their behavior in typhoid fever. In the chapter on this subject in Keen's valuable book, it is very clearly shown that the gall-bladder contains the typhoid bacillus in nearly every case of typhoid fever. Thus Chiari reports that in 22 cases of typhoid fever, he has found on bacteriologic examination the typhoid bacillus in 19. Westcott has tabulated 74 cases of typhoid infection of the gall-bladder which have accompanied or followed typhoid fever. That the bacillus penetrates even the gall-stones is shown by the result of a hundred examinations made by Fournier, in 38 of which the typhoid bacillus was found. In this connection the following case will be of interest:

CASE 5.—Mrs. Y., aged 26 years, of good family history, for several years had complained of occasional attacks of pain in the right hypochondrium, coming on with great severity at night and occasionally accompanied by vomiting. The pain soon subsided, and she was always up and about the next day. After her marriage, in April, 1894, the attacks entirely disappeared. She gave birth to a child on April 3, 1895, and her convalescence was normal; after she had been up and about for about two weeks she began to complain of chilly feelings, pain in the back and in the extremities, and sent for Dr. E. W. Hedges of Plainfield. These symptoms increased for six days, and were accompanied by a gradually rising temperature and pulse and the probable diagnosis of typhoid fever was made. There was no pain over the liver, but on May 25 a tumor of small size was palpable in the hepatic region. At the end of twenty-four hours it had increased considerably in size and was more tender on pressure. On May 29 I saw the patient, in consultation with Drs. A. H. Smith and Hedges. There was then a tumor in the right hypogastric region, which seemed about the size of a large cocoon. There was some abdominal distension and some vomiting. There was also marked tenderness in the right side of the abdomen.

The symptoms pointed either to an abscess, the result of a perforated typhoid ulcer—the diagnosis of typhoid fever having already been made by Dr. Hedges—or to a cholecystitis. The temperature was 103.5, pulse 128. The patient appeared very ill. Immediate operation was advised, and accordingly was done in the evening, under chloroform anesthesia. A four-inch vertical incision was made to the right of the right rectus muscle. A much distended gall-bladder, exceedingly tense and slightly adherent to adjacent structures was found. The patient was turned on the right side, and the bladder surrounded by gauze compresses, a trocar and canula was plunged into the distended gall-bladder. Pale, green bile spurted out through the canula with such force that it struck the wall, six feet distant. The bladder was then opened by an incision, and a finger passed in felt as if it was entering a bag of fine gravel. Gall-stones which would have nearly filled a pint measure was scooped out, the largest being about the size of a large pea, and the smallest resembling caviar. It was roughly estimated that about 5000 stones had been removed. The gall-bladder was sutured to the parietal peritoneum and a tube inserted. The wound did well, but the temperature and pulse rose steadily until on June 7 it reached 107. The spleen was easily palpable and rose-colored spots appeared on the abdomen. At the end of the third week the fever began to decrease and reached normal at the end of the fourth week. On June 8 a stitch was removed, and a leakage of bile, which had still persisted, ceased on June 12. The patient made a good recovery from her typhoid fever and has remained perfectly well ever since.

The indications for surgical interference in cases of cholelithiasis have in the past few years become much more clearly defined, though the importance of operation

for the relief of these conditions is not so strongly impressed on the profession at large as I feel sure will be the case in the course of the next few years. The different views on this subject seem to be in very much the same stage as were those on appendicitis eight or ten years ago. It is, however, true that dilatory tactics in this latter disease are much more precarious than in the case of cholelithiasis, and the public at large have not as yet become educated to that degree that our patients insist on operation for the relief of gall-stones as they so often do for the removal of a diseased appendix. On account of this less dangerous character of gall-stone attacks, I doubt if the indications for operation will ever be so clearly defined or certainly as urgent as are those for appendicitis, and there will always be room for a considerable difference of opinion on this subject.

It is often a difficult question to decide when the physician should cease his efforts to cure by purely medicinal means and should transfer the patient to the surgeon for operative interference. A great change has taken place in our views on this subject within the past few years, and the modern physician is now apt to call upon the surgeon at a much earlier date than was the custom ten, yes, even five, years ago. The results of operation on the gall-passages have been so successful that many physicians, if not their patients, will decide that operation is preferable to a life that is constantly threatened by attacks of biliary colic or to a regimen which takes away much from the charm of living. Unfortunately, however, this view is not universal, perhaps through ignorance of the success of operations on the bile-passages or perhaps as the result of the physician's own experience with operations which have been done on some of his own patients, who have been transferred to the surgeon only as a last resort when they are thoroughly poisoned, when their kidneys have become overburdened, and when the mortality of operation must be very great. I fancy that many of the surgeons here present have with difficulty been able to conceal their indignation when after weeks, yes months, of so-called "watching," a patient, semicomatose with high fever, with urine loaded with albumin and lacking in any reparative or resisting power has been handed over to him for operation. He is often tempted to decline to interfere, but still he feels that it is his duty to make an attempt to save a life, even though the chance be but 1 in 10 instead of 9 in 10 as it should have been. The reason generally advanced for such delay is that the diagnosis is uncertain and that the case must be kept under observation until it can be ascertained with certainty that the fever, that the jaundice, that the sepsis are due to a gall-stone rather than to a catarrhal cholelithiasis. Is this right? Should not rather a laparotomy be advised, call it exploratory if you like, the danger of which, should the operation be fruitless, is very slight.

I speak strongly on this subject, for it has been my lot to receive several patients in this deplorable condition when there had been every opportunity weeks previously to give the patient a fair chance for recovery through operative interference. It is but lately that I saw such a case with a physician of wide experience; on my urging immediate operation he replied, "the result of the operation on the last patient I sent you was not so favorable as to encourage me to advise operative interference in this case." Let me narrate the history and allow you to judge whether it was not the inexcusable delay rather than the operation which caused the fatal result.

CASE 6.—B. B. had enjoyed fair health, with the exception of

so-called stomach attacks, until the beginning of 1895, two years before her present illness began. Since then, however, she had never been entirely well, being troubled every three months or so with an attack which gave the following symptoms: She would be seized with sudden cramp-like pain in the region of the liver and in the pit of the stomach; vomiting would follow, which was at times severe and continuous for a day or two. The pain continued generally for from twelve to fifteen hours. There had never been jaundice. The entire attack would generally continue for two to four days. Her last attack occurred on April 23, and from the onset seemed more severe than usual. April 25 she had a severe chill, followed by fever; on the 26th her symptoms were worse, and on the 27th I was called in consultation with her physician. Her temperature was then 103.5; she was very drowsy, and distinctly jaundiced. There was some resistance and tenderness over the region of the gall-bladder. I urged immediate operation, but it was decided to "watch" the patient for a day or two. This process of watching continued for five days longer, during which time the serious symptoms continued, the temperature being from 102 to 104, the mind being more or less obscured by the choleric poisoning. The patient also vomited. On May 1 she was sent to me for operation. On admission to the Presbyterian Hospital she appeared semicomatose. Her temperature was 105, pulse 112. Her urine contained albumin and granular casts. Though the chances for recovery seemed few, it was decided to operate, and on the same day chloroform was administered and a four-inch transverse incision was made below the costal margin. The omentum was found adherent to the abdominal wall and to the edge of the liver. On separating the adhesions a shrunken, thickened gall-bladder was exposed. A stone was felt in the common duct near the duodenum. It was extracted through an incision in the wall of the duct, which was afterward closed by a catgut continuous suture. A gauze drain was led out through the abdominal wound. On May 2 the patient was stupid and drowsy, though her temperature remained below 100. On May 3 she passed but little urine, which was loaded with albumin and contained granular casts. Her temperature began to rise, and she died on May 5, from poisoning which was mainly uremic in origin.

In this connection let me briefly quote a few statistics:

Kehr performed 180 gall-bladder operations—including cholecystotomy, cholecystectomy, cystendesis, etc.—and lost only three patients. Out of 46 choledochotomies he lost 4 patients; out of 360 laparotomies done for disease of the biliary passages with all their complications he had 42 deaths—a mortality of 11.7 per cent.—and if out of this number are excluded those cases which had hopeless liver disease such as cancer, suppurative cholangitis, etc., twelve died—an operative mortality of only 3.8 per cent. Riedel, in 100 cases where he operated for cholecystitis—hydrops and empyema—lost none of his 98 cholecystotomies, the only two deaths being in cases where he had extirpated the gall-bladder. On the other hand, Naunyn reports 150 cases of disease of the biliary passages treated conservatively by medicinal treatment alone, with a mortality of 6.6 per cent., due to complications, exclusive of cancer. We must also remember that recovery in many of the 93.5 per cent. who did not die must have been temporary only, as the stone still remained.

Let us briefly consider a few of the conditions where operative interference must at least be discussed, and I will take the liberty of illustrating each variety with cases which have occurred in my own experience which will best perhaps indicate my beliefs and practice.

CHOLECYSTITIS.

This is most often due to the presence of a gall-stone, but whatever be its cause, the indications for treatment are very similar. Should the attack be acute and subside in a week or two without symptoms of sepsis or cholangitis, operation is not indicated. Should, however, the distension of the gall-bladder, with pain and some fever, persist for weeks the question of operative interference must be seriously considered. Of course, with

patience the attack may subside, but on the contrary grave complications may appear. The longer the duration of the inflammation, the greater will be the disposition to future attacks. This is especially true if the inflammation has been excited by a calculus, because the chances for its passage into the duodenum, after the attack has persisted for weeks, is so slight. With this double predisposition—an altered lining membrane and a stone as an irritant—the risk of future trouble is very great. Is it not wiser, then, to end the present attack and to remove the tendency to future attacks by means of an operation, the risk of which is so slight, provided it be done early in the course of the disease before serious structural alteration in the bile-passages and neighboring viscera has taken place, as under such conditions the operation may become one beset with great difficulties and attended by a serious risk? Whether interference is to be recommended at the end of three or in six weeks will depend on the severity of the attack and perhaps also on the social condition of the patient. Case 2 already reported illustrates my views in this connection, and I will take the liberty of reporting still another case in which a cholecystotomy was done on the fourteenth day of the attack.

CASE 7.—N. E., aged 34 years, married, until present illness had enjoyed fair health. On January 13 she felt chilly and had some general abdominal discomfort with considerable distension; she was confined to the house but did not go to bed until January 15, when she was seized with severe pain in the right hypochondriac region, radiating through toward the back. She vomited once; the pain and tenderness continued with probably some fever until January 23, when she entered the Presbyterian Hospital.

On examination she complained of slight tenderness, but said that her pain had been gradually disappearing; there was no jaundice and no vomiting and the stools were of good color. Below the right margin of the ribs was felt a soft fluctuating mass, moving with respiration, which did not seem adherent and was but slightly tender. The liver edge was felt $1\frac{1}{2}$ inches below the ribs. Her temperature remained between 99.5 and 101. Slight tenderness persisted, and the tumor seemed to increase in size.

On January 27 chloroform was administered. As the tumor seemed to be situated rather far externally there was some doubt as to the certainty of the diagnosis of distended gall-bladder, therefore a one-inch intramuscular incision was made in the right loin, an inch below the border of the ribs, and on exploring with the finger it was found that the tumor consisted of a distended gall-bladder. The wound was closed and a fresh incision four inches in length was made through the right rectus muscle; the gall-bladder was distended to the size of a large cocoon and was very tense. It was carefully walled off by gauze compresses. The patient was turned on her right side, and through a trocar plunged into the gall-bladder eight to ten ounces of a greenish bile, followed by considerable mucus, flowed out. The opening in the gall-bladder was enlarged, and the finger, inserted, felt in the cystic duct at its neck a calculus the size of a hickory nut. It was extracted and exploration failed to find any other calculus. As the gall-bladder was moderately thickened and its lining membrane unhealthy, a cholecystotomy was done, the gall-bladder being sutured with catgut to the parietal perineum and the abdominal wound closed except for a space through which a strip of gauze, which had been inserted into the gall-bladder, emerged. The patient made a good recovery, bile ceasing to flow on the twentieth day, and the wound being completely closed on February 25, when she was discharged. She has remained perfectly well up to the present time.

It must be borne in mind that both these patients were working women for whom a long illness or a state of semi-invalidism was a very serious matter.

Should at any time in the course of such an attack symptoms of cholangitis, sepsis, empyema of the gall-bladder, pericholecystitis or abscess of the liver ensue, there can be no question as to the urgency of operative interference and the delay in such cases is unjustifiable. Let me illustrate this by two cases.

CASE 8.—Mrs. N., aged 59 years, for thirty years had been

subject to severe attacks of colicky pain in the abdomen. For the past two or three years these had been so frequent that the patient had been a semi-invalid. She had scarcely dared to go out, as any excitement or undue exertion was apt to precipitate an attack. They averaged about ten a month and would last from two to twenty-four hours. During the past year they became much more frequent and more severe, were generally accompanied by vomiting, and on several occasions the patient was jaundiced. Recently their duration had been from one to three weeks. During the past year the patient had been advised by her physician, Dr. Bradshaw, to undergo operation, but she was encouraged to decline any operative procedure, by the advice of a distinguished consultant who saw the patient on several occasions. On July 1 the patient had one of her severe attacks, but it was accompanied by fever, and later by septic symptoms. The fever continued until the time of the operation, in August. She vomited frequently and became very much emaciated; had a varying temperature, from 103 to 103.5. I first saw the patient on August 8. Her temperature was then 104, pulse 120. She was thoroughly septic, looked very weak, and seemed scarcely able to endure a serious operation. The abdomen was somewhat distended and boggy; there was some tenderness and resistance over the region of the gall-bladder, and also an indistinct mass could be felt. At the earnest solicitation of Dr. Bradshaw and myself, the patient consented to operation.

Chloroform was administered Aug. 10, 1898. A four-inch vertical incision was made through the right rectus muscle; the omentum, edge of the liver and colon were found adherent. The gall-bladder was much thickened around two stones the size of a hickory nut. Another stone of about the same size was felt in the common duct close to the head of the pancreas; this was raised up by a finger passed into the lesser omentum and the stone was extracted through a vertical incision into the wall of the duct. This opening in this was sutured with catgut. The opening into the gall-bladder was not sutured, but was surrounded with strips of gauze, which emerged through the abdominal opening. Considering the patient's condition there was but moderate shock. She made a slow recovery. There was a moderate discharge of bile for fifteen days, when it ceased. Up to the present time the patient has remained in good health.

REPEATED GALL-STONE COLIC.

It is in cases of this kind that there must always be allowed a certain latitude of opinion regarding the indications for operation. In the first attack or even in the second, interference is not often indicated except complications arise, such as infective cholecystitis, cholangitis, liver abscess, etc. When, however, attack follows attack and the patient's health, or at least happiness, becomes undermined by their frequency, then operative interference must be seriously considered. The social standing of the patient may have some bearing in the treatment. If it be such that a visit to Carlsbad or that a life surrounded by hygienic safeguards can be pursued, the indications for operation are perhaps not so strong, for by such means the frequency of the attacks can be somewhat controlled and the risk of grave complications lessened. Among the "workers," however, no such precautions are possible, and the expense, from a financial point of view, the pain of repeated attacks, and the danger of serious complications must be weighed in the balance against a mortality of perhaps 1 per cent, which attends operation for the relief of this condition, when uncomplicated by serious liver disease.

There are several conditions which are of influence in deciding for or against operation. If calculi appear in the stools, and especially if they are friable, there is a better chance for spontaneous cure than in cases where the stone is locked up in the bile passages. If it does not emerge, it is probably of large size, and this is still more probable if jaundice be absent. Once trouble in the gall-passages has been excited by the irritation of such a stone or indeed by a collection of smaller stones, the chance of recurrence of the attack is great, and the safer plan of procedure is to remove the cause rather than run the risk of one of the many possible complica-

tions which occur and end so fatally in about 6 per cent. of such cases.

It is probable that a stone greater in diameter than 2.5 cm. can not emerge through the papilla into the duodenum, and the large stones which eventually pass out of the rectum have invariably entered the intestinal canal by ulceration out of the gall-bladder into the stomach or intestine. If the ulceration goes straight, the outcome is a fortunate one, but not infrequently the stomach and intestine will not arrange themselves for a safe and direct passage of the stone from the bile-tracts into their caliber, and in such cases an intra-peritoneal abscess will result or a general peritonitis be started. The following case is an example of a fortunate outcome from such an ulceration stump.

CASE 9.—I. S., aged 34 years, married, was admitted to hospital Oct. 3, 1897. Until three years ago the patient had been a healthy woman, with the exception of a severe illness eighteen years before, which had resulted in loss of sight. In 1894 she was laid up in bed for three weeks with fever, severe pain in the right hypochondriac region, vomiting and abdominal distension, and ever since she has had constant tenderness below the free border of the right ribs. She has also had several mild attacks similar to the first, each one accompanied by severe pain and jaundice. When she turns on her left side she has a sensation as if a heavy body in her abdomen dropped toward her left loin. The last attack began in the end of August, accompanied by much pain, marked jaundice and some fever.

She was admitted to the Presbyterian Hospital October 3. She complained of considerable pain in the right hypochondriac region, where there was also marked tenderness, which was greatest in the midaxillary line, just below the border of the ribs. In the region of the gall-bladder there was considerable resistance, and an indistinct mass could be felt. The patient was most comfortable when lying on the right side; her tongue was heavily coated but she did not vomit. Her highest temperature was 99; pulse 88.

Operation was performed October 13 under chloroform anesthesia. A four-inch vertical incision was made through the right rectus muscle. In the region of the gall-bladder was felt a hard mass, which was found after separation of numerous adhesions to consist of adherent stomach, gall-bladder and omentum. On separating the latter the stomach and gall-bladder were found firmly fastened together over a considerable area. On separating these two structures, an opening in the stomach wall, circular in shape and about $1\frac{1}{2}$ inches in diameter, was found communicating with a smaller opening in the wall of the gall-bladder. This latter organ was small and shrunken, not larger than a walnut, with wall very much thickened. It was excised, the cystic duct being ligated with catgut. The gastric perforation was found on the anterior wall of the stomach near the pylorus, the edges were trimmed and sutured.

It must be remembered, however, that it is not always the large stones which produce the severest symptoms. The case first reported developed the most serious symptoms and yet the cause was three minute calculi, barely larger than the head of a pin. It should also be borne in mind that the irritation of a calculus is the most common exciting cause of cancer of the liver and bile passages.

An argument which is at times used against operation in these cases is that if you remove the offending calculi it is probable that new ones will form and excite further trouble. A similar argument could be employed against almost any conservative operation in surgery and does not seem worthy of serious attention. Even if calculi should form, they can be easily removed by a simple operation, which should be extraperitoneal and free from risk.

JAUNDICE WHICH PERSISTS.

This does not always mean an impaction of a stone. It will often arise from a cholecystitis. In a case of prolonged jaundice it is often difficult to determine the proper moment for operation. In the past and, even though to a less extent, in the present the tendency

has been and is to delay operation too long in these cases. A reaction, however, from this dilatory and often unjustifiable treatment is beginning the show itself, and, as in many other progressive and beneficial movements, the pendulum may swing in the next few years too far in the other direction, but it still needs a vigorous propulsion, in this country at least, before it reaches an even medium position.

The main reasons for delay in the past have been due to doubt as to the following questions: Is the jaundice due to a stone or is it catarrhal cholelithiasis? Will not the stone be forced out of the bile-passages into the intestine by nature? Will it not drop back into the gall-bladder, where it may remain innocuous for years? In regard to the first of these reasons for doubt it may be granted that in some patients the severe characteristic pain which is caused by the passage and impaction of a biliary calculus may be absent. An anticipatory hypodermic of morphin may have cut short the pain before special attention was attracted to its severity, or the personal characteristics of the patient may have been such that the pain was not regarded as of so much importance as the severe vomiting followed by jaundice which may have been the most prominent symptoms. The following quotation is from the recent excellent address of Mayo Robson in "The Dangers of Delay:" "I think the blame rather lies in the traditions of the past that we have not yet completely shaken off, in the reminiscences of the old days when an operation was a truly dreadful business to be avoided if possible, and possibly it lies a little in that *laissez faire* policy of the old school, for there are as yet a good number of Micawbers in the world and we know that they are sometimes encouraged by the unexpected turning up.

It may be only after the expiration of two or three weeks, when the symptoms do not abate, that the probability of a catarrhal jaundice can be cast aside. When at the expiration of this time the local tenderness, the pain, the vomiting and the jaundice still persist, and especially if the fever assumes a septic course, the probability of a stone being the cause of the attack becomes very great. The presence or absence of a palpable tumor would be of the greatest importance, but unfortunately, this is frequently absent, and the longer the attack has persisted the more likely is such a tumor to be wanting, for, as has already been stated, if the impaction in the common duct has existed for a length of time, a shrunken gall-bladder is found more often than is one distended with bile. The absence of such distension is an argument which in my experience is often used against the need of operative interference. As an illustration of what I have said, let me narrate the following case which I saw on the eighteenth day of the attack and where I advised operation, which, however, was declined. The patient died on the twenty-fifth day.

CASE 10.—B. F., aged 37 years, the mother of several children, gave a history of occasional attacks of pain of a colicky nature in the upper part of the abdomen. She had, however, enjoyed moderately good health until the morning of Feb. 19, 1897, when she was attacked with cramp-like epigastric pain and vomiting, which lasted until the afternoon, when she was given a hypodermic injection of morphin. On February 20 slight jaundice appeared, which gradually deepened. From the 20th to the 28th the patient had an average temperature in the morning of 99.5, and in the evening of 101. There was great nausea and some vomiting. From March 1 to 8 the temperature varied between 99.5 in the morning and 102.5 in the afternoon. The other symptoms continued as before, except that she frequently felt chilly. On March 9 I saw the patient, with Dr. H. Her temperature was then 103.5, pulse 110; she was markedly jaundiced; her tongue was heavily coated and dry; she vomited occasionally; her abdomen was moderately distended, and just

to the right of the median line in the epigastric region there was marked tenderness on pressure and some muscular resistance. I made the diagnosis of stone impacted in the common duct, and advised immediate operation. It was, however, not performed. From March 9 to 15 I learned that the temperature was somewhat higher. The patient gradually became more and more drowsy and her urine became scant and was loaded with albumin. I was asked to see her again on March 16. It was then almost impossible to arouse her. The daily amount of urine was only 13 ounces, and it was full of casts. Her pulse was 130. The case seemed hopeless from any point of view, and I declined to operate. She died on the following day, and at the autopsy, on which the family insisted, there was found in the common duct a stone the size of a pigeon's egg. The kidneys were in a condition of advanced interstitial nephritis.

I may add that the physician in attendance would not even acknowledge the probability of the attack being due to a stone, the absence of preliminary colic and the absence of a dilated bladder being sufficient in his mind to exclude the impacted stone. It is easy to criticise, but did not the long existence of fever, jaundice, and tenderness at least suggest the probability of stone and indicate operation? The argument that is often advanced against operative interference in such cases by internal physicians is that they have often seen such patients recover without operation and that they will wait for further evidence of stone. Delay in such a case seems to me to be unjustifiable. Are its dangers not much greater than are those of a laparotomy? Even if there be a chance that the symptoms are due to catarrhal jaundice are we not justified in recommending an operation, which, in case it is fruitless, exposes the patient to a very small risk and, in case a stone is found, delivers him from the danger of grave complications which would have almost certainly brought about a fatal termination?

The main object of this paper has been not so much to place on record the cases here reported as to advocate timely operative interference in cases of cholelithiasis; in the acute cases, to act before the operative mortality has been raised from 1 to 50 per cent., on account of complications arising because of delay; in the chronic and relapsing cases to prevent the patient from drifting into a life of semi-invalidism or the establishment of grave and oftentimes incurable liver disease. Such timely interference must be based upon correct diagnosis. Unfortunately, in earlier and milder stages of the disease, this is often obscured by symptoms attributed to dyspepsia. These patients, generally in early adult life, will suffer from occasional attacks of cramp-like epigastric pain, with perhaps a tendency to vomit. Such attacks at first last but an hour or two, and occur but a few times in the year. They are supposed to be due to indiscretions in diet. As the patient grows older, they become more severe and more frequent. A hypodermic injection of morphin may be occasionally needed. Abdominal distension is common, and the vomiting may become pronounced. The pain will last a day or two, and often there is local tenderness in the right epigastric region. Such is the history often given by these patients, but it frequently can be elicited only after careful questioning. So far between attacks they feel well. Later come the more grave and typical symptoms, and it is often only when these occur that the diagnosis is made, and the propriety of operative interference is discussed.

I have refrained from discussing the technic to be employed in these operations, as this will be ably discussed in other papers to be read before you. I will only say that my preference is, as a rule, for a cholecystotomy rather than for a cholecystectomy or cholecys-

tendens—ideal cholecystotomy. In the 26 cases in which this operation has been done—exclusive of cancer—not a patient has ever been left with a permanent fistula. The average time of closure of these fistulae has been twenty-five days, the longest having been forty-two days and the shortest eleven days. Nine cases of eholedehotomy are now reported. Two of these have died, but in both those patients it may be fairly stated, I think, that the cause of death was due to the grave complications caused by delay, rather than to the operation itself. In the seven cases that survived, the duct was sutured in all, though not always completely. In three of these there was no leakage. In four the leakage ceased in an average of twenty-four and one-half days, the longest time having been thirty-two days and the shortest fifteen days.

DISCUSSION ON PAPERS OF DRs. RANSHOFF AND M'COSE.

DR. WALKER, Detroit, Mich.—There is one point to which I wish to call your attention, and that is the suturing of the gall-bladder in cholecystotomy. I find that there is considerable leakage that remains for two months; I have seen them more than that; with the exception of septic gall-bladders, persistent empyema, I see no necessity for leaving drainage. It bothered me considerably in my first operations—the incision and the leakage that occurred—and in late operations, I close the gall-bladder and let it fall back into the abdomen. I bring this point out, and that it can be easily sutured by means of the purse-string suture. I have had no trouble.

DR. A. D. BEVAN, Chicago—I would like to make just one statement in regard to Dr. Ranshoff's opening statement, to the effect that little is known of the etiology of gall-stones. I think a great deal is known. I believe that gall-stones are mycotic in origin. This has been demonstrated not only clinically, but experimentally. Clinically, I always look for a history of typhoid or an intestinal infection, and in a number of cases I have found typhoid bacilli in the gall-bladder in these operations. Experimentally, in French laboratories (Gilbert and Hourinier), gall-stones have been made in living animals by introducing into the gall-bladder pure cultures of typhoid and colon bacilli. I do not know of any concretion in the body about which so much is known in regard to its etiology as gall-stones.

There is another point to which I would like to call attention and that is surgery of the common duct. The incision which I reported at this Section of the last meeting. I have since employed in ten or twelve cases, and have found it to be of so much value that I would like again to emphasize its importance. Whenever we undertake a gall-stone case, it is impossible to say whether the case will be simple or whether a very extensive amount of adhesions will be met, whether we will have simply to deal with the gall-bladder or the duct. On that account, it is desirable to plan an incision which can be so enlarged as to meet any indication that might arise. The S-shaped incision I developed and reported at the last meeting. (Illustrating diagrammatically). We will allow this to represent the costal starch; here the umbilicus and the inguinal or pubic ligaments. It is planned in this way for ordinary work as an exploratory laparotomy. A straight incision is made through the outer border of the rectus muscle. If adhesions are met with, if a common-duct stone is found and a wider field is required, the incision is enlarged, or, if it is a simple cholecystotomy, the incision is represented as a straight one. If it is a complicated one, when the stone must be removed from the common duct, the incision is enlarged in this way; an addition is made above and below, so as to make an S-shaped incision. I did quite a good deal of work in this line, and it is surprising to find how extensive a field of operation is made by this incision without any tension, when this line of incision is opened by retractors, and there is a wide field in the gall-bladder, and the common ducts are all explored. I would like to emphasize the value of this, and that we are not apt to have hernia following an incision of this kind. The extended portions of the incisions run parallel to the nerve-supply of the abdominal wall, and I have found in cases where I have employed it that there is considerable contraction following the incision. It is carried up well against the costal arch, and I have had no hernia in this line

of work, whereas, when I used the outer border of the rectus—the long, straight, or rectangular—I had three hernias follow.

DR. ROBERT MORRIS, New York City—For some time I have been closing gall-bladders more than previously, and one method of disposing of the gall-bladder in a certain proportion of selected cases, which I have recently employed, will be of service. This represents the gall-bladder (illustrating); this the sutured incision in the fundus—a puckering-string suture is thus carried around the gall-bladder; the gall-bladder is inverted, so that the fundus impinges on the cystic duct thus (indicating diagrammatically). The puckering string has inverted the fundus so that it practically obliterates the gall-bladder. In a certain proportion of cases in which the gall-bladder is freed from adhesions, this method is applicable.

DR. J. B. MURPHY, Chicago—When will we operate? What cases are operative cases? I was pleased to notice in Dr. McCosh's paper that he urged the early operation, and was also pleased to note the tenor of his paper, that the danger was not from cholelithiasis, but from the pathologic conditions induced by the presence of calculi. Therefore if the danger is not from the disease itself, from the presence of calculi, but from the pathologic conditions produced by them, the sooner they are removed, after they have commenced to cause the symptoms, the more safely they may be removed, as the pathologic changes will be less.

The cases in which there is immediate danger, and which demand immediate operation, may be divided into two grand classes: 1, primary attacks with a virulent or malignant infection of the gall-bladder, and, 2, acute obstruction and infection of the common duct. These cases are, fortunately, not common, but they are sufficiently dangerous to demand immediate operation. Can the diagnosis of these conditions be made? Yes! Can it be made with exactness? Yes! With sufficient precision to justify, even demand, an operation that, in itself, involves but a small element of danger. In these cases the attack is sudden pain, accompanied by high temperature, associated with vomiting; if the cystic duct is obstructed there will be great sensitiveness, but less spasmodic pain; if the common duct be involved, no sensitiveness but great pain and jaundice are present. The patient usually has symptoms of severe septic intoxication. These symptoms mean certain pathologic changes? If these symptoms are referable to the gall-bladder, there is sepsis and obstruction of the cystic duct, and, as a result, increased secretion and retention under pressure, so that both biotic and toxic effects of the microphytes are at the greatest advantage to produce gangrene and perforation of the gall-bladder. How long a time does this require? A complete gangrene of the gall-bladder may occur as early as three days from date of onset. I have observed two cases in which there was gangrene of the gall-bladder within three days, and both in primary attacks.

The second class of cases, obstruction of the common duct, associated with high temperature, the onset of pain followed early by high temperature, means what? Obstruction with jaundice, obstruction of the common duct with infectious involvement of the lymphatics, of cholanges, chills and fever, dry tongue and delirium, the patient rapidly succumbing to the toxic effects of infection. This pathologic condition demands the immediate relief of the tension under which this infected material is retained—the drainage of the gall-bladder: unless it be the gangrenous type of infection or long involvement of the cholanges there will always be a rapid cessation of the toxic effect on relief of the tension. Therefore, the indication is not to perform choledehotomy, but to simply relieve the tension of the bile-ducts by the shortest and simplest operation, cholecystotomy, as any prolonged operation under these circumstances would prove fatal.

