64. **Widal's Test Results.**—Gehrmann gives the experience of the Chicago Health Department with Widal's test in typhoid fever. In all there were 715 cases observed, 570 clinical reports returned and 353 reports of the occurrence of typhoid reaction sent in. In 232 of these clinical ones, diagnosis of typhoid had been made. These tests were made with the dry blood specimens, which were the most practicable under the circumstances. Gehrmann is inclined to believe that this method is of considerable value in diagnosis and warrants a continuance, by the Department, of the practice of receiving and testing dry blood specimens sent in by practitioners. The small percentage of failures is, however, sufficient to render necessary attention to the following conditions: Close observation of the directions sent out by the Department; several examinations in cases where one or two do not seem sufficient, and the exclusion of normal and pseudo reactions in the laboratory by testing further dilutions of the blood solutions.

68. **Medical Legislation.**—Krauss' address reviews the medical laws of the country and urges further advance in this direction.

69. **Mountain Fever in East Tennessee.**—Chance describes a form of fever which he has met with, for the past eight years, in the mountain regions of East Tennessee. It seems to be a form of typhoid with, perhaps, some special features. His treatment, deduced from experience, consists largely in the use of intestinal antiseptics. To any one who claims that the sulphocarbolates are useless, he would reply that he does not use them in cases such as his or did not use them properly. Antiseptic treatment includes disinfection of the patient, bed, house, water-supply and excreta.

73. **Examination of the Stomach.**—In this article, the fourth in the series, Graham notices the various physical signs connected with the condition of the stomach, including the general aspect of the patient, the condition of the skin, tongue, teeth, pharynx, neck and abdomen, more especially the latter, by palpation, percussion and direct gastroscopy.

78.—See abstract of this paper, originally printed elsewhere, in JOURNAL, May 27, par. 22, p. 1164.

81. **Summer Complaints in Children.**—Considering these disorders as actual infections, Allen advises thorough disinfection as an important part of the treatment. The stomach should be emptied, but Nature generally does this. It should be a routine practice in the beginning to give frequent, small doses of calomel. Opiates should be given very cautiously, if at all. Subnitrate of bismuth in large doses is always in order. Salol is often of great benefit, but should be watched and the urine frequently examined. He likes the combination of salicylic acid and bismuth very much, and has at times had good results from very minute doses (1-4800 gr.) of arsenite of copper. Betanaphthol and resorcin are also worthy of consideration. Liquid taka-diastase is recommended when foods disagree. Coal-tar antipyratics should not be used; cold applied over the stomach and head is better and not so depressing. An

occasional dose of castor-oil, to thoroughly cleanse out the alimentary canal, is advised. Stimulants should be kept up regularly, and when the fever has subsided and temperature is not above 100 degrees drug treatment should be stopped, and diet and colon irrigation alone depended on.

89. **Lessons in Neurology.**—Moyer here considers typhoid neuritis, goiter, with development of constitutional symptoms, and ataxia paraplegia.

93. **Hallucinations of the Dying.**—Chenoweth discusses the phenomena of death, more especially the hallucinations which he naturally credits to pathologic causes, toxic or other abnormal conditions of the blood, etc.

94. **Diabetes Mellitus.**—Keener lays down the dietetic management of diabetes and its drug treatment. As regards the latter, he finds no remedies better than arsenic and opium. Arsenic gives in the form of a solution of the chlorid, continuing it throughout the entire treatment. Opium he gives in the form of codcin in doses of from .5 to 4 grains, usually in one dose at bedtime, but occasionally more frequently, when indicated. He claims that with proper attention to the dietetic rules, and with the medical treatment he describes here, a great proportion of cases will recover. In his own experience he has had, he says, 75 per cent. of absolute recoveries.

97. **Aortitis.**—Hoover's article is a general description of the diagnostic points of aortitis, illustrated by four cases. The intolerance of the common cardiac remedies in this disorder is noted. Iodid of potash, in small doses, and nitroglycerin are the only drugs that are well tolerated in his experience. Digitalis, strophanthus and strychnia seem to be positively harmful.

98. **Digitalis and the Heart.**—Waters' article calls attention to the value of digitalis, and he thinks that its sphere of usefulness is much wider than has been commonly supposed in heart disease. It is certainly not limited by its value in organic diseases alone. As regards its supposed dangers, he considers them practically insignificant when the drug is intelligently prescribed.

100. **Recognition of Blood Changes.**—Shoemaker's address has for its principal themes the auto-intoxication or toxic products in the blood, and the necessity of attention to this subject by physicians.

101. This paper was published in full, in the JOURNAL, April 29.

102. **Nature of Xanthomata.**—In this article, which is well illustrated by microphotographs, Pollitzer discusses the nature of xanthomata, first pointing out the difference between that form occurring on the eyelids and the common multiple xanthoma. The former is a very common disease and is apparently incurable. The latter is exceedingly rare and is always of limited duration. He thinks it well within the limits to estimate the proportion of the eyelid to generalized xanthomata as 100 to 1, and he rarely finds the two conditions associated. He, therefore, is inclined to believe them wholly distinct diseases. His conclusions are as follows: 1. Xanthoma palpebrarum vulgare is not a neoplasm; it is the product of the degeneration of embryonically misplaced muscle fibers. 2. It bears no histologic relationship whatever to xanthoma tuberosum disseminatum. 3. The common xanthoma tuberosum and xanthoma diabeticoorum are similar processes. 4. They are both connective-tissue neoplasms in which the relative proportion of fibrous tissue and connective-tissue cells varies in different cases. In both the cells undergo a fatty degeneration, resulting in the destruction of the cells and ultimately in the more or less complete disappearance of the nodule. The process is more diffuse and the degeneration more rapid in the diabetic form. 5. Generalized xanthoma is an irritative process whose cause must be sought in some systemic disturbance.

103. **Ophthalmology and General Medicine.**—The relation of ophthalmology to general medicine is discussed at length by Lewis. It would be impossible to abstract a paper made up of details as is this one, but it may be said that he attributes the prevalence of nervous diseases largely to eye strain due to civilization.

104. **Chronic Malarial Infection.**—Noting the recent discoveries in regard to malaria, and the change of views thereby necessitated, Thomson calls attention to the parasite in the blood in the production of chronic malarial infection, and re-

masks in regard to the treatment. He thinks that latent malarial infection is of more importance than seems to be generally realized, and the necessity of proper treatment is thereby emphasized. He notices that fact of individual idiosyncrasy and gives a sketch of the treatment he recommends: 1. Mercurial laxative given toward the close of febrile paroxysms and made to act within six hours. The advantage of this is that it prevents intestinal self-infection and favors the absorption of quinin, which is an unstable alkaloid in the alimentary canal. The quinin itself should be given as nearly as possible at the time of sporelation of the parasite, i. e., shortly before time for the chill, and he prefers to give the doses in three equal parts, an hour apart, the last from one to two hours before the expected paroxysm. It has been a matter of common experience in the tropics that the action of quinin is favored by addition of spices. The success of Warburg's tincture possibly depends on this fact. He therefore gives powdered ginger and quinin in equal quantities. Pulverized capsicum is sometimes given, 1 grain to 4 of quinin. In some cases, when quinin seemed to fail, he has given paregoric as an adjunct, with good results. This was given in three daily doses of $\frac{1}{2}$ ounce each with doses of 15 grains each of quinin and ginger twice daily. The results of this treatment were strikingly good and one of the most notable was the antilethargic action of the paregoric in this case. Instead of being stupifying it was stimulating.

105. **Phthisis.**—Barney treats phthisis with special attention to the nutrition, caution as to infection, plentiful supply of fresh air in bed rooms, good climatic surroundings, cold sponge baths in the morning, and a climate that allows plenty of open air exercise. He thinks isolation useless and damaging. Hemoptysis is treated by making the patient comfortable, administering morphin and atropin hypodermically and local application of ice. Guaiacol is the most efficient medical agent we possess; give in small doses gradually increased. In cases where there is high fever he uses phenobromate in 5-grain doses, and thinks it a superior antipyretic and analgesic to the other coal-tar preparations commonly used.

106. **The Term Appendicitis.**—Ellis' paper is a defense of the use of the term appendicitis as being convenient, and its change to other words on account of the necessity of Greek purism not needed.

107. **Disinfection for Tuberculosis.**—This article is a plea for the municipal control of the disinfection of departments occupied by tuberculous patients. Sanitation and disinfection left to landlords and boarding-house keepers is apt to be very inefficient, and the only remedy will be to have it thoroughly under the control of an efficient local board of health.

108. **Advice to Gonorrhoeal Patients.**—In treating either the acute or the more chronic forms of the infection, Valentine suggests that the patient be instructed to refrain, as many hours as possible from urinating just before visiting his physician, to enable the medical adviser to better judge the character and quantity of the discharge, and obtain specimens for examination under the microscope, also to obtain the first urine passed for shreds, flakes, granules, etc., findings that are most important to correctly judge of the concealed conditions present. The diet is to be limited only to the exclusion of indigestible foods. All alcohols are denied, excepting in such cases as present especially low states, when the use of a light claret may be allowed. Carbonated waters are forbidden, but tea and coffee are allowed. Copious draughts of water are to be insisted on. Exercise is always to be taken in moderation, but this moderate exercise is to be insisted on, thus preserving the general health. In treating male cases, a suspensory is always to be advised and the patient fully informed regarding general hygiene, the danger of auto-infection, as well as instructed on the danger of sexual excitement, and the prohibition of intercourse.

109. See abstract in JOURNAL, April 29, p. 941.

112. *Ibid.*, June 17, par. 53, p. 1381.

113. **Lipoma.**—Horsley reports the removal of a diffuse lipoma situated on the anterior and lateral aspects of the neck; the growth had been gradually increasing for twenty years and had attained such proportions that respiration was retarded. The tumor was exposed by the Kocher incision, consisting of a transverse incision commencing under one ear and

extending obliquely over the tumor, terminating under the opposite ear; this was joined at the median line by a vertical incision extending downward. Under careful dissection the tumor was completely removed and all symptoms relieved; the paper is illustrated by four plates.

114. **Lectures on Orthopedic Surgery.**—Ridlon and Jones consider the symptoms and diagnosis of hip-joint disease. Methods of examination are graphically represented by numerous plates. The paper is a continuation of articles previously published.

115. **Pathology of Catarrhal Deafness.**—A large proportion of the cases of chronic catarrhal deafness, Hinkel concludes, have their origin in the hypertrophic forms of middle ear disease; the prognosis he considers often favorable; with prompt and careful treatment the condition is frequently helped, and at times cured. The prophylactic treatment in early life is to aim at the removal of adenoid, tonsillar and nasal obstructions.

116. **Involvement of Eye and Ear in Cerebrospinal Meningitis.**—Reference is made to the epidemic form of meningitis. Edema of the lids and conjunctiva may occur either early or late in the course of the disease, and may occur by simultaneous invasion of the orbital tissues and meninges, or by extension through the superior orbital fissure. Involvement of the motor nerves is more common; this involvement may be due to irritation or may be truly paralytic. Conjugate deviation is sometimes present. Nystagmus is rare, photophobia common, especially so when general hyperesthesia is present, xerosis of the cornea, corneal ulcers, herpes, as well as infiltrations following exposure of the cornea. The iris is usually dilated, partially due to increased pressure. Iritis, simple or accompanied by involvement of the ciliary body and choroid, is sometimes found. The choroidal inflammation is frequently of a seroplastic nature, eventually becoming purulent. Involvement of the choroid may be due to metastasis. The optic nerve may be attacked by direct infection, extension, or metastasis, an optic neuritis being found in the majority of cases, and to this complication the loss of sight in a large proportion of these cases is due. Deafness resulting from epidemic cerebrospinal meningitis does not increase after the subsidence of the disease; the hearing is often eventually improved, if the labyrinth alone is involved.

117. **Treatment of Malaria.**—Center treats of malaria, considering it a generic term, including several distinctly separate manifestations of the disease, caused by distinct and different parasites. These organisms—the plasmodium malariae—differ in age, habits, and in morphologic characteristics, each variety with an individuality of its own. He calls attention to the necessity of selecting such remedies in treating the various forms of the disease as are found to inhabit or destroy that variety of organism responsible for the condition under treatment. The cases of estivo-autumnal fever are to be treated not alone by quinin but quinin combined with arsenic. During convalescence the use of chlorid of iron is advised.

118. **Typhoid Cases at U. S. General Hospital.**—A review is made of the treatment of 412 cases of typhoid treated at the U. S. General Hospital at Fort Monroe, Va., during the summer of 1898. The treatment these patients received did not differ materially from the ordinary hospital treatments, excepting that no baths were given, even in the cases running a high temperature. Stimulation was given in the form of strychnin in every case; whisky and some other forms of stimulants only in special cases. The mortality was 7.5 per cent. Anderson claims priority in the treatment of collapse following hemorrhage of typhoid, by transfusion. He used the normal salt solution in one case, introducing as much as three pints into the median basilic vein, with good results.

119. **Fatal Case of Scurvy.**—The case, reported by Bassler, is of interest in that it occurred in an infant 1 year of age, and that the report of autopsy is appended. The child was nourished artificially after the second month; the diet, changed from time to time, included barley water, oatmeal water, and modified cow's milk; all foods were boiled. In the fifth month the first symptoms appeared: intermittent bleeding from the mucous membrane of the vagina; the first incisors were cut in the tenth month. Anemia was well marked early; legs be-

came flexed and powerless; pressure over the lower end of the femur and upper end of the tibia caused pain; the gums were characteristic; teeth loose; hemorrhage from the gingival junction. Autopsy showed scarcity of fat tissue all over the body, heart slightly enlarged, mitral valves partially destroyed; the heart muscles showed fatty changes. The lungs showed a condition of chronic bronchopneumonia in the lower lobes. The kidneys and liver were slightly enlarged and presented fatty changes. Examining the long bones, the periosteum was found raised from femur, fluctuation distinct, and, when incised, a thick grumous blood was forced out with a jet, having apparently been retained under pressure. The changes observed in the tibia were thickening and congestion of the periosteum near the upper extremity of the bone.

121. See JOURNAL, July 8, par. 122, p. 93; July 15, par. 115, p. 157.

122. **Blood Examinations.**—Hewes' paper is a continued one and will be noted more fully when completed.

123. **X-Ray Examinations in Children.**—Williams emphasizes the usefulness of the X-ray examinations in children. They are more easily penetrated by the rays and caution should be taken to avoid too much light on this account. In some cases of pneumonia, especially in the early stages, the X-ray may be of decided value in the diagnosis, also in cases where the symptoms suggest tubercular meningitis, and in pleurisy with effusion or empyema. The size and position of the liver and spleen are more readily determined than with adults, as is also the case with the kidneys, especially the left one. By giving subnitrate of bismuth with bread and milk, changes in the size and shape of the stomach after a meal may be followed. Investigations on these points have been made in conjunction with Mr. V. B. Cannon, which are yet to be published. There need be no fear of untoward effects if proper precautions are used. Williams has had none in about 3000 examinations.

124. **Summer Diarrhea in Infants.**—The essentials in the treatment of this disorder, according to Chapin, are: prevention, which is brought about by the proper regulation of the milk supply, the providing of small parks or airing places for children in large cities, extra cleanliness in the home, frequent bathing. He would allow the child to play in a tub of tepid water for hours at a time, and in general a bottle-fed baby should have less bulk of food and a higher dilution of milk in very hot weather than it is accustomed to under more favorable conditions. He prefers boiling or pasteurization to sterilization of milk. The first signs of any gastric or intestinal indigestion should be looked for and checked before any marked diarrhea appears. In the dietetic treatment, as most cases are due to milk poisoning, all forms of milk must be temporarily withheld and many a summer diarrhea might be aborted if this were done for from twelve to forty-eight hours. If this has to be kept up long, one of the best substitutes is egg water, made by stirring the white of an egg in half a glass of cold water, and he adds to this, to overcome its tastelessness, about ten drops of aromatic spirits of ammonia, which also seems to check the stomach irritation. Other substitutes are thin gruels from barley or wheat flour and cold whey. If milk has to be kept away for several days, nutton broth with all the fat carefully skimmed off is also a good substitute. When the acute symptoms have subsided and milk is resumed, it must be given cautiously and at long intervals and highly diluted. A barley water or thin gruel are the best diluents. Medical treatment is often of less importance than dietetic, but in vomiting drafts of tepid water should be given, which, when rejected, washes out the stomach. It is rarely necessary to use the tube for this purpose. He usually gives 1-10 of a grain of calomel every hour for six or eight doses, which usually clears the canal. Enemas of normal salt solution may also hasten this. The drug he most relies on is bismuth subnitrate, but he also uses small doses of aromatic spirits of ammonia, 10 to 20 drops, which seems to stimulate the infant. Alcohol is given very sparingly, and only when free stimulation is required. Opium is contraindicated until the bowels have been thoroughly emptied and when cerebral symptoms threaten. In cases, however, in which rapid peristalsis and profuse glandular secretion persists, a few moderate doses of opium may be of great service and even save life.

125. **High Altitudes in Heart Disease.**—Babecek reports

nine cases illustrating the effect of high altitudes on the heart and circulation. The paper ends with the following conclusions:

1. All forms of cardiac disease do not contraindicate sojourn at a high altitude.

2. The ill effects of low atmospheric pressure in some forms of cardiac disease are explicable on the hypothesis of acceleration of venous flow and corresponding quickening of the heart beats.

3. Consequently those forms with which high altitude is likely to prove incompatible are pronounced aortic or mitral stenosis, and regurgitant disease complicated by pleural and pericardial adhesions.

4. On the other hand, patients with uncomplicated regurgitant lesions or arteriosclerosis with or without myocardial changes, may endure low atmospheric pressure without injury.

128. **Diseases of Sinuses.**—The parts, the diseases of which are here described, are the frontal sinus, the antrum or middle meatus, the ethmoid and sphenoid cavities. The disorders of the frontal sinus are empyema and tumors, the former of which requires early opening and injection of bactericidal solutions with free drainage and checking the suppurative process. Tumors of the frontal sinus are usually osteomata, and their treatment is solely by operative removal. Empyema of the antrum is usually the result of dental or alveolar disease, though it may be the result of inflammation in any of the adjoining parts. Its extension to the orbit is usually the result of an osteoperiostitis of the orbit floor which is very thin and often shows openings through which infection may occur. The diagnosis is here discussed and methods of elimination of the antrum described. The only curative treatment is to open the antrum and evacuate its contents and employ frequent antiseptic irrigation, and when suppuration has been completely abolished, endeavor to close the artificial opening. Tumors of the antrum, which are difficult to diagnose until they have produced pressure symptoms, are to be treated by complete removal involving a resection of the bony parts that may be diseased. The nasal meatus is most commonly affected by a purulent rhinitis, usually secondary or associated with purulent processes in the ethmoid cells or antrum, and the treatment must be directed in this case to those cavities. If advanced to the meatus, prompt curetting and removal of the diseased bones is the treatment recommended. Its tumors should be extirpated early in their development, but if a malignant tumor has already invaded the deep bones of the face and base of the skull including their cavities, the case is hopeless and interference would probably hasten the fatal termination. Ethmoid disease is perplexing in its symptoms and difficult of diagnosis. Its etiology is apt to be obscure. The treatment in all cases of empyema is free opening, curetting, irrigation and drainage. Tumors of the ethmoid are usually of a sarcomatous or myxosarcomatous variety, though other forms are met with, such as enchondroma, fibroma, osteoma, etc. The only treatment is removal. The sphenoid antrum is subject to the same diseases and the symptoms are much the same as those of the adjoining cavities. In empyema the headache is located at the back of the head and the involvement of the different nerves is to be noted. Tumors here may have no subjective symptoms or there may be severe occipital pain. If the process extends there may be blindness due to compression of the optic nerve, and if the growth extends into the cranial cavity and is rapid, meningitis or cerebral abscess will result. Sarcoma is the most frequent malignant growth. In ending his paper, Bull repeats the following conclusions published some years ago and states that his experience has led him to still further emphasize their importance: 1. The prognosis of all forms of malignant orbital tumors is unfavorable; and if the tumor is primarily one of the deep facial bones or their sinuses, the prognosis is positively bad. 2. With the single exception of encapsulated tumors of the orbit, surgical interference is almost invariably followed by a return of the tumor, and the growth of the secondary tumor is more rapid than that of the primary lesion. With each succeeding operation the period of quiescence in the return of the tumor grows shorter and the rapidity of growth increases. 3. The patient's family, and in certain cases the patient himself, should in the beginning be told of the serious nature of the trouble and be warned that complete removal of all diseased parts is a hopeless task. The burden of the de-

cision as to surgical interference must rest on the shoulders of the patient. 4. Repeated operations in these cases undoubtedly shorten the life of the patient. While it is our duty, therefore, to operate in all cases in order to relieve severe or unbearable pain, we should be slow to operate merely for the sake of temporarily relieving physical disfigurement or deformity, especially if we are convinced that by so doing we shorten the life of the patient, even if that shortened life is rendered more bearable.

130. Methods in European Hospitals.—Miller describes his observations of methods of asepsis and antisepsis, etc., of the various operators in European hospitals, including those of Hamburg, Berlin, Leipzig, Dresden, Vienna, Budapest, Prague, Paris, Brussels and London. He remarks a striking contrast in the temperature of the operating-rooms in Germany and France and England. [Some of his brief descriptions are hardly complimentary to the latter in some respects. Results, however, seem to be less different than one would expect, were all the precautions of the Continental surgeons necessary.—Ed.]

131. Cardiac Murmurs.—Coleman publishes an ingenious diagram, including not only the events of the full cardiac cycle but also their association with murmurs. It consists of a series of concentric circles representing, in order from within outward, the chambers of the heart, sounds and time, valves and murmurs. The diagram has been constructed, as he says, chiefly with regard to simplicity, that it may be used for clinical and didactic purposes generally.

132. The "Kissing Bug."—Burrall reports a case of a middle-aged man who called for treatment of an eruption on his left forearm, consisting of long vesicles with swelling of the wrist and back of the hand, causing pain on movement and a diffuse, red, erysipelatoid discoloration from the wound to the bend of the elbow, covering nearly half the circumference of the forearm. There was little constitutional disturbance or complaint of pain. The eruption was supposed to be the result of a bite of a "kissing bug," and was rapidly relieved by painting the inflamed area with tincture of iodine and internal administration of calcium sulphid. Carbolic acid ointment was also used on the parts. [This is the first medical report we have noticed of the bite of the so-called "kissing bug."—Ed.]

British Medical Journal, July 1.

Possibility of Extirpating Malaria From Certain Localities by a New Method. RONALD ROSS.—First remarking that experience has taught us, in various countries, that malaria can be banished by drainage and cultivation, Ross says that there are still some regions in which, in spite of both of these factors, malaria is still prevalent in its most virulent form, and he asks whether science cannot give us some more accurate means of detecting the precise cause of malaria in such regions, and after discovery, of removing it. We now know how and where the parasites live in external nature, and how they enter the system. We know that it is through mosquitoes that they enter the blood, an idea which has been extant for many years, but which has only lately received scientific confirmation. In 1894 Dr. Patrick Manson, noticing certain peculiarities of the parasite, suggested that it required a suctorial insect for its further development. In 1895, Ross began his experiments, and in 1897 he succeeded in cultivating the parasite of malaria in two species of mosquitoes, while in 1898 he completely worked out the life cycle of this organism. The observations have been carried out by numerous investigators and valuable details added, so that at the present time we have the knowledge that is first required of the natural history of the infection. It is sometimes said that malaria exists where there are no mosquitoes, but no case of the sort has yet been proven. The fact that we require these mosquitoes only for the first infection, must be remembered; persons once infected may carry the disease elsewhere to develop it. Many of those who accept the mosquito theory have emphasized the value of individual precautions, nettings, fans, etc., and while something can be done in this line, these do not touch the real points and more practical methods must be sought. Ross notes, from his own experience, that private houses may often be kept clear of mosquitoes by simply ban-

ishing stagnant water from the premises, and fortunately we do not have to fight all species of mosquitoes in our battle with malaria. The ordinary *Culex* is inoffensive in this respect, and it being the common insect about towns, breeding in tubs and pots, explains why malaria is often less malignant there than in the country. Mosquitoes of other kinds, however, *Anopheles*, which he calls rural mosquitoes, are found in the country and breed only in stagnant pools. These are the propagators of malaria, the hosts of the malarial parasite. The conditions they require are stagnant pools that do not dry up completely in the summer, are not subject to be washed out by rains, and yet are too small to contain fish, which would eat up the larvæ. Such conditions only exist to the full extent in country districts, and the following statements, having a practical bearing, may be made: We can detect the dangerous species of mosquitoes in a given locality by a perfectly certain method, namely, by ascertaining according to Hanson's induction whether the parasites of malaria will live in them or not. We can detect their breeding grounds by searching for their larvæ. In order to obliterate pools which breed dangerous mosquitoes, they must be filled up or drained. The question as to whether it is possible to eradicate malaria in any district depends on whether these varieties are sufficiently isolated and rare to be dealt with by public methods of repression. It is impossible to give a full answer to this question. We do not yet know all the dangerous species or their habits, but Ross is inclined to answer it in the affirmative.

Some Points Connected With Sleep, Sleeplessness and Hypnotics. JOHN BUCKLEY BRADBURY.—The second lecture on hypnotics deals largely with the chemical action of hypnotics of the fatty type, including the alcohols, the chlorin compounds, etc. It is impossible to abstract it in detail.

Sequel to Case of Acute Tetanus Treated by Intracerebral Injections of Antitoxin. WILLIAM F. GIBBS.—This communication is a sequel to one published in the *British Medical Journal* of April 15, where apparently successful results were obtained by intracerebral injection of antitoxin in a case of acute tetanus. Unfortunately, after the disappearance of all tetanic symptoms, the patient again became suddenly ill and died on May 5, eight weeks after the last injection, showing decided meningitis and abscess of the brain. Bacteriologic examination showed the presence of cocci in considerable numbers, having all the appearance of the staphylococcus pyogenes aureus. As everything that could be done to insure asepsis in the injection was employed, he doubts infection through the serum, but thinks that damage to the brain, from the injury, would predispose to subsequent infection.

Lancet, July 1.

Importance of Plastic Surgery in Renal Distension (i. e., Nephritis). HENRY MORRIS.—This article is a general discussion of the operative treatment of ureteral stenosis, profusely illustrated and with tabulated cases, including five personal ones of the author's.

Operative Treatment of Eyes Exhibiting High Degrees of Myopia. RICHARDSON CROSS.—Noting that slight degrees of myopia are of little annoyance, while a moderate amount is a disadvantage, and that in the higher degree we have a serious defect of vision, and not infrequently a damaged eyeball, the author shows how oculists are justified in recommending somewhat heroic measures in order to remedy the condition. He gives a brief résumé of the operations that have been suggested, and especially notices the contribution by Fukala on this subject. It is now agreed that removal of the lens is the only operative procedure likely to be of service, and he remarks on the degree of advantage of this operation. Each case must be judged by itself, and in the linear extraction it is necessary to specially guard against prolapse of the vitreous and iris. He does not think that the danger of detachment of the retina is as great from this operation as has perhaps been supposed. He would be very cautious about operation on a person with only one eye. The need of the operation is greatest in those who have to depend on themselves for a livelihood; the condition unrelieved may mean loss of employment. It is difficult to estimate the amount of improvement in distant vision, but making allowance for the difficulty the patient finds in wearing the best corrective glasses, and his distinct preference for wearing none, the gain is probably greater than that expressed

in figures. As a rule we do not gain improvement in vision for reading, but certainly do in a few instances. He gives a tabulated statement of forty-eight cases in which he does not regret having performed the operation in one, though no unfavorable cases are excluded.

Some Surgical Sequelae of Influenza. WARRINGTON HAWARD.—The author here notices some of the notable sequelae of influenza, suppuration of the lymphatic glands, inflammation of the mucous membrane of the throat, and nasal, maxillary, and frontal sinuses, suppuration of the middle ear, synovitis, boils, neuralgias and residual abscesses. Tendency of influenza is also to provoke into activity quiescent tuberculous or other chronic forms of joint trouble, and one of its most remarkable effects, to which he wishes to call special attention, is the active recrudescence of latent syphilis to which it gives rise. He thinks, in this case, calomel vapor baths will be found the most efficacious treatment.

Three Cases of Chronic Mediastinitis. CECIL BOSANQUET.—The author first refers to the paper of Dr. Whipple (*Lancet*, April 1 and 8), showing how small a number of cases of this affection are recorded, and takes this as a reason for offering the history of three cases personally observed, all of them with autopsies. The patients were all boys, their ages 8, 15, and 6 years respectively. In none of them was the diagnosis made on first admission. The duration of the disease, after definite symptoms had appeared, was about two years in the first two cases, and in the last the signs attributable to the mediastinal disorder only appeared three months before death, though the total duration of the patient's illness was about two years. The most striking clinical feature is the great enlargement of the liver. In all it was found in a state of very chronic congestion that had passed beyond the nutmeg stage into one of general engorgement, pigmentation and fibrosis with some fatty change. In the first two cases the heart was small, the walls thin and fibrous. In the last it was not reported. Pleurisy with effusion occurred in all three. The kidneys were much congested and in the first two cases tough from increase of fibrous tissues. He refers to two other cases reported by Mott that were not included in Whipple's or Harris' lists.

Indian Medical Gazette (Calcutta), June.

Cause and Prevention of Heat Apoplexy in Army. C. J. MCCARTHE.—Noticing the frequency of heat stroke among soldiers in India, when civilians are exempt, McCarty calls attention to the difference of dress, even in the tropical uniform of the British army in India, and claims it is far from suitable to the climate. The costume he would advise would be a Norfolk jacket with four pockets, loose trousers with four pockets and loose twill cotton shirts with two pockets. The pockets are to avoid the necessity of belts. A light knapsack should be used for rations and the greater part of the ammunition. In going into action, the latter can be stored in the ten pockets, the water bottle can be hooked on the coat, the bayonet hung on the frog on the waist-band of the trousers or on the coat.

Inoculation of an Entire Community With Haffkine's Plague Vaccine. C. H. BENNETT and W. B. BANNERMAN.—The authors give a brief report of the inoculation of the entire community with Haffkine's plague serum and with the result of almost absolute protection. They conclude that this measure is a prophylactic capable of completely controlling an epidemic of plague.

Indian Medical Record (Calcutta), June 7.

Treatment of Tetanus by Intracerebral Injection of Antitoxin, With Particulars of Case Treated by This Method, Followed by Recovery. D. SEMPLE.—After noticing the general facts in regard to tetanus, Semple reports a case treated by intracerebral injection with apparent perfect success. The technic is given in detail.

Medical Press and Circular (London), June 28.

Eradication of Tuberculosis. GEORGE FLEMING.—This paper, concluded from a preceding number, is devoted to the subject of bovine tuberculosis and the method of its eradication. The author takes the usual rather radical view of the necessity of extirpating the animals with the disease.

New Method of Ventilating Sewers. CHARLES A. CAMERON.—The method of ventilating sewers here proposed is the use of porous cylinders set in the crown of the sewer and opening into a chamber like that used in the ordinary ventilators.

As the cylinders allow air to pass freely, but bar the passage of micro-organisms the air that comes out into the streets is consequently filtered.

General Disorder Originating in Disease of Female Pelvic Organs. MENDES DE LEON.—The theme of this address is the general disorders due to affections of the female genital organs in women, and covers nearly the whole range of the subject. As regards mental disorders from these causes, he is somewhat moderately conservative in his views.

Brazil-Medico (Rio), May 15 and June 8.

Arsenic Acid as a Preventive of Yellow Fever. I. DA ROCHA.—Dr. J. P. do Rego Cesar noticed that non-acclimated persons in Brazil, who had occasion to take arsenic for any reason, were not molested by yellow fever, and he commenced to administer it as a preventive, with most satisfactory results, confirmed by the experience of other local practitioners. Da Rocha reports, in this article, the results of daily prophylactic doses of half a milligram of arsenic acid administered during the summer season to the entire force of a certain factory, over 200 men, for the last five years. The men are frequently changing, are mostly unacclimated, live in unhygienic surroundings and infected localities, and take no precautions against contracting the disease. During the terrible epidemic of 1894, three of them were attacked but soon recovered; exceptionally light cases among the prevailing mortality. In the epidemic of 1896 twenty men contracted the fever a few days after their admission to the factory, each having received only a few doses of the arsenic. But the effects were evident in the benignity of the cases, all dismissed from the hospital in from four to six days, while a couple of extra hands only rarely employed and thus not receiving the arsenic regularly, succumbed to the disease. There have been no cases in the factory since 1896, although yellow fever has scourged the city again and again, and formerly ravaged the factory. Another group of 150 men, to whom the prophylactic doses were regularly administered, have also escaped without a single case. Persons just arriving are advised to repeat the dose three times a day the first week, twice a day the second, and thereafter once a day. No one thus treated has contracted the disease to date.

Bulletin de l'Academie de Medicine (Paris), June 13 and 20.

Arsenic and Respiratory Interchanges. A. ROBIN.—Tests with five tuberculous patients to whom sodium arseniate (.005 grams a day) was administered, or rectal injections of Fowler's solution (5 c. c. of an 8 per cent. solution), demonstrated that the effect was to materially diminish the respiratory interchanges, but when the dose was increased to .01 gram a day, the effect was exactly the reverse.

Differences in Tracings of Various Sphygmographs. H. HUCHARD.—"No two sphygmographs can be used interchangeably, as they produce entirely different results even on the same patient." Marey recommends taking the tracings as small as possible, enlarging them later if necessary, thus reducing the liability to error from the inertia of the lever. Huchard recalled that the last international congress of physiology appointed a committee to collect the testimony of the most competent men in each country to establish a uniform type for the construction of physiologic instruments, and report in August, 1900. Dr. Bowditch is the American member of this committee. "It is hoped that physicians will be guided in their choice of instruments, by the recommendations of the committee."

Advantages of Creosote in Tuberculosis. C. SAVOIRE.—The novel point in this communication is that very large doses are tolerated without the slightest inconveniences, for months at a time, if there are no pre-existing gastric troubles, and the therapeutic effect is correspondingly enhanced. As much as 6 to 10 and even 15 grams a day were administered for months.