DR. E. D. EMERSON, Troy, N. Y.—Apropos of one of the points discussed, as to whether we are to close the incision in the gall-bladder at the time of the operation or leave it as a cholecystotomy, there is one principle that has not been referred to, i. e., as to whether the presence of the gall-stone itself is the special pathologic condition for which we operate. The fact is we usually operate for gall-stones, and it is desirable to be sure that we get rid of them. There is no way in which we can be absolutely sure that the gall-passages are clear. We may take out several—a great many and yet leave one or more behind. This is brought more forcibly to my mind by one case in which I expected to find a gall-stone. I was confident that there was one and yet I could not find it. I hunted the ducts thoroughly; I explored the gall-bladder internally and externally and while I think I have a fairly good sense of touch in my fingers, yet I could find no gall-stone. I did a cholecystotomy and two or three days after a large gall-stone appeared at the opening. I do not believe that the annoyances to the patient connected with cholecystotomy are such as to cause us to close the

wound at once, with a possibility that we may leave gall-stones within the gall-bladder.

DR. THOMAS, Pittsburg, Pa.—I do not wish to criticize the papers, particularly as they were written by men of vast experience, but there is only one point and that is as to the first speaker referring disparagingly to the ideal method. It appears to me that if the operator has the courage of his convictions and is satisfied that the gall-bladder is empty and that the ducts are free, I do not see any objections to closing the gall-bladder. I have a specimen from a case of the ideal operation on the gall-bladder. The patient died of intercurrent disease seven days after the operation. I succeeded in getting a post-mortem examination, and removed the gall-bladder. If you are satisfied that the gall-bladder is empty, that the ducts are empty, close the gall-bladder and drop it in. The method in this case was with one running-stitch, first taking up all the tissues excepting the mucous membrane, and then going back with a Lembert suture and dropping it in.

DR. M. F. POTTER, Fort Wayne, Ind.—There are two objections to closing the gall-bladder immediately, and these apply also to immediate closure of incisions made in the common duct. In the first place, permanent or long-continued drainage is oftentimes necessary to cure a case after a stone is removed. There is oftentimes left cholangitis, which is quite sufficient to completely obstruct the duct, and this obstruction can be cured only by permanent drainage, or drainage, if you please, that is kept up for a considerable length of time. Again, there are cases that occur in which the plugging of the common duct is due to this cholangitis, with or without the formation of putty-like mucus, which cases recur after the original operation of cholecystostomy, and which are relieved by a second cholecystostomy, and then again recur and die. Such cases require permanent drainage. Another objection to the ideal operation is that one can never be certain that the ducts are patent. If there is a man who can tell absolutely, positively, when the common duct is entirely free from disease, I want to know who he is, and I want to go to him and have him teach me how to do it.

DR. FRANK WARNER, Columbus, Ohio—If we undertake the operation of cutting into the gall-bladder early, we are going to have occasion to revise our statistics of the mortality of the operation. How many of you hesitate when anything is the trouble, or suspected of being the trouble, with the appendix, to go in at once? What is the case when there is any trouble about the gall-bladder? You hesitate and hesitate until there has been an opportunity to add a very great deal to the risks which we run, not from the process itself, but from the results which are called for by the operation. There is one thing that I want to specifically condemn here, and that is the administration of olive-oil, in the hope that you are going to get rid of any very considerable obstruction around the gall-ducts. So far as I am personally concerned, I feel that you might as well pour that oil on the outside and rub it over as to put it on the inside. It is only a relic of barbarism, only a relic of ignorance that has been handed down to us from year to year by men—and some are refusing or hesitating to condemn this. But while my experience has been very small, as compared with that of many, yet it has been sufficient for me to stamp an utter disapproval on any such procedure. With the limited experience I have, I believe that we will do better to enter the gall-duct earlier, not wait, not make so many tentative plans to get rid of the obstruction, but enter earlier, and we will meet with much better success, and will have an opportunity to revise our statistics of the death-rates and make the operation a more favorable one to undertake.

DR. W. L. RODMAN, Philadelphia—I rise to ask the several essayists, when they close the discussion, and others who may speak on the subject, if they will state whether they have seen gall-stones in the full-blooded negro. In an analysis of 106 cases operated on by a surgeon in Louisville, only one was found in a full-blooded negro. I think some of the Southern surgeons who are here have seen gall-stones, and I would thank any one who goes into the discussion to answer that.

DR. J. E. MOORE, Minneapolis, Minn.—My own experience teaches me that there are unmistakable cases of cholecystitis in which there are no gall-stones, and some of these cases require operations, particularly those complicating typhoid fever. Right along this line I would follow Dr. Warner and use the necessity of exploratory operations in these cases, just as we are always ready to make them in cases of appendicitis. Why should we hesitate to go into this region any more than into any other region? I have been in the habit of doing this operation, and have never had an occasion to regret it, and would recommend to you exploratory incision in these cases. I have been very agreeably surprised in the instances in which my colleagues and I have operated to find our diagnosis corroborated as soon as we got into the abdominal cavity.

DR. H. O. MARCY, Boston—Since I am on record as the first to have removed a gall-stone from the common duct, having sutured the same as well as the gall-bladder, and closed the abdominal wound without drainage, it is very natural that I should advise this method of procedure, but we can not emphasize too greatly the importance of absolute knowledge that the canal into the intestine is unobstructed before we close the opening made for the removal of the calculus. If we may be certain that the biliary passages are unobstructed, after the proper suturing of the same, I can not doubt that the primary closure of the wounds will make the operation safer than by leaving an external fistulous opening. Conditions will not seldom be met with where this ideal operation can not be safely performed, and then we must use drainage.

In gall-bladder operations I consider the modified S-incision, for the reasons advocated, an important aid. Until recently I have divided the abdominal wall in a line parallel to the lower rib, which certainly permits easier access to the gall-bladder than an incision parallel to the rectus muscle. The modified S-incision is a happy medium between the two, possessing the advantages of both. There can be no question that operative measures for the relief of biliary obstruction are not alone justifiable, but that to-day we are in a position to define the conditions demanding the operation and emphasizing the importance of surgical intervention at a very much earlier period than at first seemed warranted.

DR. W. E. B. DAVIS, Birmingham, Ala.—In answer to Dr. Rodman's question, I had one case of obstruction of the gall-bladder—the common duct—where the stone was not found, in a pure negro, 70 years of age.

DR. JOSEPH RANSOFF, Cincinnati, Ohio—I want, in the first place, to correct Dr. Moore in his idea that I insisted on the fact that gall-stones are the only things that we are to operate for. I have a number of cases in which gall-stones were not found, and I do not think I operated needlessly.

In reference to the etiology of gall-stones, as spoken of by Dr. Bevan, I am not ignorant of the fact that gall-stones have been produced by the use of bacteria injected into the gall bladder, nor occasionally to form around a foreign body, but for the most part, they have not been found about a foreign body. I contend that we know very little, except after an infective process like typhoid fever, but of the time in which they form—the period—I think nothing is known, and that is an important point.

In regard to the ingenious suggestion of Dr. Morris, to close the gall-bladder by inverting it, the speaker believes that it originated more in the study than at the operating-table. When the gall-bladder is small and contracted, inverting it is entirely unfeasible. Even when the gall-bladder is of normal size its upper wall is so attached to the under surface of the liver that without dissecting it therefrom, inversion of the fundus can not be done. It is a thoroughly feasible procedure in enlarged gall-bladders, but these gall-bladders are the ones that ought not to be closed, but drained, and therefore, this suggestion of Dr. Morris does not seem to me a good one.

My main reason for objecting to ideal cholecystostomy is that I have had one patient die from it. Furthermore, we do not know whether the common duct is open or not. In the vast majority of cases you can not pass a probe through into the intestinal canal. Nor do we know absolutely that all the stones have been removed. In the vast majority of cases of operations for the removal of the gall-stones, you see nothing of bile; there is no obstruction of the duct after the first dressing, then everything is flooded with bile. The backward pressure of the bile, when the swelling of the mucosa of the cystic duct subsides after operation, is often enormous; should the sutures then fail to hold, a catastrophe is imminent.

One other thing, in regard to Dr. Murphy's statement that all cases should be operated on at once when we have obstruction of the common duct. The man with the largest experience in gall-stone surgery, Kehr, with a record of 409 cases and 32 common-duct stones, says, in acute common-duct obstructions, do not operate, but wait.

Contagiousness of Acute Otitis of the Middle Ear.—Lermoyez reports that in seven out of twenty-one cases in his experience, a companion, a sister or maid, also became affected with an acute otitis of the same character. At the first case, within two to seven days, or two weeks in one case, without a cold or any appreciable cause except contagion from intimate contact. Another argument in favor of his assumption is the frequency of otitis in general hospitals and its rarity in private practice. He therefore urges isolation of all cases of acute otitis, and warns persons with the grippe or any other infection to keep away from them.—*Press Med.*, August 12.

OUR TUBERCULAR PATIENTS.

WHOM TO SEND AND WHERE TO SEND THEM.*

BY J. FRANK McCONNELL, M. D. (TOR.)

LAS CRUCES, N. M.

That we have such patients no one will deny, for the age of the millennium has not dawned, and the sad procession of blighted lives is still wending its way toward the beckoning hand, till science shall have called halt.

Who does not recall, in the student days of even the youngest of us, the sadness with which our preceptors were wont to recognize the presence of consumption in young and promising men and women, the particular bright shining lights of each one's social sphere? Let me quote Allbutt of Cambridge in this particular: "Well I remember," he writes, "the fatal—for such it then seemed—the fatal note of the 'consonating rãle'; how it impinged on the unwilling ear like a knell. For they nearly all died in those days." But surely this is a gloomy picture; is there not a brighter side? Can not some new light to be shed upon it, that the faded color may be restored? Can it not be placed amid new surroundings, that the darkness may be dispelled? I believe this is possible. I believe the dawn has passed and we are already standing bathed in the light of the noon-tide of science.

With Koch came the great victory—our certain early diagnosis; with diagnosis came treatment, worthy of the name, for it is indeed prophylactic as well as active. The profession quickly became alive to the necessity of pure air and sunshine for such patients; they were aware that certain localities excelled in these essentials; the Continent became studded with *Kuhranstalten* and *Liegenhallen*; thither the patients were sent, the early and the late, the vigorous and the hectic, and as a result of such empiricism the disappointments were many; then came discrimination; *whom to send*, was the question uppermost in the professional mind, and on this topic I should like to add my quota, giving my opinion and experience in the matter.

Let me commence with this query: Who are the patients in whom the tubercular process is arrested? In nearly every case they are those in whom an early diagnosis of the existence of tubercle has been made, and who as a consequence have immediately been placed amid suitable environment in order that the curative process might be established. There are those present, I am sure, who could place their hands on a dozen young adults, who have, as it were, been snatched from the imminent peril of certain death, as the result of the skill which their medical attendants displayed in detecting the focus of disease and providing for it.

It has been the cause of great satisfaction to me to see annually, young men and women already presenting clinical evidence of their tubercular infection, coming out to New Mexico and there regaining health and strength, converting a hypotrophic constitution into an orthotrophic one, and oftimes becoming stronger than ever before. But, again let me ask: What class of patients give these results? The early cases; those who as yet have no appearance of invalidism, in whom the slightest token of chronicism is unnoticed by the experienced observer, who within themselves are yet almost unconscious of any serious lesion, but by reason of some annoying symptom, or acting on the advice of friends,

have been led to consult their physician. The medical adviser, thus consulted, if he wish to prove himself worthy of the confidence entrusted to him, will make a careful examination, microscopic as well as macroscopic, and will, as a result, honestly advise his patient as to his true condition, not engendering the false hope of "nothing wrong," "bleeding from the throat" or a "bronchial irritation following la grippe," if inwardly he believes and knows otherwise, but, encouraged by the early discovery of trouble, will advise, if circumstances permit, climatic change, even if it be only the outskirts of the city or locality in which the patient resides. It is such cases that improve and live to thank the physician that has proved himself such a benefactor.

There is another class of patients that we who practice in health resorts meet very frequently: those unfortunates in whom the disease manifests itself with that severity which so puzzles the pathologists, and those still more unfortunate, who have been allowed to let the day of their deliverance speed by, till, beyond all help from climatic influence, they are sent away from home and friends, and all that that means, only to find death in strange places. Such scenes are of altogether too frequent occurrence.

Therefore the patient most amenable to climatic influence still possesses a fair portion of activity and bodily strength; the hand of disease has not as yet laid heavily upon him; the tubercular lesion is slight, if any; perhaps nothing more than a little cough, with hemoptysis has called attention to his lungs; or more favorable yet, some evidence is found of the pre-tubercular state—that condition of hypotrophy so frequently seen, yet so illy understood, since it lacks any well-defined form—and as a prophylactic measure, climatic change is earnestly advised.

When the examining physician has fully determined that his patient should seek other climes, then should he firmly impress the fact, not allowing himself to be influenced by the importunities, either of patient or friends for very frequently much valuable time is lost—irrevocably in many instances—by procrastination following on carelessly given or insufficiently emphatic advice as to the dire necessity of immediately seeking better suited climatic conditions. Well do I know this fact from personal experience. Give me the data as to the time lost between diagnosis and the surrounding of the patient with suitable conditions, and I will make the prognosis.

A word as to that peculiar condition so frequently met, viz., fibrosis or fibroid phthisis; it is a great—and I regret to say all too common—error to send such patients to high altitudes, there to be dosed with strychnia till, compensation failing, they are advised to seek a lower altitude, or return to sea-level. Such cases, if sent to very moderate altitudes, invariably do well, the heart accommodating itself to the slight addition, when it would not be able to do so under the great disadvantage imposed on it by a higher elevation.

Having found our patient, where shall we place him that he may receive the utmost benefit in the shortest possible time, that he may be able to earn a decent competency and obtain the luxuries as well as the necessities of life? In order to settle this rather difficult problem it is necessary to have a knowledge of the localities which are favorable to fulfillment of what I have outlined on another occasion¹, as the object of climatic change; and again, the accommodations a patient will have dur-

ing his journey, and at his destination, and that his points of careful consideration.

It has been well said that tuberculosis is a disease of civilization, and that the nearer one approaches to the primitive states the less frequently does it appear, and again, that pure air, equability of temperature, and maximum amount of sunshine are the trinity which make up the ideal "breathing spot" for the tuberculous. With these premises, I think that further consideration will tend to develop that which may be found in every part of the country, and localize those particular regions, which are especially favored from a climatic standpoint.

A leading work of the day, discussing this subject, states that, given the three requisites just mentioned, it does not matter where the location is, provided the patient lives an outdoor life; seemingly it does not occur to the author that only particularly greatly favored localities possess these necessary adjuncts to successful climatic treatment, thus making practical the carrying out of his proviso.

In order to obtain pure air, maximum amount of sunshine, and equability of temperature, at one and the same time in a given locality, it is necessary to seek a climate which is noted for its dryness, and which has at least a moderate altitude, for it is in such regions that we see almost perpetual sunshine, which, with the altitude, insures purity of the atmosphere, provided we bear in mind our primary axiom—the keeping close to primitive conditions—which is nothing less than avoiding over-crowding both in the locality chosen and the residence selected.

In regard to dryness, I think it is very generally conceded that it plays the rôle of something more than a mere "useful adjunct," as a well-known authority puts it. Clinical testimony is overwhelming in the remarkable results obtained over the tubercular process in the arid regions. You will therefore see that we now have in this ideal climate a locality which can boast of pure air, abundant sunshine, the right altitude, freedom from undue moisture, and sudden and severe changes of temperature. We have built up an ideal, yet do we possess it, almost at our very doors—New Mexico.

It is to New Mexico, and especially to that portion of it known as Southern New Mexico, that I particularly wish to invite your attention, for here we have a moderate altitude—3800 feet—a valley fair to behold, surrounded and sheltered by mountains and foothills, a country of little rain—averaging yearly about eight inches, and frequently less—which, accommodating itself to the wishes of our winter visitors always falls in summer; a land of perpetual sunshine—348 sunny days in the year—with a winter that is unrivaled in possessing the necessary qualifications of climatic therapy.

New Mexico has been aptly called the land of sunshine and sand, which name warrants our assertion to supremacy in the matter of cloudless skies and absence of humidity; it is true that in consequence we have dust in certain localities, but away from the centers of population, on some of the many fruit and alfalfa ranches, which are the best places for invalids, there is little if any dust, the alfalfa fields doing good service in preventing this annoyance. As a winter climate for tubercular patients, Las Cruces, the center of the valley of Southern New Mexico, presents an ideal location. Good accommodations may now be secured on every side; especially is this true of the suburban parts.

It is but fair to state that the warm genial months of winter give place to warmer days, that are anything but genial, in July and August. Yet the nights are cool, so that refreshing sleep may be procured. A few

miles by wagon or train into the mountains, or to the northern part of Arizona and New Mexico, and we have a summer climate that is just as cool as one may desire, the patient being able to regulate the temperature at his fancy.

As a rule I advise patients who can tolerate high altitudes to travel northward, but many will find the nearer resorts, while warmer, better suited to their physical capabilities. It is unfortunately true that no one place will suit every phase of the tubercular diathesis, since no one place will suit every temperament. Yet, I believe that in a land of almost cloudless skies, with warm genial winter days, absence of rain and snow, and accommodations suitable to all requirements, the well-selected, early tubercular subject will improve and be quickly, and in the majority of cases, so permanently restored to health that in a few years he will have forgotten that he ever possessed such a thing as pulmonary tuberculosis. Therefore to sum up, we have seen:

1. The great aid toward permanent arrest, i. e., cure, of the tubercular process which properly selected climatic treatment gives.
2. The criminality of delay in affording our patients such an opportunity.
3. The wherefore of the recovery of early cases.
4. Why late cases should be kept at home.
5. The wonderful adaptability of the climate of Southern New Mexico, and the enviable position which it possesses as Nature's great sanitarium, where unfortunate possessors of the tubercular taint may defeat the ends of the grim destroyer and be saved to society, to act as landmarks to the diagnostician when he discovers the evidence of disease in some patient who less than a quarter of a century ago would have been doomed to death, but who now, thanks to the means of an early diagnosis, at the disposal of every scientific physician, remains to become vigorous and strong, blessing the name of the man whose knowledge has borne such fruit.

TREATMENT OF ENDOMETRITIS BY DRAINAGE AND IRRIGATION*.

BY AUGUSTIN H. GOELET, M.D.

Professor of Gynecology in the New York School of Clinical Medicine, etc.
NEW YORK CITY.

It is too often the custom to regard every discharge from the uterus as evidence of endometritis and to submit the endometrium to vigorous treatment either by caustic or astringent applications or curettage or both. This is unscientific and an error both in diagnosis and treatment. Even when the diagnosis of endometritis is correct, such measures, as they are usually applied, are not effectual, and they submit the patient to needless risk and the uterus to much unnecessary violence. If every case so maltreated was actually an endometritis, there would still be no justification for the vigorous and even harsh measures sometimes blindly employed against it. I believe I am not far wrong when I say that if a cure results after such treatment it is not because of it, but in spite of it.

If the case is one of simple hyperemia of the endometrium, with hypersecretion or one of so-called cervical catarrh, both of which may be mistaken for endometritis, the traumatism such violence inflicts opens the way for infection, conveyed to the cavity perhaps from the cervix, where infective germs frequently dwell in an innocuous

*Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

state when undisturbed. In this manner a comparatively harmless condition may be transformed into a very grave one. It is little wonder that some of our methods have been referred to as "gynecological trickering." It is trickering of the worst form, and can not be too strongly condemned.

As an actual fact endometritis is not so common as is generally supposed, and hyperemia of the endometrium is often mistaken for it. This is a condition very readily cured by removal of the general pelvic hyperemia on which it depends and obviating the cause or causes which give rise to it, and local treatment of the endometrium is unnecessary. I have found bipolar faradization applied to the vagina the most prompt and most effective method of treatment.

In the other condition often mistaken for endometritis, so-called cervical cartarrh, the diseased process is, as a rule, confined to the canal of the cervix and does not extend beyond the internal os unless the affection, usually a passive type, is conveyed to the cavity above by introduction of instruments for diagnosis or treatment or for operations, such as dilatation and curettage. The condition is usually an infection of the tubular glands of the mucosa lining the canal of the cervix, and manifests itself by a discharge, sometimes inoffensive in amount and insignificant in appearance, yet in it may be found the staphylococci, streptococci, or gonococci, either alone or together. They appear in small numbers in the ordinary discharge, but when the surface is irritated the discharge is increased and their number is greatly multiplied. This means that they inhabit the glandular structure of the mucous membrane and few escape to the surface with the ordinary secretion, the orifices of many of these glands being obstructed, but under unusual stimulation the pent-up secretion is thrown off in greater quantity and with its myriads of these germs which otherwise would not find their way to the surface.

In such a condition the cavity of the uterus above should not be invaded even for the purpose of diagnosis until all evidence of germ growth, as revealed by the microscope, has been effaced. The penalty of violation of this rule is risk of infection of the endometrium, which previously may have been exempt.

Obviously, the most rational manner of dealing with such infection, which is not confined to the surface of the mucous membrane, but has invaded the glandular structure beneath, is to stimulate the glands to throw off the pent-up secretion and to irrigate the surface frequently with a non-astringent, non-irritating solution to remove the secretion and prevent migration. This process of "drainage of the glands," if persistently maintained, will cause the germs to be thrown off too rapidly for effective propagation in the glands, hence their growth is checked and they become eventually exhausted.

The same holds true of inflammation involving the mucous membrane of the cavity above the internal os. The glandular structure is involved and no form of application to the surface can accomplish a cure unless its effect is to establish and promote drainage of these glands. If it defeats drainage it must aggravate the condition. Applications that coagulate the secretion on the surface block up the orifices of the glands, and if the action penetrates beneath the surface it is all the more objectionable. Hence astringents and caustics, though they may act as stimulants, defeat drainage rather than favor it, and are therefore contraindicated.

Curettage is sometimes of service both in the canal of the cervix and within the cavity of the uterus, but it should not be employed indiscriminately. To accom-

plish the most good it should be employed within proper limitations, and caustics should not be applied afterward, since they produce necrosis, which may result in atrophy of the mucous membrane or agglutination of the sides of the cavity. The curette should not be used in a manner to destroy or remove tissue unnecessarily, or to inflict needless traumatism. It is very unwise and unnecessary to attempt to remove the entire mucous membrane down to the muscular structure, therefore the sharp curette is seldom or never required within the uterus, but it may be used in the canal of the cervix and at the internal os, where the tissue is firmer. The dull curette with rigid shaft, will, if properly used, remove everything that should be removed from the surface of the endometrium in endometritis. The object of curettage in these cases is not to destroy the mucous membrane, but to remove projecting granulations or superficial tissue which may be blocking the orifices of the glands and preventing drainage. Probably much of the benefit that accrues from curettage comes from stimulation and compression of the glands from passing the curette over the surface of the mucosa. This forcible expulsion of the secretion would as much as anything remove the obstruction in the gland ducts.

Author's dull curette with rigid shaft, showing front and back of the curetting end.

Since it is not in itself curative in these conditions, curettage should be regarded only as a preliminary step in the treatment. Evacuation and drainage of the glands, made possible thereby, must be maintained and frequent irrigation with some non-astringent, non-irritating solution, through a return flow irrigator, must be employed until no vestige of disease remains. This is the only positive way of effecting a complete cure.

Author's uterine endoscope in position in the uterus, showing lamp near extremity of the tube.

An accurate diagnosis is an essential prerequisite for successful treatment, more especially in these inflammations of the uterus, and this can only be made by careful examination of the discharge under the microscope and inspection of the endometrium by means of the uterine endoscope.

It is particularly necessary to inspect the cavity both before and after submitting it to curettage: before, to decide the actual necessity therefor, and after, to determine the completeness or incompleteness of the work.

The successful application of the endoscope for the purpose of diagnosis has been made possible by employing an electric lamp within the tube near the extremity

for direct illumination of the cavity, and by attaching a megascope for bringing out the details of the surface after the plan of the Valentine urethroscope.

The instrument is adjusted to the interior of the uterus in the manner shown in the accompanying drawing. The lamp is operated by four dry cells, which last for a considerable time—thirty hours—and may be replaced at the small cost of \$1 when exhausted.

The extremity of the endoscope is oblique, so to more satisfactorily expose the orifices of the tubes and the sides of the cavity. The lamp is placed near the extremity of the longest side of the tube, so as to direct the light on the whole surface exposed to view by the opening of the tube. By turning the tube around in the cavity all parts of the cavity may be inspected, including the fundus, the sides, etc., as the tube is slowly withdrawn.

The lamp is detachable, and is placed in position after the tube has been inserted to its full length. The endoscope tube is introduced with obturator after proper dilatation of the canal. The obturator is then removed and the lamp inserted. If there is much secretion of blood in the cavity, this is first sponged out by means of an applicator with the end wrapped with absorbent cotton, then the lamp is inserted. If it becomes necessary to dry the surfaces after inserting the lamp this may be done without removing it.

There is not enough heat developed by the lamp to make it objectionable in the uterus for a period sufficient for thorough inspection of all parts of the cavity.

116 West Seventy-fourth Street.

THE IMPORTANCE OF A KNOWLEDGE OF THE DEVELOPMENT OR EVOLUTION OF THE CHILD IN THE PREVENTION OF CHILDREN'S DISEASES.*

BY E. STUVER, M. Sc., M.D., PH.D.

Member Colorado State Medical Society (Vice-pres., 1894); Rocky Mountain Interstate Medical Association, (ex-Secretary and Treasurer); American Medical Association; Fellow American Academy of Medicine.

FORT COLLINS, COLO.

In this age of world-encircling intellectual activity in which mind has penetrated so many of the secrets of Nature, and by directing its forces, has secured such a great dominion over matter, when the thought and discoveries of the whole world are at the command of each individual worker, we are prone to lose sight of the fact that while mind controls and directs matter, matter, on the other hand, exerts a powerful influence on the normal development and integrity of mind.

Surrounded as we are by free schools, almost universal educational facilities, and a public sentiment which, subordinating nearly everything else to the cultivation of intellect, rushes the child, scarcely out of the cradle, into the kindergarten, and thence through various grades of schools, colleges and universities, until he or she emerges at the age of 25 or 30 years, a finished product of our modern educational system, we are apt to forget that cultivation of the intellect or cramming the mind does not comprise the whole of development, and, that, unless very carefully guarded, by overlooking or ignoring the proper training and development of the body as well as the laws governing the development of the mind in the race, such training may do infinitely more harm than good.

The child, instead of being "a little man," with the

*Presented to the Section on Diseases of Children, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

same thoughts, feelings, inclinations, capacities and powers, only on a smaller scale as a man, is, in truth, an altogether different being, and may be aptly characterized in his various stages of development as an epitome of the development of the race. He passes through the successive stages of savagery, barbarism and semicivilization before attaining to the full civilization in which we live. During this progress the spectral forms of his dead ancestors surround him on all sides, and the mighty mental accumulations and beliefs of a long-forgotten past impress on him the various stages of credulity, inquiry, faith and full-blown reason through which these ancestors have passed.

With these facts fully impressed on the mind, and (thoroughly grasping the great truth that a symmetric development of all the powers—physical, intellectual, and moral—is necessary to the greatest happiness and welfare of the human being, let us see whether our habits of living, and educational methods, accord with these fundamental laws of development, and if not, in what way the physician can help to point out the remedy.

As before indicated, the child is not "a little man." In both organization and function there are great differences between the two, and hence their nature and training should be different, and made to conform to their organic and functional capacities. The glands, heart, lungs, muscular and osseous systems of the child possess a high degree of organic and functional perfection, and this would logically seem to indicate that the proper exercise and development of these various organs is the rational and proper occupation of the child during childhood and early youth.

In support of this inference it may be said that in the savage and barbarous stages of development of the race to which the young child corresponds, these organs and functions are developed to a high degree of perfection. Such things as weak flabby muscles, flat chests, failing hearts, and impaired digestive organs, were unknown, because their existence would have meant extinction to their possessors.

The muscular, osseous and respiratory systems were developed to a high degree of perfection, which was attained, not by disuse and confinement in illy-ventilated rooms for a considerable part of the day and the whole of the night, but by a careful and systematic exercise of the organs undergoing development but while the physical organization was systematically developed, and attained a high degree of perfection, and the special senses, especially the sight and hearing, were carefully trained from the earliest childhood until they became phenomenally acute among savage races, the intellectual development in many particulars remained in a rudimentary state. The powers of continuous mental application, abstract reasoning, and broad generalization were unknown to the savage, and were only acquired by the race through the slow, gradual process of evolution.

In support of the proposition that the young child represents and epitomizes the far-away savage stage of the race from which he sprang, we have the further fact that while the organic development and functional capacity of his heart, lungs, glandular organs and muscular and osseous systems have reached a high degree of perfection at birth, on the other hand his nervous system is in a very immature and undeveloped state. The brain of the young child, as compared with that of the adult, contains a larger percentage of water, is softer, more easily irritated, and is much sooner fatigued on mental exertion; but on the contrary the perceptive faculties, the development of which depends on the training of the

special senses, are keen and alert, and attain a high degree of perfection if given an opportunity in childhood to develop in accordance with the laws impressed on the race by Nature throughout the ages.

With these principles clearly in mind, let us see what application can be made of them by the physician in warding off physical and mental ills, and helping the individual and the race to attain the highest physical, intellectual, and moral perfection and happiness.

When we consider the phylogenetic history which the child represents at the time of its birth, the long eons of time, and the enormous evolutionary progress through which it has already passed, we can have some appreciation of the force and wisdom of a remark once made by Dr. Oliver Wendell Holmes, that, in order to treat the child successfully, you ought to begin two hundred years before it was born. So strong are hereditary tendencies that, no matter how favorable the environment may be, they influence, either for weal or woe, the individual and his offspring for generations. This brings us to the first fundamental proposition, viz.: That in order to reach the highest development and the most complete living, the individual should be well born; that is, both parents at the time of procreation should be in good health, and free from all taint of tuberculosis, syphilis, carcinoma, or other hereditary or communicable diseases or constitutional predisposition to them. Then, during pregnancy the mother should obey the laws underlying good hygiene and correct living in the matters of proper clothing, diet, exercise, and the avoidance of all stimulants and narcotics, as well as late hours and undue emotional excitations which have a peculiarly pernicious influence on the rapidly developing fetus. One night of dissipation may cast a shadow over a thousand years of the phylogenetic history of the rapidly developing embryo.

After birth the infant should be nourished at the maternal font designed by Nature for its sustenance, and if the mother has been properly raised and cared for during pregnancy, she will in almost every instance have an abundance of milk, and it will be a rare thing, indeed, to be obliged to feed the child on cow's milk, or the many nostrum foods with which the market is flooded. Then, too, it should be zealously guarded against poisoning by stimulants and narcotics in any form. Opium and alcohol in all their varied forms, with their siren and delusive promises, should be forever banished from the nursery, and the child be given an opportunity to select its own drug habits in later years without having them forced on it at this early age. I want to make one suggestion here. As you all very well know, water is the great solvent on which the system depends to convey nutritive material to every cell and tissue of the body, as well as to remove their accumulated waste and broken-down products. These cells and tissues are surrounded by dialyzing membranes through which a constant endosmosis of nutrient material and an exosmosis of retrograde products are going on. An abundance of water is necessary at all ages, to keep these membranes in good working order, but especially is this true in infancy and childhood, when the assimilative and eliminative functions are so active. Often young infants cry from so-called colic, and are dosed with brandy, paregoric, or some such abominations, when they are suffering from thirst, and a few teaspoonfuls of cold water will relieve the difficulty, and they will fall into a peaceful sleep. All young children should have plenty of pure water at regular intervals.