Imperfect Vaccination. J. CARTERET.—Heifers, inoculated with serum from "doubtful" or "unsatisfactory" vaccination pustules, reacted, showing that these pustules are more "successful" than hitherto supposed, and a second heifer inoculated with serum from the first, developed typical pustules, as also persons inoculated with it. These same persons, afterward inoculated with ordinary lymph, proved to be completely immune. "The degree of the reaction evidently depends on the individual, and all pustules are specific, and are evidence that the subject is protected."

Journal de Médecine de Paris, June 25.

Tuberculosis. BOUCHER.—This iconoclast states that nothing but inconsistencies and nonsense resulted from the deliberations of the Tuberculosis Congress: Frankel, for instance, the rabid partisan of contagion by the bacillus, announced that these bacilli, outside of the human organism, cease to multiply and perish rapidly when exposed to light and desiccation. And yet, desiccated sputa are claimed to be extremely virulent! Loeffler announced the direct transmission of the tubercle bacillus from the mother to the fetus, but added that this did not occur unless the mother's genital organs had some tuberculous lesion. These are the bases on which rests the theory of heredity and contagion! This bacillus theory, he continues, was exploded long ago: Strauss, Dieulafoy and others have found the so-called tubercle bacillus in the organs of persons who never presented the slightest tuberculous taint during their entire existence. Middenkorp's observations, "kept rigorously secret," demonstrate that the Koch bacillus is not found even in the tubercles of any tuberculous affection of any organ whatever. In many cases of tuberculosis it is impossible to find a Koch bacillus and, in short, this bacillus has nothing to do with tuberculosis in the pathogenic sense, as Solles, Bang, Hersberger, Ernst and Durr have fully demonstrated, as also the personal research of the writer, "which has established that the famous bacilli are nothing in fact but fragments of mycelium derived from the air cells, proceeding from innumerable species of marine, fluvial and lacustrine algae, which we are continually absorbing, and which arriving from without, free from noxious properties, proliferate, become transformed in the infective media in which chance deposits them, and assume at the same time and most fatally, the properties of these media. This is the scientific truth, in harmony with logic, with all that experience has taught us, and with sound reasoning."

Berliner Klinische Wochenschrift, No. 21.

Blood Spitting in Tuberculosis. C. GERHARDT.—The rupture of some ramification of a pulmonary artery passing through a cavity is usually the cause of the blood spitting and also of infiltration of the lung tissue with blood, producing râles and dulness. In 879 cases observed blood was expectorated in 30 per cent., and over half a liter in 15 per cent. If the temperature afterward rises, this is a most unfavorable symptom but blood spitting in the early stages is usually a very favorable alarm signal. Gerhardt recommends salt to diminish the blood pressure by the nausea induced, and also the production of venous stasis in the extremities with a tourniquet. Codein, morphin, heroin, opium and large doses of ergot, also injections of atropin (0.3 mg.) and inhalations of diluted solution of chlorid of iron, also quinin were found effectual in various cases.

Deutsches Archiv f. Klinische Medicin, lxi. Festschrift.

Hysterical Fever. DIPPE.—A patient with pronounced hysterical attacks and pain in the abdomen, accompanied by high intermittent fever, was operated on but the abdomen found entirely normal. The patient was allowed to believe that the anticipated suppurative focus had been found and removed, and pains and fever vanished permanently.

Disturbances in Circulation in Infectious Diseases. I. ROMBERG.—It is evident from the numerous and carefully conducted experiments recorded, that the disturbances in the circulation in the course of acute infectious diseases are not due to weakness of the heart, as formerly assumed, but to paralysis of the vasomotors. Paralysis of the vasomotor center in the medulla oblongata alters the distribution of the blood throughout the organism: the splanchnic vessels are gorged, while the vessels in the brain, muscles and skin are empty. 2. PÄSSLER.—The therapeutic indications therefore are to stimulate the diminishing arterial pressure by substances like caffeine or coriamyrtin, which excite the vasomotor center, and hypodermic or intravenous injections of salt solution. Strychnin and ergotin are not effective except in toxic doses. 3. HASENFELD.—Malignant pyocyanic endocarditis in animals did not produce heart weakness. The heart was able to accomplish more work than normally, and even become hypertrophied. The animals died of disturbances in the circulation caused by paralysis of the vasomotor centers. 4. HOLLWACHS.—Disturbances in the circulation in diphtheria at the height of the fever process are also due to the same cause, but disturbances occurring at later stages are produced by a secondary myocarditis.

Deutsche Medizinische Wochenschrift (Berlin), June 29.

Catalytic Effects of Galvano Current With Checked Circulation. T. BÜNINGEN.—Cataphoric medication is most effective when the circulation of the blood is arrested by an Esmarch tourniquet or similar device. Büdingen recalls the one serious disadvantage of the Bier method of treating tuberculous lesions by inducing venous hyperemia, namely, the formation of cold abscesses, which has tended to prevent the general adoption of this simple, effective, logical therapeutic measure, and caused Bier to advocate the suspension of the treatment from time to time, thus reducing the liability to the development of these abscesses, although the curative results are proportionately reduced in consequence. It is evident that the injury to the tissues which unfortunately accompanies the cure of the lesion, is due to the lack of the stimuli afforded by the circulation, and he suggests that possibly the cells in the part might be kept in normal conditions, and thus the formation of the abscesses be prevented, by stimulating them with electrolysis during the period of venous stagnation, and thus relieve Bier's method from the odium of abscess production.

Surgical Treatment of Ascites From Cirrhosis of Liver. A. E. NEUMANN.—A convincing case is reported confirming the assertions of Tilmann and Talma (see JOURNAL, xxxii., p. 1169), in regard to the benefits to be derived in case of interrupted circulation in the portal circulation by establishing collateral routes for venous circulation, if the liver cells are still capable of function. The operation is as simple and free from danger as an exploratory laparotomy, and scarcely complicates the incision to relieve the ascites.

Memorabilien (Heilbronn), May.

Biology From Vitalistic Standpoint and Its Relations to Medicine. GUIDO BELL.—"The correct understanding of what is meant by constitution and temperament is of the greatest importance as a foundation for a general theory of causes in pathology." The writer traces the branching of biology into physiology and psychology, showing how each has the same basis, and that each is mutually dependent, under the same laws, and emphasizes the point neglected by the Darwin theory, that evolution is not only a development but also a subordination to a higher whole. Constitution is defined as not the result of the uninterrupted sequence of stimuli from without, under the influence of which the organism develops and is maintained; it is not the special structure of the tissues and organs. It is rather, the capacity to develop and be maintained in a special manner, as the person of the king is not the government, which applies to the power and capacity to govern, with which he is invested. The constitution is a faculty and not a condition of bones, muscles, etc. Temperament is an attribute of the constitution: the manner of thinking, feeling, and acting, which proceeds from the organization of the individual and must always so proceed, as beauty is an attribute of the rose.

Hydratic Treatment of Insomnia. B. BUXBAUM.—The most obstinate cases of insomnia, as the writer states, are in mental diseases, progressive paralysis, delirium tremens, etc., and it is especially in these cases that the beneficial effect of the wet pack is the most marked, but it is effectual in all cases of insomnia. The patient, lying on a blanket, is covered with a wet linen sheet smoothly folded and tucked in between the arms and legs and around the neck, so that it is in contact with every portion of the surface. The blanket is then brought up and folded over him, and he is left for three-quarters to one hour if the heart is normal. After the sheet and blanket are removed, he falls into a refreshing sleep in the course of half an hour, and within one to two weeks sleep recurs naturally at the accustomed hour, without any measures of the kind. The only precaution necessary is to apply a cold compress to the forehead beforehand. If the patient objects to the complete pack the body can be wrapped to the armpits alone, or the trunk alone. Great benefit is also derived in cases of insomnia due to gastro-intestinal as well as nervous disturbances from the wet abdominal bandage alone. The complete pack should never be given to children, as the surface is too extensive in proportion to their size.

Muenchener Medizinische Wochenschrift, June 27.

Milk Albumen, a Cheap Food for the Masses. W. PRAUSNITZ.—The abundance and cheapness of buttermilk would render it a valuable food product if it were not for its bulk and speedy decomposition. Siebold has perfected a process by which

it is mixed with sodium bicarbonate, worked at 70 C., with CO₂ introduced and the product evaporated to an odorless, tasteless powder—"Plasmon"—which can be sold at a profit for about ninety cents a kilo, and can be added to any dish, bread, etc., without affecting its flavor while immensely increasing its nutritive value. Professor Prausnitz' tests at Graz were made with the most scrupulous accuracy and double control, the feces analyzed in every case. They demonstrate that 8.07 per cent. was the largest amount of this albumin eliminated unutilized; the average, 6 and a fraction, proving that almost the entire amount is assimilated. A comparative table of the various food products on the market shows that the solubility, cheapness and constancy of the new product, with its great nutritive value and ready absorbability render it far superior to anything of the kind yet produced.

Bacteria in Aseptic Operations. DÖDERLEIN.—Instead of estimating by the results of the operations, the degree of aseptis secured, this Tübingen professor made comprehensive tests in "aseptic operations" lasting over half an hour, sowing scrapings of the wound, etc., at intervals. Cultures constantly developed, even when extreme efforts were used to realize aseptis, such as a damp sheet spread above the operating table, to collect the germs in the air, etc. and the operator in hood, mask and gloves on his hands like a negro's from the effects of permanganate. His conclusions are that the bacteria in the wounds are derived from the hands of the operator, from the underlying skin, as the disinfected epidermis scales off in the course of the operation proved among other facts by the almost complete absence of bacteria in tricot gloves after a long operation, if thin rubber gloves are worn under them. But instead of advocating the wearing of impermeable gloves during aseptic operations, he asserts that absolute freedom from bacteria is an unattainable ideal, and we might as well abandon our attempts to realize it beyond what is already accomplished in the ordinary well-managed aseptic operating-room. On the other hand, we must bend every effort to keep our hands free from pathogenic germs, wearing impermeable gloves in operating and examining septic or infected cases, and supplementing this precaution by assisting the organism to resist the ordinary germs that are constantly present, by every measure known to date, or that is yet to be discovered. In this direction lies the field for future achievements.

Wiener Klinische Rundschau, June 25.

Pseudopulmonary and Pseudopleural Sounds. O. ROSEN-BACH.—The writer called attention to these sounds some years ago, but few physicians bear them in mind, and thus applicants who are good subjects are sometimes rejected by examiners for life insurance companies, on the suspicion of lung disease, when in reality the sounds are due to the muscular contractions in the thorax in perfectly healthy persons, as he has had occasion to establish in a number of cases. The sounds deceptively simulate dry rales, and are most perceptible in vigorous, rather lean young persons. They can be artificially produced by electrically exciting and auscultating a muscle as it contracts. The sound only occurs during inspiration and continues when the breath is held at the maximum of inspiration. It is unaffected by coughing, expectoration, change of position, etc., although if there are transient catarrhal symptoms it cannot be positively differentiated until they are healed, when the sound will be found still persisting.

Gaceta Medica (Mexico), July 1.

Treatment of Prostatitis. R. LAVISTA.—A patient with severe prostatitis and retention, with symptoms of atheromatous arteriosclerosis, had a profuse hemorrhage after withdrawal of 5000 grams of urine, quite filling the distended bladder, which reached to the umbilicus. After a suprapubic incision the bladder was rinsed with hot water and saturated solution of antipyrin. The prostate was very much hypertrophied with a "bar" or transverse excrescence, which was removed and several furrows made in the lateral lobes with a galvanic loop. A large catheter was used to hold down and open the neck of the bladder, prostate and pubis, affording a sure guide for the cauterization of the parts desired without injury to others. The results were most satisfactory in every respect. The hemorrhage was arrested, the vesical cavity contracted and the permeability of the urethra completely restored from the first.

Societies.

Fresno County Medical Society.—This society met July 6. at Fresno, and elected the following officers: President, George A. Hare; secretary, W. T. Barr.

Wabasha County Medical Society.—At the annual meeting of this society, held in Plainview, Minn., July 13, the following officers were elected: President, E. H. Bayley, Lake City; vice-president, J. A. Slocumb, Plainview; secretary and treasurer, W. F. Wilson, Lake City. The next meeting will be at Lake City, on the second Thursday in July, 1900.

Tri-County Medical Society.—This society, comprising physicians from Ford, Iroquois and Vermilion counties, met at Danville, Ill., July 11. Officers were elected as follows: President, M. S. Brown, Danville; vice-president, B. S. Evans, Watska; secretary and treasurer, Leroy Jones, Hooperston. The times of meeting were changed from the second Tuesday in January and July to the first Tuesday in December and June.

Medical Congress of Latin America.—The government of Chili has invited all the governments, medical faculties and societies of Central and Southern America, including Mexico, to a grand medical congress at Santiago, Chili, toward the close of 1900. All the governments and most of the universities have already accepted. An international hygienic exposition is to be one of the features of the congress, and the German medical papers are urging manufacturers of sanitary and hygienic appliances for public and private use to send exhibits, as this is practically a virgin field in Latin America.

State Board of Health of Pennsylvania.—The thirty-third annual meeting of the board was held at Glenolden, Pa., July 12. Dr. Benjamin Lee, the secretary, in his annual address called attention to the resolution urging the establishment of a leper colony, which had been forwarded to the United States Marine Hospital service, at Washington. He also reported that the additional \$3000 needed to meet the expenses of the recent outbreak of smallpox, which had been forwarded to the Emergency Board, was promptly granted. Pollution of the Schuylkill was next considered and it was reported that new powers had been granted the Board of Health in the case of cities of the first class, and steps would therefore be taken to abate the practice of pollution of streams, by more stringent laws. The new ruling forbids the pollution of streams by deposits of excrement, whether from houses or boats. Ten new boards of health have been established in different parts of the state since the last meeting. In the opinion of Dr. Lee, \$5000 will be needed in controlling the epidemic of smallpox in the southwestern counties of the state.

Kansas City District Medical Society.—This society held its summer meeting July 6. Dr. M. B. Ward read a paper on "Myotomy for Uterine Fibroids," and Dr. Hal Foster one on the "Treatment of Broken and Deformed Nasal Septa." He insisted that the same care and attention given a broken limb, should be given a broken nose. Ash splints should be inserted to hold the broken parts in place until union had occurred. The drill and trephine can be used in slight deviations. In a great many cases a Bosworth saw acts excellently. The spoke shave is useful only in mild deviations. He described the Watson, Ash, Gleason, Ingals, Roe and Bosworth operations for correction of deviated septum. For severe cases he considered the Ash operation the one offering the best and most lasting results to the patient. Great care should be taken that no blood be allowed to enter the larynx while the patient is under the general anesthetic. The patient's head should be allowed to hang over the edge of the table in order that the blood may escape through the nostrils. He advocates using a solution of suprarenal capsule in the nose before doing the operation, as it prevents the blood from obstructing the field of operation.

The next meeting, October, 1899, will be the twenty-fifth anniversary of the society.

New Jersey State Medical Society.

Meeting Held at Allenhurst, N. J., June 27, 1899.

TRAUMATIC NEURASTHENIA.

DR. J. D. MCGILL of Jersey City in this paper classifies the neuroses as organic and functional; then the traumatic as depending on a neurotic diathesis, hereditary or acquired as predisposing causes, a shock and a wound as the exciting cause. He considered shock psychic and physical, as the chief cause in traumatic neuroses and discussed the pathology, the disease being due to a starved nucleus from vitiation of cell protoplasm.

PROGRESS, PROBLEMS AND PROSPECTS IN MEDICINE.

DR. JOHN BRYAERE of Trenton presented a paper on this subject, to appear in the JOURNAL.

EMBRYOTOMY AND TWO CESARIAN SECTIONS IN SAME PATIENT.

DR. J. C. MCCOY of Paterson read this paper. The patient, Mrs. F., a mulatto, aged 19, first pregnancy, had been in labor three days when he was called to her; now fatigued with vomiting for twelve hours. During pain the uterus would roll forward and assume an almost anteroposterior direction; small vaginal outlet, broad pubic arch, giving the impression of a pelvic canal contracted in all its diameters. The pains exerted no effect on the delivery. She was transferred to a hospital and at 1 a.m. an effort was made to apply the Tarnier axis-traction forceps under complete ether narcosis. After several futile efforts, version being impossible, the child still viable, the head was perforated, crushed with the cephalotribe and the body delivered piecemeal, operation occupying one and a half hours. Owing to the need of backward traction, the perineum was torn two and a half inches into the rectum. After removal of the placenta, the cavity of the uterus was thoroughly curetted with a dull irrigating curette followed by a thorough flushing with sterilized water. Bleeding having subsided, the upper portion of the vagina and rectum was packed with iodoform gauze, and the tissues cleansed with sterilized water. The tear in the rectovaginal septum was closed with interrupted sutures of fine silk. The separated ends of the sphincter ani muscle were united by deep silkworm gut suture and finally the perineum repaired. The recto-vaginal tear healed perfectly and sutures were removed on the tenth day. From this time all went well.

On June 15, 1895, he was again called to this patient, at full term and labor just started. Examination showed the head wedged in about the same position as before, and no progress. With the former experience, and the desire of the parents for a living child, Caesarian section was advised. She was removed to the hospital. Measurements gave distance between the anterior superior spines of the ilia $7\frac{1}{2}$ inches, between crest of ilia $8\frac{3}{4}$ inches, sacrepublic 5 inches, width of pubic arch at articulation $2\frac{1}{4}$ inches. Pains not being frequent she was given half an ounce of magnesia sulphate, followed by a high enema of water; next morning another high enema causing free evacuation of the bowels. She was then prepared in the usual manner for laparotomy.

At 10 a.m., June 16, median incision was made extending above the umbilicus, the uterus lifted out of the abdominal wound, wrapped in hot wet towels and firmly held by an assistant. Two sutures of silkworm gut were passed through the entire thickness of the abdominal wall above the uterus, which when tied closed the wound, preventing any undue exposure of the peritoneal cavity. An elastic ligature was passed about the cervical portion of the uterus, which was then opened in the median line anteriorly, incision extending close to the fundus; there was little bleeding from the incision. The membranes presented were ruptured, and the amniotic fluid escaped. The placenta was situated on the anterior surface of the uterus at the juncture of the middle third and directly under the line of incision; it was rapidly separated from the uterus, the feet

of the child grasped and it quickly delivered, the assistant gently kneading the uterus during this time. The uterus was then washed out with hot sterilized water, the cavity swabbed with 1-40 carbolic solution, and the organ well contracted. In removing the child, weight $8\frac{1}{2}$ pounds, the uterine wall was torn slightly at its upper portion at right angles to the incision. The uterine wound was closed by interrupted sutures of silk at intervals of one-quarter of an inch; these entering at the edge of the peritoneal surface of the uterus and passing down to the endometrium, the peritoneal surface being approximated with sutures of catgut and the abdominal wall closed with sutures through and through of silkworm gut; time one hour and ten minutes.

The child was put to breast at the end of twelve hours, and sutures in the abdominal wall removed on the eighth day, the patient leaving the hospital on the twenty-first day. At no time was temperature over 99 degrees. Six months later she had a slight discharge from the lower portion of the abdominal wound. It resembled that found in endometritis and on further examination I found that a probe could be readily passed through the abdominal fistula into the cavity of the uterus. Seven months later, after weaning the child, she had a bloody discharge from the sinus coincident with the menstrual flow. She declined any operation to close this.

November 12, 1898, at full term of pregnancy she was removed to the hospital for a second operation. The uterus was found adherent at the point of sinus in the abdominal wound, over a space of $2\frac{1}{2}$ inches. On either side of the old scar were bands of adhesions extending the entire length of the organ and across its cervical portion, these adhesions surrounding the field of operation, save at the fundus. Uniting, as they did, the anterior surface of the uterus to the parietal perineum, they made the operative field practically extraperitoneal. The cicatricial tissue about the sinus in the uterus extended over an area $1\frac{1}{2}$ inches in diameter. Under these conditions the uterus was not drawn out through the abdominal wound as before, nor was an elastic ligature placed about the cervical portion of the organ. The incision in the uterus was made along the line of the old wound. No trace of the sutures was observed, and there was slightly more bleeding from the uterine incision than before. The membranes were ruptured, placenta found attached as before, delivery accomplished, child weighing $7\frac{3}{4}$ pounds. Owing to the adhesions mentioned, supplemented by gauze packing above, thus far operation was practically extraperitoneal. At the point of fistulous tract in the uterine wall the cicatricial tissue was excised, and the opening in the uterus closed. In this instance the sutures were entered on the peritoneal surface of the wound in the uterus, and closer. Both tubes and ovaries were then removed; a wedge-shaped piece of uterus was included in the uterine end of each tube. The bases of these triangular spaces were then closed in the usual way. The cicatricial tissue in the abdominal wall was excised and the wound closed. Time from abdominal incision to delivery of child was nine minutes, operation complete in one hour, recovery uneventful, mother and child going home at end of fourth week.

In the house to which she went a case of diphtheria developed; both contracted this disease, the child dying.

The question might be raised as to relative value of symphysectomy and Caesarian section, or whether embryotomy might have been again performed. The external measurements of the pelvis were no less than one would expect to find in a woman of the stature and build of this patient, yet the conjugate vera was, owing to the extremely wide pubic arch and the unusually marked sacral prominence, contracted; this, coupled with the difficulty in removing the child at first labor, and the demand for a living child, seemed to justify the course pursued. While the external measurements of the pelvis may prove of great value to us in determining beforehand the probabilities

of a severe or an easy labor, we must take into consideration the size of the child, which can be but approximately determined, consequently any rules laid down as indications for the operation can be but relative. Given a case just subjected to embryotomy, with the extreme difficulty in removing the macerated child, he is inclined to believe that the Sanger-Cesarian in a woman before her powers have been lowered, is under favorable surgical conditions, fraught with well-nigh if not quite as little danger to the mother as the so-called more conservative procedure of embryotomy. In this case the woman was about and attending to her customary duties nearly as soon as after a normal labor. Indeed, she was left in better condition than after the embryotomy.

The Porro was not employed because the uterus was in a healthy state. The removal of the uterus must of necessity add to the dangers of a Cesarian and unless there be distinct and definite reasons, such as morbid growths, etc., it would seem that we can best conserve the welfare by non-removal. In this case I regret that in place of the double salpingo-oophorectomy, I did not follow the course of Crimail of Pontoise, in which, during the second Cesarian on the same patient, in order to provide against subsequent pregnancies, he passed a double ligature about the uterine end of each tube and divided the tube between the ligatures. Such a course, by allowing the ovaries to remain, would tend to relieve the patient of the various phenomena incident to the artificially produced menopause.

Too much stress can not be laid on the careful and methodic closure of the uterus. Time is an important factor, yet in my first Cesarian the fistulous tract might have been due to the fact that the sutures were not placed quite close enough together. Subsequently, the sutures were placed at shorter intervals and no superficial sutures were employed.

BLEPHARITIS DUE TO DEMODEX FOLLICULAROSUM.

DR. T. C. ARD of New York, in a report on ophthalmology and otology presented this topic. This acarus is found most frequently in the sebaceous glands of the face, without producing disease, yet it no doubt causes blepharitis by its presence in the follicles of the eyelids. The cilia fall out and itching is a prominent symptom; in suspected cases microscopic examination should be made and if the demodex is found, a 35 per cent. ointment of balsam Peru will rapidly effect a cure.

PROPAGATION OF BLEPHORRHEA NEONATORUM.

On this phase of his report, the Doctor cited DeWecker, who explains that the direct lodgment of gonococci within the conjunctival sac is next to impossible, so tightly closed are the lids of the child during labor. The outside is soiled and as soon as the lids are opened the infection would not be difficult. The length of the incubation period proves his assertion. It is three or four days and never less than two; in direct transmission, it would be twenty-four hours.

He spoke also of Elschnig's explanation of this association as hepatic disease leading to cholemia and jaundice impairs the secreting capacity of the conjunctiva. This leads to increase in the xerosis bacilli in the conjunctiva and the latter germs bring about desiccation, cornification and fatty degeneration of the epithelia. Thus the avascular cornea goes to necrosis and ulceration. If pathogenic bacteria are present they may develop in the wound with possible general infection; if absent, the affection is benign in character.

ANIMAL EXTRACTS IN OPHTHALMOLOGY.

DR. ARD pointed out that Lagrange has been using a solution of vitreous humor of an ox in sterilized glycerin, and after maceration a filtrate is prepared for use by the mouth or subcutaneously. The remedy was used in cases of escape of vitreous in cataract operations and detachment of the retina. Improvement followed but might have been spontaneous.

INSTALLATIONS OF ANTIDIPHTHERIC SERUM INTO EYE IN DIPHTHERIC CONJUNCTIVITIS.

Mongour observed that during an epidemic of this trouble antitoxin when given subcutaneously was successful as regards the general results, but that several children lost their sight. The next series of cases, seven, was treated by direct installation of the serum into the sac in conjunction with the other injections. He was successful in every way.

HYDROCHLORIC ACID APPLICATION TO BONY WALLS OF TYMPANIC CAVITY AND MEATUS.

DR. ARD said that Bull of Christiania proposed this remedy some years ago. He concludes, after years of experience, that the treatment is not indicated if the ossicles are diseased. When dead bone is visible he applies cotton soaked in the acid—4 per cent.—and leaves it in contact. In a cavity he introduces the cotton into it, removes it next day; applications a week apart. The acid gradually decalcifies the affected bone and acts like curettage. It is a strong antiseptic and cures from one-third to one-half of all treated.

CLOSING PERFORATED EAR DRUMS.

Concerning Okunef's method, Peltsohn has used it with great satisfaction for the past year. It has been ignored in standard works on otology, but the results of the past few years have been collected and Peltsohn regards it as a most brilliant addition to our resources. The method is simplicity itself. All perforations tend to close, but the increased proliferations of epithelium at the margins of the perforation prevent the fulfillment of this tendency. By cauterizing these epithelial accumulations with trichloroacetic acid the granulations once more reassert themselves and close the aperture. Within a short time a number of eminent otologists have adopted this method with great success.

OPERATION FOR SINUS THROMBOSIS.

In a contribution to the clinical stages and to the technic of the operation, Whiting divides the history into: 1. The presence of a thrombus, parietal or complete, not having undergone disintegration and accompanied by slight or moderate pyrexia, rigors being usually insignificant or absent. Diagnosis is made in this stage, consequent on operation for mastoiditis, and the only safe-guard against encountering the increased gravity of the second stage is to operate immediately on the recognition of the first stage. 2. The presence of a parietal thrombus, or a complete one which has undergone disintegration and resulting systemic absorption characterized by frequent rigors and pronounced septicemic fluctuations. 3. The presence of a thrombus, parietal or complete, which has undergone disintegration with systemic absorption accompanied by rigors, rapid and great fluctuations of temperature, central and peripheral embolic metastases terminating usually in septic pneumonia or enteritis. He gives a complete and exhaustive description of the symptoms of each stage and a clear exposition of the operative procedure. In concluding the article he says that it is not too sanguine to believe that as our knowledge of symptomatology and technic improves there should be no fatalities in the first stage of sinus thrombosis; the second stage should furnish only an occasional fatal result and the third stage should, in the absence of gangrene of the lungs and purulent meningitis, be regarded as a still hopeful surgical procedure.

Officers were chosen as noted in the JOURNAL, July 8, p. 100.

Medical Society of the State of Colorado.

Twenty-Ninth Annual Meeting Held in Denver, June 20-22, 1899.

KIDNEY DISEASES.

DR. LEONARD FREEMAN reported several cases.

CASE 1.—A woman 23 years of age. She suffered from pain and tenderness in the region of the left kidney, the pain follow-

ing the ureter to the bladder and often running down the thigh. Physical examination revealed nothing. Urine contained crystals of oxalate of calcium, few hyaline casts and red blood-corpuses. The increase of pain, tenderness and blood in the urine in motion, jolting the body or percussion of the lumbar region, with decrease of the symptoms during rest in bed, pointed to calculus as a probable cause. At the operation, in which the kidney was freely incised along its convex border and reunited by catgut sutures, nothing was found except an undue movability of the organ. Nephrorrhaphy was done, and union by first intention, without drainage, was obtained.

The author concludes from this case that blood in the urine may be due to movable kidney.

CASE 2.—This case presented symptoms similar to those of the above. The urine was acid, contained a few red blood-corpuses, some hyaline casts, and of high specific gravity. A movable kidney was suspected, but treatment directed to the diminution of acidity and specific gravity of the urine cleared up the symptoms in a few days.

CASE 3.—A man, 30 years old, had noticed all his life a tumor on the region of the left inguinal canal. This was supposed to be an undescended testicle. At irregular intervals inflammation and swelling took place. At the operation what was supposed to be a testicle was found to be an undeveloped kidney lying in the inguinal canal, and a hernial sac lay by its side. The kidney was filled with a black fluid and its ureter was a mere fibrous cord resembling a vas deferens. A radical operation for hernia, castration, and nephrectomy was simultaneously performed, an uneventful recovery resulting.

CASE 4.—A boy, 13 years old, fell fifteen feet from a tree, striking his left side. He suffered great pain and passed blood in the urine. Temperature was 103, pulse rapid. On the third day an exploratory incision was made and the kidney was found torn almost in two, and surrounded with a large quantity of fluid blood and urine. Recovery after drainage was complete.

CASE 5.—A man 35 years old, was shot in the left side. Extravasation of blood and urine followed. Incision was made down to the kidney for drainage. At the end of several weeks secondary hemorrhage set in. It became so profuse as to almost exsanguinate the patient. As a desperate resort a nephrectomy was rapidly done without anesthesia. The patient rallied under the use of saline solution and ultimately recovered.

CASE 6.—A man about 70 years old suffered from profuse renal hemorrhage for which no cause could be detected. He had been addicted to the eating of crude opium, which had been suddenly taken away from him before the hemorrhage began. Death from exsanguination followed. The autopsy revealed no abnormality in the kidney.

CASE 7.—A man 35 years old, suffered for several years with recurring abscesses of the prostate gland, following a perineal operation for stone. There was great irritability of the bladder; moderate fever; no tumor could be felt. It was decided to cut down upon the kidney. Five abscesses were encountered containing several pints of pus. The kidney, which was incised and drained, was found pushed over to the median side. The bladder symptoms at once disappeared and the patient made an excellent recovery. The author called attention to the fact which is not widely appreciated: that irritability of the bladder may be due to affections of the kidneys.

CASE 8.—A woman of 18 years, since 4 years of age had complained of pain and tenderness in the region of the right kidney. There was no history of renal colic or of passage of gravel. Jarring the body or pounding on the lumbar region produced sharp pain. The urine contained a considerable quantity of cystine crystals. While the patient was under observation she fell down a flight of stairs, striking heavily on the affected side. The pain at once absolutely disappeared; tenderness also rapidly subsided. The abrupt cessation of the symptom would seem to point to the existence of a stone which suddenly under the influence of the trauma, shifted its position

and ceased to be a source of irritation. An interesting fact was noted, i. e., the patient during the last five months could not wear a silver ring as it turned black almost as rapidly as it was polished. The explanation of the phenomenon undoubtedly is that those affected with cystinuria exude a certain amount of sulphur through the skin.

RESECTION OF LARGE INTESTINE.

DR. E. J. A. ROGERS reported the following:

CASE 1.—Mrs. J. M. A., aged 49, mother of thirteen children, and with previous health good, December 17, 1897, was taken acutely with pain in the bowels and tenesmus, but passed only gas and blood. After taking a cathartic she began vomiting and became distended. She came to the hospital on the 20th. A tumor could be distinguished on the left side between the umbilicus and the anterior superior spine of the ileum. The abdomen was opened by a central incision, and the peritoneum was found filled with a dark foul-smelling fluid.

The tumor proved to be a much-enlarged sigmoid and descending colon; it felt quite solid and appeared gangrenous. A longitudinal incision proved the mass to be made up of the thickened walls of the bowel, which almost obliterated the lumen of the canal. The mesenteric glands were enlarged. The upper portion of the rectum appeared fairly healthy, and a double ligature was placed around it as low down in the pelvis as it was possible to reach. The upper portion of the bowel near the gangrenous area was also doubly ligated. The mesentery was then tied off as short as possible, and the intervening bowel excised. So much of the descending colon was removed that it was hard to find a place to make an artificial anus.

The operator forced his finger from within outward up close to the margin of the ribs and as far posterior as seemed practicable, and cutting through the skin over this point, separated the muscle fibers, and forced the peritoneum into the ring thus made. He then opened the protruding sac of the peritoneum and drew the divided end of the colon into it. He stitched the ends of the ligature into the skin toward the lumbar region, some distance from the opening, thus holding the bowel in place and leaving it unopened. The central incision was then closed. The second day he cut into the bowel to allow the gas to escape. She was fed by artificial enemata. The protruding bowel was allowed to slowly necrose away. Gradually the bowel assumed the regular functions. She was discharged Feb. 2, 1898. Examination of the tumor showed the disease to have been croupous colitis.

CASE 2.—E. C., a stonecutter, aged 43, in 1895 began to suffer from pain in the abdomen, usually in the evening, which condition lasted for three months. In November, 1897, while having a severe cold and coughing much, the pain first localized itself in the right side of the abdomen, and he began having black tarry stools several times each day. His appetite failed, and he lost thirty-five pounds in weight. On Aug. 10, 1898, he had a severe chill which prostrated him. A movable tumor then occupied the lower right abdomen. The abdomen was opened on the 16th, along the median line, and the tumor was found to be a large carcinoma involving the cecum, part of the ascending colon, the omentum and the transverse colon. The glands of mesocolon were enlarged.

The omentum was ligated off, and the transverse colon beyond the tumor was clamped, also the ileum above the valve, and the bowel divided at these two places. The layers of the mesocolon were clamped as near the vena cava as possible, and the entire mass was cut away and removed. The open end of what remains of the transverse colon was closed, and approximated to the end of the ileum and made an end-to-side anastomosis with a Murphy button. The parts removed included about six inches of the ileum, the cecum, the ascending colon, about two-thirds of the transverse colon and most of the omentum.

The recovery was very satisfactory. The patient left the hospital on September 22, the button not passing until that date, thirty-six days after the operation. On leaving the hospital

he weighed 140 pounds, and now weighs 195, and has for the past month been at work at his trade.

FUNCTIONAL AFFECTIONS OF JOINTS.