The clothing should be made so as to give free move-

ment to the limbs and permit a natural and unrestrained development of all the organs and functions of the body. The young child should have, at regular periods, an abundance of plain, unstimulating food, and plenty of exercise and spontaneous play in the fresh air, and should at an early age be trained to habits of regularity in attending to the functions of the body.

As childhood is the time of active development, and as sleep is Nature's great upbuilder and restorer, children should have an abundance of sleep during all these years, and especially while attending school. All stimulants and excitements, such as late hours, children's parties, and the many artificialities of our so-called advanced civilization, which tend to bring about a premature maturity, should be strictly avoided. During childhood, when their perceptive faculties, memory and imagination are active, they should be brought in close contact with mother Nature, from whom they will gain far more physical strength, mental power and wisdom than can be obtained from the formal-methods and conventionalities of most of our schools. I desire here to enter a protest against the long hours, continuous mental strain, cramming methods, and forcing processes of most of our modern schools. Scarcely is the child out of the cradle before it is sent to a kindergarten school; here, if it is so fortunate as to have a teacher who understands and is thoroughly imbued with the true spirit of Froebel's teaching, it passes a happy time, and receives much benefit. The child's books are plants, flowers, trees, fruits, birds, insects, and the various objects, animate and inanimate, of the external world by which it is surrounded. The everlasting hills rising in majesty and grandeur, the sighing of the wind among the trees, the murmur of the brooks, the glorious sunsets, the autumn forest with all its gorgeous hues and kaleidoscopic changes, in short, the almost infinite variety of objects and the innumerable beauties of Nature can be made most impressive sermons by the true kindergarten teacher—sermons which will sink deep down into the soul of the child and leave an impression on its body, its mind and its character which the storms and vicissitudes of life will never obliterate. But, alas! such teachers as we have in mind are like angel's visits—rare, indeed—and come to us like a ray of hope from the great beyond.

In the majority of instances even the life of the kindergarten is smothered by the blighting curse of formalism, and instead of being a blessing it is made a curse, and through ignorance or disregard of the most rudimentary physiologic laws lays the foundation of physical defect or disease. But if this is true of the kindergarten, what shall be said of the average primary school? In the words of Dante, there should be inscribed over the portal: "He who enters here leaves hope behind," because from my observation and information about our schools, from the time the pupil enters the first primary grade until he completes the grammar school course, he is continually subjected to such a grind and cramming for examinations that he must indeed be made of stern stuff if he does not emerge from this course weakened both in body and mind. The object of all true education should be a well-rounded symmetric development of all the powers, physical, intellectual and moral, of the individual; but in the face of this truth, which is acknowledged by all educators worthy of the name, we see children from 6 to 15 years of age, during the time of intense developmental activity, subjected to a course of study which, in many instances, is entirely beyond their comprehension, and a source of constant irritation to their immature and unstable brains.

Especially to be deprecated is the everlasting number work and arithmetic drill, which appears to have become a mania with the larger part of the teachers in our schools to-day. From the time the unfortunate child enters the first primary, through the eight long years until he emerges from the grammar course, he is subjected to a continual grind in number work, problems and examinations; morning, noon and night they are a veritable "old man of the sea" to them, hanging like a pall over their hours of leisure, and, even invading their dreams, they have become not only a menace to the health and happiness of the children, but also a nuisance to their parents, who can not enjoy a quiet half hour because a puzzled child can not solve a long list of problems far beyond its comprehension, and appeals for help. But, after all, what results are attained from all this work, worry and grind? I believe I am justified in saying that they are nearly always inadequate, and often a dismal failure, and that any 11 or 12-year-old pupil who had never looked into a written arithmetic, but who had been carefully drilled in mental arithmetic, can do better work and obtain a clearer comprehension and more thorough grasp of the subject in three or four years than the struggling child obtains by its eight years of arduous and detestable toil.

Then, too, the system of examinations in vogue in so many schools is a veritable *bete noir* to the pupils, who are kept in a constant state of worry and irritation, and subjected to a continuous nervous strain. The work, instead of being inspired and vitalized by a love for truth, and a desire to penetrate and understand the secrets and laws of Nature, becomes a mere mechanical cram and filling-up process to pass the examinations. This sort of work, as every one knows, has not only little real educative value, but by leading to makeshifts and subterfuges of various kinds, as well as downright cheating, degrades the pupil. Healthy mental and physical growth and activity are conditioned on an enjoyment or appreciation of the work being done. A distasteful task, or one done under compulsion, fatigues the mind much sooner, and leaves a much more evanescent impression than one which arouses the pupil's enthusiasm and engrosses his whole attention.

When the teacher so directs the pupil as to call his physical and mental powers into play, spontaneously, the dry rot of formalism and routine vanishes as if by magic, from the school, and instead of the tired, disgusted look on so many young faces, produced by the mechanical leveling process, which by confining within restricted bounds, reduces all to the same plane of mediocrity, we see the flashing eye, the eager intent purpose, and the whole soul of the pupil aroused by a noble enthusiasm. Who will say that in true educative value, one hour of such work is not worth weeks, nay months, of spiritless cramming.

Nor are spontaneity and interest less important in physical than in mental work. Free, unrestrained, spontaneous play in the open air is of infinitely greater value in developing the body than any indoor formal exercise, although, properly directed, gymnastic exercises, if subordinated to outdoor sports, can be made valuable adjuncts.

So many pitfalls and dangers lie hidden in the pathway of the rapidly evolving child that in order to guide him wisely and safely through the intricate labyrinth, to avoid the Scylla of physical ills, on the one side, and the Charybdis of mental evils and abnormalities on the other, it is necessary that the physician should at least have a clear outline knowledge of his evolution, and

know something of the physical and mental characteristics and potentialities impressed on him throughout the ages.

PROGNOSIS OF LARYNGEAL TUBERCULOSIS.*

BY ROBERT LEVY M.D.

DENVER, COLO.

In view of the many authentic cases of cures, both spontaneous and under treatment, which have of late years been reported, it is with some surprise that the vast majority of general practitioners as well as a fair number of laryngologists still look with but little hope on every case as soon as the verdict of laryngeal tuberculosis is given. The general statement "prognosis-grave" is sufficient to satisfy the conscience and condemn the patient. This view is certainly to be looked on as misleading to say the least, especially as it is generally given more prominence than the modifying and qualifying statements which usually follow. It is quite as much to be regretted, as so well put by Schech in Heymann's "Handbuch," that the present "beloved joy" over the results of modern treatment produces much harm both to our science and to the patient by promises which can not be fulfilled.

It is with the hope of presenting the subject in a conservative manner, with such deductions as shall be of practical value, that I offer the results of some years' observation of carefully recorded cases. One can not as yet say that all opportunity for differences as to the prognosis of this serious affection no longer exists, and for this reason radical changes are year by year noted in the views of all observers. The history of the curability of laryngeal tuberculosis is still being made, and one must not therefore expect to be too dogmatic; and still it must be conceded that certain well-defined conditions are positive indications for reliable prognostic inferences.

For these reasons the laryngologist becomes a valuable guide in early and accurate prognosis as he is in the diagnosis of this disease, and were he to examine every case of tuberculosis of the lungs or other organs his usefulness would doubtless be increased by the detection of tubercular infiltration or other lesion in the larynx which passes unnoticed until the patient is beyond hope.

The report and demonstration of spontaneous cures of tuberculous lesions in the larynx by men of undoubted veracity and authority can not be too strongly presented and reiterated—Kidd, Heryng, Rosenberg, Zenzliak and others—for it was from this that hope first sprang and that the curability of this hitherto greatly deplored condition was established by the pioneers. Encouraged by nature's lessons in repair she was assisted by our scientific efforts, until cures under treatment began pouring in from all sides by scores of men, such as Krause, Heryng, Bergengrün, Thost, Newmann, Massei, Wolfenden, Symonds, Gougenheim, Gleitzmann, Murray, Krieg, Whistler and many more equally authentic reporters.

In spite of the enormous amount of optimistic literature on this subject one can not ignore two important criticisms, namely, the question of diagnosis and that of the proof of cure. It would be desirable could we in all cases produce such incontrovertible evidences as in Krause's and Heryng's cures, in which post-mortem microscopic investigation demonstrated to the satisfaction of Virchow and E. Fraenkel the complete absence of tubercular lesion. Even this evidence may be questioned by the hypercritical, for Schrötter, in commenting on

*Presented to the Section on Laryngology and Otology, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

Heryng's case, says that greater time must yet elapse before we may accept such conclusion.

For all practical purposes it would seem that Delavan's statement is more than sufficient, when he proposes "to call that case cured in which all trace of active disease has disappeared from the larynx and all active symptoms referable to that organ have passed away, particularly where there is no recurrence of the local trouble during the remainder of the patient's life." I would go a step further and call a case cured in which all active indications of disease fail to recur after two, or in some instances after one year from their cessation. I do not deny the necessity of waiting, but why refuse a cure to those cases which become no recurrences, but new attacks? In other words, many a case may be considered cured which in later years, because of continued pulmonary disease either through local infection or the lymph or blood channels, develops another and new case of laryngeal involvement. The lesson we draw from this statement is that without other exciting causes such cases would remain free from laryngeal disease.

As to diagnosis, it is not necessary to await the appearance of typical ulcerations. Irregular spots of redness, characteristic anemia, typical infiltration and soft papillomatous excrescences are sufficient guide to the experienced. Catarrhal ulcers are rare, and where they occur in phthisic patients they should be looked on as suspicious, to say the least. Avellis has shown that tumors not typically tubercular may yet be so, and even though Schmitzler doubts the tubercular nature of an apparently typical ulcer, because of its readiness to heal, Beale shows how easily an evident catarrhal ulcer may become tubercular.

The presence of tubercle bacilli in the sputum will often clear up a doubtful case, but where they are absent or of doubtful origin, an examination of the scrapings from a suspicious lesion will almost invariably give positive results.

Having thus briefly considered such general topics as would seem essential to a clear judgment of the prognosis of laryngeal tuberculosis, what special questions may assist us in arriving at practical conclusions?

In studying my cases I am particularly impressed with the influence on the progress and termination of the cases by: 1, the nature of the lesion; 2, the position of the lesion; 3, the combination of lesions; 4, the pulmonary complication; 5, the coexistence of syphilis; and 6, the treatment.

The Nature of the Lesion.—Tubercular infiltration is frequently seen alone, but in the majority of cases only early in the disease. It is often associated with new formations of papillomatous appearance, and alone or in this combination continues indefinitely. It is not my purpose to prove, beyond question, a position by offering statistics; these can be perverted to suit any occasion; but one may obtain at least a glimpse of the truth by a study of numbers of cases.

My records cover several hundred cases, but many are incomplete as to result. I find, however, 144 complete accounts of cases, of which 84 were of the infiltrative and papillomatous variety, and of these 26 have gotten worse or died; only 8 of the 26, however, were materially influenced in their downward march by the laryngeal complication, making a percentage of 9 plus. The remainder were either cured or improved. Cases of the ulcerative variety numbered 60, and of these 37 got worse or died, of which 29 were hurried to an unfavorable ending by the laryngeal disease, making a percentage of 48 plus, the remainder being improved or cured at last re-

ports. It is thus shown that a favorable view may be accorded the infiltrative and papillomatous variety over the ulcerative by 39 per cent.

The Position of the Lesion.—No portion of the larynx is exempt from tubercular attack, and it would indeed be tiresome and but slightly profitable to classify in minute detail and separately each site on which a lesion has been found. In a general and practical classification one may be content to divide the lesions into: 1, those which have not yet attacked the epiglottis and aryepiglottic folds; and 2, those in which the epiglottis or aryepiglottic folds or both have been also involved. My records show 103 cases of the former, of which 11 got worse or died, and 41 of the latter, of which 29 died. The relative percentage shows that of Class 1, 10 per cent. plus, and of Class 2, 70 per cent. plus succumbed, thus making the class in which the epiglottis or aryepiglottic folds were involved 60 per cent. more fatal. I am frank to admit that these figures may be subject to criticism, for so many elements must enter into an analysis of cases; still they present the relative gravity of various lesions in laryngeal tuberculosis on a more definite basis than has been heretofore attempted. In a general way many authors have shown results which are in accord with those above given. I refer principally to Krieg, Heryng, Bosworth, Wolfenden, Symonds, Gougenheim, Szech.

While therefore admitting the great gravity of cases in which the epiglottis and adjacent structures are involved, one must recall not a few cases in which even here a cure resulted. Cohen, Symonds, Castex, Heryng, Curtis, Newmann, Whistler, Gleitzmann, the author and others, have placed such cases on record. I have records of 12 such cases cured or improved. Of these, 4 were possibly mixed with syphilis, the remaining 8 being purely tubercular, of which 4 are improving rapidly and 4 are known to be cured.

The Combination of Lesions.—By this I refer to cases which are mixtures of two or more of the forms already outlined or the association with edema, acute tuberculosis or pharyngeal tuberculosis. When complicated by the last named, the prognosis is most grave.

The Pulmonary Complication.—Krause has shown that it is possible for laryngeal cures to result even while the lungs continued to fail, while Browne has shown that improving the larynx may bring about pulmonary improvement. Still the rapidity, extent, length of time, stage and nature of the lung disease must have a very close bearing on the course of the laryngeal complication. Thus also, as Heryng points out, age, constitution, surroundings, the number of bacilli and, according to Thost, whether the disease be hereditary or acquired, play a part in determining the denouement.

The Coexistence of Syphilis.—That syphilis may modify the course of laryngeal tuberculosis is well established. The question of diagnosis, however, becomes here a most important one, for doubtless many an atypical syphilitic lesion has been mistaken for a tuberculous one. The presence of tubercle bacilli in scrapings from such a lesion throws much light on the case. The weight of opinion seems to favor the mollifying influence of syphilis, but as Rice has said, "the prognosis will depend on which one of these two diseases is the more active," or, as Szech puts it, the prognosis becomes more unfavorable as the tuberculosis gets the upper hand. In four otherwise unfavorable cases which I saw cured, syphilis was a decidedly possible complication and greatly influenced the favorable termination.

Well-Selected and Skilful Treatment.—That properly

chosen surgical or medical treatment may greatly influence the prognosis of this disease must be acknowledged. The many remedies which have been followed by individual success and the many rules which have been laid down for surgical and other interference are evidence of rather chaotic conditions in the matter of indications for treatment. Above all should great care and consummate skill be exercised in the application of heroic measures. Many a case has been injured by unskilful or improperly selected treatment.

DISCUSSION.

DR. GEO. L. RICHARDS, Fall River, Mass.—At the Denver meeting I had the pleasure of reading a paper on the same subject, and when the paper was afterward published in the *JOURNAL*, some time in May of this year, I appended a footnote giving the condition of those still living on the 15th of May. One, at least, had no return of the trouble up to the present time. Two are noteworthy as illustrating a point to which Dr. Levy has referred, namely, that the laryngeal trouble may remain cured while the pulmonary condition is getting worse. One of my cases had no return of the laryngeal trouble up to the time of death from pulmonary affection. In another case the laryngeal trouble has been in abeyance for two years, although the patient is slowly succumbing to the pulmonary condition. For the local medicament I used 10 per cent. monochloroparaphenol applied either directly with a swab or with a spray, usually preceded by lactic acid. The results have been as satisfactory as with any treatment in laryngeal tuberculosis; that is, the cases get better but the tuberculosis progresses. I would like to recommend this treatment for the local lesion.

DR. S. E. SOLLY, Colorado Springs, Colo.—I much appreciate Dr. Levy's paper. His conclusions, as usual, are right. I have been gratified in Colorado in procuring comparatively good results in the treatment of laryngeal tuberculosis. The point Dr. Richards made, that many cases are cured even when the pulmonary tuberculosis progresses is true. While I have had a few patients in whom the epiglottis or the folds were affected yield to treatment, yet I agree with the essayist that they very rarely recover. I have three cases of recovery from this condition in my mind at the present time. They were, however, cases in which the laryngeal tuberculosis developed after they came to Colorado, as I saw them in the very beginning, and treatment arrested the progress of the laryngeal disease. These patients are all doing well, both as regards their local and general condition. In one I removed a considerable portion of the epiglottis and in the other two I cuetted deeply and then rubbed in lactic acid. The affection of the epiglottis most often starts in the middle of the under surface, and active and early treatment at this point not infrequently prevents ulceration developing on the free edge. I have in a bad case removed almost the entire epiglottis, with relief of the local disease.

DR. H. W. LOEB, St. Louis, Mo.—I should like Dr. Levy to state to us whether or not he considers the climate of Colorado has anything to do with the rather better prognosis in his results than we get in this part of the world. I have had but one case apparently cured or at least doing well now, five years after the treatment. I do not think the treatment did any good at all. In that case the diagnosis was verified by three other laryngologists.

DR. WILLIAM DUFFIELD, Phoenix, Ari.—I do not want to make any comments or discuss this paper. It is one of the best discussions of this subject that has been either read or printed, to my mind, and my only regret is that every general practitioner could not have heard this paper, because of its great importance to the general practitioners throughout the country. My brief experience as a laryngologist in a western health resort only bears out what Dr. Levy has said. His classification is so excellent and his prognosis so nearly that of our experience that I can only commend his paper. I want to add the testimony of one who lives in that section and who has some experience, that tuberculosis of the larynx is no longer entirely hopeless, and that our prognosis should be very much better than it has been in the past. I hope the attention of practitioners in general will be called to this paper, because I believe it one of our greatest importance.

DR. HOWARD S. STRAIGHT, Cleveland, Ohio—My experience of something like ten years is in line with that of Dr. Loeb. The statistics Dr. Levy gives are very much more hopeful than the results I have had in my cases. I have had one case that I have watched about nine years. The patient is a girl who had tubercular laryngitis with ulceration of the vocal cords and partial loss of the epiglottis two years before com-

ing under my observation. When I saw her she had a lighting up of the process and I supposed she would live only a few months, but she is still living. It is the only case that I have had a chance to follow up all these years. I have seen a good many cases, and with us the disease is almost universally fatal. They almost all die and as a rule within a year.

DR. F. J. QUINLAN, New York City—This is a paper that should provoke much expressive thought from us, coming as it does from a man who is probably in position to see these cases more frequently than we do. As I tried to follow the Doctor, he didn't seem to me to dwell on those forms of laryngeal tuberculosis that are concealed, for instance, in the first stage, viz., that of hyperemia, followed by tumefaction, and then the stage of ulceration and breaking down. I do not know whether the Doctor considered ulcerative tuberculosis in his essay. It is almost impossible, except from the examination of the sputum, to tell any form of tuberculosis. The Doctor admitted, whether intentionally or otherwise, that medication affords a great deal of ease to this class; and I think relief given the patient in deglutition, improving the voice and, improving the general health, is of the greatest importance. For instance, when the epiglottis or part of the arytenoid is involved, much pain is given him in swallowing, and if relief of the pain of deglutition could be brought about, then nutrition and assimilation would certainly be improved. I have used, and very gratifyingly of late, europhen, which arrests and clears up many of those low grades of ulcerative tubercular laryngitis.

DR. ROBERT LEVY, Denver, Colo.—There remain very few words to say in closing. In the first place, it was not my intention to deal with the treatment of laryngeal tuberculosis. All I said under that topic was that proper treatment plays an important part in the prognosis of the disease. Methods inappropriate to the case often undoubtedly hasten its serious outcome, while many cases with properly selected treatment improve. But I had no intention of dwelling on treatment. As to the results, shown by the report of cases, being influenced by the climate of Colorado I simply say that you can draw your own conclusions. Reports have been made from various parts of the country. Dr. Solly, in an essay some time ago, gave a recovery of 25 per cent. Recently another reporter in a resort in the Catskills reported some 40 per cent. of cures. But the point I wish to make especially in regard to prognosis is that the character of the lesions, the situation of the lesions, and the combination of lesions, play the most important part in determining the prognosis. That is the point I wish to particularly bring out. We are now in a position to say that the prognosis of laryngeal tuberculosis must be considered from various standpoints. This paper was presented in order that we might, on seeing a case, be guided in giving something like a reasonable assured prognosis.

RELATION OF UTERINE DISEASE TO SOME OF THE INSANITIES.

BY C. C. HERSMAN, M.D.

Lecturer on Mental and Nervous Diseases, Western Pennsylvania University, Medical Department; Alienist South Side Hospital;

Physician to St. Francis Hospital for Insane, of

Pittsburg; Member of Pennsylvania, West Vir-

ginia (honorary), Allegheny County and

American Medical Associations.

PITTSBURG, PA.

There is no organ or portion of viscera which is not intimately connected with the brain through the sympathetic nervous system.

We know that cell metamorphosis is interfered with by excessive irritation; that cell nutrition is hindered thereby, and, as a result, the function of the cell lessened.

When we consider the function of brain cells, and especially of that portion where we expect mentality to be located, the importance of perfect physiologic conditions is manifest to insure perfect psychologic action. We know that in the brain certain associations of cells called centers have control or inhibitory influence over many of the lower reflex functions when in perfect healthy action. Hence, if these lower reflex functions are badly disturbed or interfered with by disease or accident, may we not expect defects in those functions of the brain above men-

*Presented to the Section on Obstetrics and Diseases of Women, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

tioned, sufficient to cause a loss of self-control, and, in so far as they exist, constitute mental alienation? By this continued reflex irritation the energy or reserve force of the cells is so exhausted that continued mental effort is greatly weakened, if not wholly incapacitated. My object is to here show that the great advantage gained by relieving these uterine disturbances, accidents or diseases which cause the reflex irritation in the brain, is to allow whatever inhibitory power remained in these brain cell centers to become active and gradually restore them to their normal condition.

I add this advisedly, for if these uterine disturbances are allowed to return from any cause which lowers the reserve nerve force below a certain standard, we have a return of the mental overthrow, and we should never fail to impress the patient and the family with the necessity of avoiding everything which in her case seems to determine the attack. Members of the profession have often noticed that even a normal menstruation has something to do with a woman's disposition, and that some women with naturally lovely dispositions are anything but angelic during pregnancy. Menstruation, pregnancy and some of the uterine diseases seem to have a psychic condition of their own, the main features of which in many persons, especially of the neurotic type, are a slight irritability or a tendency toward a lack of mental inhibition. In menstruation you will find these symptoms just before the commencement, and with some for a week or more after, which is also her period of highest conceptive power and keenest venal activity. Take a person suffering from chorea, neuralgia, epilepsy, in fact any of the nervous affections, and you often find the trouble very much exaggerated during this period. In some instances we find women suffering from chorea or insanity when pregnant, to be relieved only by abortion or delivery at term. Only a few years ago I had a case in which death seemed imminent, but after abortion, the immediate cause of which was unknown, the insanity disappeared and she made a rapid recovery. Not only that, but we meet patients who have a persistent desire to eat unnatural things at these periods.

We, as a profession, also know that the normal performance of the functions of the organs of gestation in many cases is essential to mental soundness. We know that a profound mental impression on most women will cause a cessation of the flow, and in the insane we do not expect a regular monthly menstruation during the stage of acute symptoms. One of our writers has said, in reference to the monthly flow: "The melancholics are more depressed, the maniacs more restless, the delusional more under the influence of the delusions; if the subject of hallucinations, they are more intense, the impulsive more uncontrollable, cases of stupor more stupid, and the demented may be more enfeebled or excited." This is a fact easily verified by spending some time in a lunatic asylum; although there are exceptions, it applies to many of the insane.

The climacteric is another time in life at which insanity is liable to develop, especially in maiden ladies. By some it is called "old maid's insanity," "ovarian insanity." We are told that the disease usually occurs in the unprepossessing, who have lived a severely virtuous life in thought, word and deed, and often a very religious life, on whom Nature, just before the change of life, takes revenge for too severe a repression of all manifestations of sex. This may take a turn similar to nymphomania, or it may be true nymphomania, and the patient usually thinks that some one is greatly enamored of her, mostly some one prominent in society or the community, very often a preacher.

The possible explanation of insanity occurring at this period is, that continence means atrophy, disuse means functional decay, and the influence of persistent continence on the individual, whether male, or female, is to dwarf, yea, in many respects to destroy the breadth and fullness of physical and intellectual individuality. It is a well-known fact that the "ovaries and testicles have at least three distinct actions; the first, generation; the second, their action through absorption on the central nervous system, which give to men and women their physical, moral and intellectual characteristics. The third is a special tonic action which reinforces in a special way the action of the spinal cord and brain, the last of which is of importance to my subject. These are well-known functions which can not be disputed.

Referring again to pregnancy, few women pass through the period of gestation without there being some change mentally from the normal. However, scientific writing on the psychology of pregnancy is scarce, but without going into the discussion of this subject, we find the reasoning power, moral sense, the imagination, memory and some other natures are often different, and very different from the natural person as we have known her. And still, as a further argument of the intimate sympathetic connection of the brain and uterus, how many of us have seen in the lying-in chamber or during the menses, by a sudden mental impression, either joy, grief or fright, the flow, menstrual or lochial, suddenly stopped; if menstrual, not to return, or to do so after due course of suffering; if lochial, to return after several days, to be followed by a tardy recovery. Were every practitioner an alienist and every alienist a practitioner, many cases of insanity might be averted; but, unfortunately, the alienist seldom has the opportunity offered him to treat insanity in its incipency, and the general practitioner is too apt to hesitate when he sees the mind coming unbalanced, and after some delay seeks the advice of the specialist, thinking the disease has entirely overreached his domain and that the alienist possesses some knowledge, all his own, which makes the cause plain to him. If we could get the general practitioner to understand more generally that insanity is often a symptom of trouble remote from the brain, and that he must look for the seat of the trouble, not always in the head, but in some organ, any organ, all organs, we should possibly have fewer chronic insane.

I can not refrain from mentioning in brief two cases from the St. Francis Hospital of Pittsburg, insane department. A Jewess, married, very excited, was in the Hospital for a few months. She also suffered from chronic endometritis, was curetted and went home in three weeks with no mental symptoms. Again, a Polish girl who had been in the Hospital for more than a year with no improvement mentally, on examination was found to be suffering from chronic endometritis. She went home cured in two weeks after curetting the uterus. They have both remained well, a period of about five years.

It is difficult to draw the line where general practice should cease and special practice should begin. The two should go more hand in hand. The psychologist has given us his theories and classifications, thereby complicating and preventing the advance in the study of diseases in which mental aberration is the symptom that otherwise would have been made had general practice and special practice not been so widely divorced. I do not wish to convey the idea that insanity as a symptom is always indicative of a diseased organ. It may be a faulty condition, a slight disturbance, a functional trouble

only, which, if corrected, might prevent any further anxiety. It would be well for every practitioner of medicine to read the very able article by Dr. Samuel Ayres of Pittsburg, on "Gastro-Intestinal and Hepatic Disorders, Especially, Chronic Gastro-Intestinal Catarrh in Relation to the Etiology of Some Cases of Insanity," and that by Dr. Alice Bennett of Norristown, Pa., on "Insanity a Symptom of Bright's Disease." In these articles we have ample argument to look for a cause in many cases outside the brain.

In lunatic asylums we find a wide field for the gynecologist, but many times very unsatisfactory subjects to treat. I am aware we usually look to the brain when searching for the cause of insanity, and many times, I fear, when we should look elsewhere. It is necessarily the immediate seat of disturbances, but the remote cause may be very foreign to that organ.

I am rejoiced to know that such men as my friend and teacher, Prof. George H. Rohé, M.D., Sykesville (Md.) Insane Asylum, now deceased; W. P. Manton, M.D., Detroit, Mich.; Joseph Price, Philadelphia, and others whose very striking articles I have had the pleasure of reading, bearing on the subject, have been giving their attention to this line of thought, but in more heroic measures than I have, as they have resorted to the knife, while I have nothing severer to report than the curette or local application. I feel that they have opened up a new field for the gynecologist, and established the beginning of a new era for the alienist.

In looking up statistics for Pennsylvania I find that for the year ending Sept. 30, 1891, there were admitted to hospitals, 788 insane women and girls; in 1892, 802; in 1894, 1146; in 1895, 931; in 1896, 806. Of that number there was 9.5 per cent. of the 1891 admissions with a history of uterine trouble given as the cause of insanity. Of these 788, we have the history of 480 only, 308 having no cause assigned for the insanity. In the percentages of the years from 1892 to 1896, inclusive, I have confined myself to the physical causes alone, which include that class of causes only which produce uterine disease or disturbance. These percentages are as follows: In 1892, 21.6 per cent.; in 1894, 29 per cent.; in 1895, 23.3 per cent.; in 1896, 18.3 per cent.; the percentages of all admissions running slightly higher than in 1891. The causes given are child-birth, climacteric, dysmenorrhea, menopause, onanism, menstrual derangement, pregnancy, abortion, puberty, puerperal causes, venery and uterine disease.

Had we the history of the remaining numbers of each year not given, and the same ratio prevailing, we would have our percentage increased to an alarming degree, to say the least.

With these percentages staring us in the face, should we not be more concerned about our patients who are suffering from uterine disease, and especially those of a neurotic type? Many times, if the uterine disturbances were relieved the insanity would be removed. I can not refrain from referring to another woman in the West Virginia Hospital for the Insane, who was suffering from intrauterine vegetations and dying a slow death from slight continuous hemorrhage therefrom. After dilatation and a thorough curetting, she made a complete recovery from the uterine disease and was discharged quite well mentally. Knowing, as many of us know, the association of uterine disease and mental disturbances, it is surprising that there has not been a closer study into the relations of the two, that we have not more literature on the subject, thereby giving an impetus to the investigation of mental symptoms and their causes

in some remote organ, and to establish a relationship if possible.

No fact has been more clearly established by psychologic investigation and neurologic anatomy than that the human anatomy is wholly dominated by the sympathetic nervous system. The whole physical structure is subservient to its influence. It is a despotic force with compulsory requirements. There is no stasis, either active or passive, no modification of the activities, no irritation, however slight, but will manifest itself through the sympathetic nervous system. I have seen, as already stated, in the treatment of insanities the result of uterine disease, the local or surgical treatment of the trouble not only cure the uterine disease, but effectually cure the concomitant disease occurring in the brain, thus showing the mysterious (?) and unaccountable (?) connection between them. A woman becomes the victim of nymphomania, amenorrhea, dysmenorrhea or some one or more of the many forms of uterine disturbances; it may take on one of the amatory phenomena, especially of nymphomania, a religious turn, devotional enthusiasm of so violent a character as to necessitate removal to a lunatic asylum—and these are not fictitious cases—and all this because of local irritation.