DR. GEORGE B. PACKARD said in part: While this pseudarthrosis may be induced by an exhausted nervous system, and occurs frequently in persons of an emotional temperament, usually in women, yet it is sometimes seen in persons of an opposite temperament, and from various causes. Therefore, he thinks it should not be considered hysterical in all cases, but rather an indication of some weakness about the joint or nervous system. They simulate organic diseases so closely that it is sometimes with the greatest difficulty that a correct diagnosis can be made. The importance of distinguishing these functional affections from the inflammatory condition should be particularly emphasized because the treatment is diametrically opposite—in one case rest, in the other activity.

As etiologic factors he regards slight traumatism and muscular weakness as the most frequent. These cases not always being recognized as such, afford many opportunities for "remarkable cures" by charlatans. Presenting, as they do, many if not all the subjective symptoms of organic disease, the recovery from lameness seems almost miraculous to the uninitiated. In treating these cases it is necessary to overcome local pain and disability. When the spine is the seat of the trouble he found it necessary to use a light flexible support until the patient becomes stronger. He uses cold sponging, friction, massage and light gymnastic exercises.

In functional affections of the knee, hip and ankle it is also necessary to, in some cases, temporarily protect the joints until the circulation and muscular support has been improved by massage, electricity and passive motion.

OUTLINE RECORDS OF FLEXION AND EXTENSION AFTER SERIOUS INJURY OF ELBOW-JOINT.

DR. GEORGE W. MIEL recommends, in cases presenting difficulties and concern for restoration of function, a method of accurately ascertaining and indicating the progress of treatment: An outline record of flexion and extension; a tracing taken from time to time, with date of each properly placed. This is effected by outlining the whole arm—hand omitted—against heavy pulp-board interposed between the arm and body. The original tracing should outline the whole arm at its fullest attainable flexion and extension; in subsequent tracings, with the arm proper resting between the original outlines, the forearm alone need be outlined. Such an outline record interests the patient, usually encourages him, and perhaps satisfies him. For the surgeon it is a reliable guide, a satisfaction, and a record of scientific interest.

BONE NECROSIS FOLLOWING TYPHOID FEVER.

DR. FRANK FINNEY reported four cases of bone necrosis following typhoid fever, out of forty cases he has in his private practice. Three of the four cases involved the sixth rib on the left side almost exactly at the same spot. None of the cases recovered without an operation. The general health of the patients did not seem to be greatly impaired by the long-continued suppuration, but the disease did not show any tendency to recovery without operative interference.

(To be continued.)

California Academy of Medicine.

June Meeting.

(Concluded from page 163.)

SYPHILITIC EPIDIDYMITIS.

DR. DUDLEY TAIT presented a specimen of this condition. The patient, a Chinaman, gave the following history: Age, 25 years; contracted syphilis four and one-half years ago; has had several series of papule-squamous eruptions in that time; has received no treatment at any time; at present has a few papules on his back and chest; no bone or visceral lesions of any sort are present. Two weeks prior to our examination he

for the first time noticed a swelling in the right epididymus, the size of a bean, and sufficiently painful to compel him to ask for assistance. A suspensory was advised by the attending physician, who diagnosed gonorrhoeal epididymitis. Examination six days later, showed in the upper portion of the epididymus, a hard, indolent nodule, with a diffuse swelling diminishing downward toward the tail—globus minor. Forceful palpation elicited slight pain, but much less than normally. The testicle was apparently normal, as was also the cord. The opposite side was healthy. There was no history and no sign of gonorrhoea and no history of traumatism. Syphilitic epididymitis was diagnosed. The patient refused any treatment by mercury, and demanded extirpation of the diseased tissue. This was at once done in accordance with his wishes, the result being a very fine specimen of an unusually rare condition, and entire relief of the trouble.

Microscopic sections were prepared by Dr. Wm. Ophuls, Professor of Pathology at Cooper Medical College; the appearance of the sections is peculiar: A diffuse sclerosis, together with arteritis, both endo- and peri-, may be very clearly seen in any of the sections. (The specimen was exhibited and was indeed a most interesting one. The glandular structures of the testicle seemed to be quite intact.)

A few words as to the status of this lesion may not be out of place, for the reason that its very occurrence has been denied and disputed by some writers, and no mention of it is to be found in the English text-books. For a long time the existence of syphilitic epididymitis was bitterly contested, especially by certain Germans, Sigmund and Koerber in particular. The French were the first to describe the affection. Dron, in 1863, gave a very excellent account of this complication of syphilis; Fournier described the condition and gave it the name of "epidyme secondaire;" Balme, in his inaugural thesis, 1876, also treated of this lesion; other writers of note on syphilitic epididymitis are Mauriac, Ténédat, Cuilleret (Lyons, 1890), Reclus, in "Syphilis of the Testicle," and Fournier (1899.)

The characteristic features of the disease, or variety of disease, are: 1. Its location, it being almost always limited to the epididymus, and seldom extending to the testicle. 2. Its early development. Fournier noted it six times during the seventh month; twice in the first ten or eleven months; Balme 8 times in from the second to the fourth month, and 6 times in from the eighth to the fourteenth month; 8 times between the second and the eighth year of the disease. It is generally unilateral and belongs to both the secondary and tertiary periods. On account of the frequency of the syphilitic lesion of the testicle during the secondary period, and of the frequent occurrence of syphilitic epididymus during the tertiary period, Reclus proposed the appellation of "syphilitic epididymitis," instead of "epidyme secondaire" of Fournier.

It is mostly found in grave, secondary, untreated syphilis. The lesion is generally not noticed by the patient in the early stages; it is usually first detected by the physician. This reminds one of Ricord's advice to physicians in charge of syphilitic wards: "Watch the patients' testicles more than the patients themselves." The nodule generally involves the head of the epididymus-globus minor, contrary to tubercular lesions which have a predilection for the tail of the epididymus. The nodule is hard, resistant and indolent, except in certain rare instances where the invasion is quiescent. When the lesions have been left to themselves, without treatment, there may occur a slight hydrocele. The nodular mass increases to the size of a nut, seldom larger, then remains stationary, retaining its hardness. Diffuse infiltration is very rare. Fournier likens the nodule to a bean in a healthy epididymus. Syphilitic epididymitis does not interfere with the spermatic functions. In one of Dron's cases with bilateral lesions, spermatozoa were present. The knowledge of these lesions of the epididymus is

of considerable importance, especially in relation to tuberculosis. The evolution of tubercular lesions is more diffuse, the nodules are multiple, the results of palpation are altogether different: the cord, prostate and vesicles are frequently involved, and, as already mentioned, the lesions most frequently involve the tail end of the epididymus. The differentiation from gonorrhoeal epididymitis in a syphilitic subject may give rise to some doubt, but its invasion is generally more acute, and the lesions more diffuse and painful. The results of mercurial treatment are miraculous in syphilitic epididymitis. The iodid is seldom necessary.

SARCOMA OF TESTICLE.

DR. TAIT also presented another pathologic testicle, with the following statement and history: The patient, a Chinaman, aged 74 years, a merchant, presented himself with a scrotal tumor about the size of an adult's head. It was irregular in outline and in consistence, and extended to the external orifice of the inguinal canal. The skin was normal and non-adherent. The veins were slightly enlarged, but there was no enlargement of the inguinal glands. No lumbar glands were discernible. The attending physician had tapped the mass at the lowest point, anteriorly, thinking it to be a hydrocele. A few drops of cystic fluid slightly sanguinolent, escaped. The tumor was extirpated without difficulty after securing the cord and vessels en masse; the tumor was stripped downwards, and proved to be the very rare sarcoma of the testicle.

Sarcoma is exceedingly rarely met with in this region. Gurtt, twenty-three years in Vienna hospitals, records 16,637 tumors. Of these, 848 were sarcomata, and but 45 of these occurred in the testis; 11,131 were carcinoma, with 64 occurring in the testis. German and English records show but 114. Sarcoma of the testis exhibits some interesting features. The nearest glands are almost always involved, which partly explains the extreme frequency of abdominal involvement through metastasis. Like carcinoma, the disease does not extend to the contiguous tissues. There is generally a history of traumatism or retained testicle. As to the age of most common occurrence, Virchow thought the young and the old most commonly troubled, but Kober's statistics place the period of greatest danger between the years of 20 and 50. Clinically, it is impossible to make a differential diagnosis from carcinoma. It may be mistaken for hematocele or hydrocele, as in the case reported by Dupuytren and Kocher. Exploratory incision, under cocaine anesthesia, should always be made. The prognosis is always grave, though the results of operation are frequently very gratifying. Kocher was the first to call attention to the fact that it is quite impossible to determine the prognosis from the microscopic sections, as the evolution of tumors of the testicle is very variable.

DR. J. F. McCONE.—I removed a sarcoma of the testicle, some five years ago, which was very similar to the one presented by Dr. Tait. It was, however, only about one-half the size, and there was in the sac about a half pint of fluid. Externally, the tumor measured 9 by 12 inches in circumference. The sarcoma itself was 5 inches long by 3 in diameter. The microscopic sections showed a round celled sarcoma, but some doubt has been thrown on the diagnosis, owing to the fact that the mass was removed some five years ago, and the patient is still alive. Thirteen years before the patient had had gonorrhoea and orchitis, and eight years before there was some slight injury while wrestling. This was all the history that could be ascertained. The patient had been tapped twice for hydrocele by a homeopathic physician, and at the second tapping he stated that the patient could not live very long, no matter what was done.

DR. D. W. MONTGOMERY.—I do not exactly remember the microscopic picture, but I am sure the tumor was a round celled sarcoma, both microscopically and macroscopically. It

is not at all fair to question the diagnosis simply because the patient has not yet died. I recall a similar, and very interesting case, which occurred in a patient of Dr. Chismore's some years ago. The patient was himself a doctor, and received an injury during a runaway accident. No trouble was noticed at the time, but later a lump appeared. Some slight inconvenience was experienced from the time the lump made its appearance. It developed into a sarcoma which was removed by Dr. Chismore. One year later, however, the patient died from abdominal involvement.

DR. McCONE.—I would like to ask, in reference to the patient I operated on, whether any cases are recorded of recurrence as late as five years after operation?

DR. TAIT.—I know of one case, recorded by Kober, of recurrence after six years.

TREATMENT OF HYDROCELE.

Dr. Tait then introduced this subject as being somewhat akin to the matters just discussed. He said that each man seemed to have some special treatment which he employed in all cases of hydrocele, irrespective of the etiology of the excess fluid. The factor of causation did not seem to be very much considered, so far as he could ascertain, and all the cases were treated alike. In his opinion, it was obviously improper to treat a hydrocele in an old man, where the fluid had been slow in accumulating, and was probably due to some slight lesion of the tunica, as one would treat a similar condition in a young subject, the fluid accumulating more rapidly and indicating a decidedly different condition of causation—tuberculosis, cysts of the epididymus, etc. He strongly advocated the exploratory incision, under cocaine anesthesia, to determine the nature of the cause in all such cases, and then the modification of the treatment accordingly. The discussion was participated in by the members present.

SKULL FRACTURE.

DR. F. B. EATON reported a case of unusual fracture of the base of the skull, with certain eye symptoms, in a man about 26 years of age, the history being about as follows: He had been struck on the side of the head by a man's fist, one night, while walking along the street. The police were inclined to think the blow had been delivered by a "jack," and not simply by the fist; but this point is still an open question. The blow was not, however, severe enough to produce unconsciousness, and the man went on to his home. He was simply a trifle dazed. The next morning there was pain in the left side and shoulder, with later pain in the left eye, and headache. Four or five days later he experienced a feeling as if something were behind the eye, trying to push it outward, and a week later internal strabismus was apparent. He could hear, constantly, a quite severe noise, seemingly in the head. The strabismus passed away, but later returned. Some four months after the injury had been received, the left eye protruded quite noticeably outward and downward; there was perceptible pulsation on touch and a loud bruit could be heard with the stethoscope. The conjunctiva was congested. The ophthalmoscope showed the disc to be somewhat paler than the other, with vessels distended. The vision was but little lowered. The vision of the right eye was 20/15 and the left eye 20/20.

The diagnosis was fracture of the base of the skull, passing through the cavernous sinus, with a rupture of the internal carotid artery into the cavernous sinus. Dr. Eaton did not have a chance to test the facial sensitiveness, but believes there was, or would shortly have been, some facial anesthesia, and that the only thing was to ligate the common artery on the left side; the diagnosis and opinion were confirmed in consultation. Later, at St. Luke's Hospital, the operation was done with entire relief of the troublesome symptoms.

Foreign Postage	2.00
Single Copies	10 Cents

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION
No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting, of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Those new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JULY 22, 1899.

DEGENERACY OR OCCUPATION STRESS.

Recent analyses of prominent literati and scientists exhibit a tendency to confuse the neuroses arising from acquired neurasthenia with the neuroses of a similar type produced by degeneracy. The discussions of Zola's mental and physical constitution by Lombroso, Nordau and Arthur Macdonald betray traces of this confusion between congenital and acquired nervous states. The imperative ideas or obsessions are common to both, and it is on these that most stress has been laid as evidence of degeneracy. The occurrence of obsessions is largely due to the disturbance of the ego; that co-ordination of clear states of consciousness, of obscure states of consciousness and of physiologic states which, though unaccompanied by consciousness, are not less but even more effective than the conscious states. The automatic mental inhibitions last mentioned exercise an enormous influence in removing to the unconscious mental background ideas foreign to the general training of the individual or to his sense of major or minor morality. Many of these ideas are, however, mentally registered, unconsciously to the individual, to be reawakened in states of nerve tire produced by physical exhaustion or disease. In this way is produced the so-called subliminal consciousness of the psychologist, which is a lower and not a higher phase of consciousness. Many of the linguistic and other marvels narrated of this subliminal consciousness fall under the category of automatic remembrance, like the case narrated by Coleridge: A 24-year-old servant was seized by a nervous fever with delirium, during which she incessantly spoke Latin, Greek and Hebrew with a very distinct enunciation. The girl, before her illness,

had been a simple, unlearned, harmless creature. The attendant priest referred her case to "possession of a very learned devil."

This explanation did not suit the attending physician, who found that she had been for several years after the age of nine an inmate of the family of a Protestant clergyman, whose constant nightly habit was to read passages corresponding to the girl's ravings, from his favorite books, walking up and down a narrow passage near the girl's kitchen.

Not only during states of delirium, but also during states of adynamia which precede delirium, do such ideas rise into consciousness and trouble the possessor as being foreign to his own mentality. In ordinary life much is unconsciously assimilated by the mind, which remains without association with the daily life of the assimilator. This is shown in the use of coarsely obscene terms by refined modest women during the emotional disorders produced either by pregnancy or menstrual disturbance. The occurrence of the various 'phobias and other obsessions, with their resulting imperative acts, are an expression of this condition. Indeed, the mental processes, of whose operation as well as their results the mind is conscious, are really an expression of the same defect. The conscious mental process betrays, as Herzen¹ has shown, an imperfection of the cerebral organization, for it indicates the presence of a new unusual activity which deranges the equilibrium, the innate or previously acquired automatism, and which does not find a well-formed mechanism ready to discharge it. The conscious mental process is the transitory phase of an inferior to a superior cerebral organization. It expresses novelty, incertitude, hesitation, groping, astonishment, imperfect association and incomplete organization, a want of promptitude and exactness in transmission, a loss of tenure in the phenomena of reaction. It indicates that the nervous paths are not sufficiently cleared or distinctly enough traced to permit, without destruction in the final effect, reflex movements or reflex ideational sensations.

A sudden shock, therefore, whether mental or physical, whether occurring in a degenerate or in neurasthenia which has been acquired, may lead to imperative conceptions. As these are accompanied by cerebral circulatory disturbances and by states of anxiety and uncertainty, there is likely to be irregular cardiac action and with it irregular action, noticeably of the liver, kidneys and gastro-intestinal tract. It is a matter of common observation that the kidneys react to this condition. The frequent passage of pale urine in anxious states is a common observation. These conditions, however, must be referred to a physical cause in the shape of vibrations of the nerves of sensation and to the physical reactions produced by these vibrations. Through these circulatory psychic and nervous interactions, a vicious circle is set up and the ordinary gastro-intestinal, hepatic, renal and genital phenomena of neurasthenia of temporary dura-

¹ Journal of Mental Sci., 1884 and 1885.

tion occur. The appearance, therefore, of obsessions and of other neuropathic phenomena may be purely a product of causes arising in an individual from overwork, mental or other shock, and in no way indicate degeneracy. This last view that such phenomena must be the product of degeneracy, vitiates many valuable researches on the subject. Indeed, the whole Lombroso school is permeated by errors of this kind. These errors are the more striking since a century ago Tissot² laid great stress on the factor which produced in literati what have been excellently termed occupation disorders. Many of the nervous phenomena occurring in men of letters were referred, and with reason, to worry and uncertainty produced by circumstances connected with finance or their family life, and entirely disassociated from either their genius or from their heredity. The secondary influences of this acquired neuropathy, however, may produce, as Dr. E. S. Talbot³ says, a neurasthenia. Practically the neurasthenic in regard to his organs has taken on a degenerative function, albeit not degenerating in structure, since the restlessness of the organ is a return to the undue expenditure of force as it is unchecked by the central nervous system. Through the influence of various exhaustion agencies the spinal cord and the brain lose the gains of evolution and the neurasthenic is no longer adjusted to environment. Since the reproductive organs particularly suffer, children born after the acquirement of nervous exhaustion more or less checked in development, as the influence of atavism is healthy or not, repeat degenerations in the structure of their organs, which in the parent were represented by neurasthenic disorders in function. As the ovaries of the neurasthenic woman generally exhibit prominently the effects of the nervous exhaustion, the offspring of these do not retain enough vigor to pass through the normal process of development. For this reason genius very frequently leaves no posterity. The influence of the acquired "occupation disease" comes into play. Burns' genius led to dinner invitations, whence alcoholism. His sexual excess arose from the fact that hysterically sentimental females are attracted by the glare of genius and notoriety, like birds by a lighthouse lantern. From this springs sexual excess and abnormal marriages. The tendency to regard genius as irresponsible, based on the morbidity theory, tends to increase these factors of "occupation disease." In dealing, therefore, with the question of degeneracy in any person, care should be taken to demarcate it and its stigmata from acquired neurasthenia and its stigmata. The error has been made of attempting to separate mechanical genius from that of literati in respect to degeneracy. Dr. H. Gradle, at the Chicago Evolution Club, in 1894, asserted what was subsequently re-echoed by Dr. James Wier⁴ that (a fact not noticed by Lombroso or any other writer) "mechanical geniuses or those who for the most part deal with material facts do not as a rule show any signs of degeneracy.

Darwin, Galileo, Edison, Watts, Rumsey, Howe and Morse prove the truth of this assertion. It is only the genius of estheticism, the genius of emotion, that is generally accompanied by unmistakable signs of degeneracy." This error is an a priori one not based on a study of the authors quoted, or the lives of the geniuses cited. Lombroso⁵ points out that Darwin, among other stigmata of degeneracy, had a cretin-like physiognomy; that he stammered and that also in other respects he was a neuropath. Nisbet points out⁶ that the genealogy of Charles Darwin illustrates many of the neuropathic aspects of genius. He also shows that Galileo was a victim of neuropathy and at times suffered from melancholia, and cites stigmata in the family of Watts. Enough has been cited to show that the mechanical genius and man of science suffers as well as the esthetic class. This error is constantly made in discussing the nature of genius. Neither mechanical ability nor scientific acumen is an impenetrable cuirass against hereditary defect or occupation stress. Although science is less likely to lead to defect than the emotional state of the poet, still the great element of defect in poet and scientist alike has been financial anxiety or worry over success. Where these are removed, poets and scientists enjoy comparatively long life and good health when these are not interfered with by hereditary defect or acquired disease. The error involved in this confusion has a serious clinical aspect. From the notion that obsessions or imperative ideas are products of degeneracy alone, arises too often the ominous prognosis given to neurasthenics, which is fatal to their recovery.

FACTS AND THEORIES RELATING TO AUTOINTOXICATION.

In an address delivered before the Philadelphia Pathological Society,⁷ Chittenden states that as long as the normal rhythm of nutrition is maintained and the organs of secretion functionate normally, there is little occasion for noting the character of waste products of changes in the tissues. In disease conditions, however, the chemical nature and the physiologic action of these so-called waste products, more or less common to all active cells, demand attention.

It needs but little experience with the thyroid and suprarenal glands, for example, to learn that diminutive organs possess physiologic power out of all proportion to their size. The little groups of cells which constitute these glands manufacture substances which exercise a tremendous influence, directly or indirectly, on general metabolism. These substances may not perhaps be directly toxic, their specific action being perhaps rather in the line of prevention of formation of toxic substances elsewhere in the body. The metabolic processes are so intimately connected that disturbance of function in a small group of cells may indirectly modify processes going on in remote parts of the body. "The severing of a

³ *Degeneracy, its Causes and Effects*.

⁴ *Medical Record*, June 12, 1894.

⁵ *Man of Genius*. ⁶ *Insanity of Genius*.

⁷ *Proceedings Path. Soc. of Phila.*, June 1, 1899.

single strand in the skein may result in an entanglement fatal to life itself."

Normal products of katabolism may be distinctly toxic. Normally the body is protected against the toxic action by the rapid removal of these products, or through their conversion into harmless substances. Interference with either of these two processes may be dangerous to the organism. Toxic substances once formed may by their influence on metabolic processes increase the deviation from the normal. This notion of autointoxication does not exclude another form of toxemia, namely that resulting from absorption of products formed by intestinal bacteria.

Chittenden would therefore recognize the possibility of autointoxication resulting either because of the formation of normal products of tissue katabolism in undue amount, or on account of lack of speedy elimination or transformation. He then gives the evidence at hand to show that normal products of metabolism may be toxic; in muscle katabolism, as well as in katabolism in many glandular organs, the alloxuric or nuclein bases form part of the product. Among these substances is adenin, which has a marked toxic influence on dogs, in which it produces vomiting, refusal to take food, and after a few days death. Post-mortem shows intense gastro-enteritis, no matter whether the adenin is introduced subcutaneously or by way of the mouth. Especially noteworthy is the action of this substance on the kidney. Albuminuria, with leucocytes, granular and hyaline casts, results. Peculiar spheroliths, of more or less crystalline structure, are deposited in the kidney tubules; at the same time an abundant interstitial cell accumulation takes place.

Minkofski, to whose experiments we are principally indebted for these observations, finds that these spheroliths are composed mainly of uric acid. This shows that after the injection of adenin the excretion of uric acid from the urine is greatly diminished. At the same time there occurs a deposition of uric acid throughout the tissues of the kidney, accompanied by inflammatory changes in this organ. The exact source of the uric acid in this instance has not been established.

Hypoxanthin, a substance of similar origin, on the other hand, does not cause any disturbances in the body and is decomposed into uric acid and allantoin. Xanthin cannot resist changes within the body, but becomes more resistant when a methyl group is added to the xanthin molecule, at the same time as the toxicity increases. Of the resulting compounds, such as heteroxanthins, theobromin and caffein, in frogs heteroxanthin causes muscular rigor and paralysis of respiration.

Urea has long been considered as formed in the liver out of ammonium carbamate. When dogs from which the liver has been removed are fed with meats, symptoms of uremia develop, and the ammonium salt is found greatly increased in amount. The ammonium carbamate is formed in all the tissues and organs of the body, and its toxic action is neutralized in the liver when it is

converted into urea. When this function of the liver is interfered with, ammonium carbamate accumulates and causes autointoxication.

In certain conditions acetone is a common product of metabolism. It increases as fat is decomposed in the body and therefore acetonuria becomes especially marked in absolute fasting or when a fat diet alone is given; it is not present in a proteid diet. It is formed alike from body fat or from fat in the food, and thus it may make its appearance during hunger, when the body fat is being decomposed. Therefore, in order to prevent acetonuria one would give carbohydrates, in order to protect the fat of the food and of the tissues. The production of acetone is consequently also due to cell metabolism. Lack of carbohydrates leads to increased decomposition of body fat, resulting in a change in the proportion of secondary katabolic products eventually leading to acetone.

As to autointoxication from the intestinal tract, it has been shown by Herter's experiments on dogs and rabbits that indol is toxic, but in man its toxic power is slight. The production of toxins of various kinds is without doubt in many cases the initial cause of disturbances in metabolism, but no definite toxic body can as yet be held directly responsible for the results which eventually may appear. This, that, or the other substance, produced in due amount, may simply set in motion a chain of events from which is developed a chain of symptoms remotely connected with the primary action of the toxin. The sensitiveness of the nervous system to toxic substances renders it probable that autopoisons exert a primary influence here, and that many phases of autointoxication are due to primary disturbance of the nervous system.

LOCALIZATION OF MUSICAL CENTERS.

During the last two decades many investigators—Kussmaul, Stumpf, Preyer, Oppenheim, Knoblauch, Charcot, etc.—have conclusively demonstrated that the musical faculty is older than that of speech; that music is a primary and simple phenomenon, while speech is secondary and complex. It is a well-known fact that many birds possess the faculty of producing and reproducing themes, whereas there are but very few that can reproduce the human voice, even after a long tutelage. According to Darwin, wild dogs and jackals howl and learn to bark only after they have been domesticated. Their howl corresponds to song, and their barking to articulated speech. Owen has heard a gibbon sing an octave up and then down the scale. Stumpf relates that his child, 9 months old, could sing two tones, and when 14 months old a full octave. Preyer testifies that children between 8 and 9 months old could correctly sing a tune played on the piano. The daughter of a well-known composer, Dvorak, when 1½ years old, could sing a melody with decided modulations to the accompaniment of the piano; when 2 years old she sang the march from *Fatinitza*. The 3-year-old Lehman, the child phenomenon of a musical family, played in 1869,

in Zurich, besides Diabella and other pieces, also her own compositions, to the delight of a critical audience.

The following examples illustrate the independent functions of the musical centers. A virtuoso pianist could play most difficult airs during his sleep. A well-known violinist who was subject to attacks of petit mal, never ceased to play, even during his attacks, although he was oblivious of his surroundings. Oppenheim has described ten cases of aphasia, where the faculty of speech was absent, while the faculty of singing, the understanding of melody, notes, and the ability to play the violin remained intact. According to Wildermuth, idiots whose speech is defective have the musical faculties well developed. Seguin has observed a remarkable musical memory in an idiot who could reproduce on the piano any melody sung to him but once.

Cases of amusia, i. e., loss of ability to produce or comprehend music—an abnormality as regards music analogous to aphasia as regards the faculty of speech—conclusively demonstrate that the musical faculties do not depend on the speech faculty. Moreover, just as aphasia represents various forms of articulating defects, viz., the reading, writing, the pronunciation and comprehension of words, so does amusia represent various forms of auditory defects, viz., the reading and writing of notes, singing and playing on instruments, and the comprehension of musical works. Wallaschek and Ballet were the first to classify amusia into motor and sensory, musical agraphia and alexia, etc.

Lasegue observed a musician suffering from aphasia, who was unable to read or write, but could read and sing musical sentences with ease. Lichtheim reported a case of speech deafness who could hear whistling and singing well, but was unable to understand melody. Brazier has described a patient suffering from apoplexy without paresis and aphasia, but deaf to musical tones. The Marseillaise, played by the regimental orchestra, seemed to him like simple noises, while he himself could play the same and other tunes with ease. Charcot reported a case of a cornetist who lost the ability of using his buccinator muscles. Ballet describes a case of a professor of music who suddenly lost the ability of reading music.

The anatomic changes in amusia have been studied of late, and some light has been thrown on the subject. Edgren¹ has collected fifty-two cases of aphasia without amusia, aphasia with amusia, and amusia without aphasia. In Edgren's case the patient was deaf to musical tones; orchestral music seemed to him as noises without melody; he was unable to distinguish between a waltz, polka and march, but he heard and understood speech, and was himself able to speak. At the autopsy it was found that the anterior two-thirds of the first, and the anterior one-half of the second temporal convolutions of the left hemisphere, and the posterior half of the first temporal convolution of the right hemisphere of the cerebrum were destroyed. Edgren concludes from the above that there is only one musical center in the cerebrum,

and that it is situated in the anterior two-thirds of the first temporal convolution and in the anterior half of the second temporal convolution of the left lobe, i. e., in front of the center of Wernicke.

The physiologic experiments on animals, by Ferrier, Hitzig, Luciani and Tamburini, Bechtereff, Baginsky and Tonnini, have demonstrated that the auditory centers in various animals are situated in the temporal convolutions. The destruction of one of the temporal lobes causes almost complete deafness in the ear of the opposite side, and slight impairment of hearing of the ear of the same side. Munk², in his experiments on dogs, has found that the anterior third of the temporal lobe serves for the comprehension of high tones, the middle for middle, and the third for low tones.

Larionoff³ has made numerous ingenious experiments on dogs, with a view of defining the localization of the auditory centers, and has come to the following conclusions: There are several sensory musical centers situated in the posterior halves of the hemispheres, and several motor centers situated in the anterior halves of the hemispheres of the cerebrum. Of the sensory, two tone centers are situated in the temporal lobes, and one optic center, for the reading of notes, situated alongside of the center for ordinary reading, in the gyrus angularis. The motor center of notewriting probably develops alongside of the center for ordinary writing, in the second frontal convolution. The singing center is situated a little behind the motor center of speech of Broca, in the third frontal convolution, and is otherwise known as the center of Kraus'. The motor center presiding over the functions of performing on various instruments develops on exercising, in the anterior part of the central convolution alongside of the motor center of note writing. The center for playing wind instruments is developed in the region governing the movements of the lips, a little above the center of Krause.

There must certainly exist separate centers for the higher functions of music, musical images, conceptions and ideas. Musical images, and musical memory, judging from analogy with the centers of speech, are probably situated behind the tone centers in the region of the posterior association-centers of Flechsig. Musical conception, or the highest center of musical ideation develops in the frontal lobes in the region of the anterior association-centers of Flechsig.

It is to be hoped that greater light will be thrown on this interesting subject in the near future. Not only should autopsies be made in all cases of aphasia and amusia, but also in all deaf and dumb, the majority of whom, according to Bezold, suffer from affection of the auditory centers of the cerebrum.

MALARIA IN THE SOUDAN.

American experience with armies in unhealthy climates is not a peculiar one even in these days of sanitary progress. The British troops in the southern Soudan are, according to a late issue of the *British Medical*

¹ Deutsche Zeit. f. Nervenheilkunde, 1894, p. 1.

Journal (July 1), suffering from malaria to an extent that far exceeds our Cuban experience. At Fashoda, in the month of March, when the Nile was at its lowest, 280 out of a total of 307 were suffering from the fever. At Karkanji during November, no fewer than 308 out of a total of 390 were laid up, and at Sennaar and Abu Haraz matters were nearly as bad. Not only Europeans but Egyptians suffered. The troopers of the native Egyptian cavalry returning to Omdurman, from the Blue Nile, were almost to a man incapacitated by the fever, and their horses had to be brought down by the native Soudanese infantry. Even the indigenous inhabitants of the country along the Blue Nile do not escape, but are reported as extremely anemic from malarial poisoning. Knowing, as we do, what tropical malaria is and how severe it is often likely to be in its after-effects, this question becomes a serious one for the British military authorities. They undoubtedly have problems to meet in the occupation of their African possessions that will require their best attention. They are fortunate that yellow fever is not also one of their embarrassments, but the situation as regards malaria is had enough as it is. It is well for us to note such facts from time to time, to realize that while we have troubles of our own they are not altogether peculiar to ourselves.

FATALITIES OF THE FOURTH.

The fatality statistics of the Fourth of July are generally a striking item in the newspapers for a day or two after the anniversary, but the matter is then generally dropped. This year, contrary to the usual custom, the *Chicago Tribune* is keeping up the record and reporting the later as well as the immediate fatalities. In its issue of July 17 it gives a list of 144 deaths directly due to Fourth of July casualties, and another journal editorially remarks that in no Philippine battle has the American death-rate been anything approaching these figures. The chief medical point of interest is the very general prevalence of lockjaw after these accidents, 83 of the 144 deaths having been due to this cause. In New York, Boston, Pittsburg, and Philadelphia all the deaths reported were from this cause, while it was only a little less unusual in several other large cities. Why tetanus infection should be so prevalent on July 4, out of all days of the year, is a question we have not seen satisfactorily answered. The toy pistol has received credit heretofore for an undue proportion of tetanus-infected wounds, but it can hardly be responsible for the whole of the *Tribune's* formidable list. There seems to be an opportunity here for a thorough bacteriologic study which ought to have valuable practical as well as scientific results. Tetanus is a rare complication of ordinary wounds but on this particular holiday the infection seems to be rampant beyond all reason. The first duty of the hour, however, as the *Tribune* says, is not so much to discover the peculiar mode of infection as to remove the obvious original cause. It does not require study to discover that, and the remedy lies in legislation, provided the laws are rigidly enforced, not by empty proclamations of mayors or police instructions, not meant to be obeyed, but by absolute stoppage of the sale and use of the deadly toy pistol and the giant cracker, or still better, the suppression

of the whole class of peace-destroying noise-creators in the hands of reckless and irresponsible youths. If we need a more severe lesson, we are pretty certain to get it if we let matters go on. The useless sacrifice of human life has no excuse, and the effort of the *Tribune* to arouse public sentiment against the senseless custom is most praiseworthy. The *JOURNAL* takes this opportunity to most heartily endorse its action.

MICHIGAN MEDICAL LAWS.

A law recently enacted in Michigan classes with idiots and insane, those suffering from uncured syphilis and gonorrhoea, as incapable of marriage. They are not reckoned with idiots and insane, however, as regards responsibility, for it provides that "any person who has been afflicted with syphilis or gonorrhoea and has not been cured of the same, who shall marry shall be deemed guilty of a felony, and upon conviction thereof in any court of competent jurisdiction, shall be punished by a fine of not less than \$500 or more than \$1000, or imprisoned in the State prison at Jackson not more than five years, or by both such fine and imprisonment in the discretion of the court." The law also provides that the wife can testify against her husband, and vice versa, and removes the privilege of medical secrecy in proceedings for this cause. The enforcement of this law will be noted with interest, and it is possible some important new medicolegal question may arise; the questions of the curability and the evidence of cure of these disorders may come up in the courts. Considering the frequency of these disorders, especially gonorrhoea, it would seem possible that there is danger of a serious diminution in the number of marriages as a result of such law, and also that it might afford possibilities of blackmail and inconvenient family complications. On the other hand, if it will tend to improve morality and diminish the undesired suffering that these diseases so often entail, one can only wish the new law success. Another Michigan enactment provides that it shall be unlawful for "any person or corporation except a legally incorporated and reputable college of medicine and surgery having and requiring actual attendance at a course of study of not less than three years of eight months each to issue a diploma or certificate setting forth or implying that the holder thereof is qualified to practice medicine or surgery in any of their branches." This, we take it, applies to the diplomas of the notorious St. Luke's Hospital of Niles, and thus helps in wiping out medical diploma-mills. A penal clause is attached to this law, which will make it imprudent to violate it, and its enforcement ought to be easily practicable. With its new medical practice act and this measure, Michigan ought to be well protected against bogus diplomates and quacks.

NATIONAL DEPARTMENT OF HEALTH.

The coming Congress cannot consistently disregard the voice of the medical profession of the United States, demanding the speedy establishment of a national department of health, first formally expressed by the American Public Health Association, the foremost sanitary organization in the United States, Canada and Mexico, then deliberately and enthusiastically indorsed by the

AMERICAN MEDICAL ASSOCIATION, the representative body of medical men of the entire country; and recommended with practical unanimity—three delegates not voting—by the National Conference of State and Provincial Boards of Health of North America, at its recent meeting in Richmond, Va. While the Canadian and Mexican health officials are constituent parts of this conference, their participation in the act of approval was of the most unselfish character, since both the Dominion and the Republic of Mexico already possess well-organized Federal health departments, such as sanitarians in the United States have so long desired. The executive authority in Canada is vested in the Director General of Public Health of the Dominion, Dr. Frederick Montizambert, who has the status of a deputy minister; and that of Mexico in the Superior Board of Health, of which Dr. Edward Liceaga is president. The scheme proposed and accepted by all three of the national medical and sanitary associations mentioned, and generally known as the Spooner bill, differs in detail from both these, the more direct influence of the several state boards of health being recognized, in accordance with our system of state potentiality, in the composition of the contemplated national board. The indorsement of this measure by the conference of state boards has been, as it were, emphasized by the election of Dr. U. O. B. Wingate, commissioner of health, Milwaukee, Wis., who has been identified with its advocacy on the part of the American Public Health Association and the AMERICAN MEDICAL ASSOCIATION, to the presidency for the ensuing year. Especially since the acquisition of our tropic dependencies have the requisitions of an independent board of health of a distinctively national character been greatly augmented, while the necessity for immediate legislation has become more urgent. Since the several state boards of health are not willing to subordinate themselves to the makeshift methods—of which they have had sufficient experience—of a bureau created for another purpose, but unite in demanding a well-organized responsible, national board, with executive authority, Congress has no alternative but to meet the requisition in the manner indicated by the concerted opinion of the medical and sanitary professionals of the whole country.

LOCOMOTOR ATAXIA WITH CANCRUM ORIS AS A FATAL COMPLICATION.

While the exact nature of cancrum oris is not yet understood, its appearance, course, and termination would stamp it as an infectious process of great virulence. The condition most commonly attends the exanthemata in debilitated children, and it is almost universally fatal. It has also occasionally been observed in adults. Bacteriologic investigation has thus far resulted in the isolation of several different bacteria from the area of disease, but none of these can as yet be considered specific or causative. Therapeutic measures have also been entirely futile in controlling the progress of the disorder or in preventing a fatal issue. A case presenting features of more than ordinary interest has recently been reported by Ness¹—one of locomotor ataxia in a woman in whom cancrum oris developed as a fatal complication. The patient was 48 years old

and had complained of shooting pains in the lower extremities, with paresthesia and a sense of weakness and stiffness about the knee-joint. In a short while, difficulty in walking in the dark and in turning quickly was experienced, and gradually became more marked. There was also difficulty in expulsion of urine and the bowels were constipated, although they became unduly relaxed when laxatives were administered even in small doses. Station was much disturbed. Analgesia and anesthesia were found in both legs below the knees. The knee-jerks were completely abolished. The plantar reflexes were much exaggerated, and the abdominal reflexes and jaw-jerks were well marked. Muscular sense was preserved. There was a slight nystagmus. The pupils were contracted and almost insensible to light stimulus, while they contracted slightly in accommodation. The optic discs were slightly oval, but otherwise normal. A history of alcoholic indulgence was obtained, but none of syphilis. In the progress of the case symptoms of cystitis appeared, and increased severity of the pains required the administration of analgesics. Complaint of obscuration of vision in the right eye led to the detection of a large hemorrhage in the macular region. Vomiting set in, and the patient grew progressively worse. Finally, the temperature became elevated, and the swelling of the lower part of the face on both sides appeared, and to a less extent of the neck immediately below the jaw. The swelling was hard to the touch, as if the tissues were infiltrated with inflammatory products, while the skin itself was but little reddened. In the course of a few days the swelling of the neck had diminished somewhat, but that of the cheeks had increased, while both parotid glands were greatly enlarged. The patient now had a short rigor, and soon the mucous membrane of the mouth also became involved. The condition grew progressively worse, the tissues of the cheek began to slough, diarrhea set in, with incontinence of feces, and the patient gradually sank and died. On post-mortem examination, in addition to the lesions described, considerable necrosis of the under surface of the right temporosphenoidal lobe was found, as a result of extension of the gangrenous process from the cheeks through the skull and the base of the brain. Degenerative changes were found in both the columns of Burdach and the columns of Goll.

Medical News.

DR. JAMES C. WILSON, Philadelphia, sails July 27 for Europe, to be gone several months.

ADDITIONS costing \$10,000 are to be made to the University Medical College, Kansas City, Mo.

A ROOF GARDEN for convalescents is to be added to the Union Protestant Infirmary at Baltimore, Md.

DR. J. E. BROWN has retired from the managing editorship of the *Columbus* (Ohio) *Medical Journal*.

DR. E. E. HUBBARD, Kansas City, Mo., has been made demonstrator of pathology in the Medico-Chirurgical College of that city.

DR. M. S. FRENCH, Philadelphia, who was secretary of the National Relief Association during the recent war with Spain, has gone to Europe for rest and recreation.

THE RECEIVING wards of the University Hospital,

¹ *Edinburgh Med. Jour.*, June 1899, p. 505.

Philadelphia, are being enlarged on account of the increased number of patients being treated there.

THE ROYAL College of Surgeons of England will celebrate its centenary next year, and preparations are already being made looking forward to the event.

THE HEAD physician of an asylum at Rome, Italy, Dr. Bondi, was recently fatally stabbed on the street by a former patient whom he had discharged as cured.

DR. E. C. RENAUD, St. Louis, Mo., and Dr. E. O. Sisson, Keokuk, Iowa, sail July 29 for Europe to attend the International Ophthalmological Congress, in Utrecht.

ACCORDING to press reports the Ohio State Board of Medical Examination and Registration has refused to recognize Hygiea Medical College, or to issue certificates to its graduates.

BY THE wills of Martin H. Lehmaier and David Krakaner, the Mount Sinai Hospital, New York City, received \$3500, of which \$2500 is for the founding of a memorial bed.

ON JULY 12 the graduation exercises of the San Francisco College of Physicians and Surgeons were held. Nineteen men were given diplomas. This college was organized some three years ago.

AT THE recent centennial celebration of the Norwegian residents of Chicago, about \$2000 was realized for the benefit of the Norwegian Lutheran Tabitha Hospital of this city.

ACCORDING to the daily papers of Detroit, the question of continuing to employ teachers who are afflicted with consumption is being agitated in that city, although nothing definite has been done.

DR. A. GOLDSPOHN of Chicago leaves for Europe this week. He goes to attend the International Congress of Gynecologists and Obstetricians, at Amsterdam, and will be gone about three months.

THE OREGON volunteers arrived in the port of San Francisco, on the transports *Ohio* and *Newport*, July 13. The list of deaths in the Oregon regiment numbers 59, the major portion due to disease rather than to wounds.

SIR WILLIAM CROOKES, F. R. S., England, has had conferred on him the Albert Medal of the Society of Arts, "for his extensive and laborious researches in chemistry and physics."

DR. F. E. WAXHAM, having concluded to return to Denver on account of ill health in Chicago, has accepted the chair of internal medicine and laryngology in the medical department of the University of Colorado.

THE MANAGERS of the Maryland School for Feeble-Minded, at Owing's Mills, are contemplating extensive improvements for this institution, to include the erection of a general administration building and several cottages.

THE PARIS ACADEMIE DE MEDECINE has recently elected Professor Hutinel to membership. He occupies one of the two chairs of internal pathology in the Faculty, and is a prominent authority on children's diseases.

SINCE SUCH a long struggle over what is known as the Loan Bill has been won by those in favor of greater improvement of Philadelphia, this city has set aside the sum of \$500,000 for the improvement of its system of sewerage.

UNDER the auspices of the Children's Country Week Association, Philadelphia, 286 children were, during the past week, taken to the country for a few days' outing.

This Association deserves great credit for its efforts in lessening the infantile mortality during the hot months.

THE FIRST number of the *Illinois Medical Journal*, the new official organ of the Illinois State Medical Society, has been received. It is well printed, well edited, clear and attractive, and reflects credit on the society and especially on the committee on publication.

SINCE the festivities of July there have been reported in Pennsylvania 13 cases of tetanus, of which 11 have already resulted fatally. Doubtless as many cases have occurred which have not been reported. In 9 instances tetanus arose from lacerated wounds of the hands, and 4 from gunshot wounds.

DR. JAMES MOORES BALL, St. Louis, Mo., will attend the International Ophthalmological Congress, which convenes in Utrecht, in August. He will read a paper before the Congress on "Excision of the Cervical Sympathetic for Glaucoma," reporting four operations, which are believed to be the first made in this country.

THE NEW buildings of the Jefferson Medical College, Philadelphia, will be formally opened on October 2, next. Dr. T. A. Emmet of New York, one of its graduates, will preside. The principal address will be given by Dr. Phineas S. Conner of Cincinnati, who is a graduate of Jefferson. The old college building will give place to a new and enlarged hospital, eventually.

SUIT HAS been entered against the city of Baltimore, Md., for \$5000 damages for injurious effects resulting from compulsory vaccination. The plaintiff is a young woman employed in a business house, who claims that she was made ill by the operation and rendered unfit for her regular duty.

THE COMMISSIONER of health of that city, has been making some studies in the prevalence of consumption in Baltimore. He finds that in 1898 the greatest number of deaths occurred in the crowded sections, that is, in the tenement districts and in the negro settlements of the city.

A MAN living in Allentown, Pa., is reported as having been arrested on the charge that he had failed to comply with the laws regarding infectious diseases, in that city. He neither reported the case nor did he call in medical attendance in the case of his child, who subsequently died of scarlet fever. He had no faith in physicians, and further said, "when the Lord called a child no physician could save it."

THE CHINESE Consul General is said to have filed an objection to the decision of General Brooke that commercial treaties between Spain and other foreign countries do not apply to Cuba, and further, that negotiations must therefore be made with the United States in the name of Cuba. It is further stated that the main objection raised is that the Cubans are afraid of the introduction of leprosy by the Chinese.

A PHYSICIAN of Chambersburg, Pa., who is a graduate of the School of Medicine of the University of Maryland, and holds a license from the Board of Medical Examiners of Maryland, recently claimed of the Pennsylvania Medical Council the privilege of a license from that body on the above grounds. The license was refused and the matter taken into the courts, which have sustained the Council in its action.

THE WIDOW of the late Dr. A. A. Kanthack, professor of pathology of Cambridge (England) University, whose early death may be attributed to the sacrificial work he did in the cause of medical science, has just been granted a pension of £60—\$300—a year. "In consideration of the eminent services rendered to science by

her late husband." What a pity it is that our government cannot recognize work in this country in the same way.

ACCORDING to *Echo Med.*, July 2, Marguerite Boyenval, the celebrated sleeping woman at Thénelles, France, recently entered her seventeenth year of continuous slumber, the most curious case of lethargy ever scientifically observed. Now 35 years of age, her pallor and emaciation are extreme, although the pulse-beat is over 80. The skin is without sensation, and the arm, if lifted, remains in the air. The only nourishment is by occasional rectal injection.

ACCORDING to press dispatches, Mr. Broderick, replying to Sir Charles Cameron (Liberal), in the English House of Commons, stated that the attention of the foreign office had not been previously called to the fact that, owing to the deaths from cancer, the New York Legislature had endowed a laboratory at Buffalo to study the disease, and further that the British Charge d'Affaires at Washington would forthwith be asked to furnish the government with all possible information regarding the subject.

THE TOTAL expense of Pozzi's new gynecologic pavilion at Paris, with its sixty-six beds, amounted to \$88,000. The pavilion is like an art gallery, set down among the buildings of the Broca Hospital, of which it forms a part, as the walls were richly decorated with frescoed landscapes, etc., by some of the foremost artists of the day, at Pozzi's appeal. Other special features are an arrangement for "permanent baths," another for vaginal flushings with sixty liters of water, and a lay committee to care for convalescents after dismissal.

AN UNUSUALLY large number of cases of tetanus, with many deaths, have lately been reported in New York City and vicinity, most of them the result of pistol-shot wounds of the hand during the recent Fourth of July celebration. Several of the cases received intracerebral injections of tetanus antitoxin, and in each case the serum had an immediate effect on the symptoms, tending to show that—as was the case with those in which it was administered early—it would have proved curative if it could have been resorted to before the infection had advanced too far.

ON JULY 11 the Board of Charities and Corrections elected Dr. H. W. Cattell pathologist to the Philadelphia (Blockley) Hospital, to succeed Dr. John Guitéras, resigned. Dr. Cattell was born in Harrisburg, in 1862, and is a graduate of the University of Pennsylvania, 1887, and was for a number of years demonstrator of morbid anatomy in that institution. He was also editor of the *International Medical Magazine* for a long period, but is probably best known for his work in the translation of Ziegler's "Pathology" (American Edition).

AS TO THE danger of infection from domestic animals and pets, Dr. Keville of Baltimore has found diphtheria markedly prevalent among pigeons, and cases have been reported where the disease has been communicated by them to men. It is also readily communicated from pigeons to rabbits when the two are cooped together. He says that the "gapes" in chickens is probably diphtheria, and the "worm" which is drawn from the throat by poultry raisers is usually a piece of membrane. There is also danger of infection lurking in the fur, hair and feathers.

THE FIRST step has been accomplished in the rebuilding of the Charité Hospital at Berlin: the pathologic

museum has been completed, thanks to Virchow's untiring efforts. It has been most justly named after him, and represents all that science and experience can suggest for the utilization of the rich collection for study and class teaching. As the general public now learns at once of scientific matters, the management has thrown open part of the museum to the knowledge-hungry layman that he may learn by personal observation rather than from partially-comprehended newspaper articles.

AT A RECENT meeting in New York City, called by the Medical and Legal Relief Society, a rough draft of a bill designed to protect the public from the interference of "Christian Scientists" in the care of the sick was presented. The bill provided that whoever advised or persuaded another against employing medical or surgical aid in cases of illness or injury, will be guilty of a misdemeanor, and if such illness or injury result fatally, shall be guilty of manslaughter, provided no medical or surgical aid has been received by the patient. The bill was referred to a committee of nine, appointed by the president of the society.

A NEUROLOGICAL SOCIETY was organized in Paris, June 8. It has adopted as one of its by-laws that no member shall present a paper which will require more than fifteen minutes in its delivery, or occupy more than one page of the official organ, in print. The official organ will be the *Revue Neurologique*, which will be issued on the fifteenth of each month. The officers of the society are: president, Professor Joffroy; vice-president, Professor Raymond; secretary, M. Pierre Marie.

THE PARIS correspondent of the *Lancet* states that a Parisian who was lately traveling by train refused to show his ticket to a traveling inspector of the company. The passenger was accordingly summoned by the company for refusing to show his ticket, as he was bound to do by law. He argued, however, that he had not refused to show it (présenter), that he had let the inspector see it so that he could easily satisfy himself as to its being in order, but that he certainly had refused to let the ticket inspector take it into his hands because his hands were so dirty. He, the passenger, therefore was unwilling to put into his pocket a ticket which would be contaminated with microbes and might very likely give him some disease. After a long legal discussion as to the exact meaning of the word "show" (présenter) the court fined the ardent disciple of modern hygiene the sum of one franc.

REPRESENTATIVE W. L. CLIFFE, of the State Pharmaceutical Association of Pennsylvania, recently called on the chief officer in the Bureau of Health office relative to an act lately passed by the Legislature prohibiting the sale of medicines and drugs in second-hand bottles and jars. Mr. Cliffe is reported as saying: (*Ledger*)—"Under the terms of the act it is unlawful for a druggist to fill a bottle brought to his store by a customer unless a prescription is to be refilled. If, for instance, the customer wants Jamaica ginger and brings a bottle which has contained Jamaica ginger the druggist must tell him that he must buy a new bottle. From this fact the customer might think the druggist was working for his pecuniary interest." In his opinion the law will result in much confusion. The penalty is a fine of not more than \$25 or imprisonment for the first offense, any subsequent offense to be punished by a fine of \$100 or imprisonment not to exceed three months. No legal opinion has yet been expressed.

AN INVESTIGATION by the Lunacy Commission and

the Board of Directors, conjointly, is being held at the Agnew's Insane Asylum, California. Some time ago it became evident that a female patient was pregnant, and as she has been confined to the asylum for some time conception must have commenced while a patient in the asylum. A "trusty" had been seen at various times, by both patients and attendants, to enter a basement window of the women's building. It is stated by the attendants that the fact was at once reported to the superintendent, Dr. F. M. Sponagle, on the daily written reports. When the reports were called for by the investigators, those for the days mentioned by the attendants were found missing, so that no written evidence of the fact having been reported is available. It is rumored that the Napa Asylum is also to be investigated, as stories of similar occurrences at that institution are current. These stories are vigorously denied by the officials at Napa.

BRITISH MEDICAL ASSOCIATION.—The sixty-seventh annual meeting of the British Medical Association will be held at Portsmouth, Eng., August 1, 2, 3 and 4. The meetings of this Association are conducted in a similar manner to those of the AMERICAN MEDICAL ASSOCIATION, being different only in minor details, although there is evidently more time devoted to social functions by our British brothers than is our custom. The working body of the Association is divided up into twelve sections, viz.: *a*, medicine; *b*, surgery; *c*, obstetrics and gynecology; *d*, state medicine; *e*, psychology; *f*, anatomy and physiology; *g*, pathology; *h*, ophthalmology; *i*, diseases of children; *j*, pharmacology and therapeutics; *k*, laryngology and otology; *l*, tropical diseases. The first meeting is a religious one, and is held at one of the large churches, at which a sermon is preached and regular church services conducted. This year the sermon will be preached by the Bishop of Winchester. The general meetings for business, etc., are held in the afternoon. There is no address made at the first meeting, the time being devoted to a report of the Council, reports of committees and other general business. At the general meeting of the second day is delivered the Address in Medicine; this year Sir Richard Douglas Powell is the orator. At the third session, Thursday afternoon, is given the Address in Surgery, by Professor Alexander Ogston. The concluding general meeting is held Friday afternoon, and devoted entirely to business. The section meetings are usually held from 10 a.m. to 1 p.m., and judging from the program, this is all the time that is devoted to section work. No section dinners are held, but in place of these is the great association dinner, to be held on Thursday evening at 7 o'clock. The evening sessions are given up partly to business and partly to pleasure. The first evening, at 8:30, there is a general session, at which the president's address is delivered. On Wednesday evening a reception and concert is to be given by the local profession. On Thursday evening the annual dinner of the Association, which has been referred to above, will be given; later, at 9:30, a reception. Friday afternoon local excursions will take place, and in the evening a reception and ball is given by the Mayor and Mayoress of the city at which the meeting is held. Saturday is, as a rule, devoted entirely to excursions. This year there will be four of these. One is to Salisbury and Stonehenge, which means a trip by rail, and visit to important places at Salisbury and Stonehenge, luncheon tendered by the resident members of the profession and return by coach. The second excursion is to Winchester, which is by rail to this interesting and

historic city, with entertainment at luncheon, and return by a different route. The third is the one that would be of the most interest to the majority, it being to the Isle of Wight and Ventnor, and the fourth is to Southampton and the New Forest. As a rule, few of the members of the Association leave before Saturday, and practically all join in these excursions, which are, as a rule, a pleasant relaxation after the week's work, and full of social pleasure. Several members of the profession from the United States are represented in the program as follows: Dr. Woods Hutchinson has a paper on "The Form of the Chest in Tuberculosis, and its Significance;" Ernest Laplace exhibits his new Forceps for Intestinal Anastomosis. Among those on the program for discussion we note Drs. James Tyson of Philadelphia; Wm. Osler of Baltimore; Herman Knapp of New York; Samuel Risley, Philadelphia; George E. deSchweitz, Philadelphia; Samuel Theobald, Baltimore; Stephen Ayres, Cincinnati; H. Scheppegrell, New Orleans; Sargent Snow, Syracuse, N. Y., and J. H. Bryan, Washington.

Therapeutics.

Urotropin in Septic Infection of the Bladder.

This new drug is receiving favorable mention by many observers. In closing a clinical report in *Die Therapie der Gegenwart*, the author, Prof. O. Huebner of Berlin, says:

In the first place it seems desirable only to employ the urotropin treatment in cases in which the alkaline or neutral reaction of the freshly voided urine demonstrates the early appearance in that fluid.

In the second place the administration of the drug must not be discontinued too soon after improvement in the patient's condition has appeared. It will probably be best to continue the use of the urotropin steadily for three weeks, provided that any improvement at all is seen. If then it is discontinued, and the urine again becomes turbid and foul, it should be administered anew for double the length of time; to be then stopped for trial as to the permanency of its effect. A third course, for a still longer time, may then be necessary, etc. The older the disease the longer will be the course of treatment for which we must be prepared.

No objectionable effects upon the digestion or the nervous system from the prolonged use of urotropin in the doses that I used was observed by me. These were 9 to 30 grains (.6-1.95 gm.) daily in children from 7 to 10 years of age. In one case a four-year-old child bore daily amounts of 15 grains (1 gm.) in 3½-grain (.25 gm.) doses very well. I always administered the drug in divided doses of 3½ to 6 grains (.25-.39 gm.) given three or four times daily.

The drug has been declared of exceptional value in all the suppurative diseases of the genito-urinary tract; such as pyelitis, cystitis, with ammoniacal decomposition of the urine,—whether due to stricture or bacillary infection—chronic posterior urethritis, prostatitis, and inflammation of the pelvis of the kidney. It is an antidote for the urinary poisoning which so commonly occurs in these cases. In gouty and rheumatic affections, where increased activity of elimination of uric acid and urates is required, its beneficial effect is marked. It is very useful in phosphaturia, its action being apparent for a considerable time after cessation of its administration. It should be employed as preparatory treatment in every case of operation upon the urinary organs, to approximately sterilize the urine and prevent infection of the wound.

Crede's Ointment in Cerebrospinal Meningitis.

Schirmer reported nine cases, in the *New York Med. Monats*, treated by inunctions of unguentum Crede one ounce (31.10 gm.) being applied daily for three days and in case of a relapse one-third of an ounce (10.36 gm.) As adjuvants to the remedy hot water was applied to the spine, and trional ad-

ministered as a sedative when necessary. The nasal fossæ were disinfected. In the cases reported there were no mortalities and no sequela, while in several of the cases, the inoculations were followed by immediate improvement.

Headaches.

Dr. Joseph Collins suggests the following prescriptions for various forms of headache:

- R. Pulv. opii.....gr. ss 03
- Zinci phosphidi.....gr. ss 03
- M. Ft. pil No. xx. Sig. One pill three times a day for headaches following the infectious and exogenous intoxicants.

Early in the treatment the following tonic should be administered:

- R. Ferri et ammonii citrat.....gr. xl 2/60
- Liq. potass arsenit.....m. xl 2/50
- Syrup zingiber.....ʒss 15/55
- Infusi calumbæ. ad.....ʒiv 124/40
- M. Sig. Two teaspoonfuls after meals.

UREMIC HEADACHE.

- R. Potassii citratis.....ʒiii 7/80
- Tinct. hyoscyami.....ʒiii 7/80
- Spts. eth. nit.....ʒiii 7/80
- Infusi scoparie.....ʒvi 23/40
- M. Sig. Tablespoonful in water three times a day.

HEADACHE ASSOCIATED WITH FLATULENCY AND PYROSIAS.

- R. Sodii bicarb.
- Bismuthi subgall.
- Pulv. acacia aa.....ʒi 3/90
- Liq. ammon. anisi.....ʒiii 7/80
- Aque destill. ad.....ʒviii 248/80
- M. Sig. Two tablespoonfuls before meals, repeated in three hours if necessary.

HEADACHE WITH ATONIC DYSPEPSIA.

In headaches associated with atonic dyspepsia, but without any considerable flatulency, Collins makes use of the following pills, and especially in the headaches occurring in women:

- R. Ferri sulph.
- Quinin sulph. aa.....gr. xv 1
- Sodii arsenitis.....gr. ss 03
- Pulv. rhei.....gr. x 65
- Pulv. zingiber. aa.....gr. x 65
- M. Ft. pil No. 12. Sig. One pill three times a day after meals.

HEADACHE FROM SLUGGISH CIRCULATION.

- R. Ext. cannabis ind.....gr.1/3 02
- Ext. gennabi.....q. s
- M. Ft. pil.

HEADACHES FROM GENERAL ANEMIA.

To overcome the sluggish condition of the digestive tract with headaches dependent upon a general anemia:

- R. Quinin sulph.
- Ext. aloes aq. aa.....gr. xii 78
- Pulv. capsici.....gr. vi 39
- Pulv. ipecac. aa.....gr. vi 39
- Glycerin. q. s.
- M. Ft. pil No. 12. Sig. One pill at midday.

If associated with considerable vital depression, he uses the following pill instead, giving at the same time some absorbable form of iron:

- R. Ext. meis vom.....gr. ss 03
- Pil. rhei comp.....gr. iii 20
- Pulv. capsici.....gr. ¼ 016
- M. Ft. pil. Sig. One pill at midday.

NEURASTHENIC HEADACHE.

Hamilton prescribes the following in neurasthenic headache:

- R. Ammon. carb.....ʒiii 11/70
- Tinct. moschi.....ʒvi 23/40
- Spts. lavandulæ.....ʒi 31/10
- Extr ammon. valerianat.....ʒviii 248/80
- M. Sig. Two teaspoonfuls at a dose in water.

The following is recommended by Lucking:

- R. Ext. cannabis ind.....gr. 1/6 010
- Zinci phosphidi.....gr. 1/10 006
- Acidi arseniosi.....gr. 1/30 002

For one pill. Give twice daily for some time.

Leonard Weber claims that the following combination will relieve headaches promptly, and better than any single colateral remedy:

- R. Acetanilid.....gr. i 065
- Phenacetin.....gr. v 32
- Antipyrin.....gr. v 32
- M. Sig. For one powder.

HEADACHE DEPENDENT UPON OVARIAN DISEASE.

- R. Ammonii bromid.....ʒvi 23/40
- Ext. hydrastis fl.....ʒss 15/50
- Tinct. gentian comp.....ʒss 46/60
- Aque.....ʒiv 124/40
- M. Sig. A dessertspoonful three times a day. —Sinkler.

Quinsy.

- R. Tinct. aconiti rad.....m. xvi 1
- Tinct. ferri chlor.....ʒi 3/90
- Sodii chloratis.....ʒi 3/90
- Glycerin.....ʒvi 23/40
- Aque, q. s. ad.....ʒii 62/20
- M. Sig. A teaspoonful every hour to be swallowed slowly and left as long as possible in contact with the fauces. —A. H. Smith.

- R. Potassii bromid.....gr. lxxx 5/20
- Sodii salicyl.....ʒi 3/90
- Tinct. opii deod.....ʒi 3/90
- Cascara cordial, q. s. ad.....ʒi 31/10
- M. Sig. Teaspoonful every four hours in water. —E. Fletcher Ingals.

- R. Tinct. guaiaci ammon.
- Tinct. cinchone comp. aa.....ʒss 15/50
- Mellis despumat.....ʒss 46/60
- Benc simul agita, et adde:
- Potassi chlorat.....ʒiiss 9/75
- Aque, q. s. ad.....ʒviii 248/80
- Fiat gargarysma. Sig. Use as a gargle every half hour and swallow a teaspoonful every four hours. —Samuel O. L. Potter...

- R. Ol. eucalypti.....m. xv 7/2
- Spts. camphor.....ʒss 5/85
- Tinct. guaiaci.....ʒiiss 13/65
- Glycerin, q. s. ad.....ʒi 31/10
- M. Sig. Ten drops on sugar, to dissolve in the mouth, every hour or two. —Miles.

Hay Asthma.

The asthma of hay-fever is often intense and demands measures for its relief apart from what may be done for the constitutional condition. A combination which has served this purpose most efficiently in a large number of cases is the following, which was originally advised by Mays:

- R. Phenacetin.....gr. lxxiv 4/16
- Quinin sulph.....gr. xxii 1/43
- Ammonium chlorid.....gr. xc 5/85
- Pulv. capsicum.....gr. iv 26
- Strychnin sulph.....gr. i 065

Make in 32 capsules and give one as needed.

The phenacetin here relieves the neurotic portion of the attack which is often very prominent. The quinin is antiperiodic. The ammonium chlorid is strongly expectorant and markedly relieves the congestion of the mucous membranes. The capsicum neutralizes the depressant effect on the stomach of the phenacetin, while the strychnin of course is the strongest general tonic with very powerful action upon the respiratory system.

Cholera Infantum.

In the treatment of cholera infantum it must never be forgotten that wonderful results are possible, even in apparently moribund cases, from thorough flushing of the colon. In an infant of 14 months, ill with this disease for sixty hours, with cyanotic skin, cold extremities and a rectal temperature of 104 degrees, Stengel reports immediate relief from the pressing symptoms, with ultimate recovery, by the introduction into the bowel, through a catheter inserted 12 inches, of two quarts of water at a temperature of 90 degrees. The water is permitted to flow out through the tube, thus washing the bowel as thoroughly as possible to free it of infective and fermenting

material. By this method the temperature is reduced more surely than by the bath, and at the same time rational and harmless effort is made to remove the cause of the disease. Very often also in these cases the terrible collapse is in no small part due to a circulation depressed by the loss of blood-serum through the watery discharges from the bowels. These discharges are so profuse that the amount of uncombined water in the tissues rapidly becomes tremendously reduced, and the heart fails from very lack of sufficient pressure in the vena cava to fill the auricle, by reason of diminution in the quantity of the circulating fluid. This indication for relief, of what is practically shock, is promptly and surely met by leaving in the bowl, for absorption after the flushing, a small quantity of water. Beyond doubt it is the prompt absorption of this fluid by the thirsty tissues that causes these little patients so instantly to show beginning recovery from their terrible collapse. In addition a few fractional doses of calomel to clear the upper bowel of offending material, a diffusible antiseptic, such as spirits of chloroform and aromatic sulphuric acid, with a little paregoric for the powerful supporting qualities of the opium, and sponging the skin with cool water or alcohol, constitute a practical, simple and effective method of dealing with these distressing cases.

Acute Diarrhea.

A very excellent formula for the acute diarrhea of children in summer is one suggested by Hare. It combines antiseptic and astringent properties with the supporting and analgesic qualities of minute doses of opium. It is as follows:

R. Aromatic acid sulph.	gtt. xxiv	1	20
Ol. caryoph.	m. viii		50
Tinct. opii. camph.	℥ss	3	75
Spts. chloroform.	gtt. xlviii	2	40
Syrup zingiber q. s. ad.	℥iij		90
Mix. Sig. A teaspoonful every two hours.			

Miscellany.

Foreign Bodies in Esophagus.—If a fish bone or any foreign object has been swallowed, it can be safely and easily extracted, according to a communication in the *Journal d'Hygiene* of June 29, by swallowing some thread snarled into a tangle, keeping hold of one end of the thread. When it has been swallowed, pulling it out by the end held will bring the foreign article with it.

Treatment of Exophthalmus by Ligature of Carotis.—There are 58 cases of exophthalmus on record, treated by ligating the carotis communis, with 26 cures. Bodon reports 2 more, both successful. In one the affection persisted until the carotis on both sides was ligated. The dilated vena ophthalmica was resected on account of violent, continuous headache.—*Deutsche Zftf. f. Chir.*, li. 6.

Malaria and Lime.—A recent communication to the Paris Academie de Medecine asserts that countries in which the upper layers of the soil, the mud and river beds, contain a large proportion of lime, are exempt from malaria, and suggests that malaria might possibly be banished from localities where it prevails by artificially incorporating lime with the superficial layers of the soil.

Tuberculous Splenomegalia.—A case diagnosed as a malignant neoplasm of the spleen, accompanied by influenza, phlegmasia alba and diarrhea, although the blood was normal, was found at the autopsy to be primary tuberculosis of the spleen with no manifestations elsewhere. The organ was enormous (1200 gr.), the hypertrophy caused by hemorrhages and necrosis of the splenic tissue.—*Gaz. degli Osp.*, June 27.

Roux Method of Preventing Relapse of Femoral Hernia.—After removing the hernial sac the femoral vessels are drawn out and Poupart's ligament fastened to the pubis with a pointed wire shaped like a double pointed tack, driven into the pubis, slightly slanting, so that one leg is nearer the interior of the

pelvis than the other. This contrivance affords a solid support like a lattice work, preventing the recurrence of the rupture. —*Anjou Med.*, 1899, No. 2.

Old Oregon Law Repealed.—The supreme court of Oregon holds, in *re Ferdon*, that the medical practice act of that state, of 1895, operates as a repeal of the former law on the subject, including in its repeal the provision in the act of 1899, as amended in 1891, which required that any itinerant vendor of any drug, nostrum, medicine, ointment or appliance of any kind intended for the treatment of disease or injury, who should, by writing or printing or any other method, publicly profess to cure or treat diseases, injuries, deformities or ailments of any kind thereby to take out a license.

Fat in Urine Pathognomonic of Yellow Fever. E. EDELMANN asserts that a granulo-fatty degeneration occurs in this disease, most pronounced and first manifested clinically in the kidney. Fat in the urine is therefore pathognomonic of yellow fever, a fact never signaled before, he states. The first day mucin is noted in the urine; after this albumin and fat, and we can follow, step by step, the destructive and necrotic process of the invasion of the kidneys by the fat. When icterus follows, the renal lesions become much aggravated by the irritation of the bile.—*Havana Medica*, June.