Finally, we may have a uterine trouble, an irritation, transmitted through the hypogastric, spermatic and other ganglia and plexuses, from cell to ganglion, passing onward to the sacral, to the cord, the medulla oblongata and the cerebellar and cerebral ganglia, finally by coronata radiata fibers to the cortex of the brain, that most valuable distribution of nervous matter, the seat of mentality and intellectuality, ending in a complete overthrow of the noblest propensity of woman, driving her to a madhouse, there to drag out her existence within the walls of her life prison. Thus we have the beginning and end of a very sad picture.

TREATMENT OF CHRONIC CROUP.*

BY EDWIN ROSENTHAL, M.D.

PHILADELPHIA.

Many of us who practice intubation in the treatment of laryngeal diphtheria occasionally meet with a case that causes us much care and annoyance, by reason of the duration of the symptoms of stenosis. Since the advent of the diphtheria antitoxin our methods of treating intubation have changed. Where, before the use of this remedy, we permitted the tube to remain in the larynx at least a week before we thought of disturbing or removing it, we have found that, in the majority of cases, the tube can be removed, or removes itself by expectoration, before the period of five days, or 120 hours. If we are called early enough, that is, before intubation becomes a necessity, our cases—in the majority of instances—recover promptly on the third day, and at the most the symptom of stenosis disappears before the fifth day. Still, we meet cases that are not bad enough to require the presence of a tube, yet require treatment, by reason of that symptom—stenosis remaining or appearing at certain intervals. I have noted this quite frequently, and more remarkable, since the antitoxic action of the serum had removed all visual traces of the disease and the tube removed—if the case required it—and the case pronounced cured, the symptom—stenosis would return in a week or ten days, and would require a reintubation and a further treatment.

The question in our minds is the cause. I wish to ex-

*Presented to the Section on Laryngology and Otology, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

clude any injury to the larynx by reason of the intubation, or by the continued presence of the tube in the larynx, as these cases are in the majority of instances a mechanical injury. And the cases I speak of are found frequently where intubation was not performed, and another cause than this must be looked for. As an instance, I will briefly describe a case:

William O., aged 3 years, of Swedish parentage, was taken ill with clinical evidence of diphtheria on Jan. 6, 1899. Bacteriologic test conclusively proved the presence of the K-L bacilli, also the streptococcus. An injection of 2000 units of the diphtheria antitoxin was administered, with the result of a disappearance of all visual traces of the disease in the pharynx. On January 14, the patient had a croupy cough, which was treated with an expectorant mixture, and three days thereafter symptoms of stenosis became marked, but not to such an extent as to necessitate intubation; at this time 2000 units of diphtheria antitoxin were again injected, with the result of somewhat relieving the stenosis. The lymphatic glands at the angle of the jaw were somewhat enlarged. Medical treatment was continued and the symptoms of stenosis relieved, but they reappeared, and February 10 were as bad as if no treatment had ever been given. Bacteriologic examination—five weeks since the first—showed an absence of the K-L bacilli, but still the presence of the streptococci. At this date, 10 c.c. of the antistreptococcal serum were injected, with the result of a disappearance of all symptoms of stenosis on the third day thereafter, and a perfect cure.

The presence of the streptococcus pyogenes as a complication in diphtheria is very well known. Its absence would prove the exception; but that the symptoms of chronicity in this affection should be ascribed to it, I think is something new. The strepto-infection may alone prove sufficient to produce the disease known as croup, as may be verified by bacteriologic test, and the knowledge thereof will be a sufficient guide to the treatment.

The cause of "chronic croup" may be otherwise than this. I have seen the too energetic use of hydrogen peroxid produce croup secondarily to other varieties of diphtheria, and in cases intubated, I believe, the constant use of the peroxid may be nothing but injurious. Therefore, in treatment, and since the advent of the antitoxin, I have used the peroxid simply as a lubricant, for by its use I have been enabled to more readily practice intubation. Its further use I have limited, and only diluted and with an atomizer, to those instances where the tube became clogged with inspissated mucus or other secretions from the throat. Using this remedy so carefully, I can not charge to it the cause of the constant intubation, an intubation that may last from five to eight weeks, or in cases where the tube was removed and the case pronounced cured, the necessity of intubation after the lapse of seven or ten days. I have elsewhere reported (*Phila. Med. Jour.*) a case of chronic croup wherein intubation was practiced, the tube removed, and reintubation on the eighth day thereafter, antitoxin meanwhile being used; and another case intubated, the tube removed by expectoration on the third day, where the symptoms of stenosis recurred every week for three weeks, and in which over 20,000 units of diphtheria antitoxin were used until a final recovery. The treatment of these cases was strictly antitoxic, but when I saw there was no response, and that some other factor was at work, producing the stenosis, I investigated, both clinically and bacteriologically, with the result that I found the main and certain cause of chronic croup was, in the complicat-

ing streptococcal bacteria, and by its presence so guided my treatment that my results have been most gratifying.

The treatment is as follows: When I am called to a case of croup, whether it requires intubation or not, I immediately use the antitoxin. I then make the bacteriologic test. If I find the presence of the streptococci I immediately make a further injection of the antistreptococcal serum, and continue with the antitoxin, as the case may require. If, however, as I have seen sometimes, there is a negative result as regards diphtheria, and a positive result as regards the streptococci, I drop the antitoxin and continue the treatment only with the antistreptococcal serum.

The method of its use is precisely similar to the antitoxin, with this exception. Where in the antitoxin treatment a smaller dose is begun, and a gradual increasing dose the rule, with the serum a large initial dose is the beginning and the same or a smaller dose follows. The time to give the injection is also different. In the antitoxin, any time is of value; with the serum, the early morning or when the temperature begins to rise. The parts chosen are the loins or side of the chest. The parts are cleaned with alcohol soaked on corrosive cotton or gauze, and after injection the aperture is closed with iodoform collodion. The commencing dose is 10 c.c., or even a larger quantity, and this is repeated on the same day or the day following, and is continued until its influence is shown by a decline in the temperature and pulse-rate, and an amelioration of all symptoms. The duration of the treatment is the same as with the antitoxin, and on the third day we may note evidence of a cure. The serum can be used to any quantity, and is as free from danger as is the antitoxin, the same sequelæ as noted with the antitoxin, as eruption, albuminuria and the like, are found here, and in all the manifestations the results are equal. In all cases where the bacteriologic examination shows the specific germ, the serum should be used, and in those cases of chronic croup, or where the diphtheria bacilli are absent, it is always in order to use this serum.

517 Pine Street.

DISCUSSION.

THE CHAIR—The Chair would like to ask the Doctor the length of time required to find the streptococcus infection.

DR. EDWIN ROSENTHAL, Philadelphia—Twenty-four hours.

THE CHAIR—And in the meantime you use the antitoxin?

DR. ROSENTHAL—To be sure; it is diphtheria. But if I find only streptococci, then I use the antistreptococcal serum.

THE CHAIR—I notice the diphtheria antitoxin has been used over and over again, but ordinarily it is the Doctor's experience, I presume, that the antitoxin to be of value primarily should be used within a very short time.

DR. ROSENTHAL—In a very short time, yes.

THE CHAIR—I mention that because in going over the literature I found one case of death after the use of antitoxin reported and it was rather interesting to say the least. The patient had had diphtheria for some time without the parents allowing antitoxin to be used. On the fifth day the physician gave an injection of nitroglycerin and antitoxin at the same time, and it was claimed that death was due to antitoxin. Of course we know that is not true.

DR. GEO. L. RICHARDS, Fall River, Mass.—I would like to know what the essayist means by the word "croup."

DR. ROSENTHAL—Any stenosis of the larynx due to diphtheria. When I find, as I do sometimes, that it is not due to the Klebs-Loeffler bacillus but to streptococci, it is still croup, but of course not true diphtheria.

THE CHAIR—In other words, you use "croup" to mean an inflammatory process causing dyspnea?

DR. ROSENTHAL—Yes; there are cases of croup not due to the diphtheria bacillus.

QUESTION—I would like to ask Dr. Rosenthal if he has in any case of diphtheria been unable to get the bacilli?

DR. ROSENTHAL—Yes.

WHAT ARE ANTITOXINS?*

BY R. G. ECCLES, M.D. P.H.G.

Fellow of the American Association for Advancement of Science;

of the American Medical Association; of the American
Anatomical Association; of the Medical Society of
the County of Kings, New York, etc.

BROOKLYN, N.Y.

In a lecture delivered by Dr. T. Clifford Allbutt, regius professor of physics in Cambridge University, England, before the Johns Hopkins University in October, 1898, occur these words: "The study of origins, then, is not only the new method of modern criticism, of modern history, of modern anthropology, of our reading of the evolution of the universe itself from elements which even themselves are falling under the same analytic inquiry, but the study of origins is leading to a revolution in our conceptions of therapeutics, as all of these other studies; a revolution which as yet we have not fully understood."

Never were truer or more profound words uttered than these. The revolution to which Prof. Allbutt refers is one so momentous that but few have scanned the horizon of modern therapeutics closely enough to duly appreciate its far-reaching consequences and importance. That this fact be made clear to those present at this Section meeting, and to as many members of the AMERICAN MEDICAL ASSOCIATION as do me the honor of reading this essay when it appears in the JOURNAL, permit me to ask how much and what does the name "Antitoxin" stand for when seen in print by the average medical man? To some, perhaps to most, progressive physicians, it means a new kind of remedy that may or may not be better than the old and well-tried ones of the past. How many, do you suppose, can see more than this it is as related to the destiny of our race? To the skeptic it is but the shibboleth of a new therapeutic fad. He doubts its value, and quietly to himself mutters, "what fools these mortals be." To the hosts of the sectarian pathies and their antivivisection allies it is nothing more than a filthy and diabolic lying invention of the vivisector, concocted as a piece of spurious evidence to prop up his wicked designs against dumb brutes.

How large a proportion of mankind see any more than one or the other of these claims in it? Have you watched the steps by which we have come to believe that such things as antitoxins really exist? Have you followed the logic of the men who have claimed to discover them? Have you seen how, step by step, the belief in their existence came to these men? If you have not, then you are not prepared to fully appreciate but the smallest fraction of what their discovery means. The antitoxins themselves are of far less importance to the race than are the solutions of the problems that cluster around them. They are but stepping-stones leading back into the mystic origins to which Prof. Allbutt refers. To fully and correctly understand what they are and how they are produced is to be able to solve some of the deepest riddles of life, health and happiness. They are leading us toward a true science of therapeutics and a true conception of how we have accidentally in the past cured diseases, and how we shall in the future prevent death "by the subtle strategy which consists in knowing all the moves of the game," as Prof. Allbutt put it. What little we have discovered concerning the antitoxins has come to us from a pursuit of the same methods of thought, the same style of research, the same processes

of verification, and through the same class of minds as gave us the whole fabric of modern civilization. They have come to us as a part of the grand mental movement that built up the doctrines of the conservation of energy, the unity of natural phenomena and the universality of evolution. Have you noticed the methods of the men who are at work on the subject? Have you seen how they turn the light of counter-experiment and counter-criticism on each other in scorching concentration? Have you noticed that every question is put to Nature for final reply, and every answer verified or condemned by a competent peer? Have you observed how every mistake in logic is pounced on by a whole army of coworkers, and every mistake in experiment is mercilessly gibbeted in the same manner? Every idea and every fact must run the gauntlet and survive or perish in the struggle. The system only needs to be understood to be respected. When serums, toxins and antitoxins reached the general profession they had already been tried and found worthy of consideration by experts. They were given to us for further trial with human beings, where we have a right to experiment, but they may not. Whatever our verdict may be concerning them, it can not alter theirs, and will only prove that we had new and altered conditions to deal with, if it is adverse. To decry them without trial, or with unfair or imperfect trial, is dishonest, sinful, and unjust to the whole of animated nature, now and through all future time. We, as medical men, owe it as a sacred duty to give them a fair trial. Whether we do or not, however, workers in this field of pathology and physiology will go on making their discoveries along the same line of investigation. The laws of their action will be found, their chemical composition discovered, and their bearings on the greater questions of life as a totality worked out.

What are some of the questions now before them in which we as physicians are interested? It is only necessary to name them for all to see their importance. Here are a few. How come we to gain tolerance of poisons? What is the nature of immunity? How do neurotic poisons poison? How are toxins produced? How are they related to antitoxins? How do they act on each other? Is the action chemical or vital? To what class, or classes, of organic bodies do they belong? Is either, or are both, enzymes, albumins, globulins, or are they even proteids?

As a sample of the way the work is being prosecuted in the endeavor to get replies from Nature to these and kindred questions, let us take the late experiments of Besredka with orpiment or yellow sulphid of arsenic⁶. He found that injections of this almost insoluble substance, if very finely powdered, killed quicker than when injected in a suspension composed of coarser particles. When a membranous sac containing a quantity of the orpiment is placed in the abdominal cavity of a guinea-pig it will die almost as quickly as when the same quantity is injected directly into the same place. In the one instance the arsenic sulphid had to dialyze through the membrane, a thing it could only do by being dissolved; in the other it was brought into direct contact with the tissues. As this pigment is among the most insoluble of known poisons, it is here made manifest that it does not poison by mere contact. It evidently kills by chemical means. It can be stopped from killing by a proper chemical antidote. Besredka further found that if the quantity of orpiment injected is not too large the leucocytes take up the yellow particles into their structure, and for as long as ten days can be seen carrying them

*Presented to the Section on Materia Medica, Pharmacy and Therapeutics, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

around. Constant examination shows that the poisonous material is being slowly dissolved and a less poisonous substance produced that can be eliminated by the kidneys. That the leucocytes take up and dispose of many other poisons than orpiment in this way has been shown by Metchnikoff and Kober². The salts of silver, mercury and iron have been found to be carried throughout the system in this same manner. This work is done by the same leucocytes as are known to englobe and destroy microbes. It is evident that they have the power of secreting something that can unite with the poisons which they take up. What this something is happens to be one of the issues of the hour. That the leucocytes are not the only producers of this something that antagonizes poisons was shown by Widal and Nobecourt with strychnin and morphin⁴. They injected these hypodermically into animals with a small amount of fresh, sterile, brain substance, and found that the animals would live after double or treble the dose that would kill them without the brain substance. It appears as if the brain substance contained something that neutralized the poisons. Thoniot and G. Brouardel also found that when nerve-substance was used the results were the same. They kept their animals alive by injecting nerve substance in an emulsion before injecting the fatal dose of strychnin⁵.

In 1896 Van Ermengen discovered an anaerobic bacillus in ham which had caused some serious cases of illness at Elzelles, Belgium. He produced the same train of symptoms with sterilized cultures of his bacillus⁶. Kempner and Pollock have isolated the poisonous toxin of cultures of Van Ermengen's bacillus and studied its effects on the cells of the bodies of animals. Injections of this toxin were found to cause degeneration of the cells of the spinal cord. A finely granular disintegration or "partial pulverization" of the corpuscular elements occurs. The physical changes revealed by the microscope correspond with the symptoms observed both in time and volume. They immunized animals to this toxin, and securing a serum from the immune animals, studied the same degenerative changes under its administration. If the antitoxic serum was injected soon after the toxin, the degeneration was but slight. When the antitoxin was mixed with the toxin before injection no degeneration occurred⁷. What Thoniot and Brouardel found true regarding the action of nerve tissue injections with poisonous doses of strychnin, Wasserman found held good for nerve tissue and the virus of tetanus⁸. A. Marie found that what was shown by Widal and Nobecourt to be true regarding the action of brain substance on strychnin and morphin was equally true with brain substance and tetanus toxin. He declares that he found it necessary to have a previous direct contact of the toxin and the brain tissue to have it act⁹.

Metchnikoff has probably studied the subject of antitoxic action more than any other single individual. It was forced on him because it was at first supposed to be antagonistic to his belief regarding phagocytosis. He finds that while the brain tissue of the guinea-pig protects mice as well as guinea-pigs from the toxin of tetanus, neither the brain nor the spinal cord of tortoises or fowls has any protective effect on tetanus injected into guinea-pigs or mice. He believes that his many experiments have established it as a general principle that the more susceptible an animal is to tetanus the more efficacious its nerve substance or its brain substance is to tetanus. To this rule there are exceptions, and among them is the frog. Its brain seems to have no antitoxic power, although it is quite susceptible to the poison. In

a former communication he showed that low cryptogams, like bacteria and fungi, destroy toxins but do not produce from them antitoxins, that invertebrates can not produce the antitoxin of tetanus in amounts that are appreciable, that only in animals as high as and higher than the crocodile are antitoxins produced; that in fowls the antitoxic power resides in the blood, and not in the nerve tissue, and that phagocytic power is older than antitoxic in the life history of our planet¹⁰. He thinks that mixtures of brain substance and nerve substance with poisons do not destroy them by any kind of chemical union, but that such mixtures produce an inflamed condition of the tissues, when and where injected, that attracts leucocytes and encourages phagocytosis. Their activity is the agent of destruction, and not the nerve substance. W. W. Stephens and W. Meyers have found in their experimenting with serums that the same quantity of serum always neutralizes the same amount of toxin, whether in the test-tube or in the body of the animal. They hold that this strongly indicates an adhesion to the chemical law of definite proportions, and, therefore, to chemical and not vital action¹¹. Cantuzene comes to the support of Metchnikoff, and shows that anything that suspends phagocytic activity in the presence of a powerful toxin causes the animal to die. This he holds indicates vital activity and not chemical¹².

Ehrlich finds that toxins and antitoxins affect each other more promptly in concentrated than in weak solution, in hot than cold solutions, and, with Stephens and Meyers, that they bear quantitative relations to each other. He claims that in the case of ricin he has proof of union in definite proportions¹³. He advances the theory that antitoxins are the tissue elements with which the toxins combine in the body to poison it. The irritation of partial poisoning causes the system to produce an increased amount of such tissue substance, this enters the circulation and acts as a means of neutralization before the toxin can get at the tissues for which it has an affinity. He thinks that there could be no poisoning of the cells if they did not contain elements having an affinity for the poison, and when the poison is fixed on such elements its power for further harm is gone. Just as a poisonous alkali unites with a poisonous acid to form a non-poisonous salt, so do the poisonous toxins unite with the tissue elements to form non-poisonous products. But as the tissue has thus been robbed of its necessary elements by the poison, a demand is made on the system to produce a surplus of such material, and this surplus constitutes the antitoxins. This ingenious theory has a number of able supporters in Europe. A number of the experiments which are here referred to seem to give support to it.

R. Pfeiffer and Marx accept this theory as a partial explanation of the phenomena of acquired immunity, but they do not believe it can explain the presence in the body of substances having bactericidal power. They find that the spleen shows this bactericidal power. They find the blood, and that the spleen, bone-marrow, lymph-glands, and possibly lungs, contain larger amounts of it than the blood. Here they hold that they have evidence that the leucocytes are neither the only nor the most important agents in the destruction of disease germs and disease poisons¹⁴. A. Wasserman thinks that the toxins and some of the organs react with each other to produce by a chemical union new bodies having bactericidal power¹⁵. The fatal objection to this theory is that it violates the law of parsimony by introducing new substances that we know nothing about, with properties that are unusual. Such lawless theories are the kind that

bring all theorizing into disrepute among men not accustomed to scientific methods of thought.

Three legitimate theories now hold the field, and as they are each guiding distinct sets of exceedingly able men in their work as experimenters, it is pretty certain that the question will soon be settled by the consensus of the competent. It is not at all unlikely that all three have elements of truth within them, and that no one of them is entirely able to explain all the facts. The chief weakness of Ehrlich's theory is its inability to explain the fact pointed out by Metschnikoff, that frogs are very susceptible to tetanus, and yet their brain substance does not act as an antitoxin. It likewise fails to embrace a large number of facts that one might naturally expect it to. This last objection is equally powerful against the phagocyte theory, when pressed forward as a complete explanation of the phenomena of immunity. The experiments of Pfeiffer and Marx, already referred to, are as damaging to the phagocyte theory as to that of Ehrlich, in that they positively limit the sphere of action of each. If the spleen, bone-marrow, lymph-glands and lungs have greater bactericidal power than the blood, this throws the phagocytes into an inferior position as microbe killers. There may be a number of ways in which such destruction occurs and by which immunity can be maintained. E. de Cyon, of the Physiologic Institute of Berne, Switzerland, has shown that iodothyronin from the thyroid gland, instantly destroys the toxic effects of atropin and nicotine¹⁶. If it also destroys the toxins it would be a very useful ally to the phagocytes, as well as the bacteria-destroying organs in their work. Salkowski¹⁷, Brieger¹⁸, and Ehrlich¹⁹, have shown that sulphuretted hydrogen and some antiseptics can destroy tetanus toxin²⁰.

The theory which seems at present to permit of the generalization of the largest number of facts is the one that assumes that the antitoxic and bactericidal power of serum is lodged in substances that are of the nature of enzymes. The fact that they have been precipitated by Brieger and Boer by numerous agents in a way that pepsin, trypsin and other enzymes are thrown out of solution, indicates a possibility of their being enzymes²¹. For over a year Emmerich and Loew have been at work in Munich studying how enzymes are related to immunity²². Nencki and Pfeiffer made the suggestion of some sort of relationship between them in a way that led Emmerich and Loew to take up such work. Prof. T. Lauder Brunton, in his address at the International Medical Congress at Moscow, said: "Perhaps the hypothesis I mentioned eight years ago to my pupil and friend, Mr. Hankin, that the germicidal power of organisms is proportioned to their power to produce enzymes, may not be altogether unfounded, and possibly we may discover also that immunity, natural or acquired, is nothing more than an extension to the cells of the tissues generally of a power which is constantly exercised during digestion by those of the intestine and liver²³. It appears then that the credit of first enunciating the theory belongs to Brunton. He, however, acknowledges his indebtedness to Dr. Johan Baptista van Helmont, a celebrated iatrochemist and disciple of Paracelsus, of the early part of the seventeenth century. Emmerich and Loew claim to have found that a number of different kinds of bacteria produce enzymes fatal to themselves and other germs. When combined with animal protein the enzyme is transformed into an immunizing product. Both substances have been isolated in tangible form so that it is a fully substantiated fact. DeSchwinitz has also isolated an enzyme from hog cholera germs, that

immunizes guinea-pigs. Kondratieff declares that such evidence as he has been able to collect experimentally and otherwise compels him to believe that the antitoxins are related to the enzymes²⁴.

Enzymes are substances that have the power of causing other organic substances to alter their chemical composition by their presence while they themselves remain unchanged. Like parsons who marry two people, while the act of marrying them does not alter their own state in the slightest, these enzymes cause chemical unions to occur while they retain their condition of singleness. Those we know best, such as pepsin, ptyalin, trypsin and invertin, all force water into the chemical composition of various food stuffs, and enable them to dialyze through the walls of the stomach or intestines. They probably split all the substances they act on into smaller molecules²⁵. There are other ferments that instead of aiding solution and dialysis hinder the same by coagulating or fixing substances. It is evident that all living forms, depending as they do on foods for existence, must have the power of dissolving, coagulating, and fixing such foods as an essential condition of life. As all such changes, so far as we have ever been able to discover, are brought about by enzymes, we have no logical right to assume that any other form of agency is at this kind of work until one is found. Step by step the so-called vital force has been driven by the enzymes out of this department of life. They have been found in every form of life from the bacteria and molds up to monkeys and men. As the processes of life are unthinkable without the accomplishment of their kind of work, and as they only are known to do such work, we can not avoid the conclusion that they must have existed as long as life has existed on the planet. They have ever co-existed with protoplasm, and must have been subject to its experience. As the ameba has gone upward in development toward the brain cell, every change must have brought a corresponding change in the enzymes that made its food soluble within its structure, and that fixed that food as solid tissue again. The enzyme is the door-keeper of the cell. It is also, in its opposite form as a coagulant, the host within the cell. The first kind aids the substance in getting in, or if in and converted into waste makes it soluble so that it can get out. The second kind has a function that is just the reverse. It can keep out what is not wanted in or keep in what is not wanted out by rendering it insoluble.

Ehrlich has lately discussed this subject in connection with the administration of drugs²⁶. He uses Witt's hypothesis of "stiff solutions" to explain the processes of staining tissues and of the passage of drugs through the cell. Every chemist who has worked in commercial organic chemistry knows how by the aid of acid and alkaline radicals he can make alkaloids and the like miscible or immiscible as he chooses in different solvents. In a similar way the enzymes may render various substances soluble or insoluble in the substance of the cell. By adding the sulphonic acid radical to aniline it is at once rendered unable to stain tissues and to poison them. Its inability to enter the tissue cells in the new form renders it unable to poison such cells. If it could get in to stain them it could get in to poison them. Being excluded it can do neither. By acting on toxins and other organic poisons with the special enzymes of the different kinds of tissues so as to alter their structures and make them unable to penetrate such tissues, they would at once be rendered harmless. Not a single new enzyme needs to be formed. No violence has to be done to Nature to make such a

hypothesis true. The whole material is now and always has been ready formed in the body to meet every emergency. All that is needed is an alteration in the proportions of the fixing and of the solving enzymes that constantly are at work in behalf of the special tissue to which the poison has an affinity. Natural selection must during all past time have been picking out to live, such animals as were able under the irritation of selective poisons to increase their stock of the fixing enzyme for that tissue and killing off every animal that could not make such an adjustment. Organic poisons and foods merge into each other in their chemical structures. The processes of digesting the one are not greatly different from those of digesting the other. To split up a poison and make it immiscible in the cell matter can not be much harder than to do the same thing for a food. It may only require an increase in force. Increased volume of output of one kind of enzyme and diminished output of the other and opposite kind could easily come from a change of demand, if this function follows the laws of all other known bodily functions. According to this hypothesis, then, immunity is due to an increase in the production of the fixing enzyme of that tissue which happens to be the special point of attack of the poison, this increase being due to the irritation of the tissue elements that the poison seeks to damage. As food turned into the stomach brings hydrochloric acid and pepsin, so poison turned into a cell brings its digesting enzymes in continuously increasing proportions as the irritation persists. After the cell has been irritated for a considerable time, it gets into a habit of producing an excess, thus establishing continuous immunity. As an overproduction of gastric juice will cause intense hunger, so an overproduction of other enzymes would be expected to produce their form of hunger, i. e., a desire for the poison that caused them to be produced in excess. We find that this is actually the case. The morphin fiend has morphin hunger, and the tobacco user has nicotin hunger. The enzymes that keep these poisons from reaching the tissues for which they have a special affinity, in doses that are dangerous, when not having the poisons to act upon may produce this special form of poison hunger.

CONDENSATION AND PRESERVATION OF MILK BY REFRIGERATION.*

BY HENRY O. MARCY, M.D.

BOSTON.

In an article contributed to the AMERICAN MEDICAL ASSOCIATION last year¹, entitled "The Milk-Supply of Cities; Can It Be Improved?" I described somewhat at length a process devised by Mr. B. F. McIntyre of New York by which 80 per cent. of the water is abstracted from milk by freezing it, when in moderate agitation. The water, as ice, is taken from the milk in comparatively stainless crystals, almost without loss of solid product. It has been shown that the expense of condensation is very much less than by evaporation in vacuo, and that the resultant product is of much greater value. A considerable series of experiments was undertaken during the summer, under the supervision of Prof. W. T. Sedgewick of the Institute of Technology, in order to ascertain the effect of refrigeration on the bacteria ever present in milk.

It was found, although the resultant was not perfectly sterile, that the bacteria were in large measure destroyed, and that the concentrate put up in glass jars, such as are commonly used in the distribution of milk, has a keeping quality of weeks rather than days. Encouraged by these results, Mr. Edward Burnett of Boston, well known for his practical studies in furnishing a better milk-supply, has established a plant² of sufficient capacity to demonstrate the commercial advantages of the process. It is believed that the process offers a practical solution of the difficult and expensive problem of milk distribution in cities; that the family supply will be furnished in a concentrate one-fifth the bulk of ordinary milk, and that distribution of it from house to house made once a week will be ample for practical purposes. By this process the fat globules are uninjured, and, as a result the cream is unimpaired for table use. Pathologic bacteria are destroyed by the process, and the milk-supply will be rendered safe for use.

The economic advantages are obvious. In the first place the milk will be furnished the consumer at a material reduction in cost, and the waste in its daily use will be very greatly lessened. A far more satisfactory product in every respect will be furnished, and with a little care the pantry will be in constant supply. Mr. McIntyre is by no means satisfied with furnishing a product which contains even so little as 7 per cent. of water, and he looks forward to the practical demonstration of furnishing milk in a solid form, with keeping qualities equal to that of butter or cheese. I have in my possession a sample of solid milk prepared by him, by this process, now some months old. I make this brief report of progress, since the milk-supply of the country is of the first importance to every individual, and we indulge the hope that the work thus begun will prove so satisfactory that it will revolutionize the distribution of the milk-supply of the world.

ACCORDING to the statements made by members of the crew of the *Sequoia*, which recently arrived at San Francisco, a large number of persons on the Clipperton Islands are afflicted with scurvy and already five deaths have been reported. It is said that this was the first vessel which had visited the port for a period of four months.

*Presented to the Section on Physiology and Dietetics, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

NON-MALIGNANT STRICTURES OF RECTUM.

THEIR SURGICAL TREATMENT.

BY JOSEPH B. BACON.

CHICAGO.

It is not the purpose of this paper to enter into the etiology or pathology of strictures, but simply to compare the different operative procedures of the past and show why the methods failed to give permanent results, and to again describe two methods of operating for rectal strictures, devised by me and published some years ago. The time is now sufficiently long since the cases were operated on to determine whether the results are permanent or not.

Some years ago, when I began teaching diseases of the rectum in the Post-Graduate Medical School, I had a large number of stricture cases sent to me. Among these cases were strictures located at all parts of the rectum, from the upper part of the anal canal to the upper rectum; some were circular bands of scar tissue, others tubular masses of cicatricial tissue. None of them were called rectal strictures unless the scar tissue involved all the layers of the rectal walls, and in the case of many of them, located at the point where the levator ani muscles encircle and embrace the rectum, the scar tissue extended far beyond the rectal walls. I was at a loss to know what to do with some of these cases where they gave a history of having undergone one or more surgical operations by prominent surgeons, with but temporary relief. Most of them gave a history of having used rectal bougies persistently for months, or years. At first the bougies had been used by the surgeon; finally the patient was instructed how to use the instrument. Some of them had worn a rectal bougie every night while in bed for months, but only got temporary relief of their constipation, but not even temporary relief from tenesmus and mucopurulent bloody discharges resulting from the ulceration at and above the seat of stricture. Gradual dilatation by bougies is a very old method, dating back as far as we have a history of surgery; but there is no authenticated record of its ever having been a means of cure in a true cicatricial stricture, while it has a record of producing an enormous death-rate from perforating the bowel or increasing the ulcerations and prolonging the septic absorption until the patient succumbs to amyloid visceral changes. We have every reason to believe that if the unpublished cases of accidents from rectal bougies were published, the results would be so appalling that the bougie treatment would be justly banished for all time, and its use classed as malpractice. The reason gradual dilatation fails to permanently relieve is that while there is for a time absorption of the scar tissue at the surface contact of the bougie or the inner surface of the ring, at the same time the peripheral surface of the scar tissue is excessively irritated and if the peripheral irritation and divulsion is long continued the contiguous fibrous tissue becomes hypertrophied, later to contract, and thus new scar tissue is added from time to time from the periphery.