Diabetes from Copaiba.—Betman relates that a person with a light case of diabetes, granulo-fatty degeneration, and slight gastric disturbances, found that the amount of sugar in his urine increased from 13 and 20 grams a day to 45 and 72 with the ingestion of 2.5 to 3 grams of copaiba. Further tests confirmed this experience, that copaiba produces diabetic phenomena in the predisposed, except when there are cutaneous lesions, erythema or urticaria, in which case the renal modifications are usually absent. Turpentin has been known to produce a similar effect.—*Berliner Klin. Woch.*, 22.

Death from Electricity.—Prevost and Battelli have been experimenting with dogs, at Geneva, and announce that animals apparently killed by an electric shock can be revived by prolonged and persistent artificial respiration. The effect of a current of 2500 volts is to arrest the functions of the nervous system and cause the cessation of circulation. Artificial respiration and traction of the tongue are particularly effective in this condition if kept up long enough for the nervous system to recover from the effects of the shock, when all is restored to normal. But with a weak current, forty-five volts, if the heart partially or entirely stops beating it is necessary to send a current of a higher tension through the body for a brief stimulus, supplemented by artificial respiration, to restore suspended animation.

New Instrument for Gauging the Arterial Pressure.—Prof. G. Gartner of Vienna has invented an apparatus, the "Tonometer," which consists of three parts connected, by rubber tubes, with the three ends of a T-shaped tube: a pneumatic ring that fits over the finger, a manometer and a rubber bulb, forming a hermetically closed hole. The ring is about 1 cm. wide with a metal tube inserted at one point, a thin rubber membrane drawn air-tight over the inner end. The ring is fitted over the second phalanx of a finger or the end phalanx of the thumb. The blood is then expelled from the first phalanx by means of a thimble-like contrivance, and pressure is produced in the pneumatic ring by pressure on the bulb. The thimble is then removed, leaving the finger pulp empty of blood. The pressure on the bulb is then gradually suspended, and at a certain moment the blood rushes into the tip of the finger, when the degree of pressure can be read on the manometer. A mercury manometer is more precise in its indications, but for general use the Bourdon metal manometer will be found sufficiently accurate.—*Munch. Med. Woch.*, June 27.

Right of Physician to Practice Dentistry.—The question was presented to the supreme court of the state of Rhode

Island, in the recent case of *State vs. Beck*, whether authority to practice medicine and surgery gives the right to practice dentistry. The answer, the court says, depends on the construction to be given to the statute regulating the practice of dentistry taken in connection with that regulating the practice of medicine, as independent of these statutes, there can be no doubt of the right of a physician to practice dentistry. Now, the one Rhode Island statute provides that all persons intending to enter on the practice of dentistry must pass a satisfactory examination before the board of registration in dentistry and get a certificate which shall be registered with said board. The other statute makes it unlawful for any person to practice medicine or surgery, in any of its branches, without first obtaining and registering a certificate from the State Board of Health. In the passage of the act relating to the practice of dentistry, the court thinks that it was the evident purpose to protect the public from being imposed on by persons who, while holding themselves out as competent to extract, clean, or repair teeth, or replace them by artificial ones, yet, from want of instruction and skill in the art, were wholly unfit to perform such a delicate and highly important function. For this and other reason, it holds that, while, by the strict terms of said statute, taken by itself, it doubtless does prohibit physicians, as well as all other persons, from practicing dentistry without first obtaining the required certificate, as the inhibition is general, and no exception is made in favor of physicians, nevertheless, it is not to be construed as applying to the practice of dentistry by regular physicians. A "physician," it continues, is one who practices the art of healing disease and of preserving health; a prescriber of remedies for sickness and disease. He is presumed to be familiar with the anatomy of the human body in its entirety; to understand the science of physiology and the laws of hygiene; and to be able to minister, as far as may be, to the relief of pain, disease, and physical ailments of all sorts and kinds whatsoever. His certificate authorizes him to practice medicine and surgery in all its branches. Dentistry is now a well-recognized branch of surgery. A dentist is a dental surgeon. That sphere is included in the larger one of physician and surgeon. Thus does the court come to maintain that a fair and reasonable construction of the two statutes, taken together, comes to this: That by the use of the broad and general language used in regulating the practice of medicine and surgery it was intended to except physicians and surgeons from the restrictions imposed on other persons regarding the practice of dentistry. It also takes account of the fact that any construction of the law which would prevent the general practitioner from treating any part of the human body, or would restrict him in the discharge of his professional duties, would be a menace to the public health, and would deprive the physician of his right to practice a branch of his profession that is as old as the history of medicine itself.

Rational Treatment of Pulmonary Tuberculosis.—There is, perhaps, no more hopeful subject in the whole realm of medicine than the treatment of pulmonary tuberculosis. That spontaneous recovery not rarely takes place is well known and generally recognized, and that much can be done by judicious management and the intelligent use of remedial agents to bring about such a result is being demonstrated daily. Nor is it too much to hope that the near future will provide us with a therapeutic agent as efficacious in the treatment of tuberculosis as the antitoxin of diphtheria is in the treatment of that disease. The united and organized efforts being made at present in many parts of the world for the suppression of tuberculosis give promise and justify hope that the disease will gradually be rendered less prevalent and less fatal.

An interesting consideration of the rational treatment of pulmonary tuberculosis, based on comparative studies extending over a period of nearly twenty-four years, of some ten thousand carefully recorded cases, was presented at the Inter-

national Congress for Tuberculosis, held recently at Berlin, by Coghill, who died from perforating ulcer of the stomach only a few days afterward, and who had been for many years senior physician in the Royal National Hospital for Consumption and Diseases of the Chest, at Ventnor. Coghill recognized two distinct stages of the disease, the acute or pyrexial, and the chronic.

The former has much the graver significance. It usually passes into the second, or it may recur again and again in the course of the latter, indicating a resumption of destructive activity.

The available therapeutic methods may be grouped under the following heads: 1. Hygiene or general treatment; 2, regimen or dietetics; 3, medical treatment, including the symptomatic and the special.

In acute pulmonary tuberculosis, absolute repose of body and mind should be secured so far as possible. In extreme cases it may even be necessary to insist on the continuous maintenance of the horizontal posture, not necessarily in bed though, for a considerable length of time. The equality of the temperature of the air is of more importance than its range. It should not be allowed to vary much from 55F. It is better to make the patient comfortable, if necessary, by additional light covering than by raising the temperature. If these conditions can, with proper precautions, be fulfilled in the open air, so much the better. If the patient is confined to the room, this should be large, and well ventilated, and freely exposed to air and sunshine, with the windows, and if possible the doors also, open day and night, and with the bed standing well out from the wall. Conversation, especially on exciting or depressing topics, should be deprecated, but the patient should be encouraged to occupy his mind outside of himself by the perusal of light and cheerful literature. The general bath should be prohibited, but if possible the whole body should be sponged every night and morning with eau de cologne, or spirit of wine and hot water, or toilet vinegar. A large meal of any kind, or red meat should not be permitted at any time. Food should be given in small quantities at regular intervals, e. g., every two hours during the day, and every three during the night. It should be varied as much as possible, both in materials and in cooking, in accordance with individual or national taste. It should consist of fish, poultry, white game, pigeons, sweetbreads, eggs, light soups, milk and egg pudding, and rice, while ripe fruits, especially strawberries, may be taken freely, but always early in the day. The more substantial of these should be given in the form of meals at regular intervals alternately with the lighter, which should be taken as refreshment in the intervals. Milk *ad libitum* may alternate or be taken with each more substantial repast, if the capacity and taste of the patient permit it. If the digestion is weak, pre-digested food, or peptonized meat extracts may be given. Stimulants should be used with extreme reserve. If the appetite is poor, and the strength and vitality are low, a tablespoonful of old Cognac beaten up with a fresh egg may be given at intervals during the day, according to the demands of the case, or two or three teaspoonfuls of mature whisky in each ration of milk. A glass of dry champagne may be allowed twice a day with a meat meal if the mouth is dry and the appetite is poor. Malt liquors and all red wines are more or less incompatible with a diet into which milk largely enters. Lemonade taken with red wines seems to make them lighter, more palatable, and more digestible.

The medical treatment is general, symptomatic, or special or specific. Drugs should never be used, except on the clearest indications. If the tongue is coated, minute repeated doses of calomel may be given every ten minutes, until one-third of a grain has been taken, followed by sodium salicylate in ten-grain doses, with tincture of nux vomica and gentian mixture, once or twice a day, and if there are hepatic complications, with or

¹ Lancet, June 3, 1899, p. 1479.

without constipation, compound tincture of rhubarb may be added in appropriate doses. In case of failure, ammonium chloride in twenty-grain doses may be substituted for the salicylate. When the tongue is epitheliated or irritable, and there is nausea, preparations of bismuth are indicated. If there is anorexia and the tongue is clean, small doses of strychnin, dilute hydrochloric acid and quinin may be given. When cough is distressing or injurious a few drops of a mixture of chloroform-one part and guaiacol three parts may be inspired as deeply as possible through the mouth and respired through the nose. Cod-liver oil and malt extract are special foods directed to supplement nutrition. Tuberculin is the single remedy that has established any distinct claim to be considered a specific.

Creosote and guaiacol and their carbonates have in recent years found much favor in the treatment of pulmonary tuberculosis. These may be advantageously combined with strychnin hypodermically. They reduce the temperature without causing undue perspiration or reaction of any kind. When the pyrexia has been reduced by this means smaller doses by the mouth are substituted, and when markedly strumous indications are present, from 5 to 15 minims of tincture of iodine in cod-liver oil are given in addition three times a day. If the temperature does not quickly respond to injections of guaiacol, 15 grains of sodium salicylate together with 5 grains of antifebrin or phenacetin, or 10 grains of antipyrin are given. In the presence of cyanosis and indications of cardiac debility, 5 grains of caffeine citrate are added. Guaiacol may be given hypodermically, also in chronic cases when the destruction of lung is extensive, and the amount of expectoration is large and does not lessen when the drug has been given internally. Guaiacol carbonate has been found useful in cases complicated by diarrhea and other irritable conditions of the bowel.

In cases of chronic pulmonary tuberculosis the treatment indicated is mainly disciplinary and dietetic, and environment now takes a more important part in the process of convalescence, though the tendency of the arrested morbid process is toward repair and recovery, and purely hygienic treatment assumes an important role. To be efficacious this must be carried out systematically, and in properly located and appropriately constructed sanitariums under efficient medical control, and it must be carefully adapted to the idiosyncrasies and personal requirements of each individual patient. At the Royal National Hospital for Consumption and Diseases of the Chest, at Ventnor, the following rational therapeutic system is carried out: 1. The diet, into which milk largely enters, is ample, simple, and yet varied, and is adapted to the general condition of the patient and the stage of the disease. It is arranged into convalescent, special, and pyrexial varieties, but in every detail it is modified according to the exigencies of each case. 2. Rest and exercise are carried out on the principles generally recognized. 3. The freest exposure possible to the open air, of all the patients, pyrexial patients being carried on their beds or couches on to the veranda on which their rooms open, and the supplementing of the natural ventilation of the rooms by mechanical means while in occupation. 4. The scientific treatment of symptoms by remedies directed as much as possible to the disease processes within the body in which they originate. 5. The reinforcement of the purely medical supervision of the patients by a body of specially trained nurses. 6. The appreciation at their true value of the accessory conditions of climate, site, elevation, shelter or exposure, rainfall, sunshine, and nature, and the relations of soil to water.

New York City.

WATER POLLUTION.—The unprecedented drought of the early summer has not only brought to attention the menace of a water famine but, as well, the quality of the water-supply of the several distinct boroughs of the city. Two of these corporate entities, Manhattan and the Bronx, depend on the Croton system; Brooklyn combines both public and private sources of supply derived from outlying districts of Long Island; Queens has a small system only just capable of supplying its present needs; Richmond draws on several sources in Staten Island. The present complaints are most strongly made in the two large boroughs, Manhattan and the Bronx and Brooklyn, and the complaints bear on quantity and quality. As for the former item, temporary relief will follow the coming of normal conditions of precipitation, and the dangerous inefficiency of the sys-

tem will probably be quite forgotten until the next period of stress which shows the inefficiency of the service system. The remedy of the poor quality will not be the same, for abundant rains falling on the polluted watershed and catchment area will at first make matters worse. At present the Croton water is muddy to look at, populous under the microscope, and decays most rapidly when set aside in any vessel. This has been found particularly true of the Croton service in Manhattan, and in Brooklyn, of the municipal supply known as Ridgewood. Whatever is now suggested for the improvement of the water-supply, both in quantity and quality, falls for the present under two heads. The first looks to the increase of the present supply by including larger territory in the catchment area. In the case of New York and Brooklyn there are physical reasons why such measures shall be only palliative. The available area of watershed is determined by the engineer with his application of physiographic principles, and these show that the limit has been almost reached. The fuller appreciation of the eventual needs of the metropolitan district looks to the Adirondack sources for the supply of unlimited water of the purest character. The distance is great and the initial expense will be great. But there are intermediate cities along the Hudson which will take the service and by so doing reduce the cost to New York City. This plan is now being worked out in full detail, and enough of its possibilities is known to prove that it is no more difficult than the plan now under way to supply the cities of central California, as far as San Francisco and Oakland, with mountain water from Lake Tahoe.

SOFT COAL SMOKE NUISANCE.—Among the many duties imposed on the Department of Health, by the New York Consolidation Act or charter, is the repression of the nuisance caused by the using of soft coal on vessels within the municipal waters and ashore at various factories. The evil is of recent growth, for New York has always been an anthracite-burning community until the opening of new fields of bituminous coal, new transportation combinations, together with the enhanced cost of mining anthracite has made it an objective point for bituminous operators. The law prohibits the use of bituminous coals, but in practice the law is not enforced in cases where smoke-consumers are used which really do consume the smoke. The first offenders were the tugs and ferry-boats. When it was found impracticable to equip these vessels with efficient smoke-consuming devices the law was rigidly enforced against them and they were obliged to return to the use of anthracite. The most recent offenders are certain manufacturers in Brooklyn, mainly breweries and a new sugar refinery. For several weeks they have been belching out foul clouds of black smoke. There is an active citizens' association organized expressly to look after users of offensive soft coal. They brought suit through the ordinary police channels and met a setback. But the Department of Health took note of the matter from press reports, and the sanitary police are now securing the necessary evidence which will shortly enable the Department to take action in the case. Over any large city there must be a certain amount of smoke, but in the clear air of New York any offender against the smoke ordinance is very noticeable, and with interest manifested by the Department of Health the nuisance is soon abated.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including July 13, 1899:

Fercy Ahrous, acting asst.-surgeon, from New Orleans, La., to Division of Cuba.
 Dallas Bache, colonel and asst. surgeon general, U. S. A., president of a board convened at West Point, N. Y., for the physical examination of candidates for admission to the U. S. Military Academy.
 Edward N. Bowen, acting asst.-surgeon, from Springfield, Mass., to San Francisco, Cal., for duty in the Department of California.
 Henry H. Bradley, acting asst.-surgeon from the general hospital at

Savannah, Ga., to Camp Meade, Middletown, Pa., to accompany the 18th Inf. to Manila, P. I.

Thomas S. Benton, captain and asst.-surgeon, U. S. A., from Fort Stevens, Tybee Island, Ga., to Camp Meade, Pa., to accompany the 19th Inf. to Manila, P. I.

Rollin T. Burr, acting asst.-surgeon, from Pomona, Cal. to Division of Cuba.

Joseph H. Chmelicek, acting asst.-surgeon, from New York City to San Francisco, Cal., for duty in the Department of California.

A. F. D. Clerly, acting asst.-surgeon, now on duty at Atlanta, Ga., to proceed to Camp Meade, Pa., to accompany the 19th Inf. to Manila, P. I. Samuel P. Cottrell, acting asst.-surgeon, from the Department of Santiago and Puerto Principe, Cuba, to duty at Camp Meade, Middletown, Pa.

A. Deane, lieutenant and asst.-surgeon, U. S. A., from duty as attending surgeon and examiner of recruits at St. Paul, Minn., to San Francisco, Cal., for duty in the Department of California.

Lieben De Poorter, Jr., acting asst.-surgeon, from New Orleans, La., to the Division of Cuba.

Charles M. Gandy, captain and asst.-surgeon, U. S. A., member of a board convened at West Point, N. Y., for the physical examination of candidates for admission to the U. S. Military Academy.

Leonard K. Graves, acting asst.-surgeon, leave of absence extended.

Joseph N. Henry, major and surgeon, Vols., assigned to the 31st Inf. Vols., to proceed from Washington, D. C., to Fort Thomas, Ky., for duty with his regiment.

Deane C. Howard, captain and asst.-surgeon, U. S. A., from Fort Columbus, New York Harbor, to West Point, N. Y., for temporary duty.

Jefferson R. Keen, major and surgeon Vols., (captain and asst.-surgeon U. S. A.) now on duty as chief surgeon Department of the Province of Havana and Pinar del Rio, Cuba, is relieved from his station at Fort Warren, Mass.

Louis A. La Garde, major and surgeon, U. S. A., member of a board convened at West Point, N. Y., for the physical examination of candidates for admission to the Military Academy.

Clarence B. Millhoff, lieutenant and asst.-surgeon, U. S. A., former orders so amended as to direct him to report to the commanding general, Department of California, on the arrival of the 18th Inf. at San Francisco, Cal.

Francis S. Nash, acting asst.-surgeon, to examine recruits for the 27th Inf. Vols., at Washington, D. C.

George J. Newgard, captain and asst.-surgeon, U. S. A., from Fort Adams, R. I., to Camp Meade, Pa., for duty at the camp hospital.

George Newlove, acting asst.-surgeon, member of an examining board at Fort Leavenworth, Kas., in place of Lieut. Basil H. Dutcher, acting asst.-surgeon, U. S. A., relieved.

James M. Parrott, acting asst.-surgeon, from Kinston, N. C., to the Division of Cuba.

Frederick H. Sparrenberger, acting asst.-surgeon, from Passaic, N. J., to the Division of Cuba.

Frederick C. Weaver, acting asst.-surgeon, to San Francisco, Cal., for duty in the Department of California.

J. L. White, acting asst.-surgeon, from the Department of Porto Rico to report at Washington, D. C., to the Surgeon-General.

Timothy E. Wilcox, major and surgeon, U. S. A., from duty in New York City to post duty at Fort Schuyler, N. Y.

Assignments.—The following assignments were made of medical officers recently appointed in the U. S. Vols., to rank from July 5, 1899:

To the 24th Infantry, Vols., headquarters at Plattsburg Barracks, N. Y.: Major Charles F. Mason, surgeon; Capt. Frederick A. Washburn, Jr., asst.-surgeon; Lieut. John E. Boyd, asst.-surgeon.

To the 27th Infantry, Vols., headquarters at Camp Meade, Pa.: Major Ogden Rafferty, surgeon; Capt. James H. Hepburn, asst.-surgeon; Lieut. Leonard K. Graves, asst.-surgeon.

To the 28th Infantry, Vols., headquarters at Camp Meade, Pa.: Major Thomas C. Chalmers, surgeon; Capt. S. Chase de Krafft, asst.-surgeon; Lieut. Allen J. Black, asst.-surgeon.

To the 29th Infantry, Vols., headquarters at Fort McPherson, Atlanta, Ga.: Major Charles L. G. Anderson, surgeon; Capt. James C. Miner, asst.-surgeon; Lieut. Leoman S. Anderson, asst.-surgeon.

To the 30th Infantry, Vols., headquarters at Fort Sheridan, Ill.: Major John R. McMill, surgeon; Capt. James J. Irwin, asst.-surgeon; Lieut. Albert H. Eber, asst.-surgeon.

To the 31st Infantry, Vols., headquarters at Fort Thomas, Ky.: Major Joseph N. Henry, surgeon; Capt. Abram L. Haines, asst.-surgeon; Lieut. Ralph S. Porter, asst.-surgeon.

To the 32d Infantry, Vols., headquarters at Fort Leavenworth, Kas.: Major Frank C. Armstrong, surgeon; Capt. John R. Hereford, asst.-surgeon; Lieut. William H. Cook, asst.-surgeon.

To the 33d Infantry, Vols., headquarters at Fort Sam Houston, Texas: Major B. Albert Lieberman, surgeon; Capt. W. E. Parker, asst.-surgeon.

To the 34th Infantry, Vols., headquarters at Fort Logan, Colo.: Major James E. Shellenberger, surgeon; Capt. Frank W. Foxworthy, asst.-surgeon; Lieut. Patrick J. McKenna, asst.-surgeon.

To the 35th Infantry, Vols., headquarters at Vancouver Barracks, Wash.: Major Julius A. Schmelke, surgeon; Capt. Luther B. Grandy, asst.-surgeon; Lieut. John A. Metzger, asst.-surgeon.

Captains James H. Hepburn and Luther B. Grandy will join their respective regiments upon the arrival thereof in the Philippine Islands.

The other officers named in this order will proceed at once to the headquarters of their respective regiments and report in person to their regimental commanders for assignment to duty.

Movements of Navy Medical Officers.—Changes in the medical corps of the U. S. Navy for the week ending July 15, 1899:

Surgeon L. B. Baldwin, detached from the Key West Naval Station and ordered to hospital, New York, for treatment.

P. A. Surgeon R. G. Brodriek, granted sick leave for six months.

Asst.-Surgeon R. K. McClanahan, detached from the naval hospital at Philadelphia, Pa., and ordered to the Key West Naval Station.

P. A. Surgeon L. L. Young, sick leave extended three months.

Surgeon J. M. Steele, detached from duty in connection with recruiting rendezvous at Baltimore, Md., and ordered home to wait orders.

Marine-Hospital Changes.—Official List of Changes of Station, and Dates of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended July 13, 1899.

Asst.-Surgeon W. R. McAdam, granted leave of absence for fourteen days.

Asst.-Surgeon Carl Ramus, relieved from duty at the Cape Charles Quarantine Station and directed to proceed to Havana, Cuba, and report to Acting H. R. Carter for duty.

Surgeon Asst.-Surgeon J. P. C. Foster, granted leave of absence for thirty days.

Hospital Steward W. J. Stearns, relieved from duty at New York City (Stapleton, Staten Island), and directed to report to the medical purveyor New York City, for duty.

Hospital Steward G. C. Allen, relieved from duty at Baltimore, Md., and directed to proceed to New York City, and report to the commanding officer for duty and assignment to quarters.

Hospital Steward F. H. Peck, relieved from duty at the Egmont Key Detention Camp and directed to proceed to Baltimore, Md., and report to the commanding officer for duty and assignment to quarters.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended July 15, 1899:

SMALLPOX—UNITED STATES.

Florida: Jacksonville, July 1 to 6, 3 cases.

Illinois: Chicago, June 24 to July 1, 2 cases.

Kentucky: Louisville, June 23 to July 6, 8 cases.

Louisiana: New Orleans, June 24 to July 8, 5 cases, 1 death; Shreveport, June 24 to July 8, 1 case.

Massachusetts: Boston, July 8, 3 cases, 2 deaths.

Mississippi: Natchez, July 7, 1 case.

New York: New York, June 24 to July 8, 7 cases, 1 death.

North Carolina: Charlotte, June 24 to 30, 1 case.

Ohio: Cincinnati, July 7, 2 cases; Cleveland, July 1, 2 cases.

Oregon: Portland, June 29 to date, 4 cases.

Pennsylvania: Philadelphia, July 1 to 8, 1 case.

Virginia: Cape Charles, July 8, 1 case; Danville, July 6, 3 cases, total 30 cases.

North Carolina: Norfolk, July 6, 6 cases; Portsmouth, July 8, 4 cases.

Washington: Tacoma, July 3, 1 case.

SMALLPOX—FOREIGN.

Argentina: Buenos Ayres, April 1 to 30, 1 death.

Brazil: Rio de Janeiro, May 27 to June 8, 77 cases, 29 deaths.

China: Fuchuan, May 6 to 13, prevalent.

Cuba: Havana, June 23, 1 death.

England: London, June 17 to 24, 1 case.

France: Marseilles, June 25 to July 1, 1 case.

India: Bombay, June 6 to 13, 4 deaths; Madras, May 27 to June 2, 2 deaths.

Mexico: Mexico, June 23 to July 2, 8 cases, 3 deaths.

YELLOW FEVER.

Argentina: Buenos Ayres, April 1 to 30, 4 deaths.

Brazil: Rio de Janeiro, May 27 to June 9, 19 deaths.

Cuba: Havana, July 6, 2 cases; Santiago June 15 to July 10, 148 cases, 28 deaths.

Mexico: Vera Cruz, June 29 to July 6, 25 deaths; on bark *Dolores Romano* at Vera Cruz, Mexico, July 1, 7 cases.

CHOLERA.

India: Bombay, June 6 to 13, 1 death; Calcutta, May 27 to June 3, 23 deaths; Madras, May 27 to June 2, 3 deaths.

PLAGUE.

Egypt: Alexandria, June 16 to 23, 6 cases remaining.

India: Bombay, June 6 to 13, 55 deaths; Calcutta, May 27 to June 3, 32 deaths.

Japan: Formosa, Tamsui, April 23 to May 3, 147 deaths.

CHANGE OF ADDRESS.

Adams, J. L., from Morgan, Minn., to Anacondas, Colo. Beckler, J. P., from 503 S. Warren, to 318 W. Onondaga St., Syracuse, N. Y. Brown, G. M., from Chicago to Davis Junction, Ill.

Brooks, S. D., from Nat'l Quarantine Sta., Angel Island, Cal., to U. S. Marine Hospital, Portland, Me.

Bennett, A. L., from St. Anne, Ill., to 1483 Pearl St., Denver, Colo.

Croschmitt, W. L., from Louisville, Ky., to Holland, Texas.

DeBor, H. B., from 352 Blue Island, to 625 S. Ashland Av., Chicago.

Edmondoff, E. H., from Galveston to San Antonio, Texas.

Gates, L. A., from Thermopolis, Wyo., to Bridges, Mont.

Goggia, R. J., from Pulcifer to Swing, Wis.

Kay, from Dupont to Continental, Ohio.

Hix, A. E., from 1431 Monroe St., to 1009 Warren Av., Chicago.

Lawson, F. W., from 1-1/2 Irving to Caldwell, Mich.

Mincey, J. N., from Van Alstyne to Howe, Texas.

O'Brien, M. C., from New York City to Lewiston, Me.

Paquin, J., from St. Louis to Asheville Sanitarium, Asheville, N. C.

Ransom, C. C., from New York City to Richfield Springs, N. Y.

Snow, B. G., from Ann Arbor to Caldwell, Mich.

Saltzger, W. R., from Van Wert, Ohio, to Knoxville, Tenn.

Tappan, J. C., from 507 B. St., E., to 65 R. St., N. W., Washington, D. C.

Thompson, J. R., from Richmond, Va., to Colley, N. C.

Weitz, J. A., from Detroit, Mich., to Montpelier, Ohio.

The Journal of the American Medical Association

CHICAGO, ILLINOIS, JULY 29, 1899.

No. 5.

Address.

THE ESOPHAGUS.*

CICATRICAL STRICTURE THEREOF: ITS TREATMENT.

CHAIRMAN'S ADDRESS.

BY W. J. MAYO, M.D.

SURGEON TO ST. MARY'S HOSPITAL,
ROCHESTER, MINN.

Esophageal obstruction is a subject which must command the attention of every thoughtful surgeon. The inaccessible situation of the gullet, its relation to important structures, and the difficulty attending manipulations within its narrow lumen, all tend to place it among the surgical problems which are difficult of solution. The cases are sufficiently rare to render an individual experience incomplete, and yet are frequent enough to stimulate our best endeavor for their relief.

Koenig makes a very practical classification of esophageal obstructions into:

1. Those located within the esophagus, such as inflammatory spasmodic or cicatricial strictures, foreign bodies, tumors and diverticula.

2. Pressure obstructions located without the esophagus, especially tumors involving the thyroid body, tracheal and mediastinal glands, or aneurysms of the arch of the aorta. Abscess from Pott's disease may also be the cause of pressure obstruction.

It is to a variety of the first group that I wish to call your attention at this time.

ETIOLOGY AND GENERAL CHARACTER.

Cicatricial stenosis of the esophagus is the result of the healing of an ulceration. The latter is produced by a traumatism, such as the swallowing of caustic alkali, acids or hot fluids; occasionally by a wound, or may be due to the prolonged lodgment of a foreign body. The most common cause, and especially so in children, is the accidental swallowing of concentrated lye.

In adults carbolic acid, ammonia, etc., are not infrequently taken, but the immediate mortality from the poisonous effects of the substance swallowed reduces the number who live to develop cicatrix to a small proportion.

The breaking down of a syphilitic gumma may leave an ulceration, and cases of stricture having its origin in this manner have been reported by Lubinski. Sonn says that syphilis may cause a fibrous stricture of any portion of the alimentary canal and states that it is not ulcerative in character.

Tubercular ulceration of the esophagus is usually secondary to the swallowing of infected sputum. Flexner reports 19 cases and Cone 28 of this variety. None of these cases healed to such an extent as to cause stricture. Primary tuberculosis of the gullet is very rare:

however, it occurs and may be the cause of stenosis. Zenker reports such a case. Poncet cites a case of obstruction due to the ulceration attending actinomycosis; no attempt at healing was noted, the interference being mechanical. Fibrous strictures of the esophagus without ulceration have been variously described as idiopathic, syphilitic, gouty, rheumatic or due to chronic esophagitis. Audry records two such cases supposed to be cancerous, which after death proved to be due to hyperplasia of the muscular coat. Ingals reports several instances occurring in one family. Rumpel cites a case of fusiform dilatation of the esophagus, due as he believes to a spasmodic contraction of the thickened muscular coat at the lower end of the gullet and collects 20 cases from medical literature.

The pathologic condition found in the reported cases of this description shows a remarkable resemblance to the large fibrous stricture of the pylorus and to that form of fibrous stricture of the rectum the etiology of which has been the subject of controversy for years. It is probable that these strictures of the alimentary canal have a common origin, and for convenience fibrous strictures of the gullet are classed with the cicatricial form.

Simple strictures of the esophagus, of unknown origin, are not uncommon. Kendall Franks records a number of this variety. Ewald states that the simple or peptic ulcer may be the cause of stenosis and cites cases; it is possible that this is the etiology of many of the so-called simple strictures. Congenital strictures are described at length by Carey, with a report of cases from the literature of the subject.

As the treatment of the simple and congenital forms is essentially the same as that of the variety under discussion, they are included in the same class. The locations of strictures of the gullet for anatomical reasons are most common in three localities: 1, at the isthmus of the esophagus opposite the cricoid cartilage; 2, at or near the bifurcation of the trachea where the gullet is crossed by the left bronchus; 3, at the diaphragmatic opening. According to the researches of Hacker this latter locality is most commonly affected by caustics.

In the adult the gullet is from nine to ten inches in length, and Richardson has shown that from the incisor teeth to the diaphragmatic opening it is about 14½ inches, measurements which aid the exact location by the sound. If the stricture can be passed by an olive bougie, Tillman advises that the tip be inserted well beyond the stenosis; on withdrawing, the handle is marked as resistance begins and again as it passes through the stricture. The distance can thus be easily estimated. Not infrequently several strictures are found, or the whole of the esophagus may be obliterated, as in cases reported by Richardson and also by Hacker.

DIAGNOSIS.

The diagnosis of the obstruction is easy, in fact, advanced mechanical stricture gives a group of symptoms which are self-evident; of these dysphagia and regurgi-

*Presented to the Section on Surgery and Anatomy at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

tation of food are most prominent and if the obstruction lies in the cervical portion dysphonia and dyspnea may be observed. Sounding with suitable bougies completes the diagnosis.

In children with advanced cicatricial stenosis, the emaciation, the anxious, hungry expression, the constant desire for liquids and rapid regurgitation form a clinical picture which hardly needs a question. In adults the differentiation as to the nature of the stenosis may be more difficult.

Spasmodic stricture is not rare, and usually occurs in people of a hysterical tendency. According to Mansell Moullin, slight traumatism are frequently the exciting cause of the hysterical form and the injury may be grossly exaggerated by the patient. The lack of sufficient cause, the suddenness of the onset and the neurotic history will usually suffice to clear up the diagnosis. Yet cases are recorded by Pepper and others in which it was necessary to resort to sounding under anesthesia to positively exclude organic stricture.

Esophageal diverticuli may cause difficulty in diagnosis. The origin of these pouches is stated by Maylard to be: 1, congenital; 2, the result of a strictured condition below; 3, from pressure or traction. These diverticuli are most common on the posterior wall about on a level with the cricoid cartilage. Error in sounding is thus liable to occur, the bougie passing into the pocket. The possibility of such occurrence will put one on guard and prevent serious difficulty in differentiation.

Butlin has collected a number of cases from the London hospital reports, many of which have been diagnosed as stricture. Malignant strictures and pressure tumors suggest at once clinical phenomena which will render exclusion easy.

Esophagoscopy cannot be considered an important aid to diagnosis. Hacker in Billroth's clinic used a Leiter pancelectric light, with small benefit, and while numerous devices have been developed since, not much evidence of value has accumulated. Stork describes a new esophagoscope, but its usefulness seems uncertain. Einhorn is one of the few authorities who place reliance upon this clinical method in diagnosis.

PROGNOSIS.

The prognosis of untreated cicatricial stenosis is bad, there is a constant tendency to contract, indeed there seems to be no limit to this process.

The esophagus gradually dilates above the stricture, its muscular coat hypertrophies and by a squeezing process some nourishment is forced through the stenosed portion until a late date, the starvation being a very slow process. In time fatty degeneration of the muscle fiber renders it unequal to its task and also makes instrumentation exceedingly dangerous. Many deaths have been reported from instrumental perforation, by Sands and others. A casual examination of the literature of the subject leads one to think that this is not an uncommon accident in attempts at sounding in late cases. Weinelechner describes an island-like stricture which may prevent the passage of solid food and yet not cause complete obstruction to a fluid diet for an indefinite time. I have observed such a case.