Divulsion or forced dilatation of rectal strictures, with or without anesthesia, although a common practice of years gone by, produced such an alarming death-rate with no permanent authenticated results that it seems unnecessary to speak of the method at this age of common-sense and advanced surgical pathology. Yet several of my cases gave a history of having been treated by this method and suffered for weeks with pelvic cellulitis and sepsis; others suffered for months with pelvic or general peritonitis, and their history gave evi-

dence that they had very narrow escapes from death, while none of them was permanently relieved from the constriction. Any cylinder or ring that is overdilated always ruptures first at the periphery; thus forced divulsion tears the periphery first, then the intervening tissue admits pathogenic germs, which are always present in the diseased rectum, direct into the perirectal connective tissue, or into the peritoneal cavity, if stricture is in upper or middle part of rectum. This method of treatment is never justifiable under any circumstances, except when the stricture is confined to a circular scar of the mucous membrane. In these cases, if the ring of cicatricial tissue is broken, a bridge of mucous tissue will sometimes form between the severed ends and thus prevent the re-formation of a stricture.

Proctotomy for the relief of stricture has been practiced by surgeons since very remote times, probably dating almost as far back as the use of the bougie. It has been described and classified under the terms of internal and complete proctotomy. Internal proctotomy consisted in making one or more incisions from within the rectum through the stricture. These incisions give but temporary relief, and the absurdity of making a wound in a septic field, with no chance for providing free drainage, has been abundantly illustrated by the enormous death-rate even in the reported cases. Except as a rare procedure for extreme emergency, where otherwise death from obstruction is imminent, this operation should be relegated to the archives of ancient history to amuse the relic hunter of prehistoric jokes. In complete proctotomy the incision made through the stricture and all the tissues including the anal canal, the sphincter muscles, and everything back to the sacrum and coccyx, giving a free drainage, and the relief from obstruction is temporarily complete. The free, open drainage makes the operation comparatively free from danger. But the wound gradually heals by granulation, and eventually this extra scar tissue is added to the previous stricture tissue, and the constriction is worse than before any operation was performed. The exceptions to this are very rare indeed. But worst of all is the almost universal fecal incontinence following this operation. Within the last few months a man brought his wife to me to see if anything could be done for her incontinence, following a complete proctotomy for the relief of a rectal stricture. The case was one of the saddest possible, the husband stating that he should get a divorce if she could not be cured. The tubular stricture and the newly-formed scar tissue, with atrophy of the sphincters, precluded any possible operative procedure that would give fecal continence.

After aseptic surgery became a fact, the surgeons were very greatly encouraged over the possibility of resecting the stricture tissue and reuniting the gut by end-to-end anastomosis, but this fond hope was blasted after the statistics of a few years' work were published. The deaths from peritonitis, from one or more or even all the sutures giving way from the tension, from peristalsis of the gut or more often by the tension caused from the gut sufficiently to draw it well down in the lower pelvis, gave a discouraging mortality. The few cases that escaped death, with rare exceptions, found after one or two years that a stricture had re-formed at the seat of anastomosis. Then we realized that the brilliant results from intestinal anastomosis of the tract above the pelvic brim could not be attained within the pelvis. Anatomical reasons make it impossible. The rectal walls contain an enormous amount of fibrous tissue, far more indeed than any other part of the intestinal tract. Be-

sides this, the rectum is buried in a bed of fibrous connective tissue, and its fibrous tissue is intimately connected with the dense fibrous fasciæ of the pelvis. What happens after end-to-end anastomosis here? First, a circular scar is left at point of union. This scar is constantly irritated by peristalsis forcing formed fecal matter through it. The old pathologic law holds good: that fibrous tissue if continuously irritated becomes hypertrophied, and then contracts. Thus the circular fibrous tissue begins the process, and the contiguous fibrous tissue takes on the same process at the point of irritation. The pathogenic process begins and continues to add more contracting tissue to the periphery. This latter contracts and every month more tissue is added, eventually to re-form a true stricture. I doubt if there are exceptions to this rule. If there are cases, they have been kept studiously away from any of the clinical exhibitions of the societies in Chicago.

More recently, Howard Kelly and others have amputated the rectum just above the stricture, inverted the cut end of the rectum by suturing, and anastomosed the proximal end of the sigmoid into the rectum below the stricture. The same reason that caused the failure of end-to-end anastomosis of the rectum will operate to make the lateral anastomosis fail. Time after time I have made a lateral anastomosis of the sigmoid into the rectum in experimental work upon dogs and in every case, after a few weeks, the anastomosis opening would be so contracted that I could not insert my finger through it. I doubt very much if any of these cases would be relieved for more than one year after lateral anastomosis.

Naturally, after the surgical operations for the relief from rectal strictures had failed to give any encouragement to the surgeons, they began falling back upon the last resort for saving life and professional reputation, and inguinal colotomy was recommended as being sure of relief from obstruction and from the danger of perforation at the seat of ulceration above the stricture.

With these discouraging reports from the literature, I determined to devise some method of curing rectal strictures that would not increase the dangers of the old operations and at the same time would leave the sphincter muscles in their normal conditions, so that I could assure my patients that they could be left with perfect continence. The former methods failed: 1, because of new fibrous tissue forming and reuniting the severed stricture bands; 2, because of incontinence; 3, because of the high death-rate; 4, because of contraction of the lateral anastomosis opening.

I devised and advocated two operations: one for strictures located at or above the junction of the levator ani muscles of the rectum, and one for that class of strictures located below the levator ani muscles. For a stricture of the first class a laparotomy is made in the median line from pubis to umbilicus with the patient in the Trendelenburg posture. The sigmoid flexure is now seized and enough of it selected to bend down over the stricture and anastomose the sigmoid with the rectum below the stricture, either by sutures or a small Murphy button. In doing this two peritoneal surfaces are brought in apposition from the point of anastomosis. The abdomen is now closed as in an ordinary laparotomy and the drainage-tube remains from forty-eight to seventy-two hours, according to conditions. The button will come away in about a week, leaving a small fistulous opening between the sigmoid and rectum below the stricture. We have now only to clamp the whole or part of the septum from time to time until the stricture is

severed. The severed ends can never unite, because a plastic operation is completed, with the sigmoid uniting the severed ends of the stricture. To do this I use a clamp forceps with a lock similar to an obstetric forceps, inserting one blade through the anus and into the sigmoid through the buttonhole and the other blade through the stricture along the rectal wall. The forceps are now locked and a rubber ring drawn over the handle so as to clamp the septum gradually for two days; then the handles are firmly compressed as an ordinary catch forceps and left to produce pressure atrophy of the septum until they completely sever it.

For that class of strictures located below the levator ani muscles, I produce a mucous fistula posterior to the stricture, so that when finally at a second operation the stricture is severed, this mucous tract lies between the severed ends of the stricture tissue, and prevents scar tissue forming to reunite them and re-form the stricture. This is done by taking a blunt-pointed aneurysmal needle threaded with heavy braided silk. The needle is pressed within the anal canal just above the internal sphincter muscle: the point of the needle is forced through the rectal wall back to the coccyx and then carried up posterior to all stricture tissue above the stricture, when the needle is again forced into the rectum. With a blunt hook passed through the stricture, the thread is now caught at the eye of the needle and drawn down. The needle is withdrawn and the suture loosely tied so as to form a seton surrounding the stricture tissue. The heavy thread gives free drainage, and none of the cases have had any symptoms of infection. This thread is left in place for three months, during which time the bowel is washed twice daily with boracic acid solution.

If the stricture is very tight I make a superficial incision on its anterior surface, just cutting the inner circle of scar and avoiding cutting the rectal wall, as a temporary relief from constipation. After three months the patient is put under anesthesia, the sutures removed and a grooved director passed along the fistulous tract. I now take a Paquelin cautery and sever the stricture down on the probe. I have performed this operation with perfect success in a number of cases. One case never returned for the second or complete operation; fortunately after three years she came to my gynecologic clinic at the Northwestern University a few weeks ago. I examined the rectum and had several of my students confirm the fact that there was no stricture. The patient said she left the suture in place until it cut its way out after many months. Some of these cases have been lost track of and may not have been cured. One case failed of a complete cure I know, as she comes to my clinic when I desire it. I am now satisfied why she was not permanently relieved. The suture was passed too near the stricture both below and above, and all the hypertrophied tissue was not included. Both these operations have been severely criticised, but I shall keep improving them until some one gives us some method that is better.

WE ARE informed that Professor Arons has been offered the chair of physics, left vacant by Roentgen's departure. The *Gazette Medicale de Paris* remarks that in this the Bavarian University is faithful to its traditions in welcoming scientists persecuted for their political opinions. In 1848 the chair of pathology was offered to the young Virchow, persecuted by the Prussian Government.

Therapeutics.

Phenocoll in Malaria.

In the *American Gynecological and Obstetrical Journal*, Dr. Cesare Mondini of Brooklyn publishes a note relative to the value of phenocoll in malaria. The physiologic and therapeutic powers of the drug have been studied by Professors Mosso, Albertini, Cervello and Golgi. Upon the basis founded by these investigators Dr. Mondini has tried phenocoll in all the febrile conditions which he had diagnosed as of malarial origin. The salt which he employed in all cases was the hydrochlorate. The doses prescribed varied from 1½ grams (nearly 24 grains) to 2 grams (about 30 grains) daily for children. The results were brilliant. Sometimes the amelioration was temporary and in some cases the effects were negative. He had, however, made use of phenocoll in over a hundred cases and met with but few failures. These were due less to the action of the drug, he thinks, than to the manner in which it was used. Dr. Mondini appended brief memoranda of several typical cases treated by phenocoll, one in particular being that of a child, 5 years of age, who had suffered from malarial intoxication for a year and who had an enormous splenic tumor. He was rebellious to quinin, but was cured by phenocoll.—*Med. Bull.*

Diuretics.

Martz, of the Faculty of Medicine in Lyons, gives a number of prescriptions for diuretic purposes. Pills composed as follows:

- Extract of convallaria.
 - Powdered convallaria, aa gr. i
 - Make in one pill, and give a pill night and morning.
 - Or a syrup made of:
 - Extract of convallaria ʒiv
 - Syrup of bitter orange ʒvi
 - A teaspoonful night and morning.
 - In other cases we may use:
 - R. Tinct. of squill m. lxxv
 - Syrup of bitter orange ʒi
 - Distilled water ʒiii
 - One teaspoonful every few hours.
 - Or
 - R. Extract of squill.
 - Powdered squill, aa gr. i
 - Make into one pill and give one night and morning.
 - Or
 - R. Theobromin gr. vii
 - Place in one cachet and give four a day.
 - Or
 - R. Caffein gr. xv
 - Benzoate of sodium gr. xxx
 - Syrup of bitter orange ʒi
 - Water ʒiv
- This may all be taken in twenty-four hours in divided doses.
- Or again:
 - Powdered digitalis
 - Powdered squill
 - Powdered scammony, aa gr. i
 - Make into one pill, and give one such night and morning.
 - Or,
 - Carbonate of lithium gr. vii
 - Leucnade with carbonated water Oi
- This to be drunk each day.
- Or, by the bowl:
 - Nitrate of potassium gr. xxx
 - Oxytel of squill ʒvi
 - Milk ʒiii
 - This to be given by the bowl.—*La France Medicale.*

Treatment of Anal Fissure.

M. Jules, in the *Gaz. de Gynecol.*, recommends the following treatment: The anus being partly everted and the fissure discovered, a small tampon of absorbent cotton saturated with a 1 per cent. solution of cocain hydrochlorate is applied. At the end of five minutes local anesthesia is obtained, and the fissure can be touched with pure ichthyol. This procedure is renewed on the following days. After the fourth or fifth application,

the tampon of cocain is introduced as far as the internal sphincter, and at the end of five minutes it is possible to make a slight dilatation of the anus with Nélaton's dilator. In this way the fissure is distinctly exposed to view and can be thoroughly touched with ichthyol.

Serofulosis.

In serofulous affections of the glands, skin and mucous membranes Saint Philippe finds the iodid of arsenic of great value. He prescribes it in the following form:

- R. Iodid of arsenic gr. vii
 - Distilled water ʒiiss
- Dissolve and give 5, 10, 20, or 30 drops of this solution a day, according to the age of the child.

As the remedy is an active one, it is wise, in his opinion, to commence with a small dose—for example, only a drop may be given morning and night, and this dose gradually increased.—*Therapeutic Gazette.*

Lactic Acid in Vaginitis.

According to the *Jour. of Medicine and Science*, Ilkewitch favors the use of lactic acid in the treatment of vaginitis and endometritis, basing its value upon the fact that the normal acidity and consequent germicidal power of normal vaginal secretion is due to lactic acid. He applies it to cervical erosions and to the diseased uterine mucosa in strength varying from 50 to 100 per cent., and in other cases in irrigating solutions of 3 per cent.

Local Application in Acute Rheumatism.

- R. Acidi salicylici
- Olei terbinthinae
- Lanolin, aa ʒiv
- Adipis ʒii

M. Sig. Apply to joints and cover with non-absorbent cotton, gutta-percha tissue, and over all a bandage. After the superficial epidermis has been destroyed, the oil of turpentine should be left out of the formula.

Treatment of Ozena With Citric Acid.

Hann (*Munch. Med. Woch.; Med. News*) recommends the application of citric acid in ozena, as the best means of taking away the terrible odor, which not only disgusts all with whom the patient comes in contact, but also often destroys the appetite of the afflicted individual. Hence, the mere removal of the odor is often followed by a marked improvement in the patient's general condition. The citric acid, however, has also a slight beneficial effect on the nasal lesions. It can be used pure, or better, mixed in equal parts with sugar of milk. The nose is thoroughly cleansed in the morning and the powder is then blown into it, and the insufflation is repeated at noon and at night. The deodorizing effects continue some days after the discontinuance of the powder, and as the citric acid has no harmful action, it may be used as often as necessary.

Treatment of Eczema by Ointments Containing Sugar.

Hodara of Constantinople uses for cases of moist eczema, impetigo ethyina, subnasal sycosis, and other skin diseases of vesicular or pustular nature, an ointment of zinc oxid and sulphur containing sugar, the desiccative and keratoplastic properties of which he highly values.

- R. Sacchari pulv
- Zinci oxid
- Lanolin
- Vasolin
- Sulphuris sublim, aa ʒxxx
- Glycerini, aa ʒx

M. Ft. unguentum. Sig. External use. For subnasal sycosis he advises continuous application of the ointment to affected parts of the upper lip, and in addition repeated swabbing of the nasal mucous membrane with a solution of silver nitrate, at first 1 per cent. gradually increased to 4 per cent. As improvement advances, the ointment may be used but once a day, but swabbing should be continued for a time after the

ure is complete, to avoid a relapse. Hodara has thus effected cures without epilation.

SEBORRHEAL ECZEMA.

For seborrheal eczema of a psoriasis type he prescribes as follows:

B. Sacchari pulv.	5xx
Chrysolobini	5i-ii
Glycerini	
Sulphuris sublim, aa.	5x
Lanolini	
Vasolini, aa.	5xxx
M. Ft. unguentum. Sig. External use.	

Dyspepsia.

B. Sodii bicarbonatis.	5i
Tinct. nucis vomice.	5i
Infusi gentiane, q. s. ad.	5viii
M. Sig. Tablespoonful before meals, in dyspepsia with deficient secretion of gastric juice.	
B. Acidi hydrochlorici diluti.	5iv
Tinct. gentiana comp.	5iiss
M. Sig. Teaspoonful in water after meals, in atonic dyspepsia with deficient secretion of gastric juice:	
B. Acidi hydrochlorici diluti.	5vi
Tinct. capsici.	5iv
Tinct. nucis vomice.	5iii
Tinct. quassie, q. s. ad.	5iv
M. Sig. Teaspoonful in water after meals for atonic dyspepsia of alcohol drinkers.	
B. Acidi hydrocyanici diluti.	gtt. xl
Tinct. belladonnae.	5iii
Bismuthi subnitrat.	5vi
Aque, q. s. ad.	5iii
M. Sig. Shake well. Teaspoonful an hour before meals or painful dyspepsia with excessive gastric secretion.	

Treatment of Gastralgia, Gastritis and Gastrodynia.

Dr. Thos. Stretch Dowse, in the "Pocket Therapist" says that these conditions are sometimes associated with dyspepsia. They may be peptic (rarely), they may be congestive, associated with gastric catarrh, or they may be neurotic (neuralgia). It is sometimes at first somewhat difficult to diagnose these states from derangements of the gall-duct, but the diagnosis is easily cleared up by the absence of bile in the feces. Gastritis of an acute character rarely exists, unless it is the result of some direct irritant. Congestive gastritis, leading to catarrh, vomiting and ulceration, is much more common, and must be treated more or less as a dyspepsia. It is here that we have a gastrodynia. Gastralgia, in the writer's experience, is a pure neurose and requires neurotic treatment. The pain comes on in paroxysms, and may be relieved by opium, quinin, atropin, chloroform, ether, peppermint, cocain, menthol, cannabis indica, and the bromids. During the paroxysms of pain this draught is very effective:

B. Chloralis	gr. xv
Liq. atropia.	m. ii
Ammon bromid.	5ss
Extracti cannabis indicae.	gr. ʒi
Aque, ad.	5ii
M. Ft. Haust. Sig. To be repeated in one hour if necessary.	

Faradization and massage are very useful, especially if dilatation exists. Lavage of the stomach is often of very great value in these cases.

Convulsions in Children.

When a period of intensely hot weather occurs late in the season and severe intestinal diseases develop in children as a consequence, it has been noted that their ailments are more frequently complicated by convulsions than under similar circumstances earlier in the summer. The wear and tear of life during the difficult heated months has apparently augmented the almost normal instability of the infantile nervous system, and as a consequence convulsive explosions of nerve

force are to be expected. An interesting discussion of convulsions in children at the recent meeting of the British Medical Association brings out the present English views as to the etiology and treatment of the affection, and it seems a timely topic for the attention of all general practitioners.

Drs. Gossage and Coutts, to whom the subject was referred for special consideration and introduction to the Section, suggested in their conclusions the following points for discussion: First, the frequency of convulsions in children has been vastly overrated; second, the immediate danger from future neurotic manifestations has been underestimated; third, the predisposing causes are of much more importance than the exciting causes; the slighter exciting causes will not produce convulsions except in predisposed children. There was very little disagreement with these propositions. The overestimation of the danger of convulsions, it was pointed out, came from the fact that in the terminal stages of many diseases of infancy convulsive movements occur, and that the death was then, unwar- rantly, of course, set down to convulsions. As to predisposition, nervous heredity, etc., statistics were quoted to show that in over one-half of the cases in which patients reached adult life after having had convulsions in childhood they suffered from some variety of neuroses. These were not due so much to the malnutrition of the nervous system during infancy or to damage during the convulsive stage as to congenital faulty development. It is particularly the children of nervous, gouty, rheumatic, or diabetic parents that are liable to fits, and it is in patients in whom such a family diathesis is known to exist that any extreme of reflex irritation must be repressed or it will result in a nervous explosion. As to treatment the discussion did not bring out anything striking, except, perhaps, by negation of the necessity for active measures. The referents said:

All that is necessary during an actual attack of convulsions in most cases is to loosen the clothing about the neck, chest, and abdomen, and lay the child on its back with the head slightly raised until it recovers from the fit and the subsequent drowsiness. The placing of the child in a hot bath, as is such a common practice, probably does no harm, and if the child be in feeble health it may be advantageous to use a mustard bath, which has decided stimulating properties.

Very few American physicians would be content to be as inactive as our English friends suggest with anxious parents and relatives about. For the very severe convulsions or prolonged unconsciousness after a fit inhalations of chloroform even to deep narcosis were suggested. Small doses of the bromids were recommended for some days after the attack. The recurrence of an attack suggested the continuance of the bromids for weeks at least, any harm that may be supposed to attend their use being more than counterbalanced by their benefit if they prevented the return of the convulsions.—*Medical News.*

Chlorosis.

Regarding the treatment of this disease, we quote from "Progressive Medicine," Vol. ii, June, 1899: "Brosin reports upon the treatment of cases of chlorosis with hot baths. The author treated some fifty cases, using baths of 32° R., with cool applications about the head during the fifteen to thirty minutes which were spent in the bath. After the bath a rapid cool douche was administered, and thorough friction was then employed, the patient finally resting one hour in the recumbent posture. Three baths a week during four to six weeks constituted the treatment. The results were excellent, the patients feeling extraordinary well after the baths. Many of the symptoms of the disease were quickly controlled by this treatment, and the general effect upon the disease was satisfactory. De Dominicis decries the venesections that have been recommended in recent years, which he believes act only in occasional instances by suggestion. He himself recommends transfusion of blood."

AMERICAN.

1. **Operations in Gastric Ulcer.**—Noticing first the comparative newness of this line of surgery and its importance, Bidwell discusses the symptoms and physical signs of the condition of perforation of round ulcer of the stomach and insists on the importance of prompt operation. In view of the amount of shock, everything should be done to keep the patient's temperature up. A brandy enema may be required and occasionally the intravenous injection of saline solution. On account of the tenderness of the abdomen, vigorous antiseptic measures are contraindicated before anesthesia but after anesthesia has occurred, thorough scrubbing and cleansing can be done. The incision should be about 3 inches long, in the left semilunar line or in the middle above the umbilicus. There is usually much gas in the peritoneum and considerable purulent fluid if the ulcer has perforated anteriorly. When found the adhesions should be separated, the extravasated contents sponged away and the perforation be brought forward as far as possible. The ulcer should be invaginated and the adjacent part of the stomach wall coated over it by one or two rows of Halsted or Lembert sutures, inserted at a considerable distance from the ulcer so as to be in healthy tissue. The peritoneal cavity should then be thoroughly flushed with normal salt solution, and if the gastric contents have reached the lower part of the abdomen it will be necessary to make a counteropening over the pubes and in addition irrigate Douglas' sac. Special care must be taken to thoroughly irrigate the upper surface of the liver and the region of the spleen, to prevent subphrenic abscesses. Drainage-tubes are inserted and the wound closed in the ordinary way. If no extravasation is found but there is some injection of the peritoneum, with other marked signs of perforation, we should suspect the rupture of the ulcer in the posterior gastric wall. To reach this, after shutting off the general cavity with sponges, the gastrocolic omentum must be torn through, opening up the lesser cavity of the peritoneum. If here there are no signs of extravasation, we may assume that there is no perforation, or that adhesions have shut it off. If extravasation be present, the ulcer must be found and sutured as before described, and the lesser cavity be carefully irrigated, special care being taken to thoroughly cleanse the portions above and behind the liver. The operation must be as rapid as possible to minimize the shock. The patient should be fed by nutrient enemata and suppositories for the first three days, then cautiously by the mouth with predigested foods. The gauze drain and the suprapubic tube should be removed at the end of three days. The rubber tube at the end of the upper opening should remain a few days longer. When adhesions have formed prior to perforation, there may be communication with the colon, the pericardium or the small intestines or a localized abscess between the stomach and the under surface of the liver, or between the stomach and the anterior surface of the pancreas and duodenum. In either of these cases, it should be opened as high up as possible in the middle line and drained.

with very cautious irrigation to avoid breaking down adhesions. In some cases when there is no abdominal swelling, but evidence of abscess by dullness over the left lower costal region, it can best be opened by resection of the eight and ninth ribs in the axillary line, the pleura, of course, being opened, but the diaphragmatic portion sutured to the costal pleura before the diaphragm is divided. The author discusses the statistics of the operation for perforation and subphrenic abscess, its uses and prognosis. He concludes his paper with the following list of cases in which the operation should be done: 1. In all cases of perforation at the very earliest possible moment; also in subphrenic abscess. 2. In cases of hemorrhage *a*, when there is continual oozing of blood, especially if the stomach be dilated, and *b*, in cases of repeated severe hemorrhage. 3. In cases where there is severe pain and vomiting unaffected by treatment, and which is producing progressive emaciation. 4. In cases of dilatation of the stomach from contraction within or from adhesions outside the stomach. The operations to be performed are: In Class 1, laparotomy and suture of the ulcer; in Class 2, gastrotomy and suture of the ulcer, with a purse-string suture, combined with gastro-enterostomy; in Class 3, gastro-enterostomy, in order to give physiologic rest to the ulcer; and in Class 4, either gastro-enterostomy, or, if the pylorus be affected, pyloroplasty or pylorotomy.

2. **Epithelioma After Psoriasis.**—Hartzell reports a case of epithelioma occurring on the heel of a woman 35 years old after psoriasis of many years' standing, and discusses the literature of similar cases. He thinks the evidence presented thus far permits us to conclude that the arsenical treatment of psoriasis has a causal relation to epithelioma and calls attention to the importance of this subject in connection with recent theories of the pathogenesis of carcinoma in general.

3. **Cystic Degeneration of the Kidneys with Exfoliative Dermatitis.**—Parker describes a case of cystic kidney degeneration followed by general dermatitis exfoliativa. The combination of these two affections, he thinks, is rather unique. He discusses the theory of cystic kidney degeneration and thinks it impossible to apply any of the retention theories to their formation.

4. **Congenital Dilatation of the Colon.**—Griffith uses this term to designate an actual dilatation present at birth and a congenital tendency to early dilatation, the latter being probably much more common. He reports in detail a case with autopsy and gives a synopsis of others in the literature which may fall under this head. The prognosis of these cases is unfavorable. Eighteen of the twenty-four enumerated terminated fatally, only three of the patients reached adult life. In all cases, there is great dilatation of the large intestines with thickening, the small intestines being normal. The treatment consists in attention to the general health, carefully performed massage, electricity, and emptying of the bowels by purgatives or enemata, which, while weakening, are useful here; and in case it is not relieved, early operation.

5. **Toxicity of Urine.**—Forchheimer and Stewart report experiments as to the toxicity of urine obtained from a number of patients, many of them suffering from various morbid conditions. They used it fresh, or fresh and filtered, boiled, and with boracic acid added. Examining their table, they point to the fact that those two methods which excluded bacterial activity absolutely after the urine had passed are followed by comparatively no mortality. In fresh urine immediately used there was only one death out of 14; in filtered urine, no deaths even after the urine had been kept as long as four days; in urine with boracic acid used before the lapse of 24 hours, a mortality of 39 per cent.; after 24 hours, a mortality of 43 per cent.; in boiled urine, kept for longer than 24 hours, a mortality of 59 per cent., and in fresh urine kept for longer than twenty-four hours a mortality of 66 per cent. They conclude that most of the toxicity of urine is due to formation of substances the result of the action of bacteria on some body or bodies in the urine and that they are not justified in stating that there is no other toxicity than that due to bacteria, but they are justified in claiming that in all those investigations that have been made where this activity has been overlooked, the results must be regarded as inconclusive.

6. **Edema in Hemiplegia.**—Allen reports a case of severe edema of the arm and, to some extent, the leg of the paralyzed

side, coming on some weeks after the attack. The swelling was excessive, especially in the arm. The patient died of exhaustion and diarrhea some months after the beginning of the attack and the autopsy showed no pathologic condition to account for the edema. In searching the literature, the author finds but three cases entirely comparable to his own.

12. Tumor of the Oblongata.—Dercum reports a case which was diagnosed in life as tumor of the medulla. The most striking feature of the case was the symptom of astereognosis which had never been previously observed from tumors in this situation. The patient could not tell the position of the right arm. There was distinct loss of muscular sense, diminution of pain sense and disorders of the localization of tactile impressions. Only just before death were there any symptoms referred to the left arm and then they were very slight. The autopsy showed a large irregular mass spreading from the occipital bone to the right side of the junction of the pons and medulla, forming a slight depression in the right lobe of the cerebellum, and markedly distorting the medulla, the fibers of which for a short distance above and below showed by Marchi's staining method, degeneration of the pyramidal tracts, posterior and lateral columns and right direct cerebellar tract.

15. Surgical Treatment of the Urethra in Old Age.—Greenlee reports briefly the results of treatment of difficult micturition in old men, associated with prostatic hypertrophy and stricture. His practice is to use dilatation by graded sounds, assuming that in the majority of cases at least there was an original contraction of the urethral cavity. The results were very generally good. He reports also a case in which there were similar symptoms with extensive hypertrophy of right side of the prostate gland and the corresponding testicle was normal, while that of the left side had been removed in early life. Removal of the remaining organ caused complete cure.

16. Certain Landmarks in the Prognosis of Modern Medicine.—This article considers the subjects of anesthesia—after fifty years, the development of State Medicine, and the advent of bacteriology.

20. Fractures of the Skull.—Some years ago Bluhm collected a series of over 900 cases with the intent of demonstrating a lessened mortality in delayed operation following fracture of the skull. These statistics show that in the immediate operation the mortality reaches 23 per cent., while in the delayed or later operation, the mortality is only 33 per cent. Clinton points out that in these statistics no statement was made to the ultimate condition of the patients with reference to epilepsy, insanity, etc., or what portion of the 53 per cent. would come under the head of hopeless cases. The object of his paper is to show that to avoid these late results, early operation is most advisable.

28. Modern Treatment of Fractures.—Tracy calls attention to the principal indications in fractures, that is, to get fixation of the bone in the natural position, there being only one fracture best treated without fixative apparatus, that is, fracture of the neck of the femur in the aged. In this case the best surgical treatment is purely medical. In all other fractures mechanical fixation, where it can be obtained, is necessary. He alludes to the use of plaster of paris for fractures as uncertain, inefficient, and concealing the real state of affairs, and thinks that it will be soon relegated to disuse. Splints made of felt or wood fiber, especially the latter, are preferable.

29.—This article was published in this JOURNAL, March 4, Vol. xxxii, p. 479.

33. Intestinal Obstructions.—Jelks reports a case in which there was pain, constipation and vomiting, which later became stercoraceous. The diagnosis was obstruction, probably due to adhesive bands, as the patient had undergone a laparotomy some years before. On operation, instead of obstruction, they found a gangrenous appendicitis with septic peritonitis. In discussing the case he takes up the subject of the time and necessity for operation in appendicitis and thinks that in a great majority of cases where skilled surgeons and the necessary appliances can not be had the majority of patients will do better without operation.

34. Surgery and Insanity.—The point in Coc's paper is the necessity of watchfulness and care after surgical operations in order to avoid post-operative mental disturbances.

36. Vaginal Section.—After describing preparation and technic, Taylor reports a large number of cases operated on by the vaginal route and believes that its advantages are unquestionable. It gives less shock to the patient; the operator can work with more ease; recovery is more rapid; unabsorbable ligatures may be tied and left exposed until ready to be taken out; it permits a second operation, if necessary, with little danger, and the nervous phenomena are much less pronounced and serious.

37. Vaginal Hysterectomy.—Lindley reports four cases of vaginal hysterectomy, in two of which there was serious bleeding, occurring late after the operation. In another there was an instrument broken in the vagina and in still another death occurred apparently from septic peritonitis without any known cause.

39. Abdominal Pain.—Thomas calls attention to the importance of the symptom of abdominal pain. While about 50 per cent. of the cases will recover with simple analgesics, others indicate serious conditions, such as hepatic lithiasis, appendicitis, nephrolithiasis, intestinal obstruction, tubal pregnancy, etc. He believes that severe abdominal pain should be thoroughly investigated in every case and that whoever does so as a routine practice will not regret it.