CASE 1.—Stricture of Esophagus Impermeable to Bougie—Comfortable Existence for Years on a Fluid Diet.—Mrs. P. McK., aged 36 years, the mother of a large family, in August, 1891, gave a history of having swallowed caustic lye when a child; since that time she has lived on a fluid diet, being able to swallow only strained liquid food. She has frequent attacks of regurgitation lasting several days at a time, and

thinks that on an average one-third of the food is regurgitated. At times she gets very thin.

She is a badly nourished woman, of slender build and anemic appearance. Careful sounding reveals a dense stricture near the cardiac end of the esophagus. Above the stricture the esophagus is dilated to a considerable extent. Repeated examination failed to pass the stricture. The patient refused any operative interference, and has passed from observation.

TREATMENT.

The treatment of traumatism of the esophagus at an early period, before contraction takes place, is of the utmost importance. Many of the unfortunate results in this way can be avoided or rendered manageable. After the swallowing of a caustic substance systematic sounding should be commenced in from two to four weeks (Meyer). Foreign bodies should not be allowed to remain in the esophagus until ulceration is produced, and prolonged attempts at removal through the mouth can not be considered good surgery. Gerster directs attention to the case with which foreign bodies can be removed through an external esophagotomy if done early, before ulceration has taken place; in this way Dr. C. H. Mayo has on five occasions readily removed foreign bodies from the lower part of the esophagus. The X-ray is of great value in locating many of these bodies, and a right incision in the neck instead of the ordinary left may be indicated, as in a case of an impacted overshoe buckle in which the loop to the right and the sharp prongs to the left decided the question.

In the lower esophagus the method of Maurice H. Richardson—removal through an incision in the stomach wall—is of the greatest value and must rank as one of the achievements of modern surgery. Tillman strongly advocates preliminary gastrostomy for feeding purposes in the primary stages of acute ulceration, thereby lessening the infection and hastening cure. In tubercular and syphilitic ulceration appropriate constitutional treatment should be used in conjunction with the sounding during the period of cicatrization.

DILATABLE STRICTURES.

Gradual dilation is the method of choice in this form of stenosis. The larger and softer the dilator the better, but in many advanced cases such instruments are wholly worthless. In these cases the use of whalebone olive-tipped probes are best for the smaller varieties, and for the larger bougies a whalebone stem to which increasing sizes of metal or ivory olive tips can be attached are the most valuable. If the tip is made very long and tapering it will engage in the stenosed portion more quickly than the ordinary olive tip, which expands so rapidly that one can not easily appreciate whether it is engaged in the stricture or not.

In a previous paper on this subject, read before the Minnesota Academy of Medicine in March, 1894, I exhibited what I then believed to be a new probe in which three or four increasing sizes of bulbs were made on a single stem (Trousseau's), the idea being that the small tip would railroad the others through. As a matter of fact it prevented that elasticity within a few inches of the tip which is a prime essential in a good bougie, enabling one to pass through the curved pharynx without injuriously impinging on the posterior wall. This elasticity is necessary, as it also permits of some play at the point and facilitates search of the face of the stricture for the opening.

Many cases appear to be impermeable to the probe, which in time may be safely passed. The frightened little sufferer adds to the general discomfort and renders a hasty judgment in this regard only too natural. I once heard an eminent genito-urinary surgeon say that

impermeable strictures of the urethra happened largely in an early experience, and I am sure that this is true of esophageal stricture. With care and gentleness a bougie can usually be inserted in the opening, although several sittings may be required. In such cases a number of whalebone bougies lubricated with glycerin should be passed into the gullet and against the stricture in the same manner as filiforms are used in the urethra, and by alternating probes one will usually slip through. It is best to stop here, and then every other day repeat the process, using perhaps several increasing sizes at one sitting; the first probe introduced should have a very flexible handle, and when in place straightens the throat curve so that the larger and stiffer bougies readily follow, each one being left in the stricture until the next one is ready by its side. In a few cases it may be necessary to use an anesthetic the first time or two, but usually the patient will sit on a low stool facing the opera-

At no time since the injury has solid food been taken, and a large part of liquid nourishment swallowed is regurgitated. Before admission to the hospital several attempts at sounding the esophagus had been made, but without success. On examination a stricture was detected in the thoracic esophagus. Under anesthesia several whalebone bougies were placed in position, and by using first one and then another, a probe was finally passed into the stomach. The stricture dilated easily and a fair-sized bougie was introduced at this time. Systematic sounding every third day was carried out, and March 8, 1898, the little patient was discharged, able to take liquids easily, and chopped meat and softened bread with but little difficulty. Since that time Dr. S. H. VanCleve of Mantorville has continued sounding at intervals, the esophagus being of nearly normal caliber.

NON-DILATABLE STRICTURES.

Stenosis involving a large extent of the esophagus may prevent gradual dilatation or even continue to contract while attempts at dilatation are being carried out, and in a few cases the difficulties and dangers attending the sounding of a tight stricture makes a resort to some more rapid method desirable.

Figure 1 shows manner of introducing the silk cord with the rubber drainage tube looped in position ready for introduction.

Figure 1a shows the manner in which the tube is drawn out in order to pass through a tight stricture.

tor, and from the relief afforded by the ability to retain a little nourishment will soon face the ordeal with an unexpected degree of fortitude. The frequency of sounding depends on the case, every other day being sufficient, and in sensitive cases perhaps too frequent. Many months are occupied in this gradual dilatation, and after apparent cure a sound should be passed occasionally for years.

Case 2.—*Stricture of Esophagus—Gradual Dilatation—Recovery.*—T. C., a male, aged 2 years, of Mantorville, Minn., was admitted to St. Mary's Hospital, Rochester, Minn., Feb. 24, 1898, with a history of having accidentally swallowed concentrated lye seven weeks previously. Difficulty in swallowing developed at once. At first this was due to traumatism and resulting ulceration, later to the contraction.

Figure 2 shows a double rubber drainage-tube, looped into one already drawn through. As many tubes as may be necessary to obtain the desired dilatation may be drawn through in this way.

For strictures in the vicinity of the cricoid cartilage external esophagotomy after Billroth is the operation of choice. Like the perineal cut for stricture of the urethra, funnel-shaped retraction of the cut portion is caused by adhesion to the external tissues divided and it lessens future contraction. This operation, first performed by Mitchel and later by Annandale, has stood the test, and should not be long delayed. A most interesting case of this kind is recorded by Christian Fenger. Kendall Franks has successfully performed esophagectomy in a case of simple stricture in this portion of the esophagus, the divided ends being sutured over a tube passed through the nose.

For dense stricture above the arch of the aorta and

below the point which can be directly divided, Gussenbauer's combined esophagotomy is the best operation; through an external incision in the neck a tenotome is introduced and passed downward to the stricture, which is then divided.

I take the liberty to introduce an illustrative case previously reported:

CASE 3.—*Two Strictures of Esophagus—Prolonged Dilatation and Combined Esophagotomy—Recovery.*—J. Hanev, aged 4 years, was seen in January, 1893. In the spring of 1892, while living in North Dakota, the child swallowed concentrated lye. After a month's severe illness, he gradually recovered, but with an increasing difficulty in swallowing. During the past three months all food had to be strained and he has frequent attacks of regurgitation. The material regurgitated is brought up somewhat slowly. He is a moderately nourished boy, of good disposition, which materially aided treatment. On the introduction of a catheter it was arrested at the isthmus of the gullet. After some manipulation a No. 3 urethral catheter was passed three inches farther downward, where it was completely arrested.

It was very evident that there was a stricture at the level of the cricoid cartilage, and a second in the intrathoracic portion of the esophagus, undoubtedly produced by the action of the esophageal muscles at the time of the original accident, causing the effect of the lye to be located at these points.

Regular sounding was instituted and continued at intervals of three to ten days, by myself or Dr. C. H. Mayo, with but slight interruption for one year. At the end of two months the lowest stricture was passed by a fine whalebone bougie. This stricture was very dense, and resisted sounding obstinately; it could be only at intervals of several sittings that the bougie could be introduced into the stomach. At the end of a year's perseverance the upper stricture had yielded to the extent of admitting a No. 5 catheter and the lower one a No. 3. The boy was well nourished, did not regurgitate unless he took solid food, and was able to take softened bread and finely chopped meat. During the preceding two months no perceptible improvement was manifest; therefore, on Feb. 15, 1894, he was admitted to St. Mary's Hospital, Rochester, Minn., and on Feb. 16, left external esophagotomy was performed by Dr. C. H. Mayo. The upper stricture was now readily dilated by forceps. The lower stricture, which was below the level of the upper end of the sternum, was carefully nicked with a dull knife on a grooved director and dilated with forceps, permitting of easy catheterization of the esophagus.

Unfortunately, the majority of dense strictures are in the lower esophagus, or if there is one stricture in the upper portion another will usually be found lower down. In three cases in the experience of the writer more than one stricture was present, but the lower in each instance was the more dense.

How to reach strictures situated below the arch of the aorta in the thoracic esophagus by direct means has been, and is yet, a problem. Nasoloff, Quénu and Hartmann developed an operation for external esophagotomy on the cadaver, which Rehn first performed on the living subject, an incision from the fourth to the eighth rib on the right side of the spinal column being employed.

The difficulties and dangers of this plan of attack are so great that indirect measures are to be relied upon.

For this purpose two methods are available—Abbe's string-saw and Ochsner's operation; in the latter a loop of rubber tubing is used as a dilating medium. The one method supplements the other. Division of the stricture by the string-saw invented by Abbe has been performed a number of times with great success.

Through a gastrostomy wound a stout silk cord is passed in a retrograde way through the esophagus and out through the mouth or through an external esophagotomy. The stricture is made tense by engaging bougies into it from below, and by a sawing motion of the cord, the tight bands are divided, while the important soft parts are crowded back out of the way. After full dilatation has been secured the incisions can be closed, or a rubber tube is inserted to a point above the stricture and brought out of the gastric incision, the

latter being united to the margins of the abdominal wound. In two or three days the tube is removed and sounding from above employed in the usual manner.

CASE 4.—*Stricture of Esophagus—Division and Dilatation After Gastrostomy and External Esophagotomy—Testimony as to the Value of Abbe's String Method of Division.*—H. W., aged 3 years, of Amboy, Minn., was admitted to St. Mary's Hospital, Rochester, Minn., on Oct. 5, 1892, with the following history, given by her mother.

One year previously the child accidentally swallowed caustic lye. For four years she was very sick, then gradually improved for several months, although totally unable to swallow solid food at any time. During the last six months she has had great difficulty in swallowing liquids, and has regurgitated from the esophagus more than half of the nourishment taken. She is emaciated to a considerable degree. Upon being given two ounces of milk it was drunk with avidity, but was nearly all regurgitated. The dilated esophagus above the stricture holds nearly four ounces of fluids. Bougies were inserted through the pharynx into the esophagus, but were completely arrested at its lower end, while careful search of the face of the stricture with a number of whalebone bougies, under anesthesia, failed to pass the stenosed portion. At intervals of four days this search was continued, but without result. While undergoing these repeated examinations the child became much better and was able to retain a larger proportion of liquid nourishment, and improved visibly.

Proper manipulation was much interfered with by the short, sharp curve of the child's pharynx and its small size; therefore external esophagotomy was urged upon the parents to permit of more direct access to the parts involved. This was declined, and the little girl was taken home at the end of two weeks.

On July 19, 1893, the child was readmitted to the hospital. The slight improvement had been of short duration, a gradual closing of the small channel had taken place, and for the past four weeks it had been nearly, if not quite, impermeable, so that the little patient had been nourished by rectal enemata.

She was emaciated to a marked degree. As before, careful search utterly failed to pass the stricture. External esophagotomy with a hope of finding a way through the damaged esophagus did not promise the rapid relief that the child's nutrition demanded; therefore, on July 20, 1893, a gastrostomy was made after the method of Fenger, the incision being made as high up and as close to the median line as possible, to permit of retrograde dilatation.

Fenger's operation was chosen, as permitting more direct and easy access to the cardiac orifice of the stomach, in place of that of Hacker or that of Witzel, which are far superior as to the preventing of leakage from the fistula, but also present greater obstruction to intragastric manipulation. The child was now well nourished through the gastric fistula, and twice a week the lower face of the stricture, which was at the diaphragmatic opening, was carefully searched for an outlet. On two occasions the finger was introduced through the fistula into the stomach and used as a guide for the probe, the patient being anesthetized. The dilation of the fistula necessary to introduce the finger in so small a subject greatly increased the leakage through the gastric opening, and the child again began to fail, from the inability of the stomach to retain nourishment.

On Aug. 25, 1893, a left external esophagotomy, at a low point in the neck, was performed by Dr. C. H. Mayo, and a bougie introduced by him through this opening and pressed against the stricture, pushing it downward into the stomach and holding it steadily. With a finger in the stomach, careful search now enabled me to pass a long malleable German-silver probe from the stomach through the stricture and out of the esophageal fistula in the neck, and a heavy double strand of braided silk was drawn through the channel, having an end out of the opening in the esophagus and also out of the gastric fistula. The stricture was about three-quarters of an inch in length, as nearly as could be ascertained. By using one strand to cut the tissues, after the method recommended by Dr. Robert Abbe, while knots were tied on the second strand and pulled into the obstruction to keep the stricture tense, the opening was greatly enlarged. This method of Abbe's was of the greatest value, and had but one disadvantage—that of cutting the edge of the gastric fistula when drawn taut. This was in part obviated by holding the lower end of the cutting thread in the bite forceps, held on a plane with the stricture from within the stomach. Knots on the second thread, to render the stricture tense, were equally good and easier of execution than pushing bougies from below into the small opening, as recommended by Abbe.

During the succeeding month at intervals of four days, this

process of division was carried on, and perforated shot clamped upon the thread were drawn through to assist in the dilatation, as they readily followed the tortuous passage. Bougies then became permissible, inserted first from the neck and later through the mouth.

In five weeks the threads were removed and dilatation was carried on with olive-tipped whalebone bougies made for the purpose. A sister of the little patient was taught to pass the probe, and the child was discharged in two months in a good general condition and able to drink milk readily and to take chopped meat and bread with little effort. The esophageal fistula had spontaneously closed, and the gastric opening, after being touched with the cautery was nearly cicatrized. March 19, 1899, the patient is well.

Ochsner's operation is performed as follows: The anterior wall of the stomach is drawn out of a left oblique incision through the abdominal coverings; a small opening is made into the stomach sufficient in size to introduce the finger. A whalebone probe, to the tip of which a silk string guide has been tied, is now passed through the esophagus either from above or retrograde, as in the Abbe method. With this guide a loop of silk is drawn out of the gastric incision in such manner as to leave the guide as a third string. Into this loop a small soft rubber drainage-tube three feet or more in length is caught in the middle; by traction on the ends of the doubled thread through the mouth, this loop of rubber tube is drawn through the stomach and made to engage in the stricture.

The greater the amount of traction the smaller the stretched rubber tube until it is sufficiently reduced in size to enter the stenosed portion; by alternating the direction of the pull the tube is drawn out by its free ends and in by the silk loop. Increasing sizes of tubes can be employed, and if necessary the third string can be used as a string saw after the Abbe plan of procedure. This operation was first successfully performed by Dr. A. J. Ochsner, of Chicago, in February, 1899. In April, 1899, I had an opportunity to employ this method, with the most satisfactory result.

CASE 5.—Stricture of the Esophagus—Gastrostomy and Dilatation by Ochsner's Method—Recovery.—G. H., a female, aged 9 years, of Etna, Minn., was admitted to St. Mary's Hospital, March 3, 1899, with the following history. Four months before, she accidentally swallowed concentrated lye. The ulceration produced was slow in healing and the difficulty in swallowing gradually became more pronounced. For the past month only liquids have been attempted, and the greater part has at once been regurgitated. Emaciation was extreme. On examination, a stricture in the lower esophagus was readily detected by a bougie. After considerable effort a fine whalebone probe was passed. There appeared to be two points of contraction, about an inch apart, the lower being at the diaphragmatic opening. Systematic probing during the next seven weeks did not yield much result; occasionally a larger probe could be passed, and again only the finest could be used. During this time renal feeding was employed to supplement the very limited nourishment obtained by means of the esophagus. The little patient became so reduced that on April 20, 1899, the abdomen was opened by a left oblique incision. A fine probe armed with a silk thread was passed through the esophagus into the stomach. The thread was caught and drawn out of the incision; by this means two threads of heavy silk were drawn upward and the silk guide left in position.

A quarter-inch rubber drainage-tube was lubricated and caught by the middle in the loop; by traction from above, the tube was drawn through the stomach and into the esophagus, considerable traction being required to engage it in the strictured area. By first using traction upward on the strings and then downward on the free ends of the tube, the stricture was rapidly dilated. The dilating tube was removed and a half-inch rubber tube was introduced into the gastric opening, and through this tube the three threads were drawn, the free ends being tied to the ends projecting from the mouth.

A gastric fistula was then formed after the method of Bernays, the rubber tube being enclosed by three superimposed circular purse-string sutures of catgut, one-fourth of an inch apart, introduced in the wall of the stomach around the incision, the margin of the fistula being then sutured to the ab-

dominal wound. This causes a cone or nipple-like projection of the wall into the lumen of the stomach, and through this tube sufficient nourishment was introduced. The general condition rapidly improved and systematic sounding was carried on as before, with increasing sizes of bougies. The patient is still under treatment.

Internal esophagotomy, first performed by Maisonneuve in 1861, has been made about twenty-five reported times (Richardson), with a death rate of over 25 per cent. Above the arch of the aorta it is unnecessary, below it is a chance shot and success a lucky accident. Koenig believes that permanent gastrostomy is preferable. Sands' instrument shares with Mackenzie's the doubtful honor of being best for the purpose. Meyer, in an interesting summing up of internal instrumental esophagotomy, says that the danger of accidental injury to important structures is not greater than the introduction of infective material without the gullet, such infections being responsible for more than half the mortality. He recommends gastrostomy for the purpose of feeding and also to allow of preliminary cleansing of the operative field, if internal instrumental esophagotomy is adopted. Internal division is nearly as dangerous as the cutting operation and less effective. Fletcher's esophageal divulsor has been used a few times. Dr. S. J. Mixer has devoted a great deal of attention to this subject. He recommends that Symonds' tube as originally advocated for malignant strictures be introduced, and believes that that steady pressure will gradually increase the caliber. It would seem that a stricture of sufficient size to permit of permanent tubage could be overcome by gradual dilatation. The literature of the subject is filled with cuts of more or less ingenious instruments for the purpose of dilating these strictures: the spiral rolled tin sounds of Rosenheim, the laminary tent of Senator, and a host of others, interesting but of questionable value; of these linear electrolysis as introduced by LeFort has had the greatest reputation. The marvelous nature of the cures wrought in many cases leads one to think that the enthusiastic advocates of electricity failed to exclude the spasmodic variety with sufficient care. One bears much less of the cure of strictures in this manner than five years ago.

IMPASSABLE STRICTURES.

In a moderate number of strictures a probe can not be passed through the mouth, yet after an external esophagotomy the bougie can be manipulated to so much better advantage that the opening may be found and, after a few soundings, conducted through the fistula; the future dilatation is continued through the mouth. Graser particularly advises this in children. Kammerer reported a case before the New York Surgical Society in which, after failing to pass the stricture by retrograde sounding through a gastric incision, success followed probing from above through an external esophagotomy. Koenig had a series of fine silver balls made and threaded; one swallowed at bed-time would usually pass the stenosed area during the night and was drawn back through by the thread in the morning. Zeeheisen records two cases in which an opening passable to a sound was secured in this manner. Billroth succeeded in several cases with a cylindrical cloth bougie partly filled with mercury, the weight and adaptability of the metal carrying it through.

Gastrostomy and retrograde dilatation were recommended by Schede in 1883, and first performed by Trendelenburg. Kendall Franks collected twenty cases cured in this manner. Since that time a large number of successful cases have been recorded. Great and unexpected difficulty is often experienced in attempting

retrograde dilatation through a gastric fistula. It is a surprising fact that under such circumstances it may be next to impossible to find the cardiac opening. For this reason the dilatation should be carried out as the primary operation if possible. Richardson directs that the anterior wall of the stomach be delivered and a small transverse incision made into its cavity near the lesser curvature, in the neighborhood of the pylorus; by traction on the stomach just below this incision the lesser curvature forms a sulcus along which the instruments glide into the cardiac orifice.

Hagenback turned defeat into triumph in a case in which he was unable to find the stricture from below, and made a gastric fistula for feeding purposes. He caused the patient to swallow a small perforated shot to which a thread was attached; this passed through the stricture and was hooked out of the fistula, acting as a guide for future manipulation.

Abbe recommends that a string guide be introduced by which dilating bougies can be drawn upward retrograde, and that this guide should be retained in place until a sound can be introduced from above. Observation has shown that it is possible to pass an instrument retrograde when impassable from above, but that regular dilatation from below without a guide may prove very difficult.

Twenty-eight cases from the literature of retrograde dilatation are analyzed by George Woolsey, and the comparative merits of the various methods of cutting are clearly stated.

It may happen that the condition of the patient will not permit prolonged attempts at retrograde dilatation, and a rapid gastrostomy should be done by the Witzel or the multiple purse-string method of Bernay, as either permits immediate feeding, does not leak, and yet can be readily converted into a direct opening by a dilator when needed for later attempts at retrograde dilatation. With the improvement in nutrition which follows gastrostomy and the absolute rest to the esophagus, in a short time a probe may be passed from above.

CASE 6.—Cicatrical Stenosis of the Esophagus—Gastrostomy—Gradual Dilatation Through the Mouth.—V. M., aged 3 years, of Madison, S. D., was admitted to St. Mary's Hospital Rochester, Minn., July 1, 1894. Nine months previous to admission the little fellow had accidentally swallowed concentrated lye. Symptoms of esophageal obstruction becoming more and more pronounced, attempts were made to dilate the stricture gullet without success. At first solids were regurgitated, later fluids, and for six weeks nourishment had been maintained by rectal feeding.

The child is emaciated to an extreme degree and is too feeble to stand. Fluids were eagerly swallowed only to be at once regurgitated. Attempts to pass whalebone probes through the stricture were unavailing. Gastrostomy after the Witzel method was performed and immediate feeding resorted to.

Regular feeding through the gastric fistula soon improved the general condition. Systematic search for an opening through the stricture from above was made every other day for several weeks before a small whalebone probe passed. After this success the bougie failed to find the orifice a second time for a number of days. Three months of persistent effort finally developed a moderately sure passage. For five months all the feeding was carried on by the gastric fistula, a good-sized opening through the stricture having developed by this time.

On Feb. 22, 1895, the patient was discharged, being able to eat ordinary food and since that time he had been regularly sounded and had remained in excellent health, until June, 1898, when he was readmitted with complete obstruction, having three days before accidentally swallowed a mass of chewing gum which had tightly wedged in the opening; this was removed with some difficulty.

During the four years which had elapsed the same bougies were continued by his parents without taking into account the growth of the child.

Proper sized probes were obtained, and he has since remained in good condition.

There will yet remain a few cases in which a large part of the esophagus is obliterated, and permanent gastrostomy after the Frank method is the melancholy outcome.

In summing up, the following conclusions may be formulated:

1. Systematic sounding should be commenced in from two to four weeks after the swallowing of a caustic substance.
2. Should the traumatism be severe, immediate gastrostomy will lessen inflection and hasten cicatrization, sounding being carried on as before.
3. Non-dilatatable strictures in the vicinity of the cricoid cartilage should be divided by external esophagotomy.
4. Stricture above the arch of the aorta may be safely cut by a combined internal and external esophagotomy.
5. Dense thoracic strictures are best dilated by Ochsner's method, and, if necessary, divided by Abbe's string saw.
6. Impassable strictures should be treated by retrograde dilatation.
7. A dilated stricture should be occasionally sounded for years, if not for life.

QUININ IN MALARIA.*

BY GEORGE DOCK, M.D.

ANN ARBOR, MICH.

A perusal of current literature and an experience with physicians in active practice show many differences of opinion regarding the use and value of quinin in various malarial diseases. The recent war, by exposing large numbers of men to real or imaginary malaria, brought out in a striking manner many of the most common views, and the numerous articles directly and indirectly touching the subject seem to justify a somewhat dogmatic consideration of certain salient features.

Why We Use Quinin in Malaria.—It should not be forgotten that our use of quinin is due to an accidental discovery and that the value of the drug and fairly reliable methods of administration were known long before we had any accurate knowledge of the cause of the disease or the nature of the changes produced by it in the body.

As is well known, malaria is a disease that in most cases tends naturally to recovery, so far as each attack is concerned, with a tendency, almost as strong, to relapses. It might, therefore, be considered good practice to treat the patient expectantly as many treat other self-limited diseases. Without wishing to appear as advocating such a policy in any self-limited disease, I wish to point out why we should not, as a matter of routine, in malaria.

Each malarial paroxysm does harm in certain well-known ways, and in some not so well known. Of the first it is enough to mention the destruction of red blood-corpuses, which, even in a seemingly mild case, may be quite extensive, and in a severe paroxysm may amount

* Presented to the Section on Practice of Medicine at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus Ohio, June 6-9, 1895.

to the loss of a fifth or more of all the blood-corpuscles in the body within less than forty-eight hours. At present we have no means of recognizing in practice whether a given attack is going to cease spontaneously or not. Rather complicated stains and considerable time spent in an examination may enable an expert to make a very accurate prediction, but such methods may lead us astray by revealing very few parasites in a specimen, suggesting the probability of a mild case, when the very next paroxysm may be very severe. So, about twelve hours after the first chill in the relapse of a malaria acquired at Santiago, in an examination lasting half an hour, I found very few organisms. Dried preparations, stained and examined carefully, later on confirmed the examination, but the next day it was easy to find parasites belonging to three distinct generations, tertian, in large numbers.

When we remember that we have a drug that will cut the attack short with almost absolute certainty, and usually with little risk to the patient, it is easy to see how the problem differs from that of treating rheumatism with salicylates, or any other acute disease by specific means, not excepting diphtheria and its antitoxin.

Choice of Preparations.—In this paper I use the term quinin in a wide sense, including all the more useful of the cinchona alkaloids. At present the quinin salts and the promising euchinin are the only ones necessary to choose from.

Dose.—One of the most unsettled problems among practitioners in general is the dose of quinin, although among those with special experience the diversity of view is not so marked. In the late war doses of quinin as large as 50 to 100 grains of the sulphate per day were frequently given in the West Indies, and even in army hospitals in this country 48 to 60 grains per day were often used. Yet the most experienced men in Africa, Italy and the East Indies rarely find it necessary to give more than 30 grains per day and usually get good results from half that dose, while 45 grains per day is the maximum of many of the most judicious physicians. In the northern half of the United States the milder intermittents are often checked by a single dose of 5 grains, more certainly with 10. In general, however, 15 grains may be looked on as an average dose in such cases. In the severe and more obstinate estivoautumnal forms 20 grains a day may be taken as the normal dose.

One Dose or Divided.—There is another point on which views differ. A consideration of the processes involved seems to prove to me that the remedy will be most effective if given in one dose. The problem is to check the growth, or to kill, if possible, the parasites. This can most reasonably be expected by bringing the greatest possible quantity of the remedy, consistent with the safety of the host, in contact with the parasites. This is the method most frequently followed by success in the case of many intestinal parasites, and the conditions in malaria would seem to be not dissimilar. In practice it is not uncommon to find patients unaffected by doses of two grains every hour, who are at once relieved of further paroxysms by a single dose of only one-half or one-third the quantity formerly taken in a day. As an intermediate method we may consider that of giving moderate doses, say 5 grains three or four times a day. This method is often successful, much oftener, I believe, than that of giving two grains every hour. Its success, I believe, depends on the fact that the single dose was large enough in the case in question, if given at the right time, to produce a distinct effect on the parasites, and there are some cases in which, owing to the con-

dition of the patient, and his temporary or usual reaction to quinin, this method may be followed with advantage. In ordinary cases, however, where the paroxysms are distinct, the best method is that of giving the whole amount at once, or within a time not longer than two hours.

At What Time Should the Dose be Given?—From the time of Sydenham some of the most eminent physicians have given the drug in the decline of the paroxysms. This is the method recommended within recent times by such men as Baccelli, A. Plehn, Maclean, Manson, Ziemann, and many East Indian physicians. On the other hand there is a tendency at present to give quinin with reference to the expected paroxysm. This practice is perhaps largely due to the influence of Golgi, whose authority in matters malarial is deservedly great. The subject has always been more or less affected by speculation. Sydenham thought that if he gave "the bark just before the fit," he would "check the method by which nature would get rid of the febrile matter." The explanation advanced in favor of the other plan is that by giving the drug several hours before the paroxysm, the parasites just set free would be taken in their most susceptible stage.

The matter seems one that should be settled rather by experiment than by a priori reasoning. This was indeed the method followed by Golgi,¹ but it has always seemed to me that his observations do not bear the conclusions he and others drew from them. He showed that quinin given in the stage of segmentation prevents the growth of the young forms. He claimed that the action of the drug was less certain when the parasites were in the endoglobular stage, and asserted that although given in this stage the paroxysms were often checked, especially in tertian fever, yet there was greater risk of relapses than when the drug was given before the paroxysm. Golgi's observations were made for the most part on quartan fevers, of mild type. In tertian fevers he found that the paroxysms could be checked by giving the drug in the apyrexia, when the parasites were in the endoglobular stage, and he had to suppose that in tertian fever the red blood-corpuscles offer less difficulty to the entrance of quinin than they do in quartans, a supposition that seems rather gratuitous. Golgi, of course, did not aim at aborting the oncoming paroxysm by giving the remedy several hours before. He thought that by so doing he had the greatest certainty of preventing the next paroxysm. Baccelli² made some careful experiments with reference to the most favorable time for giving quinin, using intravenous injections. He found that quinin given at the beginning of the febrile attack, or three hours earlier, did not abort the paroxysm, and that given in the acme, the crisis was not hastened. If given at the decline or end of the paroxysm, it either prevented the next one or rendered it milder. He therefore recommended the decline as the best time for giving the drug, especially in subcontinued fevers.

I had been making observations for two years on the effect of quinin given at different times, when Baccelli's article appeared, and immediately began to give the remedy in the decline. The results were more certain and more satisfactory in every respect than by other methods, so that I have followed it with rare exceptions. In some cases I have given the remedy from three to five hours before the paroxysm. I have also had opportunities for seeing cases treated in the latter way, or at various other times, by colleagues. A number of medical acquaintances have taken up the Sydenham plan, and among these Dr. F. H. Williams³ has published some in-

structive histories, with charts. The real and apparent contradictions between the Sydenham and Golgi methods are well worthy of careful control-observations in which the conditions of the parasites and the temperature and other symptoms, and the administration, absorption and excretion of quinin go hand in hand. As an example the following may be given:

H. G. acquired malaria in Santiago in July, 1898. He was admitted to my clinic, December 31, having had a chill about 11 a. m. The last chill prior to this was two weeks before. For several days before admission there was pain in the back. Just after the chill the blood showed a few half-grown endoglobular bodies, and very few larger ones. In dried and stained preparations the latter showed numerous small vacuoles and in general stained badly. At 8 p. m. there were only a few endoglobular forms, larger than at noon. Many of these were in many small round masses, connected by narrow filaments, suggesting degeneration. No medicine had been taken and none was given.

January 1, at 9:30 a. m., there were many parasites in the blood, one or two in every field—oil-immersion. These were about equally divided between half-grown and almost mature bodies, indicating a double (tertian) infection with paroxysm imminent. The larger forms disappeared without showing segmenting bodies, between this and 12 m., and the temperature rose—between 12 and 1:30; 99.5 degrees and a chill at the latter—reaching 104.5 degrees at 3 p. m. The chill lasted an hour. The temperature began to fall at 4 p. m.: at 4:45 sweating began and continued until 6.

At noon the smallest ameboid forms began to appear in the red corpuscles, and by 4 p. m. it was clear that the endoglobular forms seen before really belonged to two distinct sets, one then about half grown, the other almost mature. The latter were too numerous as well as too far from the stage of segmentation to permit the conclusion that they were belated bodies from the paroxysm in progress, so that a triple tertian was diagnosed. During the chill and fever the patient was given codein in spirit of mildereris, and lemonade.

At 6:45 p. m. the temperature having fallen to 101.6, 5 grains of quinin hydrochlorate were given in solution, and repeated at 7:15 and 7:45. By the time the last was taken the ears were ringing.

The urine was collected every half hour from 6:45 p. m. and quinin tests (bromin) made in the ethereal extract by my assistant, Mr. S. R. Boyce, Ph. C., who devoted much skill and care to the work. Fluorescence appeared half an hour after the first dose, the blue color half an hour after that, and the thalleoquin reaction was most intense from that time up to 8:45 p. m.

At 9 p. m. the temperature rose without a chill to 103.8 degrees and fell from 12 midnight to 9 a. m., reaching 101 degrees. It again rose, reaching 103.8 degrees at 11:30 a. m. At 11:45 there was a chill, lasting 45 minutes. Sweating began at 4.

In the morning the blood showed only large endoglobular bodies, with one flagellate. At 12 noon a few unpigmented ameboid bodies appeared in the red blood-corpuscles. There was, therefore, only one generation left.

At 1 and 1:30 p. m. five grains of quinin were given in solution as before; at 1:45 the patient vomited. As the temperature record shows, the medicine was given too early. The decline of the fever was not positively in progress. Tests of the urine at 1:45 and 2:30 made it probable that some quinin was absorbed, since the reaction became more intense after the second dose. At 7,

7:30 and 8 p. m. the medicine was again taken and the urine examined as before. All traces of the former doses had disappeared. In half an hour after the first dose the reaction was present; marked in an hour, and for two hours after that. It was weak after twelve hours, but visible up to nineteen hours. The parasites were therefore brought in contact with the drug not less than about eight hours after segmentation. They failed to develop, and the patient remained free from paroxysms after 30 grains of quinin retained and 10 partly absorbed, no more being given for seven days.

The case illustrates the rapid absorption of quinin. We did not have an opportunity of making observations on the time of absorption when given before the paroxysm, but two observations on prophylactic doses in the same patient, seven and fourteen days after the last chill, showed slower absorption and more persistent final reactions.

It has been thought by some that Professor Koch has come out as an advocate of the Golgi method in African fevers, which are etiologically the same as our summer and autumn malaria. The matter is only apparent. Koch claimed that in these fevers the quinin must be given at the time when the parasites are in the large stage. In the cases whose charts are published this corresponds to the later part of the decline, and from six to eight hours before the rise of temperature in the next paroxysm.