43. Surgical Complications of Pneumonia.—The complications noticed by Freeman are pneumococcus arthritis, local abscess, peritonitis, and septicemia, empyemata, and abscesses of the lungs.

44. Sterility in Women.—Nilsen discusses the cause of sterility in women and calls attention to the fact that very minute lesions may have their influence.

45. Hydramnios.—In this paper Polak discusses the condition of excessive secretion of amniotic fluid and its consequences. He reports a case and discusses the principal causes and complications and the importance and significance of the condition. The excessive amount of fluid is a cause of malpresentation. It also is one of the most common causes of the excessive vomiting of pregnancy. It favors prolapse of the cord, post-partum hemorrhage, inversion, and may be placed well to the front in the etiology of repeated abortion. It is, however, admitted that syphilis is coincident with hydramnios in the majority of cases and the part that it plays in these abortions must be considered. Treatment depends largely on the degree of the condition and the essential indications in each particular case. The maternal condition may often demand early rupture of the membranes but especial care should be taken to prevent too rapid escape of the fluid. He has found that rupturing of the sac from the cervix with the patient in an exaggerated Trendelenburg position has its advantages in this regard. Instrumental and manual delivery should be avoided when possible on account of the increased tendency to sepsis. The third stage of labor should be managed with the greatest caution and in no way hurried unless hemorrhage occurs.

47. Cesarean Section.—Fancourt Barnes concludes, as regards this operation as compared with symphysiotomy, that the latter has not justified its existence and he can not help thinking that in a few years the eminent obstetricians who have been advocating it will abandon the operation. Induction of premature labor within certain limits will always hold a recognized and useful position among obstetric operations, and we are forced to the conclusion after a careful study of the latest figures that have been published on Cesarean section, that it is a scientific and justifiable operation and that it will be more widely resorted to in the future, as the science of obstetrics advances, than it has in the past.

50. Is Leprosy Curable?—In opposition to the general opinion, Dr. Roger S. Chew maintains the affirmative. He gives his experience with a large number of remedies and a table showing results of the treatment, by different remedies, asclepias, anaeridium, arsenic, chaulmoogra oil, chrysarobin, etc., which are very variable, though the total of the cases gives 156 cures to 612 failures. He finally obtained a crystalline substance from a maceration of the roots, leaves and seed of a three year growth of *Gynocardia lanceifolia*, and gives its chemical formula at length in combination with gold. He calls this remedy "Gynocyanuridarizarin" and when given internally to dogs and cats in doses from 0.01 to 0.0025 grains, these crystals produce cramps, diarrhea and vomiting, with paralysis of the

musculo-cutaneous nerves and great physical prostration, while doses of from 1/10 to 1/2 grain caused violent convulsions resulting in death in less than 24 hours, while the autopsy revealed some of the post-mortem appearances of potassio-cyanide poisoning. Doses of 0.00001 to 0.0001 grains, on the other hand, appear to act as a powerful musculo-cutaneous neural stimulant, causing in the healthy subject, anesthetic areas, ulcers and crops of papillae, but in the ailing subject inducing rapid granulation of indolent ulcers, converting pus and sanious exudates into serous discharges which rapidly lessened and disappeared, retarding the development and movement of tubercle bacilli, increasing the number of red blood-corpuscles and apparently stimulating the leucocytes to increased energy. He went into details concerning this to various journals, but had difficulty in obtaining recognition, and finally experimented with it on a man with the result of producing a perfect cure in his first case. He then sent packets of the drug to various relatives and medical friends and claims that of 256 cases treated with every one made a recovery. He then treated twelve cases before a test committee of physicians and others, with a cure in each case. He says, having made no secret of his plans, he does not see why it has not received attention from the medical profession, nor had its merits appreciated.

51. **Simulated Mental and Nervous Diseases.**—Bell discusses the subject of simulation and its frequency, which he thinks is common in prisons but not so common in general practice, especially under the observation of neurologists. The person who attempts to feign insanity has a difficult task. There is practically only one form not easily detected, that is, the dumb or speechless type. The feigning of health is common however, in asylums, with the idea of being released. There are some symptoms that are almost impossible to feign, such as loss of sensation or consciousness, and the simulator must, it is to be remembered, be fully as familiar with the symptoms he imitates as is the physician he attempts to deceive.

53. **Determination of Sex.**—Dunsmoor's paper discusses the various theories of production of sex, the author himself announcing his belief in the Thury theory, that the degree of ripeness of the ovum is the natural factor in the determination of the sex of the animal produced. His article contains a number of communications from physicians, stock-breeders and others as to their experience and observations.

55. **Diet in Typhoid Fever.**—According to Abbott, the present accepted ideas as to diet in typhoid need some change. A milk diet is open to certain objections and does not agree with every individual even when sick. It has been his practice or years to give his typhoid patients what might be called a soft diet, consisting of milk when it is agreeable, buttermilk, all kinds of soups and broths, raw and soft eggs, and the yolks of hard boiled eggs. As regards the use of fruits, in his section constipation is rather more common than diarrhea and he does not prohibit stewed or baked apples, the pulp of grapes, the juice of oranges, and even bananas if properly ripened and sound. In regard to the intervals of feeding, he believes in longer intervals of 2, 3 or 4 hours or even more. Alcohol he never he thinks is not only unnecessary but often injurious and he does not encourage its use.

57. **Malaria in Children.**—Moncovo continues his description of malaria in children as observed by him in Brazil. He discusses the mosquito theory and believes that his experience confirms it. He has never been able to observe any of the alleged antagonism between tuberculosis and malaria but finds that the two conditions react upon each other to a serious extent. In fact phthisis, like other dystrophic diseases, increases the predisposition. He reviews the symptoms in these cases and finds that they do not indicate that diet is at all at fault. Hypertrophy of the spleen is absent in many cases of infantile malaria, but its situation and the difficulty of its examination make this symptom more difficult and less valuable than in adults. The article is to be continued.

60. **Infant-Feeding.**—Leavell's paper reviews the subject of infant-feeding at length, showing the modification that cow's milk requires to make it a proper food for infants, and he favors the establishment of milk laboratories in cities which will provide to the consumer milk prepared by any prescribed formula. Regularity in feeding is of the utmost importance and he gives the periods and intervals at the different ages. The tem-

perature of the milk should be about 99; it should be kept free from germs by Pasteurizing or boiling. The only accurate way to determine whether or not the child is thriving is by weight. An infant should gain at least four ounces a week for several months. If it shows no evidence of indigestion and does not gain in weight, the quantity of food should be increased. It is by watching this symptom of weight that we are often able to prevent serious nutritive disorders before they reveal themselves in other ways.

61. **Cholera Infantum.**—Brown discusses the subject of animal toxins and suggests the question whether these products may not be the original factors in the causation of cholera infantum.

62. **Gall Stones.**—After noticing the symptoms of gall-stones and the course of the disease if untreated, Simpson states the following indications for immediate operative interference: 1. Any case of hepatic colic in which a tumor of the gall-bladder can be made out. 2. Persistent jaundice with pain, even at the risk of finding a cancer. 3. Recurrent biliary colic. 4. Biliary colic followed by persistent jaundice. 5. Colic with prolonged rise of temperature and high pulse. 6. Obstruction of the common duct evidenced by jaundice and acholic stools. 7. Obstruction of the bowel and peritoneum. 8. Empyema of the gall-bladder and liver abscess. A state of choleraemia does not contraindicate the operation. He describes the method of Bernays of performing cholecystotomy, which he considers preferable and adopts in his practice. He says also the combined longitudinal and oblique incision is the best in case a cholecystotomy or cholecyst-duodenostomy has to be performed, when stricture of the common duct has been found. In the latter operation the incision into the duodenum must be twice the size of that in the fundus of the gall-bladder, or the contents of the former will enter the latter and lead to trouble.

66. **The Relations of the Coroner to the Undertaker.**—This paper, delivered before an undertakers' association, is one that is certainly of interest to the average physician. The author brings out various points in regard to the cause of death, medicolegal expert testimony, and appeals to the undertakers to give more attention to the phenomena they observe between death and burial, as they have it in their power to add materially to our knowledge of cadaveric changes.

71. **Conditions Leading to Fibroid Changes.**—The subject of Anderson's article is the fibrosis that occurs usually with old age, which while efficient in producing pathologic symptoms may almost be called physiologic, and its premature appearance. He notices especially the conditions in the circulatory apparatus, the kidneys, liver, etc. The etiology is obscure. Heredity seems to have its influence. Syphilis, gout, rheumatism and infectious diseases are also causative. Among the theories that have been advanced, the uric acid and toxin theories are most popular but none fully explain the condition. As regards treatment, the most important are regulation of diet, mode of life and hygienic surroundings. Those who have lived high should be restricted, and alcoholic beverages, excessive work, irregular hours and worry must be avoided. Exercise must be governed by the condition of the heart muscles. A moderately warm equable climate and out-of-door life are favorable conditions for patients of this class. Among drugs, potassium iodid, arsenic and phosphorus are mentioned. The condition of the heart will be met best by the special remedies indicated.

72. **Appendicitis.**—Joy reports a case of a young man in whom the persistent pain was in the region of the right kidney except at the beginning of the attack, and the diagnosis could not be made until septic symptoms appeared. Then, on the presumption that they had to do with kidney abscess, an incision was made for lumbar nephrectomy, but the finding was a retroperitoneal appendix abscess. A second operation was required three weeks later, after which the patient did well.

74. **Ear Disease.**—Strangways objects to the frequent use of syringes and believes that the value of peroxid of hydrogen in aural troubles is greatly overestimated. To cleanse the ear he uses the head mirror and aural speculum, applicators, aural forceps, and occasionally, Anel's lachrymal syringe with a long end piece. He speaks favorably of the use of tincture of iodine in inflammatory diseases of the aural canal, also of compound tincture of benzoin. Cleanliness stands first as a remedy and, in his estimation, compound tincture of benzoin next.

75. **Overcrowding in the Profession.**—Sherman's paper is a radical argument for single tax and government ownership of land as a cure of evils of overcrowding in the medical profession.

80. **Matrimony.**—Aronstam advocates government regulation of marriage and examination of all candidates as to physiological condition and family history.

82.—See abstract in JOURNAL, May 20, p. 1113.

83.—Ibid., p. 1112.

84.—Ibid.

85.—Ibid.

87.—Ibid., September 9, p. 670.

88. **Cerebrospinal Meningitis.**—Irwin discusses the literature of three epidemics of cerebrospinal meningitis that have occurred in Louisville since 1874, and gives an account of the symptoms and treatment. The later epidemics have presented no new features.

89. **Treatment of Tuberculosis.**—Flick believes that tuberculosis can now be considered a curable disease. The fundamental principle in the treatment is immunity and the chief means at our command for attaining this are: 1, nutrition; 2, drugs; and 3, antitoxin. Nutrition must be assigned first place and combines forced feeding and artificial digestion, rest, exercise and climate. By forced feeding is meant the taking in of a large quantity of easily digested and readily assimilated food, and in connection with this the liver, kidneys and intestines must not be unattended to. Oxidation is also important and a liberal air-supply is as essential as food. Life in the open air should be pursued as far as possible. Rebreathed air should be avoided. No matter where the air comes from let the patient have plenty of it. Outdoor life, however, must not be interpreted as constant exercise, overexertion being dangerous. Exercise should be graduated according to the patients' powers and improvement. Climate is reckoned as less valuable now than was formerly the case, and better results can be obtained at home as a rule than in any other place except a well-ordered sanatorium. As regards drugs, he believes that much can be done with them. He has found iodine the most valuable remedy, in the form of europen. The formula that he employs is europen 1 dram, oil of rose 1 minim, oil of anise 1 dram, and olive-oil 2½ ounces. Of this he has the patient rub from a teaspoonful to a tablespoonful into the arm-pits and inside of the thighs once or twice a day. As tolerance increases, he sometimes gives europen by the mouth in addition. This treatment should be kept up for a long time. The next most valuable drug is creosote, and in case the disease has passed to the stage of breaking down, he gives creosote in addition to europen treatment. Large doses should be given. He begins with one drop and increases it regularly until the patient takes from 40 to 50 drops a day in hot water. The third place is assigned to strychnin, changing the dose from time to time. Other drugs are mentioned, such as arsenic, calomel, ammonia, nitroglycerin, etc. Antitoxin is yet on trial, and he employs as a modification of it, which has given good results, the use of a fly blister, causing a large vesicle and allows it to reabsorb. The symptoms from this treatment are much those as described after the injection of tuberculin, and he thinks he has seen benefit in this method.

90. **Empyema from a Surgical Standpoint.**—In this article Munro discusses the subject of anesthesia in empyema, believing that ether is generally a safe agent. As regards expansion of the lungs, he thinks an early operation is necessary to prevent consolidation. The deaths in his cases have come either from dislodgement of an embolus: from the relapse or extension of pneumonia; and in the streptococcal cases from a rapid general infection. He describes his technic, making, as a rule, resection of a rib, generally the seventh or eighth, at which level the cavity is usually as well drained as anywhere and the danger of injuring the diaphragm is avoided. He thinks that the anterior or midaxillary line is as advantageous for the incision as one farther back. The drainage-tube should be short and should not project beyond the inner surface of the chest. When a suitable operating-table is at hand, the operation may be done with the patient partially sitting up, the arm on the affected side being held over the head. This allows free respiration and free access to all but the most remote posterior parts of the chest. After operation, patients improve more

rapidly if they are allowed to sit up as soon as they can safely do so. Systematic exercises, etc., are valuable in expanding the lungs.

93. **The Specific Cause of Yellow Fever.**—Reed and Carroll, in this article, reply to Sanarelli's recent communication. They resent his charge that they have made mistakes and mixed their cultures and state that the culture used was obtained from Pasteur's laboratory where it was opened by Dr. Roux, and bore the label of the Laboratory of Hygiene, University of Montevideo. It was from this that their subsequent colonies were made and their experiments performed. They traverse many of Sanarelli's criticisms of their work, showing that the difference claimed of the growth on potato of the hog-cholera and Sanarelli's bacillus is not as he states, that the bacillus *icteroides* does not always grow on potatoes as a colorless, scarcely visible growth, as Sanarelli says, but may show various methods of growth, and they propose to show that his statement as to the supposed effect of certain temperatures on the hog-cholera bacillus is entitled to no credence, and refer him to the literature. They believe that Dr. Selander has never plated on gelatin the genuine hog-cholera bacillus as known in this country. They also point out that Sanarelli, in emphasizing the specific character of the necroses in the liver of guinea-pigs and rabbits, shows a surprisingly limited knowledge of the work that has been done in this line. As regards his criticisms that Reed and Carroll failed to produce acute stentosis of the liver in dogs with his bacillus, they publish a table of the observations by Sanarelli, by themselves, and by De Lacerdo and Ramos, showing that while the former has more such results than they, the latter observers have even less and the statement that they themselves failed to do so is incorrect. Concerning Sanarelli's criticism as to the resistance of the yellow-fever germ to cold, Reed and Carroll say that they never questioned the vitality of the bacillus, but its effect as the specific germ of yellow fever, and they will leave to Dr. Novy the easy task of answering this part of Sanarelli's article. The paper concludes with the account of their experiments in feeding bacillus *icteroides* to young hogs, and they believe that they justify them in expressing the opinion that it is a variety of the hog-cholera bacillus.

94. **Cardioesophageal Gush and Click.**—Curtin here describes two symptoms, the description of which he has not heretofore found in the literature. The first patient complained of being troubled with a queer noise which the doctor could hear without applying the ear to the chest. The sound occurred before or early in the systole and was loudest when the patient's mouth was open. It appeared like a short gush of air from the throat, modified by the upper air-passages, giving it a low pitched grunting sound. It continued while she was talking and breathing, and apparently had no connection with the stomach. It was relieved by potassium bromid and nuxvomica. A second case was also observed. The sound was diagnosed as of endocardial origin. The patients all had organic heart disease with enlarged organ. He explains the sound by the heart in diastole pressing out of the esophagus a small amount of air, which was readmitted during the contraction or systole of the organ. He also describes what he calls "esophageal clicking," which has similar peculiarities and which is faucial in its origin and was explained by him as caused by the separation of two moist surfaces. As it keeps time with the heart, it is evidently of cardiac origin. He recapitulates as follows: 1. The sounds were heard at the beginning of the systole of the heart and, in two cases, diagnosed as an endocardial murmur. 2. The sounds of both were modified by respiration, being heard most markedly at the end of expiration. 3. They were all more or less evanescent, except in the case of the old soldier. 4. They were increased or developed by a full stomach, stimulants or excitement. 5. The sounds were increased by opening the mouth, and dulled by closing it. 6. They were heard by auscultation at the middle of the sternum, but very much subdued as compared with the sound heard at the open mouth. 7. The sound was not transmitted in any direction from mid-sternum. 8. They were not heard by auscultation over the stomach.

95. **Hydriatic Treatment of Pneumonia.**—Macalester, after noticing the general effects of hydriatic applications, their pathologic action on the nerve-centers and their prophyl-

lactic power against heart failure, describes his method in applying water treatment in pneumonia. He finds the chest compress the best application and describes it as follows: "The chest compress is composed of three folds of linen or old muslin cut in a manner to fit the entire chest, from above the clavicles down to the umbilicus, with slits in the axillary regions to form flaps and cover the shoulders. It is then wrung out of water, so that it does not drip, at a temperature of 60 F., snugly applied around the thorax, covered with a piece of closely woven, thin flannel of the same shape but at least an inch wider in all directions, and secured by safety-pins. At first the compress is changed every half hour, then every hour or two, until the patient's temperature is below 100, when it may be discontinued. The compress should not be covered with oiled silk, a very popular proceeding on the part of attendants for the sake of convenience and protection of the patient's bed and clothing, as this would convert it into a poultice and deprive it of its stimulating and gradually cooling action."

97. Fracture of the Lower End of the Radius.—Noticing first the erroneous views in regard to Colles' fracture, Beck remarks that the anatomic aspects of this lesion differ more than those of any other fracture and that the Röntgen rays reveal to us of late years more in regard to it than ever could have been known before. In classifying the different varieties he distinguishes epiphyseal separation, fissures (infracture), complete fractures, incomplete fractures, fractures of the lower end of the radius combined with infracture or fracture of the head of the ulna, and fracture of the lower end of the radius combined with fracture of the styloid process of the ulna. All these different varieties may be extra-articular and intra-articular. Epiphyseal separation shows the same symptoms and is to be treated on the same principles as complete fracture. In very young children there are real chondroepiphyseal separations, while later at the age of between 14 and 17 osteoepiphyseal separation is observed, the fracture line extending to the diaphysis. Fissures are extra-articular as well as intra-articular and are far more frequent than was supposed before the use of the X-rays. There being no displacement, no reduction is required, and this shows why the results in these cases are nearly always good. Adhesions, however, may be formed in the joint too long immobilized. Beck treats these with a wire splint slightly bent downward, applied at the flexor side of the arm, where it reaches from the tips of the fingers to the elbow, the downward bent portion being attached to the palm of the hand. After three or four days, when the swelling has subsided, this long splint is removed and a bracelet consisting of a piece of mossboard about four inches wide is substituted. It fixes the wrist sufficiently and permits motion enough to prevent adhesions. The patient carries his hand in a sling in such a manner that the ulnar margin rests on it. Movement of the fingers is advised. Complete fracture is divided into intra-articular and extra-articular, the first being the most important. It can only be certainly determined by the X-ray. The extra-articular complete type is the best known, the typical Colles' fracture. The deformity is characteristic. Abnormal mobility and crepitus is always present except in case of impaction of the epiphyseal end into the upper end of the radius. Local pain is generally severe. The paper is to be continued, and will be further noticed with its next issue.

98. A Test Case for Taste.—Beers gives an account of a newly devised case for testing the sense of taste by colorless solutions in the contained bottles and gives directions for use.

99. Adenocarcinoma of the Nose.—Newcomb reports a case of adenocarcinoma of the nose, and has collected four others in the literature to be added to a table prepared by Dr. Hopkins two years ago. He adds simply a paragraph as to the surgical treatment. "Up to the present time two general operative plans have been followed: First, removal of the superior maxilla with more or less of the surrounding structures, and, second, attempted starvation of the growth by shutting off its blood-supply. In pursuance of the latter end the external carotid has been ligated. I have been interested to learn of a modification of this procedure, first made, I believe, by Dr. R. H. M. Dawbarn, a well known surgeon and anatomist of New York. He found, upon studying the anastomotic circulation, that after simple ligation of the external carotid there were fully twenty channels through which collateral circulation

could be established. With a view, therefore, of still further cutting off the blood-supply, he conceived the idea of ligating, one after another, the eight branches of the external carotid, and then, as the trunk of the vessel was thus rendered useless, of resecting it entire. He has done this operation sixteen times on eight patients, a two-weeks interval elapsing between the two operations in each case. It has been done once or twice by others. While the period covered by this work is too short and the number of cases thus operated on too few to allow of decisive conclusions, he believes that time will demonstrate the logic and effectiveness of this operative modification."

101. Synchiotomy of the Stapes.—By the term "synchiotomy" Dench means the division of adhesions about the stapes, which usually lie between the posterior crus of the ossicle and the corresponding wall of the oval niche, but occasionally occur superiorly and anteriorly. He says:

"The operative technique is comparatively simple. The procedure can easily be conducted under cocaine anesthesia, or, if this is found to produce unpleasant constitutional effects, a solution of eucaïn B may be used. As this latter drug causes a hyperemia of the tissues, its application should be followed by that of a sterilized solution of suprarenal extract. This latter application will sufficiently control the engorgement caused by the eucaïn to assure the operator a clear view of the field of operation. Prior to any operative procedure of this character the parts should be sterilized by thoroughly mopping out the canal and tympanum with an alcoholic solution of bi-hlorid of mercury, of a strength of 1 to 3000. After the field of operation has been properly prepared, the first step is to divide any adhesions which may lie between the posterior crus of the stapes and the adjacent wall of the oval niche. If a fragment of the drum membrane remains and prevents a clear view of the stapes, it is better to excise this as a primary procedure. In certain cases, owing to the position of the stapes, the ossicle can not be seen. This is particularly true where posterior adhesions are present, the ossicle being drawn backward behind the tympanic ring. Knowing the normal position of the stapes, it is a comparatively simple matter, after local anesthesia has been thoroughly established, to divide these adhesions, although the ossicle itself may be completely hidden from view. In order to do this a sharp-pointed knife is introduced into the middle ear in the upper and posterior quadrant, close to the tympanic ring. The knife is carried inward until the bony wall of the tympanum is encountered. It is then swept downward, the point being still kept in contact with the internal tympanic wall. In this way all adhesions lying between the posterior crus of the stapes and the adjacent wall of the oval niche are divided, including the tendon of the stapedius muscle. Not infrequently, where the stapes is invisible before the procedure, it is easily seen after the incision has been made, owing to the division of the adhesions which have drawn the ossicle upward and backward. The operation itself, if carefully conducted, is absolutely painless.

Prior to the operation a careful functional examination should be made, and this should be repeated after each successive step, so as to note the effect on the lower tone limit and on the power of audition. It is not uncommon to find a marked improvement in hearing after a simple division of posterior adhesions. If this does not follow, the operator should next pass the knife beneath the crura of the stapes and the adjacent wall of the niche. Careful mobilization of the ossicle by means of the cotton-tipped probe is also advisable, both the hearing and the lower tone limit being tested from time to time to see what improvement follows the procedure."

He has records of 26 cases thus operated on, with improvement of hearing in 25. In many instances the effect on the opposite ear has been exceedingly marked, the hearing not only being improved, but the subjective noises often relieved and incipient inflammation of either the labyrinth or the middle ear effectually prevented.

The after-treatment is exceedingly simple. If the field of operation has been properly sterilized, it is only necessary to occlude the meatus with a pledget of sterilized cotton. This should be changed daily, and at the same time the meatus wiped out with a pledget of sterilized cotton. Frequently there may be a serosanguinolent discharge from the ear for from three to four days after the operation; at the end of this time the tym-

panum becomes dry. He usually directs the patient to keep the meatus occluded while in the open air for at least ten days after the procedure. At the end of four or five days, if there is no discharge, the ear may be left open while the patient is in the house, a cotton pledget being inserted when the patient is in the open air or in a dusty place.

102. Bovine and Human Tuberculosis.—In this article, which was commenced in a previous number, Moore questions the prevalent view as to the transmission of bovine tuberculosis to the human species. After having gone over the subject of the prevalence of tuberculosis in herds and the methods adopted to stamp it out, he discusses the question of the relation of the disease germ in the two species, the bovine and the human. He questions the possibility of bovine tuberculosis being transmitted to man and points out certain differences in the organisms. Man is omnivorous, cattle are herbivorous. The normal human pulse is 72, that of the ox, 40 or 45. The normal temperature is 98.6, that of cattle from 100 to 100.5. He believes that there is something in the human body antagonistic to the germs of the ox, and vice versa. He calls attention to a similar state of affairs in other species. Glanders kills field mice but not house mice, while the reverse is the case with mouse septicemia. The bacillus of tuberculosis in man he believes practically specific to him and the same is true of cattle, and the environment being changed, the pathogenic power is lost. In all his experience with cattle tuberculosis he has never met with a case of transmission to man, and he believes that reported cases have been incorrectly interpreted. As regards the transmission of human tuberculosis to cattle, the case is equally strong. There is no instance that he can find where the infection of the disease in man has passed to the animal. The herd at the Saranac Lake Sanatorium, which was exposed if any could be, was found free from tuberculosis. He quotes Theobald Smith as reporting similar views in regard to this subject, and maintains that a few statements like that of Sternberg in his "Manual," and others, have scared us into believing that bovine tuberculosis is a human danger. He finishes his article with a number of letters from various parties supporting his views.

103. Etiology of Tuberculosis.—The chief point made in Girdsansk's paper is the danger of tuberculosis infection from sweeping. The broom is, in his opinion, the chief and most serious danger to man. While infection may occur by other routes, that by inhalation is by far the most frequent. He says:

"If 60 per cent. of all men die of pulmonary tuberculosis (Biggs)—if the main, almost the only, cause of pulmonary tuberculosis is bacilli-laden dust, and the broom by far the main cause for such dust, the broom is evidently responsible for more deaths than the sword ever was.

"The inevitable consequences of the above are: 1. That the broom, far from serving any hygienic purpose, is the cause of the maintenance of organic dust in the atmosphere of the large cities of the world, and as such is the most important cause of the existence and spread of tuberculosis, probably also of various other infectious diseases, and should therefore be abolished. 2. That the carpet is an unhygienic article serving as a fine breeding-ground for vegetable parasites, necessitating the use of the broom and the duster, and thereby becoming a reason for existence and spread of tuberculosis, probably also of various other infectious diseases, and should therefore be abolished. 2. That the carpet is an unhygienic article serving as a fine breeding-ground for vegetable parasites, necessitating the use of the broom and the duster, and thereby becoming a reason for the existence of organic dust. 3. That the only proper and safe way of procuring cleanliness of the floors and streets of our large cities is by the free use of water as a cleansing agent in the shape of showers, sprinkling wagons, hose, mops etc. 4. That all floors and floor coverings of the home and the street ought to be so constructed as to facilitate the free use of water in the shape of shower or mop to produce cleanliness.

104. Tetanus Treated with Carbolic Acid.—Woods reports the only case of tetanus he has seen recover, the patient treated by hypodermic injections of 10 per cent. solution of carbolic acid every half hour until he was able to swallow, except when he was quiet in the night. When he became able to swallow a dram of the solution in glycerin was administered every three hours until the spasms ceased, and after that a dram three times a day, gradually diminished to one-half dram until all

rigidity had disappeared. He appends the report of a case of tetanus in a horse similarly treated, with like results.

105. Reflex Irritation and Eye Strain.—Drew's paper calls attention to the importance of reflex irritation from eye-strain in the production of mental disorders. He advocates the views promulgated by Stevens, Ranney and others in this regard.

106. Inoculation of Scarlet Fever.—This paper contains the report of 10 cases of children inoculated with scarlet fever with mucus obtained from the throat and buccal cavity of a mild case of scarlet fever, after the eruption had appeared. The inoculations were originally made, it is stated in a foot-note, to prove that a protective virus had been discovered, but it was found that genuine scarlet fever was produced. The following are the author's conclusions: 1. The mucus of the throat and mouth has been shown with absolute certainty to contain the contagion of the disease. 2. The early eruptive stage of scarlatina is exceedingly infectious because of the presence in the discharges from the mouth and throat of the special poison of the disease. 3. The contagion of the disease being in the mouth and throat secretions, care should be taken, not only to disinfect these parts as thoroughly as possible, but to keep the tongue, mouth and lips moist constantly, if possible, in order to prevent the contagious principle being forced into the air of the room by the exhalations of the patient. 4. Mouth and nose wipes should be used instead of spit-cups and costly handkerchiefs and they should be destroyed by fire before the discharges on them dry, i. e., at once. If fire be not available, disinfecting solutions should be used strong enough to render the poison inert. 5. The soiling of the bed-clothing and personal apparel with mouth discharges should be prevented if possible. In the event of such contamination, they should be disinfected as soon as possible. 6. No toys or implements of any sort that can not be boiled or subjected to the strongest germicidal solutions should be given the patient, as they are apt to become soiled by the mouth secretions. 7. Those who minister at the bedside should be especially careful as to personal contamination and disinfection from the moment they enter the room. 8. The nostrils should be taken thorough care of, as the morbid matter which finds its way into these parts will, in the dry state, easily find its way into the atmosphere of the room, thus making the spread of the disease more probable.

112. This is an abstract of a paper read before the American Gynecological Society, May 22, 1899.

113. Dysphonia.—Christy describes dysphonia as the result of any interference with normal respiration and phonation, and it may be accompanied by either pain or cough or both. It is: 1. Due to any interference with physiologic functions of the glottis and true cords, generally from inflammatory causes. 2. Not always in direct relationship with the intensity of the inflammation. 3. Not always present in inflammatory affections. 4. Not always associated with the constitutional diseases, presence of growths, etc. 5. Found occasionally with that rare constitutional condition (mentioned by Morell Mackenzie), a chronic inflammation of the mucous canals. 6. Found in cases of trachoma of the true cords known as singer's nodes. 7. Found in cases of lithemic throat, also in gouty and rheumatic conditions. 8. Found in cases of enervation of the larynx from general debility or localized paresis. 9. Frequently present during the period of pregnancy. 10. Causal relations not always determined by local inspection of the parts. 11. One vocal cord only may be normal, its companion useless. 12. Pain may or may not be a symptomatic feature. 13. Mild forms of dysphonia are occasionally due to gastric conditions. 14. Stenosis of larynx; pathologic changes found in subglottic space; chronic use of tobacco and alcohols. 15. Caused by an elongated uvula. After noticing the anatomy of the vocal organs, he gives the results of his treatment of this condition with the constant electric current, reporting four cases. His conclusions are that the galvanic current, as a curative agent in laryngeal and tracheal affection, a, is easy of application; b, is soothing and agreeable to the patient; c, relieves the congestion, pain and irritation; d, does not excite pain or spasm of the glottis or trachea; e, relieves the swollen lymphatic glands; f, cures more promptly than any other agent; g, patients recognize its value and return regularly for its application.

115. See JOURNAL June 24, 1899, p. 1443, for abstract of this article with discussion.

118. **Effects of Training.**—Darling's paper is concluded from a previous number, and he finds that the physiologic effects of training, on the heart and kidneys in particular, may approach unpleasantly near to pathologic conditions, and there should be some competent supervisor to see that the safe limits, when they are ascertained, are not passed. He thinks that it is well to suggest that too much work is not thrown on the muscles, especially on the heart, until they are strengthened by preliminary work, and to watch the nutrition carefully and to avoid nervous fatigue by providing a variety of exercise and not confining the attention too closely to the approaching contest.

120. **Staphylococcus Infection.**—The first part of this paper reviews the opinions in regard to certain skin diseases and concludes with investigations by the author, by inoculation and examinations, and with some remarks on impetigo contagiosa from a clinical standpoint. The author's results support strikingly the theory of staphylococcus pustular skin affections.

121. **Multiple Vulvar Ulcers in Typhoid.**—After remarking that vulvar ulceration of the kind described in the two cases reported are new to literature, Lartigau reports two cases of typhoid fever in which multiple ulcers occurred in the vulva and vagina, in one of which a bacteriologic study of this lesion produced a pure culture of typhoid, the bacillus reacting to all the tests. The second case was similar, but there were no bacteriologic studies made.

122. **Appendicitis.**—Harrison concludes that in all mild cases without severe complications the use of an ounce of prevention rather than a pound of cure is advisable, and operation is recommended as soon as the diagnosis is complete. In the fulminating variety of appendicitis, all will agree as to the advantage of the early operation. In those cases seen late, where there is suppurative peritonitis without collapse, the patient is entitled to the very small chance offered by the operation after he has been advised as to the gravity of the situation.

123. **Does the Practice of Medicine Pay?**—After reviewing the facts as they appear to him, the overcrowding of the profession, the multiplicity of medical colleges, etc., Monroe concludes that it does not pay, financially, to be a physician.

126. **Ligation of the Dorsal Vein of the Penis.**—Broome reports six cases of ligation of the vena dorsalis penis for functional impotence, with good results. He thinks that in properly selected cases this operation has its advantages, while it would be unavailing in neurasthenic cases with relaxed organs and very little sexual impulse.

Lancet, August 26.

Some Details in the Treatment of Acute Intussusception in Infants. H. STANSFIELD COLLIER, F.R.C.S.—The author recommends the method of treating intussusception in infants by injections with water or air, and on location of the tumor, the reduction of the bowel through a very small incision. He thinks that while injection alone is inefficient and large incision is perilous in infants, by this method there is less shock and danger. He reports three cases, briefly.

Cases of Amenorrhœa Associated with Raynaud's Disease and Pulmonary Tuberculosis. JOHN V. BYERS.—Byers has met with a series of cases within the past ten years characterized by: 1, arrested or diminished menstruation; 2, local symmetrical asphyxia of the extremities—especially of the arms and hands (Raynaud's disease); and 3, pulmonary tuberculosis. He gives details of four cases, and discusses the relation of these symptoms. The association of tuberculosis with Raynaud's disease is apparently a new fact.

Acquired Oblique Inguinal Hernia; 150 Consecutive Cases of Radical Cure; One Death and Two Recurrences; A New Operation. JOHN O'CONNOR.—The author, finding that orchitis followed Halsted's operation in 80 per cent. of his cases, and was frequently also met with after Bassini's operation, has devised the following method, which, in the fifteen cases in which he has used it, has been followed by no relapses or serious complications.

"A three-inch incision is made, commencing at a point half an inch internal to the anterior superior pubic spine, and is carried inward and downward to a point one inch above Poupart's ligament. The external oblique, internal oblique, and

transversalis muscles are opened by separation of their fibers, as in McBurney's appendicectomy. The funnel-shaped process of the peritoneum is then sought for and a finger is passed behind it in order to differentiate the cord, and with a little dissection the latter is freely separated from the former. The funnel is incised and the intestine and the omentum are pushed upward into the abdomen by a sponge inserted through the wound. If any bowel or omentum be found adherent in situ the complication is easily dealt with, but if such adhesions should have formed low down in the sac upward traction is made on the latter until the testis reaches the external ring, and the portion of sac thus exposed is divided from above downward on its anterior aspect. By this maneuver the majority of low adhesions can be easily brought into view. In cases of old adherent sacs upward traction might be useless, and then nothing would remain but to open the canal from above downward. In none of my 15 cases have I had occasion to do this. In two cases where there were low omental adhesions I doubly ligated the omentum, divided between, and allowed the distal segment to drop back and remain in the sac, and no ill effect followed. The sac is next ligated below the funnel and divided on the proximal side of the ligature, and the distal portion is dropped back into the inguinal canal and there it remains. It may act as filling material for the canal—not that I think any such is required, but that I do not consider it expedient to divide muscular fibers for the sake of removing it. In cases of bubonocoele the small sac may be removed with facility. The funnel-shaped process of the peritoneum is then completely snipped away at its base—i. e., at the level of the normal parietal peritoneum. A large gap is left; pressure forceps are applied, and the cut edges of the peritoneum are drawn down and are united by a continuous catgut suture. Having removed the funnel, the opening in the transversalis fascia appears as little like a ring as anything that can be well imagined. I have frequently been struck with the large size of this hole and have wondered how it was that yards instead of inches of bowel had not escaped through it, particularly if the great amount of intra-abdominal pressure which must be constantly concentrated on this point be thought of. Doubtless the oblique muscles save the situation and this in itself is a strong reason for objecting to operations in which these protective muscular fibers are ruthlessly divided. No muscle is strengthened by having a transverse cicatrix formed in it and, moreover, I am very dubious as to the durability of any cicatricial tissue barrier. The edges of the transversalis fascia are next caught by forceps and are drawn well into the field of operation; from four to six silk-worm gut sutures are then passed through the external oblique and transversalis muscles and the fascial pillars and are brought out in the reverse order on the opposite side. Care is taken to leave room for the cord to pass into the canal without compression. The edges of the deep wound are now firmly approximated, the sutures are tied, and the ends are cut off. The wounds in the external oblique and the skin are united by separate continuous catgut sutures.

"In none of the cases treated by this method has orchitis supervened and no recurrence has so far taken place. I may here mention that I never order a truss to be worn after an operation for radical cure. The advantages which may be claimed for this operation are: 1, the vitality or function of the testicle is not endangered; 2, there being no division of muscular fibers the natural anatomical support is not weakened; 3, the cause of the trouble only is dealt with, and all superfluous surgery is avoided; and 4, the wound is comparatively small, is further removed from the septic area, and it contains no pockets for blood or serum."

Suggestion As to Treatment of Graves' Disease by Administration of Bile by the Mouth, Hypodermically, and Intrathyroidal, with Cases. C. M. ALLAN.—In a case of Graves' disease Allan's attention was called to the absence of bile in the feces, and this suggested to him a probable paresis of the liver-cells in the disorder. Salicylate of soda and phosphate of potash, both powerful chologogues, did not influence the secretion. This led him to give pig's bile internally, supplementing it part of the time with intrathyroidal injections of the same. The dose was eight grains of extract every four hours, equivalent to 1500 grains of bile daily, and this was

later increased to 2250 grains, with great benefit. In all the patient received 48,000 grains, 3640 of which were given hypodermically. Recovery was perfect, and there was great general improvement and gain in weight. He concludes that bic has a digestive effect on other ferments or toxins, and reports a case of a boy treated by thyroid extract, which alone seriously disagreed with him but exercised its good effects without its untoward ones, if mixed two hours before use with bile. A second case of Graves' disease thus treated with success is also briefly reported.

Diphtheritic Paralysis in Cases Treated with Antitoxin. F. J. WOOLLACOTT.—This paper contains some interesting statistics in regard to the antitoxin treatment of diphtheria and the occurrence of diphtheritic paralysis. The author says: "In conclusion, the influence of antitoxin on diphtheritic paralysis may be summarized as follows: Up to the present the percentage of paralysis has increased on the whole. There is some evidence that large doses—i. e., not less than 4000 units—of antitoxin are more effective than small ones, both in preventing paralysis and diminishing the mortality due to it. The earlier antitoxin is given in diphtheria the less likely is paralysis to follow. Should it occur after early injection it will probably be mild and of comparatively short duration. The type of paralysis has on the whole, become less severe or, at all events, less dangerous to life. Finally, diphtheritic paralysis has become more prone to attack the young. This change in age incidence has probably made some minor difference in the relative frequency with which the various forms of paralysis are observed. The practical conclusion is that the full value of antitoxin is obtained only by using it early and in efficient doses. If this be done, not only is life saved, but tedious complications are prevented, or at least deprived of their dangerous characters."

Medical Press and Circular (London), August 23.

Notes on a Case of Hematuria from Healthy Kidneys. T. MYLES.—A case is here reported of hematuria, with pain, vomiting, etc., and movable kidneys, in a nurse, aged 26. Operation on the left kidney, which appeared to be the seat of irritation, revealed no adequate cause for the hematuria, and the kidney was fixed after an X-ray examination, which was also futile. The operation was in every respect a success, but the hematuria continued, and the patient's anemia and other symptoms became serious. A nephrectomy was then made twenty-three days later, and examination of the removed organ revealed a diffuse myxangiomatic condition of the pelvic submucous tissue. Recovery was complete. The points of interest in the case were the obscurity of the pathologic condition before removal, the examination by the X-ray of the kidney outside the body before fixation in the first operation, the mode of fixation, which was by removal of perineal fat and stripping of the capsule, and the pathologic findings, which Myles thinks are unique.

A Case Bearing on the Etiology of Rickets. CHARLES ELGWOOD.—After remarking on the popular notion that rickets is due to improper feeding, Elgwood reports a case that seems to point to other causes. A woman, aged 23, gave birth to an illegitimate child; the father a healthy young game-keeper. The boy has grown up healthy. In 1886 she married a farm laborer of degenerate type and of limited intelligence, who was defective in infancy, did not walk till eighteen months old, and at 8 years was considered to be in a decline. To him she bore five children, one of whom died rickety at 4, and the surviving ones all developed into marked rickets in different degrees. During most of this time the family lived in an old farmhouse in a healthy situation. In 1893 the man committed suicide, and the woman and her children moved to a cottage in a similar situation. Here, in 1896, she gave birth to another illegitimate child, so far healthy. Shortly after this she married again, and has one child, puny, but with no signs of rickets. According to her testimony, the feeding of her children has varied little, and during her first marriage her surroundings were much better than later in the cottage. Rickets is not common in the neighborhood. Elgwood has seen none other of such severity as some of these. He suggests that heredity may be an important cause, but that in cities where the disorder most prevails, this is obscured by other causes: overcrowding, lack of sunlight and ventilation, etc.

Uric Acid and the Circulation: Some New Methods of Estimating Its Effects. A. HAIG.—Quoting Raynaud, that in his disease as much as thirty seconds may elapse before the skin rendered white by pressure regains its normal color, while healthy skin does so in one or two seconds, Haig, assuming Raynaud's disease to be of uric acid origin, concluded that similar time-phenomena would be observed with other uric acid states. He, therefore, has utilized the metronome in testing this capillary reflex with an instrument devised to give exact areas and degrees of pressure, and finds, he says, that it goes parallel with high blood-pressure and with the disappearance of the after, or fatigue, image in the retina, indicating the capillary circulation there. He claims that testing this capillary reflex is an index of the amount of uric acid in the blood and urine, and that the capillary circulation is controlled by uric acid.

South African Medical Journal, August.

Notes on Some Recent Cases of Plague in South Africa.—Dr. A. J. Gregory, assistant medical officer of health, Cape Colony, publishes, in the *South African Medical Journal* for August, an account of a case of plague examined by him at Middleburg, Natal. While the bacteriologic examination and inoculation experiments were not absolutely conclusive they are sufficiently so as to leave little doubt as to the nature of the disease. Other facts, such as a mortality of rats at Delagoa Bay, where the patient came from, and the occurrence of other similar cases at that place, led Dr. Gregory to conclude that plague in a mild form has existed there since early in January, and probably for some time prior to that date. The lessened severity of the disorder, as compared with that in Bombay he attributes to more favorable sanitary conditions, and the measures adopted by the authorities. Dr. Gregory's diagnosis has been agreed to by the special medical plague officer at Johannesburg, Dr. Hornabrook, who examined the microscopic specimens and cultures.

Revue Hebdomadaire de Laryngologie, etc. (Bordeaux), August 12.

Center for Phonation. ONODI.—Study of a number of monsters and of fetuses whose skulls had been perforated, but who had used their voices, confirms the existence in man of an infracerebral center of phonation, the same as Onodi has already established for dogs, and in the same spot, that is, between the posterior quadrigeminal tubercles and the domain of the vagus.

Annales de Dermatologie (Paris), July.

Cazenave's Pemphigus Foliaceus.—LEJEUNNE.—The important pathologic rôle of the bone-marrow is still generally unrecognized, and osteomalacia, chronic rheumatism, dermatoses, etc., are explained by nervous disturbances or a diathesis. Leredde asserts that it is a lesion of the blood which determines certain cutaneous affections at least, and probably many more, and that the causes of the alterations in the blood are the primary causes of the dermatoses. He relates several observations showing that in pemphigus foliaceus over half the whites in the circulation are altered and abnormal in some respect. In one case, complicated with osteomalacia, the number of reds was less than normal (2,608,000); also the hemoglobin (8.50); slight increase in whites (8200); pronounced eosinophilia (27.5 per cent.), increasing and diminishing parallel to the intensity of the lesions; polymuclears less than normal (18.3 per cent.); mononuclears and lymphocytes (45.8 per cent.) He states that the blood differs from normal in the same way in Duhring's dermatosis, and the cutaneous lesions in each also belong to the same class, showing an exaggerated production of serum and an important adapedesis of eosinophilous cells and their elimination through the skin. He concludes with the statement that our present knowledge in respect to "drug eruptions," induced by agents which are not toxic except for a limited number of subjects—mentioning instances of Duhring's dermatosis induced by potassium iodid—throws light on the sensibility of the organism, and indicates that the origin of this sensibility should be sought in the blood-forming organs rather than in the nerves. The persistence of the lesions after the elimination of the medicinal agent should be attributed to a persisting reaction on the part of the hematopoietic organs rather than to a nervous reaction. These lesions persisting in the blood may engender a series of dermatoses, such as pemphigus foliaceus or vegetans or dermatitis exfoliativa.

Treatment of Leprosy with Chaulmugra Oil. TORTOULIS-BEY.—The prompt and remarkable benefit derived from subcutaneous injections of 5 grains of chaulmugra oil impels our Cairo confrère to publish a case in detail. The leprosy was severe and of fifteen years' standing. The improvement was evident after fifty injections (1894), and the disease continued retrogressing until for three years the subject has presented no evidences of the disease and has been appointed vice-consul and representative of a large bank. He had received 551 injections by the end of 1898, and 33 since; a total of 2720 grams of the oil. It was injected into the arm or leg; very slight and transient pain. All swelling subsides within twenty-four hours.

Archiv. f. Exp. Pathologie (Leipzig), xlii, 6.

Remedies to Arrest Hemorrhage. F. PICK.—In a series of experiments blood was allowed to flow from an opening in a femoral, mesenteric or jugular vein, and various drugs tested in respect to their power to control the flow. Ergotin was found entirely destitute of hemostatic properties, while hydrastinin and atropin proved effectual in diminishing the flow. Suprarenal extract produced the same effect, although it increased the blood-pressure.

Centralblatt f. Chirurgie (Leipzig), August 19.

New Methods of Treating Wounds. C. L. SCHLEICH.—Scrubbing and chemical disinfection are rejected entirely. Schleich claiming that his soap made of stearin, wax and marble dust, with which the hands and region are washed, accomplishes the purpose of coating the skin with a microscopic, aseptic wax covering, or glove for the hands, insoluble in serum and other organic fluids. The soap removes all grease and flakes of epidermis, and the hands can thus be sterilized as often as desired during the day at a trifling expense and without waste of time. His control-tests have been remarkably favorable, and the cosmetic advantages of the soap have already been confirmed by others. He disapproves of catgut, and keeps his silk in nutrient gelatin. He dresses wounds with "homogeneous" substances, preparations of gelatin, peptone and serum, on account of their fibrinolytic, etc., properties. His work describing his theories, methods and results in full has just been published at Berlin. (J. Springer, 378 pages.)

Muenchener Medizinische Wochenschrift, August 15 and 22.

Function of the Thyroid Gland. A. OSWALD.—All the iodine-containing substances in the thyroid gland pass into the extract when extracted with physiologic salt solution, and Oswald has found that these substances are albuminoids, and that the extract after the albuminoids have been removed no longer contains any iodine. He has also succeeded in isolating from the aqueous organ extract (with ammonium sulphate) two distinct albuminoids, one resembling globulin, but precipitated by acetic acid although dissolving again with an excess. This he calls "thyroglobulin." It contains 1.6 per cent. iodine, and is much more abundant than the other albuminoid, which he finds contains phosphorus but no iodine, and is essentially a nucleoprotein. He found by numerous tests (pigs) that the entire specific effect of the thyroid on the metabolism is due exclusively to the thyroglobulin; also that the colloid substance is merely a combination of these albuminoids, thyroglobulin and the nucleoprotein, and hence that the colloid is the effective element of the gland, and is in fact its "specific secretion." The thyroglobulin probably gives up its iodine when it has accomplished its purpose, and the iodine circulating in the blood is in turn retained by the thyroid to make new thyroglobulin. The next question to be decided is whether the function of the thyroid gland is restricted to the elaboration of thyroglobulin, and experiments are now in order to determine this. Oswald warns that administering it per os is not a reliable method of testing its action on the organism, as it is possible and probable that it loses some of its properties during the process of digestion.

Perforating Wounds of the Alimentary Canal. F. HAHN.—Two observations are reported, one a wide stab in the stomach after a hearty meal and the other extensive laceration of the small intestines by the kick of a horse. Both were cured with a prompt laparotomy, extremely careful cleansing and tamponing of the abdominal cavity, especially of the sub-phrenic space and Douglas' sac, and abstention from opiates. The subjective condition did not seem to warrant an intervention in the second case, but Hahn followed the indications of

the increasing area of dullness, the rigid tension of the abdomen and emission of feces.

Comparison of Indications for Sectio Cesareae, Symphysiotomy, Craniotomy and Premature Delivery. LEOPOLD.—Far above every consideration is the value of the mother to the home. Other children may be born; another father may take the father's place, but a mother's place can never be filled. Far better to perforate once too many times than once too few. The practitioner must deliberate with himself whether he is equal to a sectio or a symphysiotomy, and will not regret his rashness before he has finished it; also whether he has reliable and skilled assistance and whether the surroundings of the home will not jeopardize the success of his best efforts. Bearing these axioms in mind, he summarizes the indications as follows: Before term, artificial premature delivery is indicated for women who have had trouble in previous deliveries from a narrow pelvis—limit, 7 cm. conj. vera, for a flat rhaehitic pelvis; 7.5 for a generally narrow pelvis. Best time is the thirty-fifth week of the pregnancy. Retention of the bag of waters and head presentation are essential conditions for success. At term. The extreme limit for craniotomy is 6 cm. conj. vera. The indications are a dead or dying child. Even if delivered by sectio, the probabilities of the survival of the child are too slight to counterbalance the danger to the mother, except in most exceptional cases. Craniotomy may also be indicated in private practice with a living child and woman in good condition when the practitioner dares not venture upon sectio or symphysiotomy, and the pelvis is too narrow for natural or forceps delivery. Sectio Cesareae is imperatively indicated in case of a conj. vera of 6 to 6 cm.; relatively indicated with 7.5 to 6, after spontaneous delivery has been found impossible even with colpo-urinary and Walcher's position, and it is impossible to use the forceps, the child is living and the surroundings of a hospital or residence ensuring a successful after-treatment. If the conditions are not all fulfilled, craniotomy should be preferred. Symphysiotomy is restricted to pelvis of 7.5 to 6.5 cm. conj. vera and the conditions should be the same as for sectio, with craniotomy the alternative. The choice between it and sectio depends upon the taste and experience of the operator. They stand on about the same plane in respect to the results for mother and child.

Implantation of the Ureter in the Bladder to Cure a Utero-Cervical Fistula. J. A. AMANN.—Brilliant success was attained in three cases in which, after a laparotomy, the ureter was cut off above the enormous cicatricial growth around its mouth and implanted in the bladder near the abdominal incision, according to the method devised and described by Witzel in *Ubl. f. Gyn.*, 1896, No. 11. Extirpation of a sound kidney or transformation of a uretero-cervical into a uretero-vaginal fistula are no longer necessary since Witzel's method has proved satisfactory for all cases of the former except the rare ones accessible through the vagina.

Wiener Klinische Wochenschrift, August 17.

Sensibility of Transplanted Skin Flaps. E. STRANSKY.—The degree of sensibility is usually in inverse proportion to the size of the flap, and is least around the edges, where the regenerative processes destroy the nerve terminals. As the nerves in the new region grow into the terminals in the flap, these transfer their allegiance and serve the newcomers as terminals, although in respect to tactile sensation at least, they seem to retain the characteristic of the mother region. The points sensitive to pain do not coincide with the points of maximum tactile sensation nor of temperature. Tactile sensation appears first, followed in turn by pain and temperature sensation. Stransky is inclined to believe that the specific nature of the sensation transmitted is due to a sort of selection among the stimulations received. He noted a duality in the sensation in some cases; slight pressure felt through the stem flap in the mother region, but harder pressure, felt in the underlying region, but failed to find any such phenomenon in flaps without a stem.

Experimental Stimulation of the Cortex After Dividing Part of the Central Nervous System, to Throw Light on Cortical Epilepsy. H. E. HERRING.—Experiments on twenty-seven dogs and twenty monkeys dividing the pyramidal tracts, etc., demonstrated that the nerves which produce contraction in the muscles also relax them. It was impossible to find any inhibiting tracts—like the heart-inhibiting vagus fibers, for

instance—or inhibiting centers. Neither was it possible to find any specific routes for the transmission of clonic contractions; all the corticofugal nerve-tracts capable of producing movements can also produce the cortical clonic contractions, but all are not equally excitable; the pyramidal tracts transmit the impulse to clonic contraction relatively much more readily than the others. He found that in monkeys the pyramidal tract plays a more important part than in dogs, in isolated movements of the contralateral extremities—in men still more than in monkeys. The dog, on the other hand, possesses a contralateral tract transmitting impulses for isolated movements comparatively readily, while in the monkey this tract only functionates, associated with the homolateral tract, and is difficult to excite. The homolateral tract in the monkey has a much more detailed function and is more readily excited than in the dog.

St. Petersburger Medicinische Wochenschrift, August 5 and 12.

Abdominal Fat Necrosis. TRUHAUT.—The acute affection characterized by hemorrhages in the pancreas, fat necrosis of the gland and surrounding tissues, with patches in the mesentery, omentum and peritoneum, and the omentum bursa filled with a septic chocolate fluid, retained if Winslow's foramen is closed by adhesions, if not, disseminated and producing abscesses in or outside of the peritoneum, first described by Balsler, is ascribed by some to a microbian origin, but Truhart is confident that it is due to chemical action by the steapsin—the fat-decomposing enzyme of the pancreas—destructively in contact with the abdominal fat tissue. He proves this assumption by a number of facts derived from experimentation and clinical experience, both personal and collected in literature, some equivalent to experiments in *hominie vivo*. The fat necrosis is never an idiopathic disease but is merely a symptom, a manifestation of an existing affection of the pancreas. It affects well-nourished persons with a tendency to be fat, usually in the midst of perfect health, commencing suddenly with intense pain in the epigastrium, vomiting, constipation or diarrhea and collapse, terminating fatally in a few hours in some cases. (See Scott's observation, JOURNAL, xxxii, p. 882.) In the subacute, more chronic cases, an important sign is a tumor-like distension of the upper abdomen, extending from the left hypochondrium to the left lumbar region. In 20 per cent. of the 100 observations of "Balsler's disease" collected the symptoms simulated ileus to such an extent that the abdomen was opened and closed, the operator no wiser than before. It was correctly diagnosed *in vivo* only seven times (Körte 4 in 5; Fitz, Halsted and Atkinson, 1 each); two of these cases were successfully operated on. Diabetes appeared 1½ years later in one. Prognosis is grave, although spontaneous recovery has occurred three times after expulsion of quantities of necrosed fat tissue and pancreatic substance per anum. Truhart suggests that even slight gastroduodenal catarrh in persons with a tendency to obesity should be treated with especial care to prevent the extension of the lesions into the pancreas, and general arteriosclerosis with other hygienic and local prophylactic measures, milk diet, etc. Reviewing 1000 observations of affections of the pancreas on record, he notes that 10 per cent. are mentioned as accompanied by more or less abdominal fat necrosis.

Behavior of the Uterus After Extirpation of Both Ovaries and Their Transplantation to Another Point in the Abdominal Cavity. H. RUBINSTEIN.—Various theories have been advanced to account for the atrophy of the uterus after extirpation of the ovaries, some assuming a nervous connection between them, a trophic dependence of the uterus upon the ovaries, etc. The theory that explains it as due to an "internal secretion" by the latter, indispensable to the life of the former, has received strong confirmation by the experiments described in this preliminary communication, in which both ovaries in rabbits were extirpated and replanted in another part of the abdominal cavity remote from the uterus. If the ovaries then atrophied, the uterus atrophied also, but if the ovaries took root in their new home and continued their functions, the uterus remained normal in every instance, and some of the rabbits had several litters afterward. Clinical facts also confirm this assumption; Curatola and Tarulli's statements that the metabolism in castrated animals is very different from that of uncastrated animals; the success of ovariin, and of castration for osteomalacia, etc., all tend to establish that the ovaries have an important function besides the genital.

Gazetta degli Ospedali e delle Cliniche (Milan), August 6 and 13.

Diagnostic Value of Kernig's Sign. A. CIPOLLINA.—Netter found this sign in 90 per cent. of his cases of meningitis, but Cipollina missed it in some cases of severe meningitis and has found it in other affections without meningitic symptoms or lesions. He notes the fact that when it is absent the meningitis is nearly always of tubercular origin. Attempts to produce it experimentally failed absolutely. He recommends it as an indication of great value, although not infallible.

Protecting Action of the Lungs. C. CAFFARO.—A series of experiments on animals is described in detail, which confirm the assumption that the lungs have a decided protecting action in respect to toxins, and that it is due to the living lung, and not merely to the living tissue of the non-respiring lung, but to the respiratory function of the living lung.

Capacity of the Red Corpuscles for Hemoglobin. A. RIVA.—In studying the physiopathology of chlorosis, radiography has confirmed the hypoplasia of the blood-forming organs noted by many in this disease, showing the predominance of the bone tissue. The most important point in this communication is the announcement that in chlorosis the capacity of the red corpuscle for hemoglobin is reduced. The number of red corpuscles produced may not vary much from normal; Riva has frequently observed in pure primary chlorosis that the number of erythrocytes were scarcely inferior and occasionally superior to normal. But they are delivered to the circulation with certain inherent peculiar biochemical differences from normal, which interfere with the normal formation and accumulation of hemoglobin, and to this he ascribes the essence of chlorosis, although this factor may be accompanied by hypoglobulia, poikilocytosis, etc. The cytogenic and hemoglobinogenic functions of the red corpuscle are quite distinct, and correspond to different phases in its life, as it is born colorless and gradually accumulates the hemoglobin in its stroma, except when this function is compromised. He also ascribes to this reduced capacity of the corpuscle the inefficacy of preparations of organic iron. The small amount and the stability of the iron render it impossible for the chlorotic and impotent corpuscle to derive any benefit from it, while preparations of inorganic iron are utilized to a remarkable extent.

Havana Medica, August.

Tropical Anemia and Its Relation to Malarial Infection.

A. PLEHN.—The sallowness and anemia noticed in persons in malarial localities, even in the absence of or previous to malarial manifestations, is explained by Plehn as due to the presence of certain granules in the red corpuscles, which he considers the fundamental forms of the malarial parasite, living possibly, months and years in the red corpuscles without producing any symptoms except more or less anemia, until circumstances arise that favor their development into the plasmodium, and consequent pronounced malarial infection. When evidences of anemia and a diminished amount of hemoglobin appear, if a drop of the blood on a cover-glass is treated with alcohol and hematoxylin, album and eosin (Ehrlich), dots and spots of dark blue will appear in some of the red corpuscles, usually round and grouped in chains of two or more, about 1/3 μ in diameter. They are some times noted also in the plasma, after destruction of the red corpuscles. These granules disappear completely when the anemia passes into acute malarial infection, especially during hematocrit bilious fever, to reappear during convalescence. He has noted them in Camarones, in the Roman Campagna, in sailors after voyages in malarial latitudes, etc. The mosquito can not be the only means of contagion in Camarones as there are comparatively few insects there, and the crescent forms of the plasmodium are extremely rare. (From Rev. de Med. y Cir. Practs.)

Significance of Melanin in the Blood Plasma in Malarial Infection. E. EDELMANN.—After establishing that the melanin found in the blood is not a product of the plasmodium, but is derived from the hematin, Edelmann states that during an attack, when the blood is loaded with malarial parasites, and the fever is destroying the red corpuscles, the blood will be found to contain numbers of living and dead plasmodia and melanin free and enclosed in the leucocytes. But if the blood is examined after the attack no parasites will be found nor any leucocytes containing melanin. The question what has become of them? He answers by asserting that they have all been imprisoned in the spleen, where the normal number of lymph-cells has been multiplied to protect the organism from the invasion of the parasite.

Societies.

COMING MEETINGS.

American Association of Military Surgeons of the United States, Kansas City, Mo., September 27-29.

American Association of Obstetricians and Gynecologists, Indianapolis, Ind., September 19-21.

American Electro-Therapeutic Association, Washington, D. C., September 19.

Medical Society of the State of Pennsylvania, Wilkesbarre, September 18-20.

Medical Society of the Missouri Valley, Council Bluffs, Iowa, September 21.

Venango Medical Society.—This Society will hold its next monthly meeting at Oil City, Pa., September 19.

Bradford County Medical Society.—This Pennsylvania Society held its fiftieth anniversary banquet at Towanda, Pa., September 12.

Lancaster City and County Medical Society.—This Society held its regular meeting at Lancaster, Pa., September 5, when three members were elected.

Miami and Shelby County Medical Societies.—A joint meeting of these two societies was held at Piqua, Ohio, September 7. These meetings are held quarterly.

Calhoun County Medical Association.—This Association met in Marshall, Mich., September 5. It was decided to hold the next meeting in Battle Creek, December 12.

American Association of Military Surgeons.—This Association will hold an open session at their coming meeting at Kansas City, on the night of September 27.

Tri State Medical Society.—The eleventh annual meeting of the Tri-State Medical Society of Alabama, Georgia and Tennessee will be held in Chattanooga, Tenn., October 24-26. Those desiring to read papers should send titles to Dr. Frank H. Smith, Chattanooga, Tenn.