There are some practical facts bearing on this question that are not introduced into the discussion as much as they deserve. It is often forgotten that the chill does not always occupy the same place in the temperature curve, but comes anywhere from the beginning to the end of the rise, or even later. Since the chill is often taken as the guide to the time of the paroxysm, the difference may render illusory the time limit of three to five hours given by Golgi. Many of Golgi's followers have lengthened the time to eight hours, thus going back to a period at which Golgi claimed the results are likely to be poor. Directions based on the chill are especially faulty in the severer fevers, because there may be no chill.

The real condition of the development of the parasites can only be discovered by the microscope, but such observations may take a great deal of time, and, except in the case of an expert with plenty of time, may be misleading. Even in such a case, the ripening of the parasites in successive individuals extends over so long a time as to throw difficulty about a strict following of Golgi's rule. In tropical cases, such as occur in many parts of the United States, the generations are often very much confused, and the disease is rarely so simple and typical as Koch assumed from his first observations in Africa. Prolonged examinations of the blood are essential for those who wish to study the therapeutics of malaria, but in practice we can hardly ask more than that the microscopic diagnosis be made, with as close an approximation to the stage of development, the forms of the parasites and the condition of the blood as the exigencies permit.

The Golgi method involves two risks which, though usually trifling, can be avoided by the Sydenham plan. The first is that a patient seen in a primary paroxysm may anticipate a tertian fever, and, while waiting for the five hours' time, be taken with the paroxysm of a double infection. Had he taken his medicine in the beginning at least one, perhaps two, fits might have been prevented.

In the second place, the last dose ordered five hours

before the expected paroxysm is often useless, since the parasites are gone. This can be discovered by the microscope. As Williams has well remarked, the method advocated saves quinin.

That absorption from the stomach is less certain and prompt in the time just before the paroxysm, and in the onset, is widely believed, and I think it is true. It is also widely believed that the symptoms of cinchonism are more marked if the effects of the drug appear in the early part of the fever. I think this is also true, though the point is difficult to demonstrate.

A careful consideration of all the data led me to the following conclusions:

In a tertian or quartan intermittent, or any combination or duplication of these, quinin should be given in the decline of the paroxysm if possible; or not later than at the end of the apyrexia. The difference depends on the time the patient is seen or the diagnosis made. The dose should be given at one time, or in parts at short intervals, in such a form that absorption may be confidently expected. I have found it very satisfactory to give the full dose in the form of the hydrochlorate, in capsules, followed by 15 drops of dilute hydrochloric acid. In patients who have been unable to retain other preparations, I have been successful by giving three five-grain capsules half an hour apart, with a small dose of dilute hydrochloric acid after each, with directions to repeat in half an hour if any dose was vomited.

In an ordinary single infection, when the drug is given in the decline, there will not be another paroxysm. In double infections there may be another paroxysm, often milder than the preceding. If there is a rise of temperature of more than a degree, or if the blood shows parasites, a second dose should be given, also in the decline, and if necessary even a third or more. Few cases require more than three. After the temperature falls no quinin need be given for the specific effect, and if it be used as a tonic not more than two grains three times a day should be taken. Other remedies may be used as indicated, the indication for iron being controlled if possible by an expert examination of the blood besides that of the patient in general.

The evidence of the decline of the temperature is best based on the thermometer, used every hour after the chill, but in case the characteristic profuse sweating occurs, it is a sufficiently accurate guide, and the great changes in the body following sweating probably assist in the absorption of the drug.

In the remittent or estivoautumnal fevers, the intervals are not so clearly defined as in the tertian and quartan infections. If they are, the decline of the fever can be recognized by careful use of the thermometer, or by the improvement in the subjective sensations. Very often in these cases the parasites become mature at times varying widely, so that not only is the curve difficult to interpret but the parasites are not equally influenced by the remedy. Very often, too, the symptoms are so alarming or the number of germs found in the blood so large that immediate treatment seems necessary. In such cases the quinin should be given in doses of five to ten grains, according to the severity of the case, at intervals of four to six hours, until a marked remission occurs, and then the daily intermittent dose be given until the fever disappears, or, better, until the condition of the blood shows that quinin is not indicated.

Relapses.—The treatment of the relapses of malaria is a matter of importance. Except in mild cases, a return is to be expected and guarded against. This is a fact long known but apparently often forgotten. Pa-

tients are often aggrieved to find that the "dead-sure" prescriptions of their doctors—usually polpharmaceutic marvels—have not stopped their chills for all time, as they were led to expect.

The relapse often takes place on the seventh day or some multiple of it, either fourteen or twenty-one days, or later. In severe infections, it often comes earlier and in the relapse of Cuban fevers the fifth day or the fourth after the last fit may see the return of a paroxysm. The cause of the relapse is not difficult to explain. The parasites are scotched, not killed, and only reach sulciant numbers to cause another paroxysm after a lapse of time. They can be found, by careful search, before the day of the paroxysm, and they sometimes cause slight elevation of the temperature in the days preceding the relapse. Golgi's claim that relapses are less frequent in cases treated according to his plan than if the drug is given in the decline must have many exceptions. It is therefore advisable to give quinin at intervals after the paroxysms have stopped, even if his method is used. The interval in ordinary tertians should be seven days, in more severe cases five days. In this way we not only lessen the danger of relapses, but we also cause a discontinuous or intermittent sterilization of the blood and hasten the complete recovery of the patient.

Prophylaxis.—The study of relapses throws light on the prophylactic treatment of malaria. Up to the present time no unanimity has been reached regarding the prophylactic use of quinin. We still find that daily doses, both large and small, are in use, usually without securing the desired end, and rarely failing to be more or less deleterious to the stomach. It appears, however, that the discontinuous method is gaining ground. A. Plehn modified the method of F. Plehn by giving the medication every five days instead of every week, and in severe malarial localities this is certainly advisable, on account of the shorter time necessary for the development of an attack in such places. According to his latest statement, F. Plehn prefers to give from one-half to one gram of quinin every week for five or six weeks, then to gradually lessen the dose and lengthen the interval, and to use similar doses after unusual exposure or other probable assisting causes as necessary. The fact that this has been recommended by Professor Koch¹ will no doubt go far toward extending the use of Plehn's method.

Malarial Hemoglobinuria.—One of the most important subjects at present before the profession is that including the so-called malarial hemoglobinurias and quinin hemoglobinurias. These questions are important from the practical standpoint in many parts of the world, though it is probable that the problem is one that really varies in its essential nature in different parts. As examples of the conditions in the eastern hemisphere, we can take the contradictory statements of Koch, the Plehns, Doering and others on the theory and practice of the disease.

Koch was inclined to think, after his first investigations, that the so-called black-water fever of Africa, called by many malarial hemoglobinuria, is a quinin poisoning due to an idiosyncrasy.

Doering² has a report in the same volume in which Koch published his report, in which he considers this subject in detail. His experience with malaria has evidently been more extensive than Professor Koch's. Whether he is as trustworthy I do not know. Doering calls blackwater fever "malarial hemoglobinuria." He declares the immediate cause to be quinin in combination with active malarial parasites. In some cases quinin causes the hemoglobinuria in persons whose blood has

been altered by the tropical life, but he has also seen simple malaria, untreated by quinin, pass into black-water fever. Doering avoids the use of quinin during the existence of black-water fever, but looks on the use of Plehn's method of prophylaxis as the most certain method for its prevention. While Plehn and Doering avoid the use of quinin, many other African physicians, German and English, use it, seeing no bad effects, but obtaining good ones.

It seems hardly satisfactory to ascribe the results of quinin, reported by so many physicians in different parts of the world, to an idiosyncrasy. The geographical distribution of the cases seems to oppose such a view. That quinin may cause breaking down of red blood-corpuscles in those whose blood is already impoverished by malaria, with or without other depressing factors, may easily be admitted. Even if we admit this, however, the question why this occurs in East Africa and not in Algiers, in Arkansas and not in Italy, is not answered. The germs appear to be the same. A further consideration of this would lead us too far from the present subject.

Hemoglobinuria (and Hematuria) and Malaria in the U. S.—From the titles in medical journals one might suppose malarial hemoglobinuria or hematuria very common in this country. Yet a careful study of the literature gives very little valid evidence that such is the case. Proof of malaria, the finding of the characteristic parasites in the blood, is rarely forthcoming in the works of those who claim the disease is malarial at the time of the hematuria. It is generally conceded that microscopic evidence must be submitted before a discussion of even so simple a process as intermittent malarial fever can be profitably carried on. How much more necessary then is such evidence in a condition like hemoglobinuria. In fact, in the current reports even the ordinary clinical features are not always as clearly presented as one might wish, and in discussions of the pathology the more recent additions to our knowledge are often conspicuous by their absence. One finds the work of Béranger Péraud quoted more frequently than Bastianelli, while the important observations of the Plehns, Doering and other recent writers seem almost wholly neglected. It is a suggestive fact that, while in Africa the malarial black-water fever is a hemoglobinuria, in the United States the condition is almost invariably hematuric. In some parts of the country all hematurias are called malarial, just as all neuralgias, all fevers, and many other symptoms are so called. Yet in the South, besides the ordinary hematurias, there is the possibility of numerous cases due to other parasites, neglected as completely in diagnosis as those of Laveran. In some of these districts the patients with hematuria from any cause may easily have a history of past or present malarial infection. This may have an important bearing on the treatment, but does not necessarily entitle the disease the predicate malarial. The profitable inquiry as to the possible relation of past attacks of malaria to the hemoglobinuria, and the careful study of the blood, have been even more neglected than the search for active infection.

The positive study of the so-called malarial hematurias has just begun, and, as was to be expected, statements differ, just as we may readily understand the facts may differ in various cases.

Pending a conclusion, the first thing to do after taking charge of a case of suspected malarial hematuria is to ascertain the possibility of malarial origin or influence, by the history and by exclusion of other possible causes. This is obviously not an easy thing to do. Even outside of malarial regions we find numerous cases of hematuria and hemoglobinuria, the causes of which are difficult,

or sometimes even impossible, to discover within a time useful for etiologic treatment.

More important still, and fortunately easier, is it to discover the presence or absence of malaria at the time. Here the blood examination is all-important, and it cannot be denied, impossible as the thing seems, that ability to make the necessary examinations should be expected of those who practice in malarial localities. I say it seems impossible because it is a fact that other similar knowledge, much longer available, is not as generally applied as it should be. One has only to mention examinations of the urine and sputum.

Taking for granted that the precise conditions have been made out by a complete examination, the question remains: What is to be done? I must limit myself to the use of quinin.

If there is no evidence of active malaria, no matter how much there may have been, quinin is not to be used. This truth is still far from being generally accepted. There is still a belief, difficult to eradicate, that quinin has some mysterious properties in all things called malarial. Yet so far as we know, quinin cannot stop the breaking down of red blood-corpuscles, nor the exit of red cells through the kidneys. True it may act as a tonic, in small doses, but there are other drugs, if necessary, just as useful for that purpose.

It would perhaps be safe to lay down the rule that, in a hematuria the malarial nature of which is not known but only a matter of conjecture, quinin in more than small doses will probably do more harm than good.

If there is a malarial infection with active parasites shall quinin be used? Around this question discussion has been more than warm. Both theory and practice have been called in to solve the problem, but the answer seems more remote than ever. A number of facts should be borne in mind. Quinin is often more or less irritating to the urinary tract. It may therefore, especially in large doses, aggravate a local disease of the kidney—malarial in origin—and cause or increase hematuria. In chronic malarias, with active parasites still present, there may be a large number of young and vulnerable red blood-corpuscles. They may be broken down by the circulating quinin and hemoglobinemia and hemoglobinuria result. This is possible, but whether it occurs, or will occur, in any given case has not been proved and can hardly be positively predicted. In the cases in which quinin is said to have done harm the material element has not been demonstrated. On the other hand some of the most capable Southern clinicians deny such an occurrence, and Woldert, who appears to be the only one who has had experience with the microscopic diagnosis in the South, agrees with them. Curiously enough, many who fear to use quinin in such cases use drugs apparently as dangerous, especially turpentin, and claim to get good results.

Even if the quinin can cause or increase hemoglobinuria, it is not logical to give it up without further consideration. Without the quinin a destruction of blood is likely to occur that is often greater than any hitherto attributed to quinin. The development of each parasite breaks up a red blood-corpuscle, if not completely, at least so much so that it must speedily be entirely broken up in the body. This development of parasites may continue a number of days, unless checked by quinin. In some cases it has been noticed by African observers that the hemoglobinuria seems to coincide with the disappearance of the parasites, but this cannot safely be assumed except by the aid of the microscope. Viewed in this way quinin in malarial hematuria may be compared with an operation for the cure of a dangerous disease—

the anesthesia may be fatal. Or, just as quinin may cause so much breaking down of blood that the kidneys cannot functionate properly, so may the anesthetic seriously affect the heart or kidneys, or give rise to pneumonia.

To sum up, the question of quinin in malarial hemoglobinuria must be settled by careful clinical observation and experiment, and statements regarding it must be given credit in proportion to the accuracy with which the observations are made. In the meantime, quinin can be used cautiously, if parasites are present, giving the drug in a form most likely to be absorbed, in doses within the limit of ordinary safety, and stopping its administration as early as the microscope shows this to be proper. A temporary increase in the severity of the symptoms should not alarm the physician. It is not necessarily due to the drug. At the same time that the specific is being given, other methods of treatment must not be forgotten. The quinin is given to check the malaria, not for any particular symptom or complication.

QUININ IN MALARIA.

THE UNSATISFACTORY RESULTS OF ITS HYPODERMIC ADMINISTRATION.*

BY G. A. FACKLER, M.D.
CINCINNATI.

The application of medical knowledge is most gratifying when it results in accuracy of diagnosis and treatment. In the consideration of malaria we certainly have an opportunity to indulge in such gratification. The clinical picture, supplemented by manifestations on the part of the blood as presented by microscopic examination, furnishes the data for accurate diagnosis. The efficacy of quinin as a curative agent in the treatment of malaria has placed it among the small list of specific remedies. The comparative ease with which we can now diagnose a case of malaria and the confidence with which we can predict its defeat by quinin leaves only the consideration of the best and most reliable method of its administration.

Prior to the summer of 1898 I had occasionally resorted to the hypodermic administration of quinin in the treatment of malaria, but lack of brilliant results failed to stimulate me to the general adoption of this plan. The encouraging reports casually offered by some army surgeons who had resorted to the subcutaneous use of the drug in malarial patients of the Southern camps induced me to employ it in a series of cases which came under observation in the Cincinnati Hospital in the summer and fall of last year. Herewith, then, are offered the clinical facts elicited by a review of twenty cases, confirming the cursory previous observations made as to the unreliability of quinin administered hypodermically in malaria. Refraining from a complete report of these cases such as would render them proper for publication, I submit an abridged statement of the salient features thereof, adapted to the time limit and your patience. The cases may readily be assigned to one of three classes: Three to the first class, successfully treated by hypodermic injection of quinin; 7 to the

second class, successfully treated by quinin administered by the mouth; 10 to the third class, treated ineffectually by quinin hypodermically, but effectually by substitution of quinin by the mouth.

Classes 1 and 2 may be offered in sums total, Class 3 will be treated with sufficient detail to bring out the points that exemplify the object of this report in the most striking manner.

CLASS I.

Cases 1 and 2 were patients presenting all symptoms of double tertian fever, Case 3 a patient with a history of irregular chills and fever for three weeks, and blood examination disclosing numerous crescents and ovoids—a total picture of an estivoautumnal type of malarial infection. In these three cases quinin bisulphate, gr. xv administered hypodermically twice daily, controlled the paroxysms within thirty-six hours, and, continued in gradually decreasing doses for a week, prevented a return.

CLASS II.

Cases 4 to 10, inclusive, were readily diagnosed as double tertian. In all these cases the daily administration of gr. xx to xxx of quinin bisulphate, usually in morning and evening doses, controlled the paroxysms within twenty-four to forty-eight hours. In none did the daily temperature attain a height above 100 after twenty-four hours of quinin treatment and in none did the temperature rise above normal after seventy-two hours.

CLASS III.

Case 11.—James Scott, admitted Aug. 19, 1898, had paroxysms of chills and fever daily since August 15.

Aug. 19. At 1:50 p.m., temp. 105. Intracorporeal pigmented and non-pigmented plasmodia found in large numbers.

Aug. 20. At 9 a.m., temp. 98.4; quinin, gr. x hypodermically; at 12 m., chill for twenty minutes; at 1 p.m., temp. 105.6.

Aug. 21. At 6 a.m., temp. 98.8; quinin bisulph., gr. x, at 9 a.m. hypodermically; at 12 m., temp. 105.8, preceded by chill at 11:20 a.m., quinin bisulph., gr. x, at 9 p.m. hypodermically.

Aug. 22. At 6 a.m., temp. 99; quinin bisulph., gr. x, at 9 a.m. hypodermically; 12 m., temp. 104.6, after chill; quinin bisulph., gr. x hypodermically at 9 p.m.

Aug. 23. At 6 a.m., temp. 99; quinin bisulph., by the mouth, 9 a.m.; 12m., temp. 102.2; quinin bisulph. by mouth at 6 p.m.

Aug. 24. At 9 a.m. and 6 p.m., quinin bisulph. by mouth, gr. x; temp. not over 99, normal throughout succeeding three days during which this treatment continued.

Case 12.—Harry Carr, admitted August 19, had been ill for six weeks, with irregular attacks of fever daily. His daily lowest temperature was about 12 m. varying from 98.2 to 98.8, rising with occasional chill.

Aug. 19. Temp. rose to 103.4 at 6 p.m.

Aug. 20. Temp. rose to 101.2 at 6 p.m.; quinin bisulph., gr. x, hypodermically at 8 p.m.

Aug. 21. Temp. 102 at 5 p.m.; quinin bisulph., gr. x, hypodermically at 5 p.m.

Aug. 22. Temp. 102.6 at 5 p.m.

Aug. 23. Temp. 102.6 at 5 p.m.

At 6 p.m., Aug. 23, and at 9 a.m. and 6 p.m., Aug. 24, quinin bisulph. was administered by mouth. As a result, the temperature never rose above 99. Treatment continued for three days.

Case 13.—George Wilson, admitted Aug. 20, had quotidian chill and fever during the preceding two weeks.

Aug. 20. Intracorporeal pigmented and a few hyaline plasmodia. Lowest daily temperature, between 6 and 9 a.m., from 98 to 98.6.

Aug. 21. Highest point reached was 102.2, at 6 p.m.

Aug. 22. Quinin bisulph., gr. x, hypodermically at 10 a.m.; temp. rose to 104.6 at 6 p.m.

Aug. 23. Quinin bisulph., gr. xv, hypodermically at 12m.; temp. rose to 104.6 at 6 p.m.

Aug. 24. Quinin bisulph., gr. xv, hypodermically at 12m.; temp. rose to 104.2 at 5 p.m.

Aug. 25. Quinin bisulph., gr. xv, by mouth at 12 m.; temp. rose to 101 at 3 p.m.

Thereafter quinin was administered at 6 a.m. and 6 p.m., in doses of gr. xv, and temperature normal.

Case 14.—Armstrong, admitted Aug. 29, had been ill for six weeks prior to admission. During the first three weeks he had chills and fever on alternate days, and thereafter quotidian paroxysms.

Aug. 29. Found intracorporeal pigmented hematozoa occupying nearly the whole of the corpuscle. Lowest daily temperature at about 6 a.m., varying from 97.6 to 98.2. Highest point reached was 101, at 4 p.m.

* Presented to the Section on Practice of Medicine, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

Aug. 30. Quinin bisulph., gr. x, hypodermically at 10:30 a.m.; temp. 104.4 at 12 m.

Aug. 31. Quinin bisulph., gr. x, hypodermically at 9 a.m.; temp. 105 at 12 m.

Sept. 1. Quinin bisulph., gr. x, hypodermically at 9 a.m.; temp. 98.4 at 12 m.

Sept. 2. Quinin bisulph., gr. x, hypodermically at 9 a.m.; temp. 105 at 3 p.m., and repeated the dose at 9 p.m.

Sept. 3. Quinin bisulph., gr. x, hypodermically at 9 a.m.; temp. 103 at 9 p.m. Repeated the dose at 9 p.m., and thereafter at 9 a.m. and 9 p.m.; quinin bisulph., gr. xv, by mouth, brought and held temperature at normal.

Case 15.—Chas. Stahl was admitted Sept. 16, with history of irregular attacks of chills and fever during preceding two weeks. Blood examinations were negative until Sept. 19, p.m., when large flagellate plasmodia were found. From Sept. 16 to Sept. 20, temp. varied from 98 to highest between 6 and 9 p.m.—from 104 to 105.4.

Sept. 20. At 9 a.m. and 9 p.m., quinin bisulph., gr. xv, hypodermically; temp. 9 p.m. 104.

Sept. 21. At 9 a.m. and 9 p.m., quinin bisulph., gr. xv, hypodermically; temp. 9 p.m. 104.

Sept. 22. At 9 a.m. and 9 p.m., quinin bisulph., gr. xv, by mouth; temp. 99.8 at 6 p.m.

Sept. 23. Treatment continued with temperature normal.

Case 16.—Albert Miers, admitted Sept. 16, had onset of present illness the day before admission with chill and fever; lowest daily temperature between 3 and 9 a.m., varying from 98 to 99. Highest temperature Sept. 17, at 12 p.m., 103.8; Sept. 18, at 12 p.m., 103.6; Sept. 19, at 12 p.m., 102.2. Blood examination showed intracorporeal bodies.

Sept. 20. Quinin bisulph., gr. x, hypodermically, at 9 a.m. and 6 p.m.; temp. 102 at 9 p.m.

Sept. 21. Quinin bisulph., gr. x, hypodermically, at 9 a.m. and 6 p.m.; temp. 102.2, 9 p.m.

Thereafter quinin by mouth, gr. x, twice daily, with total subsidence of symptoms; no elevation of temperature over 99.2.

Case 17.—H. Herberg, admitted Sept. 19, with history of chills and fever daily for several weeks. Sept. 20, blood examination showed intracorporeal pigmented bodies; lowest daily temperature between 3 and 6 a.m. varying from 97.4 to 98.

Sept. 20. Highest point attained 105, at 12 m.

Sept. 21. Quinin bisulph., gr. xv, at 9 a.m.; temp. to 104.4 at 1 p.m.

Sept. 22. Quinin bisulph., gr. xv, at 9 a.m. and 6 p.m.; temp. to 105.4 at 12 m.

Sept. 23. Quinin bisulph., gr. xv, at 9 a.m.; temp. to 104 at 12 m.

Sept. 23. At 6 p.m. and Sept. 24 at 9 a.m., quinin bisulph., gr. xv, by mouth; temp. to 100.2 at 9 p.m.

The same treatment continued resulted in elevation of temperature Sept. 25, to 100 at 6 p.m.; thereafter normal.

Case 18.—Jacob Jauch, admitted Sept. 19, with history of chills and fever for two days preceding admission. Sept. 19, small hyaline intracorporeal bodies found; lowest daily temperature at about 6 a.m., varying from 100 to 102.

Sept. 19. Highest temperature at 3 p.m., 106.

Sept. 20. Highest temperature at 9 p.m., 106. Quinin bisulph., gr. xv, hypodermically at 9 p.m.

Sept. 21, 22, 23. Quinin bisulph., gr. xv, hypodermically, twice daily; temp. rising with chill each day between 3 and 6 p.m., to 104.8 to 105.5.

Sept. 24. Resorted to administration of same doses of quinin by mouth, morning and evening, and continued this method with following result.

Highest temp. on Sept. 24, 103; Sept. 25, 101; Sept. 26, 99; thereafter normal.

Case 19.—Schwenk, admitted Sept. 21, had chills and fever daily for about two weeks. On day of admission numerous pigmented and nonpigmented intracorporeal bodies were found; lowest daily temperature at 3 to 6 a.m., from 97.8 to 98.2.

Sept. 21. Temp. at 3 p.m., 105; quinin, gr. xv, hypodermically, at 6 p.m.

Sept. 22. Quinin, gr. xv, hypodermically at 9 a.m. and 6 p.m.; temp. at 3 p.m., 104.6.

Sept. 23. Quinin, gr. xv, hypodermically at 9 a.m. and 6 p.m.; temp. at 3 p.m., 104.

Sept. 24. Quinin, gr. xv, hypodermically at 9 a.m.; temp. at 3 p.m. 102.6; quinin by mouth at 6 p.m., and thereafter at 9 a.m. and 6 p.m., with abeyance of all symptoms on Sept. 25.

Case 20.—Seiler, admitted Sept. 21, onset of illness indefinite.

Sept. 22. Numerous crescents and ovoids and some hyaline intracorporeal bodies were found; ostivoautumnal; lowest daily temperature at about 6 a.m., about 99.

Sept. 21. Temp. to 103 at 12 p.m.

Despite hypodermic administration of quinin bisulph., gr. xv, at 9 a.m. and 6 p.m. on Sept. 22, 23, 24, temp. rose to 103 to 104.2 between 9 and 12 p.m.

Sept. 25. Order was changed to quinin by mouth, in same dose and at same interval. Temp. highest Sept. 25 at 9 p.m., 99.4, and thereafter normal.

A general resumé of the 20 cases furnishes the following data: In 3 cases quinin hypodermically was successful; in 10 cases quinin was not successful; in 7 cases quinin by the mouth was successful; in 10 cases quinin by the mouth was successful after hypodermic administration had failed—a total of 17 cases in which quinin by mouth was successful as a curative measure in the treatment of malaria. In only 3 out of 13 cases, in which the remedy was introduced subcutaneously was an abeyance of symptoms secured. This experience was certainly at variance with that reported casually by some of our army surgeons.

It is but natural that we should seek for a rational explanation of this fiasco of hypodermic medication. We were assured of the correctness of the diagnoses, for no cases were designated as malarial unless the blood examinations furnished evidence which would warrant the diagnosis. All compounds of quinin, or better said, all salts of the alkaloid, have a toxic effect upon the malarial organism, and hence a curative action when administered in malarial diseases. The failure cannot be attributed to the compound employed, per se. The beneficial effect of the same preparation from the same stock when given by the mouth dispelled all doubt as to the therapeutic power of that compound. The procedure adopted for injection and the site selected were in perfect accord with the plan followed by most clinicians and observers. Where then was the defect in the inherent curative value of the method? The therapeutic failure of any remedy can not be ascribed to it essentially unless positive evidence of its absorption is furnished. It was a noticeable observation in all of our cases in which hypodermic medication was resorted to that after the majority of injections, the patients complained of pain in the region implicated by the injection. In some instances a distinct deep-seated hardness of tissue persisted for days after the treatment. It is a conjecture, in all probability bordering upon a certainty, that the solution, while dilute, as it must be with the use of the bisulphate, causes decided irritation of the tissues with which it comes in contact. The resultant localized disturbance of the circulatory conditions of the parts involved interferes with the absorptive power of the area and thus the remedy creates a bar to its own absorption.

If the observations thus submitted to you are indicative of the general experience among a larger number of cases with the same or other compounds of quinin we are forced to the assumption that the hypodermic use of quinin in malaria is never indicated except in cases in which stomach and bowels reject the dose ingested or injected. Unless my observations and deductions are erroneous, because of the uncertain action of the hypodermic injection of quinin, its administration by the mouth should be adopted in all cases.

DISCUSSION ON PAPERS OF DRs. DOCK AND FACKLER.

DR. CHARLES G. STOCKTON of Buffalo.—It seems to me the papers are most timely. For some time there has been growing confusion as to the exact place of quinin in the treatment of malaria. Now, in the matter of the time for the administration of quinin by the mouth, as suggested by Dr. Dock, I beg to take exception. There should be no rule of time for all individuals alike; it requires a study of each individual case to determine at what particular time the drug will affect the plasmodium. It depends too upon the primary digestion of individuals. In some instances the effect of the drug is ex-

erised in the course of an hour. Dolge's method of giving quinin previous to the paroxysm has not met with the expected success.

Cinchonism is found to be more intense if the quinin shows an effect, and yet the paroxysm still comes on. Quinin is said to be difficult of administration; all will not agree with the writer; it is easy of administration. I question the hypodermic use of quinin mentioned by Dr. Fackler; I have had experience during the past year, and I have come to the same conclusion that he has reached. In one case there was failure to relieve the paroxysm by hypodermic use of the drug, but the patient was relieved by the administration of the drug by the mouth. In that case, as well as in two others, there happened troublesome abscesses at the seats of injection, which was something I had never seen before. The local irritation probably accounted for the slow absorption of the quinin and the non-relief of the symptoms.

Dr. JUDSON DALAND of Philadelphia.—I wish to express my pleasure in hearing the paper and wish to speak in regard to two points. So far as the use of quinin is concerned, my experience has taught me that two things are to be considered—does malaria exist, and is quinin absorbed? Exclusive of hospitals, experience teaches that less than half the cases diagnosed as malarial are truly malarial. I am speaking of the cases that come in the ordinary course of practice, and not the cases that come under close observation in hospitals. I was especially pleased with the statements made in reference to the quantity of quinin to be employed, and also as to the time it should be administered. Personally, I am distinctly of the opinion that the bichlorid of quinin is the preferable salt, on account of its solubility and the fact that the solution is reliable. So far as the dose is concerned, I agree with the statements made by Dr. Dock. As to the time of giving the dose it seems to me that one particular point should be considered, i. e., the time in the life cycle of the plasmodium when it is most susceptible to the action of quinin. In other words, I am inclined to the opinion that the time for giving the quinin is soon after the violence of the paroxysm has passed over. This corresponds to the time that there is a maximum quantity of free amoeboid bodies in the blood. It is highly probable that when the malarial parasite enters the red blood-cells, quinin circulated in solution in the plasma could not exert its effects so completely as when the parasite is free in the blood. This particular time accords well with the observations of Dr. Stockton and I am sure that benefit is to be obtained from a preliminary course of calomel. After the paroxysm there is an increase in the absorption of the cinchona salt. It is interesting to know that non-absorption of quinin is a common occurrence.

While observing a case of ordinary tertian intermittent fever the hematocrit showed a loss of 10 per cent. of red blood-cells as the result of a single paroxysm of chill, fever and remission.

Hemoglobinuria is a rare occurrence. I recollect one specimen sent me from Louisiana. Hemoglobin alone was present, but upon examining the sediment, a few shells of red blood-corpuses could be seen. I also recollect another case in which the albuminuria increased during each succeeding paroxysm of the attack.

Dr. F. S. JOHNSON of Chicago.—The absorption of quinin is very uncertain. It is impossible to treat in any other way than by hypodermic injection or by inunction and be sure of your results. I will relate one case as an illustration of this. A man who had been very strong and who became extremely weak, was given quinin by the mouth without effect. Hypodermic injections of large doses of quinin were given, 40 to 60 grains by deep injection, and soon the malarial subsided and the patient got well. It was so weak at the time that it was impossible for him to rise from the bed. The hypodermic injection was made by deep puncture. Quinin given subcutaneously may cause sloughs; but if deep injections be given there will be no sloughs or abscesses if the solution used be sterile. In many cases quinin by the mouth has a different effect from that given in some other way. I saw a lady with well-pronounced intermittent fever, not of severe type. When she took quinin by the mouth she had delusions and hallucinations. She took it several days without effect, but when the fever began to respond to the quinin and the paroxysms became less severe she had dreams. She recognized them as dreams, but one morning she thought that all the dreams she had had were real. The quinin was stopped and the hallucinations subsided, but then the fever returned. I was in a quandry as to what treatment to give. The rectum was irritable, so I could not treat her in this way. She was a highly nervous, sensitive woman and I did not dare to propose the use of this method. I then gave her from 150 to 200 grains of quinin mixed with equal parts of oleic acid

and one-third the amount of cocoa butter, and this was rubbed in daily. The temperature then came down and did not return, nor did she have any more hallucinations. Quinin by the mouth has a different effect from that when given by the skin, by inunctions or hypodermatically. In another case of a returned soldier the quinin was given by inunction; 200 grains were given daily. He could not take the drug by the mouth or rectum, for it would not be absorbed. He was afraid to take the injections through fear of abscesses. He took it by the skin in this way, and his recovery was very prompt.

Dr. H. A. HARE of Philadelphia.—It seems to me the discussion of an important subject illustrates one of the most important points. The readers of the papers and the discussers, including myself, are men who may have less opportunity of studying the conditions now discussed than many of the gentlemen in the audience. I think it is rather unfortunate that physicians who have large opportunities credited to them have not done more toward the study of this subject.

What has been said regarding the absorption of the drug is true. I think one of the greatest questions connected with the therapeutics of quinin is regarding the time to give the drug; physicians are not sure of the alimentary canal, whether it is in condition to receive the drug. Quinin is precipitated by the juice of the stomach, and it is often found that it will not be absorbed at all. The use of mercurials and acids as resorted to in the South is exceedingly advantageous. I am inclined to believe that many physicians, not having been trained in the use of the microscope, often make a diagnosis of this disease when malaria is not present at all; I often come across cases illustrating this point. Again the diagnosis is often made of malarial fever, mild in character, which is not malaria at all. I would like to reiterate the fact that where the clinical course is like certain types of malarial fever a blood examination alone will prove the diagnosis to be correct.

It is unfair to Dr. Dock to refer to a certain method as the God's method. My experience has taught me that this is the proper time to give the quinin, and I have used it months with great success.

One other point regarding the hypodermic administration of the drug; this is most useless. I make a difference between the hypodermic method and the intravenous injections. There is great difficulty in absorption except in an acid medium. Quinin in the tissues is precipitated by the alkaline juices of the tissues. The quinin is precipitated and is immediately surrounded by an inflammatory exudate and is absorbed like cat-gut ligature. The drug should be injected into the veins; the medium in which it is carried is a normal saline solution, and it should be injected slowly. There is one important point that physicians should remember: that is that when quinin comes in direct contact with the heart it is terribly depressing; in animals it acts in the same way as in man. In a Newfoundland dog quinin was injected into the veins and the heart stopped at once. Do not forget the point that large doses are depressing to the heart, and may do the patient much damage.