McLean County Medical Association.—The regular monthly meeting of this Association was held at Bloomington, Ill., September 7. Dr. Nushbaum presented a very interesting paper on "The History and Origin of Johns Hopkins University and Hospital." The Association proposes issuing a booklet containing the names of its members, with a brief sketch of each, and the names of all deceased members, from its organization.

International Congresses in Paris in 1900.—July 23-28, International Congress of Medical Ethics; July 27-29, International Congress of the Medical Press; August 2-9, Thirteenth International Medical Congress; August 2-9, Fourth International Congress of Dermatology; August 10-17, Tenth International Congress of Hygiene and Demography; August 12-15, International Congress of Hypnotism.

Conference of Michigan Health Officers.—The important meeting of health officials in Michigan, the date for which was not fixed at time of first announcement, will be held at Grand Rapids, Oct. 26 and 27, 1899, and the conference will probably be one of the most instructive and useful ones ever held in Michigan. Besides the members of the State Board of Health, other prominent sanitarians, of national reputation, will be present.

Mississippi Valley Medical Association.—The twenty-fifth annual meeting of this Association will be held in Chicago, October 3, 4, 5 and 6. Dr. H. N. Moyer, Chicago, is chairman of the committee on arrangements. The officers are as follows: President, Duncan E.ve, Nashville, Tenn.; First Vice-President, A. J. Ochsner, Chicago; Second Vice-President, J. C. Morfit, St. Louis; Secretary, Henry E. Tulcy, Louisville, Ky.; Treasurer, Dudley A. Reynolds, Louisville, Ky.

California Academy of Medicine.

August Meeting.

TABES WITH UNUSUAL SYMPTOMS.

DR. PHILIP KING BROWN presented, for the consideration of the Academy, two cases of tabes with unusual symptoms.

CASE 1.—Mrs. S., aged 44½ years, was first seen in May, 1899. She was married at the age of 18½ years, and subse-

quently gave birth to a normal child, still living and well. Three miscarriages followed, one at six weeks, another at six months and the last at three months; she has not been pregnant since. At the age of 19½, following the birth of the first child, she had what was called "ulceration of the womb;" this was treated with blue vitriol, and cured. She had no further trouble from this source, nor has she ever had any headache, eruption or sore throat, save at one time, when in New York, when she had headache, eruption, and other symptoms, which were said to have been caused by sewer-gas poisoning. At the age of 21 she had an attack of pleurisy, and sixteen years ago she suffered from very severe neuralgic pains in the left hip, which seemed to be confined to the joint, and lasted for five weeks, with occasional brief intermissions.

At the age of 33 she first had dyspepsia; distress, accompanied by a great deal of gas, following everything eaten. This persisted for two years, and was followed by a period of three years when she was well and comfortable, complaining of no physical ailments. At the end of this period of rest, nausea first made its appearance, lasting all day for a time after its advent, but latterly being present only in the early morning hours. After vomiting, relief is felt for the rest of the day. When the nausea appears during the day, if she can eat and then immediately lie down, she experiences relief from the distress. For the past four or five years she has had occasional "girdle sensation." The sharp neuralgic pain which appeared in the right hip sixteen years ago has returned from time to time since that date; it is always referred to the same location, though at times the pain shoots down the right leg. In September, 1897, the pain appeared in the right heel; it was also neuralgic in character, and would last all day, with sharp exacerbations about every ten minutes. In February, 1897, she first noticed some dizziness, persisting day and night, and worse when lying down. In March, 1897, while in a condition of fair health and comparative ease, the patient awoke one morning with the right pupil dilated; it remained dilated three days, when she applied to Dr. Martin for relief. He instilled drops which contracted the pupil; it then remained contracted for three months, in spite of all efforts to dilate it. The left pupil then suddenly dilated, and after two days slowly contracted to the present size; both pupils have remained contracted, as at present, ever since. Dr. Martin gave her potassium iodid and mercury. She later consulted Dr. Barkan, who gave her potassium iodid, 30 grains three times a day. She next consulted Dr. Hirschfelder, who prescribed 300 drops of a 50 per cent. solution of potassium iodid, three times a day, and also gave her thirty-six inunctions of mercury. With the onset of the trouble in the left eye, the patient noticed numbness in the right foot and the left heel, both of which conditions have persisted since then, never disappearing, though at times becoming somewhat better.

The record of the patient, made two years ago and filed in Dr. Barkan's clinic, is as follows: "The patient has diplopia in both eyes, especially marked when she looked down; there is paralysis of all the muscles of the eyes except the external recti; ptosis is marked; the discs are normal." She complained of vertigo and could not stand with the eyes closed nor walk a chalk line; the hearing was normal. Some anesthesia was noted about the eyes, particularly above them.

She has never been constipated, but on the contrary had occasional attacks of diarrhea, coming on without apparent cause, and lasting for four or five days; these attacks have been noticed at times for a period of between four and five years. For six years past, she has been subject to occasional laryngeal crises, and pharyngeal crises have been of occasional occurrence for about the same time. During the pharyngeal crises she is unable to swallow while sitting up, but is able to do so, with some effort, when lying down. These crises recur every few months. In May, 1899, she had for the first time a cardiac crisis, the pain strongly resembling angina, lasting for two days and being somewhat paroxysmal in character. It was for the pain in the region of the heart that the patient called in the services of Dr. Brown, who then first saw the patient.

His notes, taken at that time, show the patient to be a small woman, fairly well nourished, with no signs of eruption on the body, no motor paralysis and no anesthesia of the chest on objective examination. The Argyll-Robertson pupils are present

and the Romberg symptom is marked; the patellar reflexes are greatly exaggerated but the achilles and plantar reflexes are abolished. The Fränkel sign is wanting. Examination shows the heart to be physically normal; no increased area, sounds normal, and no arteriosclerosis. The urine was normal and the stools showed the presence of much mucus. She was placed on a treatment of 20 grains of potassium iodid three times a day, together with inunctions of mercury. Bimiodid of mercury was later substituted for the inunctions. Up to August 5, when last examined, the chest showed no anesthesia, though an area of partial anesthesia, about half an inch wide, and extending down the inner side of the arms and forearms, was noticed; this is somewhat variable, but on the whole, persistent.

The stomach was frequently tested with the following result: Normally no hydrochloric nor no lactic acid could be detected. The vomited material was slightly alkaline, and showed neither hydrochloric nor lactic acid. After a test breakfast, following an attack of vomiting and hence when the stomach was otherwise empty, the result showed a faint reaction to litmus, no hydrochloric acid and a large lactic acid acidity. The stomach contents have been examined many times, but on no occasion has any trace of hydrochloric acid been found, and this in spite of all effort to stimulate secretion. A fairly well defined girdle sensation has been present for some time previous to my examination.

The patient was presented, and the various symptoms demonstrated. The Argyll-Robertson pupil was marked; the knee-jerks were very evidently exaggerated, but the amount of inco-ordination was markedly small. Difficulty was evidenced in standing with the eyes closed and in walking a chalk line.

Dr. Brown said: The case is reported for the reason that it seems a clear case of tabes, presenting some very rare and unusual symptoms. The knee-jerk is exaggerated, instead of being abolished, and this condition is extremely rare. The nature and occurrence of the various crises, too, is rather rare and unusual, and the amount of inco-ordination is much less than one would expect. The patient has the tabetic jaw, all the teeth having suddenly fallen out some time ago. While this woman does not present a perfectly clear, classical picture of tabes, there are present so many of the distinctive characteristics of that affection that I feel justified in classing the case as one of tabes, with unusual symptoms.

Another case came within my notice in July, it also presenting many symptoms of tabes, while at the same time many of the conditions present were unusual for that affection. The history obtained from the patient is as follows:

CASE 2.—Mrs. H., aged 45 years, for the past four years has had attacks of pain in the region of the angle of the scapulae, lasting continuously day and night for two weeks at a time. Her past history is as follows: She was a strong, healthy woman up to the commencement of the pains mentioned, about four years ago. She has had several miscarriages, one fifteen years ago, at three months, and one two years ago, at six months; she has had several children, the oldest being 17 and the youngest 8 years old. One child died a year ago, at the age of 3 years; the patient had pains in the back three months before this child was born. She has had no headache, no sore throat; she has lost in weight in the past four years, falling from 145 to 95 pounds; much of her hair has fallen out during this time, but there is no history of other trophic disturbances. An eruption appeared on the body about six years ago, following the birth of a child, which is still living. The patient has not menstruated for the past two years. Four years ago, at the onset of the present trouble, attacks of nausea made their appearance and have been of daily occurrence since that time. The pain in the back is frequently relieved by vomiting; she has never vomited blood nor coffee-ground material. The pain in the back seems to be worse after taking food and is aggravated by bathing.

Examination shows the right pupil to be more dilated than the left and to react more quickly to light stimulus and accommodation. The knee-jerks are abolished; inco-ordination is much more marked in the upper than in the lower extremities; it is slight in the legs. Anesthesia is strongly marked over the intermammary region. The anesthetic area is sharply defined, extends from nipple to nipple, and is about 5.5 cm. in

width. The patient is very constipated and has been so since the beginning of the present illness. For the past three or four months the bladder has been irritable. The epitrochlear, cervical and inguinal glands are all enlarged. The urine is pale, acid, sp. g. 1.020, shows a trace of albumin with hyaline and granular casts. Justus' test is negative. It was attempted, on the statement of the patient that she had had no inunctions and, so far as she knew, no mercuric treatment. On the feet, especially the left foot, are found areas of irregular anesthesia, not corresponding to any nerve areas, and not constant. The speech is slow and at times slightly thick; patient states that this is always so. She is an exceedingly nervous woman, and seems not to be altogether well balanced mentally.

This woman has consulted a large number of physicians and has not remained under the care of any one of them long enough to demonstrate the result of any one line of treatment. Dr. Moffitt saw the patient some time ago, and perhaps he will give us the benefit of his findings at that time.

DR. HEBBERT C. MOFFITT said: "I saw this patient in February of the present year. I gave her prescriptions for potassium iodid and mercury, but she did not again consult me. At that time she gave me a history that differs materially from the history subsequently given to Dr. Brown and just reported by him. What I gathered from her was substantiated and added to by her husband, who called upon me the day following her visit to me. She told me that she had had the abortions induced and that her trouble dated from the last one which she had successfully attempted. She also said that the eruption referred to as following the birth of a child had appeared on the child and not on herself. The knee-jerks were present at the time of my examination, the left one being somewhat livelier than the right. There was then no anesthesia on the chest, but there was analgesia on the back. The inco-ordination seemed to be more of the nature of a muscular paralysis than anything else, and I noticed some wasting of the muscles on the left side. There were no symptoms, of any particular importance, and I thought the case one of cerebrospinal syphilis rather than tabes. There was also a large element of hysteria. The symptoms of which she spoke to me, and the only ones which I elicited, were the pupils, the analgesia and the bladder affection; the husband spoke of lightning-like pains; there was nothing of the nature of the girdle sensation at that time. It seems to me that the knee-jerks disappeared too rapidly for it to be a case of tabes. The onset, too, was rather sudden, and while there is nausea, there does not seem to be any definite crisis."

DR. BROWN did not agree with Dr. Moffitt, but thought it a case of tabes with rather unusual history and symptoms. The tabetic lesions would explain the symptoms and conditions as presented, and such diagnosis seemed more probable than cerebrospinal syphilis. The cases were reported to the Academy. Dr. Brown said, with the hope that they would draw attention to a by-no-means small class of cases that pass from one physician to another, the actual condition not often being diagnosed, on account of the number of symptoms and their being masked to a greater or less extent.

DR. DOUGLASS W. MONTGOMERY said that in mentioning the fact that many cases do wander from one doctor to another, Dr. Brown had brought to his recollection an instance in point, and one akin to the cases reported. Dr. Montgomery said: "The history of the case, as I remember it, was about as follows: A man consulted me one day some few years ago, giving a history of nausea and vomiting which had persisted for a long time, recurring at intervals and occasionally sufficiently severe to completely prostrate him. He had lost considerable flesh as a result of these attacks of nausea and vomiting. In his search for relief he had consulted a number of doctors, various diagnoses and opinions having been rendered by the gentlemen consulted. One opinion was to the effect that he suffered from an overfilling of the gall-bladder, which then emptied into the stomach, thus producing the nausea. He was sitting very near to me, at my right, as I was taking the notes of his case, when suddenly he clapped his hand upon his thigh and exclaimed 'there! Sometimes I have sudden pains, just like that!' referring to a pain in his leg which had very suddenly appeared. I was at once aroused, looked at his eyes, found the Argyll-Robertson pupil, and then extracted a fairly good history and picture of tabes. The knee-jerks were absent, he could not

stand with the eyes closed, and he could not walk a chalk line. The sudden lightning-like pains had been in evidence for some time past. He was seen by Drs. Newmark and Sherman, who both agreed as to the diagnosis. I told him what the trouble was, that the nausea and vomiting were a symptom and would probably disappear after a time. Subsequently, he had quite an adventurous life. He was trephined by one man, on account of an old injury to the head, he having been shot many years before. Later he submitted to a laparotomy for the purpose of examining the liver and stomach. When I last heard of him he was somewhat improved, for the stomach crises had not occurred for quite an interval. This man's history is certainly appropos of what Dr. Brown said as to the many cases going about from doctor to doctor with the true cause of the trouble not understood or made out."

Dr. HARRY M. SHERMAN said: "I saw this patient with Dr. Montgomery, and I think there can be no question as to the fact that the man had tabs. He had been frequently exposed to syphilitic infection, though I do not remember whether a history of syphilis was obtained from him. A rather curious fact in connection occurred in my own experience. I was treating a child of this man for what I supposed was hip-joint disease. But the joint trouble improved so rapidly that I was forced to abandon the diagnosis. Very shortly after the child got well and left my hands, I learned of the syphilitic trouble with the father and rather concluded that the hip-joint affection was the result of syphilis. A short time afterward I treated a child for spinal disease; what I thought was tuberculosis of the spine. He did very badly, much to my disappointment, and finally left me. In speaking of the case to Dr. Montgomery, somewhat later, I learned that the father of this second child was a syphilitic, and the conclusion that here too the trouble may have been of syphilitic origin was forced upon me. These two cases form a distinct class in my mind. In both cases the diagnosis at first apparently clear, had to be given up; and in both cases I later learned that the father was syphilitic and had been so for years."

PLASTER-OF-PARIS INJECTIONS TO LOCATE FISTULA

Dr. J. F. McCONE sent a communication which was read, as Dr. McCone was unfortunately prevented from being present himself and presenting the matter in question in person. The communication set forth what Dr. McCone thought to be a new method of surgical procedure, and one which certainly was original with him. The suggestion of Dr. McCone was that, ischio-rectal fistule, the fistulous tracts and canals be injected with soft dental plaster-of-paris, that it be allowed to harden, and that the fistula and its ramifications could then be more easily and effectually dissected out, leaving a clean fresh wound which would heal by first intention. He had employed the method in one case with entire satisfaction and requested that it be tried by other members of the Academy and the results considered. This novel method of locating fistulous ramifications was discussed to some length.

Dr. DUDLEY TAIT, who at the request of the Chair read Dr. McCone's communication, thought that in its present shape the subject was not in the best light for discussion; Dr. McCone had not entered sufficiently into the special feature he advocated, and the previous treatment of the case reported was decidedly open to criticism. He would suggest that it be referred back to Dr. McCone for his revision and presentation at a future meeting.

Dr. MONTGOMERY, the president, stated that it was at his personal request that Dr. McCone had sent in the communication read. He had requested the doctor to do so in order to secure a record of publication of the method employed, which seemed to be original, and thus not run the chance of the loss of priority of an improved procedure.

Dr. PHILIP KING BROWN was inclined to doubt the possibility of injecting all the ramifications of a fistula with the plaster, for the reason that they would be, in all probability, already filled with debris, broken-down tissue, etc., and hence the plaster would not penetrate the canals far enough and well enough to be of any unusual value. He also called attention to the fact that many of these sinuses were of tuberculous origin, and such being the fact, in any given case, it would not be possible to remove all the tissue involved, even should the plaster penetrate all the sinuses. The tuberculous involvement would be

more extensive than the sinus. If sufficient force were employed to inject the sinuses fully, he was of the opinion that damage could result.

Dr. HERBERT C. MOFFITT called attention to the fact that forcing the plaster into the sinuses by pressure would possibly induce more extensive septic infection through the forcing of the septic germs into the surrounding and healthy tissue where absorption would be rapid, perhaps resulting in a general infection.

Dr. TAIT suggested that the plaster might penetrate, under the pressure employed, tissue not diseased, and that hence a greater amount of tissue than necessary might be removed in the subsequent operation. He referred to the fact that the simple excision of fistulous canals was not at all a new procedure; that for a long time it had been a recognized surgical practice to treat fistula by complete excision, the wound healing by first intention.

Dr. HARRY M. SHERMAN spoke of the injection of arteries with plaster of paris, in which process the force required to completely inject even the smallest arterioles was not great. He thought that a fistula could be as easily injected, the secretions and debris that might be present in the canals offering little or no objection to the process. In considering the possibility of inducing a general infection, it must be remembered that fistulous canals are surrounded by walls of thickened tissue, often very dense, and that the small pressure required would scarcely force the disease germs into the healthy tissue surrounding the fistula's wall. There would also, in all probability, be a regurgitation of the contained material, the plaster solution being permitted to penetrate all the diverticula.

Dr. HAROLD BRUNN said that the method seemed to him to be a most unique method of dealing with a very troublesome condition. It is at best exceedingly difficult to locate all the diverticula and ramifications of a fistula. The method suggested seemed to give promise of making this somewhat easier, and while it might be open to objections, it certainly presented many excellent features and was well worth a trial.

CANCER OF THE OVARIES.

Dr. HAROLD BRUNN presented some specimens of cancer of the ovaries, with microscopic slides. The two ovaries, removed from one woman, showed very clearly the cancerous nature of the involvement. The right ovary had been the site of a large ovarian cyst, some thirteen pints of fluid contents having been drawn from it prior to removal. On the inner surface of this cyst wall were numerous nodular masses, from the size of a pea to masses larger than a hen's egg. Some of these masses were papular in nature, but most of them showed clearly the cancerous formation of the tumors. The left ovary of the same woman was purely cancerous; it was with difficulty dug out, together with another cancerous mass in the omentum.

To Remove Blood from Clothing.—Several years ago, while contemplating the removal of a large blood spot from my clothes, I recalled the action of hydrogen peroxid on albuminous substances during operations, and immediately applied it to the spot in question and was delighted to see the stain entirely removed. Since then I have used it many times and always with the same results. The earlier the peroxid is applied after the blood spot is received, the better the effects, but I have used it on spots more than a week old, and they were completely removed. It should be used in full strength, and, after oxidation has ceased, it should be wiped off and another application made. Several such trials may be necessary before the stain disappears, but the process may be hastened by rubbing with the finger or a cloth while oxidation is in progress. If hot water has been used, or anything which will coagulate the albumen, the peroxid will not remove the stain, but otherwise its action is all that could be desired. I have frequently removed spots from my shirt-front, collars, and cuffs, and after the place was dried there was no evidence of any soiling having occurred. Quite recently I removed a very large stain from the carpet, following an operation in my office. I may add that I have never seen clothing bleached by the peroxid during the removal of spots.—J. T. Rugh, in *Phila. Med. Jour.*, August 12.

No. 51 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting, of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

These new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 51 Market Street Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, SEPTEMBER 16, 1899.

REED AND CARROLL'S REPLY TO SANARELLI.

As foretold in our editorial on "The Microbes of Yellow Fever," Sanarelli's remarkable attack on the bacteriologic technic of Reed and Carroll, who are stated to have claimed the close relationship of the bacillus *icteroides* to the bacillus of hog-cholera because of "some deplorable neglect of technical precautions in the laboratory;" did not long remain unanswered. In the *Medical News* of September 9, Drs. Reed and Carroll, fearing that silence on their part might be construed by the general medical public as an admission that they had followed faulty technical methods in their work, make a vigorous and, it seems to us, wholly successful defense of their methods in the investigation which led them to announce the rather startling view that the bacillus *icteroides* should be regarded as a variety of the hog-cholera bacillus. Reed and Carroll express full willingness to acknowledge that the cultures of two microorganisms might become mixed, by some oversight, in any laboratory, and if it can be proved that such is the case in this instance, they will hasten to admit their mistake. They then go on to show that they worked for seven months with a pure culture of Sanarelli's organism, obtained from the Pasteur Institute, before a culture of the hog-cholera was brought into their laboratory and that during this time, before there was any possible chance for any mixture to occur, they had frequently obtained focal necroses in the livers of guinea-pigs injected with Sanarelli's bacillus—focal necroses which Sanarelli states are "entirely specific for hog-cholera." They also remark that Dr. Theobald Smith, whose extensive work on hog-cholera is authoritative the

world over, on being told of some of the early results, stated it as his opinion that the bacillus *icteroides* would yet be placed in the hog-cholera group.

Reed and Carroll then take up one by one Sanarelli's criticisms of their work and find good reasons and abundant opportunities to suggest to their critic that he should follow the same advice he so willingly gives others, "and spend a brief time consulting the literature" on various subjects. It appears that Sanarelli has fallen into the error, and this error is not new, of confounding the bacillus of swine-plague with the bacillus of hog-cholera—two quite distinct organisms; furthermore, that Sanarelli lays bare an apparently astonishing ignorance of the wide-spread occurrence of focal necroses in many infections and intoxications, including their development in animals injected with the bacillus *icteroides*, which is also described by De Lacerda and Ramos and by Della Rovera, who thus contradict Sanarelli's statement that focal necroses never occur in the livers of animals so treated. Reed and Carroll consider extensively the question of fatty degeneration in the livers of dogs injected with bacillus *icteroides*, and show quite conclusively that the amount of fat produced is variable, depending on variations in the resistance of the animals rather than on the microbe used, the livers of some of the dogs injected with bacillus of hog cholera being markedly degenerated. They emphasize again the remarkable agglutinative power which yellow-fever serum exerts toward the hog-cholera bacillus and the remarkable similarity in the clinical symptoms and anatomic picture produced in dogs by bacillus *icteroides* and bacillus of hog cholera.

On the whole, Reed and Carroll have strengthened their position in holding the opinion that bacillus *icteroides* is a variety of the hog-cholera bacillus. Sanarelli's refuge to the supposed victimization of Reed and Carroll by some "gross and deplorable error" seemed from the first a decidedly weak point in his part of the controversy because the methods followed in the laboratories of the Army Medical Museum are above all suspicion. His aspersions on the scientific spirit of the workers in the laboratory are certainly nothing more nor less than contemptible.

ZOÖPHILISM AND DEGENERACY.

Undue love for animals (zoöphilism) such as so frequently finds expression in antivivisection fanaticism, has frequently been found associated with various forms of degeneracy and especially with its mental expressions in connection with suspicious and persecutory conceptions.

As the JOURNAL pointed out some time ago, the suspicious world-betterers whose cruelty marred the French Revolution were all of them zoöphilists whose love for animals contrasted markedly with their severities toward human beings. The fanatics who were guilty of such brutalities during the East Indian mutiny were intensely opposed to the taking of animal life. Very frequently

the suspicious ideas are especially extended toward blood relatives. The mother of Savage, the poet, who persecuted him with such malignity, was very fond of cats and lap-dogs. The fifth (or "wicked") Lord Byron, the immediate predecessor of the poet, was notorious for his dueling propensities, for his disregard of major and minor morality, for his cruelty toward his kin, and for his brutality toward his servants. Having built mock forts on a lake in his park, and put a fleet of toy gunboats on the water, he used to amuse himself with mock-fights of a naval character, the toy ship firing away at the forts, which returned the fire in gallant style. When he was weary of this ridiculous game, the old man used to lie on the ground and gossip with the crickets, whom he loved far more than his descendants. When the crickets were troublesome, he used to whip them with a wisp of hay. The crickets are said to have left the Abbey in a body as soon as their one friend of humankind was dead, and never to have returned thither. The same feature appears in the wife and daughters of Claude Bernard, the French physiologist. According to the recent life of Claude Bernard, by Sir Michael Foster, the physiologist married a woman of degenerate stock, descendant from the French aristocracy of the pre-Revolutionary epoch. This woman had suspicious and persecutory ideas of that systematized type which so often occurs in degenerates prior to the full development of paranoia. After making Bernard's life miserable, his wife took her daughters and left him, alleging as a reason his experiments in vivisection. One of the daughters carried her antivivisectionism so far as to interrupt physiologic lectures, and was arrested therefor more than once, but the offense was condoned because of the manifest mental disorder present in her. There was evidence to show that her zoöphilism took at times a sexually abnormal direction. In a will, which was subsequently modified by the court as in violation of the French laws governing wills, she left large sums for a hospital and asylum for dogs and cats.

Commenting on her procedures, the *Chicago Chronicle* remarks that on the theory of heredity, this daughter's performance reflects more suspicion on the father's sanity than anything he ever did himself. The usual but erroneous inference is drawn of the exclusive importance of the father in heredity while that of the mother is here entirely ignored. The *Chronicle* comments severely but logically anent the antivivisectionists. The curious thing about these pranks is that motive never seems to have any weight with them; it would not surprise one if they some day object to the study and destruction of bacteria as cruelty to animals. This erroneous view of bacteria—whose zoölogic position is not settled, whence the name "microbe"—has already been taken by zoöphilists in New York, Boston, Philadelphia and Chicago, who have denounced the experiments in this direction for the reason stated by the *Chronicle*.

In New York a curious inconsistency has occurred. Some years ago experiments in vivisection made by Spitzka, for the purpose of demonstrating the nosologic limitations of hydrophobia, were approved by the New York Society for the Prevention of Cruelty to Animals, on the ground that they tended to prevent cruelty to dogs wrongly suspected of having hydrophobia. Some thirteen years later the Society, having obtained the spinal cord of a dog which had bitten several people, refused to allow this cord to be used in Pasteur experiments for the purpose of allaying the fears of the persons bitten. Experiments in vivisection for the benefit of animals were praiseworthy, but the same experiments for the benefit of human beings were atrocious brutalities.

RENAL INSUFFICIENCY.

Recognition of the condition in which diseased kidneys are no longer capable of performing their function is a matter of great importance and interest for both physician and surgeon. For this purpose purely clinical evidence is insufficient; nor is it possible to reach a trustworthy conclusion from examination of the urine, or from a study of the bodily metabolism or of the constitution of the blood, while the determination of the latter would, besides, be attended with considerable difficulty. A more practicable and a more satisfactory method of gaining the desired information consists in a determination of the molecular concentration of the blood by ascertaining its freezing-point.

It has been found that the molecular concentration of human blood, as well as the blood of various animal species, is, as represented by the freezing-point, fairly constant under physiologic conditions, being between 0.56 and 0.58 C. lower than that of distilled water. This constancy is to be attributed largely to the activity of the kidneys, as the most important of the eliminative organs. In the event, however, of failure or insufficiency in the function of the kidneys the molecular concentration of the blood is increased and the freezing-point falls. The accuracy of this observation has been established both experimentally and clinically, and additional experimental evidence is furnished by Richter and Roth¹, who, as a result of their investigations, have arrived at the following conclusions: 1. The normal reduction of the freezing-point of rabbits' blood, as compared with distilled water, is a constant physiologic standard—0.56 C.—from which there may be slight variations—0.54 to 0.59 C. 2. When the activity of the kidneys is abolished by bilateral nephrectomy, and the products of nitrogenous metabolism are not eliminated, the molecular concentration of the blood is increased, in consequence of molecular retention, and the freezing-point of the blood falls. 3. Unilateral nephrectomy does not cause molecular retention in the blood, because the remaining (healthy) kidney assumes the functions of both organs. Molecular retention takes place, how-

¹ Berliner Klin. Woch., July 24, 31, 1899.

ever, if the remaining kidney is injured. 4. Nephritis due to poisons, bilateral and hematogenous origin, are characterized by molecular retention and consequently by more or less marked pathologic reduction in the freezing-point. The disturbance is greater and sets in earlier when the vascular apparatus of the kidney is principally affected or the nephritis is diffuse than when the tubular apparatus is in greater degree affected, but in all instances the reduction is proportionate to the intensity of the pathogenic factor and the degree of anatomic alteration. Mechanical obstruction of the urinary tubules by means of artificial infarcts also results in molecular retention and in corresponding reduction in the freezing-point of the blood. 5. Pathologic reduction in the freezing-point of the blood is induced by the retention of the products of nitrogenous metabolism, but not by that of sodium chlorid; the latter may even exhibit attenuation.

The existence of anemia or of anasarca may prevent the usual reduction in the freezing-point in the presence of molecular retention, and the phenomenon is not of so much importance in the diagnosis of renal disease as it is in formulating decisions as to the performance of nephrectomy in suitable cases.

"CHEAP JOHN" MEDICINE.

The medical profession has not been troubled in this country as much as in Great Britain, by competition of low-priced club practice, but we now and then see signs of its existence. In our large cities we have the possibly greater evil of dispensary abuses, and everywhere exists the cheap and nasty in quackery of every variety. To some form of this, we assume, refers the following quotation from a lay paper that has recently come to our notice: "It might have been supposed that the climax of low-priced medical treatment had been reached when patients could receive medical advice, with medicine, at the rate of \$5.00 a month, and later as low as \$1.00 a month, but it seems the bottom has not been touched. A medical institution advertises in the local papers to give the best physician's advice, consultation and examination and furnish medicines all for 50 cents." The lay journal goes on to say that the next step will probably be for newspapers and magazines to furnish subscribers with medical advice and medicine gratis, and then perhaps some one will go one better and throw in life insurance. It may be some little consolation to feel that this sort of fraud in time makes work for the true physician, but it is a melancholy one at best to the philanthropist. There is a great waste of pain and suffering generally in this world through the "cheap John" doctors.

PAINLESS CAPITAL PUNISHMENT.

A new proposal has been offered to lessen the sufferings of the unfortunate murderer who has to undergo the pangs of capital punishment. Instead of hanging, which has already been held as barbarous and has been abolished in New York, or electrocution, which it is claimed is not the same in its action on all persons and

therefore may even sometimes cause pain, it is now proposed, in a paper read before the American Association for the Advancement of Science, to carry out capital punishment by poisoning with hydrocyanic acid and under conditions that will make it entirely painless and unexpected. The convicted criminal is to be taken to the death-chamber, which is to be connected by pipes with retorts generating the vapor, and some night when he is peacefully sleeping, it is to be suddenly turned on and he will peacefully pass out of this mortal existence. The date is not to be fixed, but is to be at the discretion of the authorities, within certain limits, covering several months, so that it is presumed he will be spared the mental agony of expectation to a large extent. The proposition might go still further and leave him in ignorance of his conviction, but that does not seem to have been suggested. After all, it may be considered questionable whether any of the plans offered has any great advantage. Sudden death of any kind is likely to be comparatively painless, and the elimination of the element of expectancy is a rather dubious advantage. If capital punishment is deemed necessary, it is to some extent as an example and deterrent, as well as to eliminate harmful individuals, and it is doubtful whether it should be made attractive. The old public executions made popular heroes, the newer suprahuman methods may err also in another way.

IS CHILD HOMICIDE LEGALIZED?