Dr. DEXHAM of Cincinnati.—I wish to make a plea for the use of the hypodermic syringe. There is a salt of quinin which is sometimes overlooked, and that is a double salt put up by Merck. It is soluble in equal parts of water, and can be injected in small quantities between the gluteal fold. This injection will be absorbed, and cases will yield readily if it can be kept out of the muscles, and the inflammation kept down. All cases of malaria need not be treated by hypodermic injection, but only those cases where it is impossible to get quinin into the system in any other way. The great trouble seems to be in finding out when to give the quinin, and whether you have not something else to contend with. There is nothing nicer to give with quinin than calomel or a little acid; I prefer the calomel. The time of giving quinin is very important—that is, the time of getting quinin into the blood. If quinin is brought into the blood at one time it is one thing; but if at another time, it is another. If the malarial organism is surrounded by red blood-corpuses it is difficult to get the quinin to act upon the organism. If the quinin is introduced after segmentation, good effects will follow. In the tertian or quartan forms you do not get the full effects in the first day; it is best to catch the organisms as they are segmenting. By using the double salt of quinin you can place in the blood your drug at the time it is needed. The pain in using the hypodermic injection is very greatly reduced—almost to a minimum—by using the double salt of quinin, using two parts of water, and by keeping between the deep gluteal muscles.

Dr. J. C. WILSON of Philadelphia spoke of his experience in the German Hospital of Philadelphia with reference to outbreaks of malarial disease latent for weeks and months, in soldiers who had served in Cuba and Porto Rico. Many of these cases had stubbornly resisted quinin by the mouth, even

in large doses and administered under most varied circumstances, but yielded to moderate doses by the hypodermic method—in some instances the double salt of quinin and urea being used; sometimes the hydrochlorate of quinin.

With reference to the precipitation of the quinin salts in the alkaline fluid of the subcutaneous tissues our knowledge is somewhat limited. If precipitated it is certainly redissolved and absorbed, as shown by unquestioned therapeutic results. If precipitated under these circumstances, it is equally liable to be precipitated in the blood when introduced into the veins.

The cases of Panama and Chagres fever, at one time common in our coast-wise vessels, usually admitted to the hospital comatose, yielded promptly to large doses of quinin hypodermically and by the rectum.

Dr. GEORGE DOCK of Ann Arbor, Mich.—In order to make my paper short I left out all else except that which referred to quinin alone. Individuals differ, and a great deal is often required besides the giving of quinin. Regarding Dr. Fackler's paper, he has given strong evidence of what a number of observers have stated. In all cases of Dr. Fackler's, quinin was given at a time when it was less likely to do good. In regard to the hypodermic injection I only wish to state that the hypodermic method, in my opinion, is necessary in many cases. Deep injections are better than strong injections. If given in the muscles there is less pain and less tendency to the formation of abscesses. In any case the salt of quinin is apt to give pain and to cause abscess; these facts cannot be lightly turned aside.

Dr. G. A. FACKLER, in conclusion, wished to be positive that his statement in regard to the method of quinin injection was not misconstrued. In every case the deep injection was resorted to. In no case was an effort made to administer the remedy at a time coincident with a certain phase of the fever, and, yet, to some of our patients it was accidentally given in accordance with the suggestions of Dr. Dock. The question of the proper time for the exhibition of quinin in malaria is still *sub judice* and will probably never be settled to the satisfaction of all. The preceding discussion illustrates the various opinions ascertained as to the absorption of quinin. It is universally acknowledged that the condition of the digestive tract and of the circulatory organs play an important role in the absorption of the drug. The amount absorbed and the period required for this act must vary with the condition of the part into which it is introduced. Hence the utter folly of predicting the positive action of quinin within or at a specified period of time after its administration by mouth or injection. Much more rational is the introduction by either method into the body, of a dose, at stated intervals in the course of the day so as to insure the presence of a therapeutically effective amount of quinin in the circulating media at all times during that day. This plan was followed in all our cases and the results secured were certainly practical illustrations of its efficacy. I desire finally to call attention to the dearth of detailed reports of series of cases treated by the hypodermic injection of quinin and the uncertainty of the value of observations made upon one case by one individual. It would certainly be desirable that those who have made general assertions as to the efficacy of this method in the treatment of malaria should contribute specific reports of their cases to the literature upon the subject.

EXSTROPHY OF THE BLADDER.*

BY C. A. WHEATON, M.D.
ST. PAUL, MINN.

None of the congenital defects of man have elicited a greater diversity of opinion as to etiology, or more difficulty in correction than those affecting the genital extremity. Until a comparatively recent date the deformities of the genitalia of the male and female offspring were attributed to failure in the evolution of the structures which go to make up the distinctive characteristics of sex.

Embryology teaches us that the allantois is the fetal structure from which is derived the bladder and its suspensory ligament; that the urethra is primarily a groove opened below, which gradually advances from the urogenital sinus, and from the imperfect closure of this groove and the imperfect elaboration of this allantoic structure arise the defects which I have selected to here

discuss briefly. The latest, and perhaps the best, résumé of this subject is to be found in an article written by F. Tilden Brown¹. In this he leads us to understand that the etiologic factor in the production of hypospadias and epispadias is practically the same, that "both conditions are due to the rupture of the urethra in consequence of urinary retention by the absence or retarded formation of the glandular urethra."

"The usual theory of epispadias is similar to that which explains hypospadias as due to incomplete or faulty development of the parts affected. Thus, Thiersch regarded the malformation as due to a pelvic closure and division of the cloaca, which was faulty as regards time. Under normal circumstances pelvic closure occurs first, so that the corpora cavernosa, developing in connection with the rami of the pubes, are already agglutinated to the sexual buds before the sinus urogenitalis is pushed forward by the developing perineum. But if the cloacal division occurs before pelvic closure, the two halves of the corpora cavernosa are not united; the urogenital sinus is pushed forward between them, and they unite below instead of above it. This hypothesis evidently depends for its premise on the absence of the symphysis, and, unfortunately for it, the symphysis is not always absent. On the other hand, a number of facts undoubtedly favor the rupture hypothesis, and are quite inexplicable on any theory of defective development. Absence of imperviousness of the urethra leads to accumulation of urine in the bladder and dilatation of that organ; a rupture occurs at a time when the abdominal envelopes are not yet quite perfect, and this rupture may affect the entire urinary sac and the navel down, or only its lower part. So we get epispadias with extrophy of the bladder, or simple epispadias. Thus, Thiersch has proved, both in the dead and living subject, that the ureters are much dilated in all these cases; he even succeeding in passing a No. 6 English catheter through the ureters into the pelvis of the kidney. Scar tissue also is found all around the bladder opening, as from an unsuccessful plastic operation—distinct evidences of rupture and cicatrization.

"But the most incontestable proof of the correctness of this so-called mechanical theory of the origin of epispadias is found in the cases of intra-uterine healing of extrophy of the bladder and of epispadias, of which the best case is that of Kuster. Here, in a boy 1 year and 7 months old, an unmistakable scar stretched from the umbilicus on to the dorsum of the penis. In fact, it may well be that the separation of the pubic rami is the direct effect of the same urinary retention that causes rupture of the vesical and urethral walls. Thus, an early rupture of the urethra would give us a simple epispadias with normal symphysis, whereas, if this early rupture does not occur, the symphysis separates; if the urethra now ruptures, we get simple epispadias with absence of symphysis. If both bladder and urethra rupture we get extrophy of the bladder and epispadias."

It has been unquestionably demonstrated that the excretion of urine is active during the latter months of fetal life, and that the bladder undoubtedly fills and empties itself frequently during that period, and a careful review of the literature of the subject leads me to believe that this is the correct explanation of these peculiar caprices of Nature. It is not my purpose to discuss the causes of these defects; but to submit for your consideration the following cases which seem to me to be of special interest.

* Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

¹ Disease and Injuries of Urethra; Morrow's "Genito-Urinary Diseases," vol. i.

The case of a Prussian, 23 years old, who presented himself for examination with the hope that I might be able to relieve his hypospadias and correct the incurvation of the rudimentary penis, is of interest. He was of good physique, but with a somewhat effeminate face; just a suggestion of a beard about the cheeks. Stripped, standing erect, with his face covered, he seemed to be a muscular woman. He had a well-developed bust, effeminate shoulders and upper arms. From the navel down, however, he was decidedly masculine. He had masculine hips, masculine thighs and legs; the external genitalia suggested a female vulva, but unusually prominent. When he lay on his back, with thighs separated, I was able to demonstrate a perineal hypospadias; that the structures which resembled the vulva were really the scrotal pouches containing a testis on either side of the median fissure and the urethral opening deep in the

this unusual condition by providing the young man with a mammary development which would be in consonance with his apparent sex. This case, in this light, is unique and worthy of record. I would add that an examination per rectum demonstrated the existence of a prostate and other pelvic structures normally a part of the genito-urinary apparatus.

Another case, a male of 17 years, of American parentage, and fair physical development, came to me for the relief of incontinence, the urine escaping from a penile epispadias of which he had been the unfortunate possessor since birth. The penis presented on its dorsal aspect, from beneath the pubic arch to the glans, a groove lined with mucous membrane which could be followed back beneath the pubic arch so that the finger could be

perineum, with a groove running forward to the rudimentary penis, lined with mucous membrane, and which suggested the introitus vaginae. This young man was masculine in his tastes and voice, and had it not been for the development of the mammae would have been of no special interest other than that of an aggravated hypospadias. He has no affinities for his own sex, stating that they were entirely confined to the opposite sex. There had never been any suggestion of menstruation; there had never been any periodic bleeding. The mammae were quite symmetric and the size of those of a girl of ordinary development at the age of 18 years. They were not of unusual size until the age of puberty, and developed at the time when the sexual characteristics became a pronounced feature of the development of the boy. He was then a mixture of the two sexes. It would almost seem that Nature, realizing the imperfection of the congenital development, had supplemented

introduced nearly to the neck of the bladder. The prostate seemed rudimentary, but was normal in shape. He was unable to keep himself dry because of the incontinence of urine.

I did not adopt the operation advised by Thiersch, namely, that of establishing a perineal fistula before attempting to close the epispadias; but made a roof to the urethra by bringing down a flap of skin which occupied the crescent-shaped, hairless surface immediately above the arch of the pubis. A trap-door was dissected down and laid along the dorsum of the penis, its epithelial surface being applied to the roof of the urethral furrow, and its lateral margins being let into slits on either side of the prospective urethra and there fixed by interrupted sutures. A catheter was kept in the bladder for a week and the boy kept sufficiently under the influence of opium to prevent erection. About half of the transplanted flap united, and incontinence has been entirely

overcome. The operation was a failure so far as restoring the canal in its entirety is concerned, and will have to be repeated in order that the organ may be of service for procreation. The physician who attended the accouchment at the birth of this child states that the little rudimentary penis was adherent to the abdominal wall and that he separated it from its adhesion by simple traction. These cases are sufficiently rare to justify their being made a part of the literature of this most interesting deformity.

The third case is one of aggravated epispadias with exstrophy of the bladder. This one I operated on when he was 16 years of age. He suffered, as all such unfortunately do, from eczema of the lower abdomen and thighs; was a constant source of offense to himself and everybody else, in consequence of the exposed surface of the bladder and the constantly leaking ureters. There

down beneath this bridle and fixed it by sutures. I then turned down a crescent of skin from above the bladder, inverting it, thus turning the epithelial surface inward. Then flaps of sufficient size were brought up from the groins, rotated on their pedicles and brought in contact with the raw surface of the crescent brought down from above. He recovered from the operation, which was made some five years ago, and has been made infinitely more comfortable by it. Of course, he has incontinence, but the urine is discharged only through the one opening, i. e., the urethra which I made, and he is able to direct it into a rubber urinal, which keeps him dry.

All these cases presented, in the immediate vicinity of the defects, the peculiar condition of skin referred to above, suggesting old cicatrization. There was comparatively little hairy development on the surface of the last boy's abdomen at the time I turned the crescent down to make a roof for the bladder. When I saw him a few days ago he told me that he was suffering from the presence of phosphatic deposits in and about the bladder, and on examination I was able to detect the presence of numerous little stalactites which had their origin from the deposits of urine salts on the hairy projections from the bladder roof.

In the case of epispadias without exstrophy of the bladder, the urethra terminated in a funnel-shaped opening beneath the pubic arch. The bladder was continent until the quantity of about eight ounces of urine was overpassed, when the incontinence commenced. The boy, while wet all the time, if asked to urinate, would pass about eight ounces of urine. The urine emerged from beneath the pubic arch in explosive fashion, and there was absolutely no ability to direct it into any receptacle. Since the operation he has been able to direct it with comparative accuracy. This condition of affairs demonstrates that, while the repressive influence of the deep urethra was deficient, it was not entirely wanting, inasmuch as my having been able to extend the urethra about an inch beyond the pubis has done away with incontinence and has put the function of the organ practically within his control.

EXSTROPHY OF THE BLADDER.*

BY DUDLEY P. ALLEN, M.D.

Professor of Surgery, Western Reserve Medical College; Surgeon to Lakeside Hospital; Member of the American Surgical Association.

CLEVELAND.

In presenting to this Association a case of exstrophy of the bladder, it is not my purpose to enter on a prolonged discussion nor into a lengthy historic sketch of the various operations which have been proposed for its relief. I wish simply to present a case on which I have operated, that it may be added to others operated on in the same way, and thus bear evidence of the success of this method of treatment. It may be in place, however, in presenting the case, to speak very briefly of the various operations which have been introduced for the relief of the malady, together with some of the objections to them.

All methods which have been introduced for the formation of a covering for the exposed mucous membrane of the bladder have two objections. The first is that, although by covering the exposed mucous membrane they preserve it from external irritation, they do not prevent

was a rudimentary penis and a rudimentary corpora cavernosa attaching to the rudimentary pubic bones on either side, the pubic symphysis being entirely absent. The right testicle was in the inguinal canal; the left undescended and could not be felt. The cutaneous margins of the exstrophy, particularly in the median line, presented a peculiar cicatricial appearance "as though an unsuccessful plastic operation" had been made, as mentioned in the foregoing portion of my paper, but strangest of all in this boy's case, was the absence of a navel. The allantoic structures had evidently failed to be continued to the normal point of attachment for the urachus, and the umbilical cord had emerged from the opening immediately above the exposed bladder. I dissected a quadrangle of skin free, the long axis of which was transverse to the vertical axis of the perineum, leaving both ends attached. I pulled the rudimentary penis

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus Ohio, June 6-9, 1899.

the escape of urine. This escapes and soils the patient, exactly as it did before the operation. The method of covering the mucous membrane by turning a flap of skin over on it, placing the epithelium of the skin next to the bladder, by whatever means it is accomplished, has a second very grave objection, viz., that the hair of the integument favors the incrustation of the interior of the artificially formed bladder with phosphates. The discomfort caused by the presence of phosphates in the cases which I have observed is far greater than the discomfort arising from the exposed mucous membrane. In several cases of this sort, operated on by other surgeons, and which have come under my observation, it has been necessary for me to clear away the phosphates. The suffering which they caused was so great that the operation has been worse than useless.

Murrey¹ has proposed an operation differing somewhat from those usually employed. He describes three cases in which he has covered the mucous surface of the bladder by flaps cut from either side of the bladder, the flaps being a little broader than the exposed mucous membrane, these rectangular flaps being drawn together over the bladder and united in the median line. The integument is not turned inward, as in most other operations, but the raw under surface of the flap comes in contact with the mucous surface of the bladder and heals by cicatrization. He claims that his cases have been less troubled by the accumulation of phosphates than those operated on by other methods of inverting the flaps.

I shall not undertake to describe the suggestions of Simon, Czerny, Segond, Pozzi, or any other of the vast number which have been made for relieving this deformity by plastic operations. By none of them, so far as I have been able to ascertain, has there been a single case in which the free escape of urine has been efficiently controlled. A plan proposed by Sonnenburg, of drawing the ureters downward and forward, close to the base of the penis, which is always in a condition of epispadias, has the advantage that it makes it much more easy to catch the escaping urine in a receptacle than it otherwise would be, and by this method the exposed and sensitive mucous membrane of the bladder is dissected away. In my judgment it is one of the best methods proposed, excepting that of Maydl, which I shall soon describe.

The plan suggested by Trendelenburg, of forcing the pelvic bones together at the pubes, where they are always separated to the distance of an inch or thereabouts, by dividing the pelvis at the iliosacral synchondrosis and afterward uniting the edges of the exposed bladder by drawing them together in the median line, while forming a small bladder out of the existing mucous membrane, does not form a new sphincter nor does it relieve the patient from the free escape of urine.

The methods of uniting the pubic bones, suggested by Koenig and Küster, by dividing with a chisel the iliac bone down to the great sciatic notch, or that proposed by Koch of Groningen, Holland, of bringing the bones together by *brissement forcé*, do not differ in principle from that proposed by Trendelenburg, offering no superior method for controlling the free escape of urine. Rutkowski² has reported a case in which he removed from the small intestine a section of the gut, preserving the mesenteric attachment, and bringing it outside of the abdomen and laying open this section longitudinally, used it to form a new anterior wall to the bladder. The method is most ingenious, but does not provide a sphincter to control the escape of urine.

The plan proposed by Reginald Harrison of extirpat-

ing one kidney and drawing the ureter of the other kidney out through the patient's side, so that the urine can be more easily caught than can be done in the pubic region, has little to recommend it. In fact, none of the methods mentioned prevent the uncontrolled escape of urine, and although they may make it easier to catch the urine as it escapes, they do not relieve the patient from what is one of the most extremely trying conditions.

In 1894 a method was described by Maydl of Prag, of grafting the ureters into the sigmoid flexure of the large intestine. At that time he described two cases operated on in this way. Two years later he described three other cases, and publishes³ five additional cases, making ten operated on by himself, and ten others operated on by other German surgeons. He says he has thus far found no cases operated by this method outside of Germany. He also reviews operations made by the Trendelenburg method.

The method which he proposed and the one which I have adopted in the present case is to remove all of the exposed mucous membrane of the bladder excepting that which is immediately around the openings of the two ureters. After this has been done the abdomen is opened, the ureters are mobilized and the sigmoid flexure is drawn from the abdominal opening. A longitudinal incision is made into the intestine and the extremity of the ureters with their mucous covering is inserted into the sigmoid and made fast by a series of sutures. When this has been done the intestine is dropped backward into the abdominal cavity and the abdominal cavity is closed. An operation of this sort requires great delicacy in its execution, to avoid infection and to insure a perfect result. The wounding of the ureters can be avoided by inserting a small bougie into their openings. In my case this was easy on one side. On the other it was attempted, but I failed to insert the bougie into the orifice of the ureter. The existing separation of the pubic bones from each other to a distance of an inch or thereabouts, and the dissecting away of the mucous surface of the exposed bladder leaves a weak spot in the abdominal wall which it is difficult to repair. In my case I split the rectus muscle on either side and united the divided portions of the muscle in the median line, thus repairing the defect and greatly strengthening the lower abdominal wall. After the ureters had been implanted into the sigmoid and the anterior abdominal opening had been closed, in order to insure the free escape of urine through the bowel, the sphincter ani was thoroughly stretched and a drainage-tube was carried well up into the rectum. The patient bore the operation well, complained of relatively little discomfort, and within a few hours after the operation began to pass urine per rectum. At no time was the patient's condition at all serious, and he made a rapid and most satisfactory recovery.

The operation was performed on November 3, and the patient was discharged from the hospital on Dec. 10, 1898. He has been in excellent health since the operation. He has had no irritation of any sort from the retention of the urine in the large intestine, and he retains it without difficulty during the day, from four to five hours, and during the entire night.

Dr. Fowler⁴ of Brooklyn has reported a modification of Maydl's method for implanting the ureters into the rectum. He surrounds the divided extremities of the ureters by an infolded flap of mucous membrane taken from the bowel. The method is very ingenious, but it seems to me questionable whether the artificial protection against infection of the kidneys thus secured sur-

passes that afforded by the natural openings of the ureters through the mucous membrane, as formed by nature.

The statistics of the operations which have been performed by various other methods up to this date are well summarized by Pousson*.

Up to the present time it seems to me no method proposed gives as much relief as that used on the patient above. The number of cases already operated on, the small number of deaths, the relief gained, and the exemption from consequent infection of the kidneys for periods extending up to several years are strong evidence of the value of the operation. It is far superior to any other method previously attempted. A final judgment must be reserved until the results have been followed for a longer period, but even should the kidneys become ultimately diseased as a result of the operation, I question whether a few years' comfort, permitting an individual to mingle freely with his fellows, would not be preferred to a longer existence under the previously existing disabilities and necessary isolation.

EXSTROPHY OF THE BLADDER.

OPERATIVE TREATMENT WITH SPECIAL REFERENCE TO
MAYDL'S OPERATION.*

BY RUDOLPH MATAS, M.D.

NEW ORLEANS.

The remarkable and brilliant results obtained by Dr. Allen, and the interesting practical paper by Dr. Wheaton, forcibly exhibit all the possibilities and resources of the most advanced surgical technic in dealing with this rebellious and pitiable condition, and they encourage us in the belief that the aspirations of a half century of earnest, incessant and laborious effort in a special field of surgical thought are about to be crowned with success. It is just such evidence as that presented to us by Dr. Allen that the mass of the profession has been patiently awaiting before accepting, as an accomplished fact, that which until recently has been looked on only as a hope, a possibility—the radical cure of exstrophy of the bladder. The importance and value of these contributions can not be overestimated when we consider that they are presented to us just as we have reached the turning-point between the two great epochs in the history of the subject—epochs which we would distinguish as the old or palliative and the modern or radical period.

The surgical history of exstrophy of the bladder is a fair reflex or mirror of the progress accomplished in surgery. The cure of ectopia vesicæ is a problem that has confronted and vexed the surgeon for nearly a century. The ancients simply referred to this condition and described it; to them it was a hopeless state, a *luxus naturæ* which was as distant from the resources of art as it was pitiable, distressing and degrading. If we except the early and unfortunate attempts of Dubois and Dupuy, in 1806, and of Gerdy, in 1845, we find all references to the treatment of this deformity passed by in silence until the last half of the present century, when, under the impetus given to operative surgery by an-

esthesia, we discover the first serious and sustained efforts to ameliorate the condition of its unfortunate victims. Here and there a daring genius, more adventurous than his contemporaries, had the courage to attempt methods of relief that were in advance of the resources of his period, but these isolated attempts failed and lapsed into oblivion. To this category belong the early, daring operations of Lloyd (1851), John Simon (1852), and Roux (1853), who suggested and attempted means of permanent relief by extirpating the offending organ and deviating the course of the urinary flow into the rectum. But the failure of such early efforts is not surprising when we consider the imperfection of the technic. As in the history of many other rebellious and difficult morbid states, such premature efforts had to remain sterile until further evolution had made the conditions ripe for their fructification and fulfilment. Thus it is that the surgical treatment of exstrophy of the bladder has in the last fifty years witnessed two distinct periods of surgical activity and enterprise, during which suggestions and methods of relief have accumulated and multiplied until the literature of the subject has attained voluminous and exhausting proportions.

As characteristic of the older period, which extends from the fifth to the ninth decade of the present century, we notice the prevalence and dominance of extraperitoneal operation—the purely plastic period in which every imaginable method of utilizing the skin adjacent to the bladder is suggested and devised. It is the period which Richard, Alquié, T. Holmes, N. Wood, Lefort, Thiersch, Humbert, Rydygier, Pancoast, Ayres, Greig Smith, Pozzi and many others have enriched with their ingenuity and experience. By these methods all that was aimed at and obtained was a cosmetic and palliative effect; the protruding, prolapsed bladder was covered with skin, and the accompanying epispadias was sometimes cleverly, though more often only clumsily, relieved. These methods have been fruitful in teaching us how to overcome the obstacles in the way of plastic repair in regions which are bathed with a septic and irritating fluid, and how best to utilize the skin so as to cover a large loss of substance. But, at best, the results were chiefly cosmetic, and only helped the sufferer by making his complaint more bearable, and by placing the parts in a more favorable condition for drainage. But apart from this, what could be expected from the purely dermatoplastic methods? They were incapable of providing a sphincter which would regulate the urinary flow, and they left the unavoidable cystitis unrelieved; on the contrary, even when a small receptacle or pouch was formed for the retention of a few centimeters of decomposing urine, the growth of hair on the inner or inverted surface of the skin flap favored the precipitation of urinary salts and the deposit of calcareous incrustations, which irritated the sensitive mucosa more than ever. No better results were obtained by the suggestion of Segond, who dissected the vesical mucosa out of its peritoneal bed and used the dissected membrane to cover the penile defect (epispadias), and held it in place by a flap ingeniously borrowed from the scrotum. Nor better, functionally, is the old and original method of Dubois and Dupuytren, resurrected subsequently in a more formidable and dangerous form by Trendelenburg, Passavant, and Neurdorfer. These operators aimed at a direct approximation of the vesical edges by forcibly narrowing the pelvic girdle and approximating the undeveloped pubic arch by sections made at the sacroiliac joint and other parts in the pelvic skeleton. The peril of such violent methods, coupled with their insufficiency, even when

*Presented to the Section on Surgery and Anatomy at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

the patients survived them, has led many operators, even up to the present, to abandon all efforts at reconstructing the bladder, or making it a useful receptacle. Many now satisfy themselves with Sonnenberg's (1882) operation, and simply transplant the ureters from their insertion in the bladder to the root of the penis, or even into the glans, where the urine can be directed more effectually into the artificial receptacle intended for the purpose.

While surgeons were still busy pursuing the ignis fatuus of a mode of cure by purely plastic methods, others sought a solution of the problem in more radical but also more perilous directions. The old and forgotten experiments of Roux, Simon and Lloyd were revived, and, with the encouragement offered by the success of aseptic methods, the modern radical period was inaugurated by the clinical and experimental observations of Thomas Smith of London (1879), Gluck and Zeller (1881), Bardenheuer, Novaro (1887), and more especially by Tuffier (1888), who obtained a unique success in the human subject by his method of extirpation of the bladder and transplantation of the ureters into the lower intestinal tract. But the results of these experiments and isolated operative attempts were almost constantly and uniformly unfavorable. Septic peritonitis and, more often a secondary pyelonephritis from ascending ureteral infection beginning at the open mouths of the transplanted ureters was almost the unavoidable and promptly fatal consequence of this mode of intervention.

Septic peritonitis, nephritis and stricture of the ureter constituted the formidable trio which had apparently combined to defeat the advance of the surgeon in this direction, and for a time the goal appeared to be as far from reach as ever. Nevertheless, the complexities and difficulties of the problem only appeared to arouse greater interest in the solution of the problem, and new methods and suggestions by which to avoid the most dangerous of the complications—pyelonephritis—soon multiplied to an almost embarrassing extent. The names of Morestin, Chaput, Giordano, Maclaure, Harvey Reed, W. Van Hook, Kuster, Budinger, Boari, Witzel, Vignoni Pisani and Krynski are among those made familiar to the student of the subject by the more or less practical suggestions and improvements they have contributed to the solution of this difficult question.

Nevertheless, and apart from a few isolated successes obtained in transplanting a single ureter (Chaput, Boari), the operation of ureteral grafting when simultaneously applied to both ureters had not been demonstrated to be a practical and successful operation in the human subject until Maydl, of Prague, startled us in 1893-94, with the report of two cases of exstrophy of the bladder which he had relieved permanently and happily by his original method of transplanting the ureters, including the sphincter apparatus, into the sigmoid flexure of the colon.

At first Maydl had few imitators. Berghem followed in 1895, then Krynski, Resigotti and Trombetta in 1896, in all five operations and five successes. In 1896 Maydl reported three additional new cases of his own with one death. In his latest contribution¹ he tabulates a total of twenty operations, including his own, and if we now add Dr. Allen's case, we will have a total of twenty-two cases with only three fatalities. This total of twenty-two cases and three deaths, or a little over 13 per cent., is a most extraordinary record for a new operation involving delicate and difficult manipulations in the abdominal cavity. Few abdominal opera-

tions of this magnitude have been followed by such a measure of initial success as in this case, and what is more striking and encouraging is that these results have been obtained not only by the initiator himself, but by a number of operators who have followed each other in close succession in different parts of the world.

The question arises, how many cases operated on by this method have not been reported; and, again, how many of these ended fatally? The well-known aversion of most men to admit or publish their failures justifies the belief that the mortality could probably be increased if we only knew where to ferret out the facts. But, on the other hand, this argument holds equally true for the other methods, and the fact remains that since the cure of exstrophy has been attempted by extirpation of the bladder and the grafting of the ureters into the lower intestinal tract, no record has been anywhere published which could compare in the number of cases and brilliancy of results, with that which Maydl can claim for his operation.

Are we prepared, on the strength of the evidence presented, to say with Trombetta that "the therapeutic problem involved in the radical cure of exstrophy of the bladder has found its complete solution in Maydl's operation, and that from this on it would be foolish to return to the autoplasmic methods which, up to the present have so unproductively exercised the brain and hand of the surgeon?" That this is not the opinion of all surgeons, and that there is still some doubt as to its superiority and greater safety over all methods recently suggested, is attested by the diverse procedures that have appeared and have been applied with variable success since Maydl's results became known to the profession. The contribution of Boari, who experimented successfully on animals, with his ingenious anastomotic button; the operations of Krynski, Vignoni, Pisani, G. Ryerson Fowler and Franklin H. Martin, are subsequent to Maydl's work, and suggest to us that these observers regard the advantage obtained by the transplantation of the elliptical piece of the vesical trigone, which contains the valvular insertion and sphincter apparatus of the ureters—a capital and distinctive point of Maydl's operation—to be illusory, or at least of doubtful advantage.

More recently still we have read in an article on exstrophy and vesical plastics by Max Rutkowski², an assistant in Obalinski's clinic at Cracow, that it is not in accordance with the conservative tendencies of modern surgery to sacrifice existing organs or parts of organs, provided these are healthy. He is therefore not in favor of Maydl's operation, which extirpates a rudimentary bladder, though he is compelled to admit the remarkable success thus far obtained with this procedure. He accordingly believes in a return to plastic methods, provided these are radically modified in accordance with modern and more rational ideas. He contends that the cause of failure of the old plastic operations was due to the unphysiologic attempt to repair a defect in the urinary bladder by substituting, for mucous membrane, skin, which not only acts as a foreign body, but is devoid of muscular fibers, and serves no useful purpose in the repair of a contractile organ. He then refers to the remarkable experiment of Tizzoni and Poggi who, in 1889, succeeded in completely reconstructing the urinary bladder, which they had previously extirpated, by borrowing mucous membrane from the intestinal canal. They formed this organ out of a segment of bowel which had been separated by exclusion from the intestinal tract; they then grafted the ureters into a newly-made receptacle and thus succeeded in creating a new bladder.

¹ Wiener Med. Woch., 1899, Nos. 6-8.

² Centralbl. f. Chir., April 22, 1896.

In imitation of this procedure, Rutkowski very ingeniously and with extraordinary skill proceeded to cure an exstrophy of the bladder in a boy, 12 years of age, who had previously undergone Trendelenburg's and Rydygier's operations unsuccessfully. Rutkowski's procedure is as novel and ingenious as it is dangerous. He made an abdominal section above the level of the exstrophied bladder and drew out a loop of the ileum and resected 6 cm. of intestine. This section of bowel he kept alive and nourished by leaving a mesenteric pedicle attached. The continuity of the intestinal tract was then restored by circular enterorrhaphy, the excluded segment was split at its convexity and the mucous membrane stretched out and sutured to the refreshed margins of the bladder. The mesenteric pedicle was sufficient to nourish the intestinal graft and then the abdominal walls were approximated so as to cover the bladder, and the boy recovered. Eight weeks after the operation he was able to retain 25 cm. of urine—over an ounce—for three-quarters of an hour, the urine being expelled in a jet at a distance of 30 cm. from the body. This is certainly a remarkable exhibition of what modern surgical technic can accomplish when it is reinforced by long and diligent training in a special direction.

Rutkowski's operation is certainly unique in the history of surgery, but does the survival of the patient and the result obtained justify the risks involved in the procedure? Does it convince us that the author's argument in favor of a revival of the plastic treatment of exstrophy has been demonstrated to be correct by the results obtained in this case? Can such a result remarkable as it is, compare for an instant with the final results of Maydl's operation? No! The only advantages that we can appreciate in Rutkowski's operation lies in the fact that the ureters are not disturbed from their attachment to the bladder, and that the dangers of septic pyelonephritis are obviated, but in every other respect it is a failure when we consider the functional result as compared with such cases as those reported by Dr. Allen and other surgeons who have followed in Maydl's footsteps. We believe that we are safe in prophesying that Rutkowski's case is destined to remain a unique precedent of its kind in operative surgery, and that it is not likely to find many imitators.

The operation that now remains for our consideration, and that must command our attention, is Maydl's operation, and our efforts should be directed toward perfecting its technic in order that its risks and dangers may be reduced to the safest minimum. The dangers that must be apprehended in this procedure are, in brief: 1. The sloughing of the valvular insertion and sphincter apparatus of the ureters, after this has been severed from its vesical connections and transplanted to the bowel. 2. The possibility of contaminating the peritoneum in the course of the vesicocolostomy, and subsequently, if sloughing should occur after the operation has been completed. 3. The possible failure of the valvular insertion of the ureters to serve efficiently after the vesico-ureteral graft has been successfully implanted into the bowel; in which event there is nothing to prevent the dreaded and fatal infection of the ureters and kidneys. 4. The existence of a congenital anomaly in the sigmoid or omega colon, in which the mesentery is so short that it will be impossible to drag the colon to the median incision, thus seriously complicating the technic, as in Park's fatal case.

The operator who cuts off both ureters from the bladder, and transplants them into the colon must experience a certain and unavoidable anxiety—an anxiety that only further experience will overcome—that is born of

the feeling that he has burned his ship behind him and has staked all his patient's chances, all his hopes, in the hazard of the game. It is the utter and absolute hopelessness of remedying the evil when this does occur that must make any conscientious operator vacillate and question his mind and his responsibility many times over, before deciding to embark in so perilous an undertaking. But is this an argument against Maydl's operation in particular? Again, No! For the dangers that we have referred to apply equally as well, and indeed with much greater emphasis, to all the methods of ureteral grafting alike. The danger of sloughing of the bladder graft, with its attendant dangers, which is uppermost in the mind of the operator, has been to a great extent dispelled by the careful anatomical researches of Margarucci, who demonstrated at the Twelfth International Congress, held in Rome in 1894, that the ureter is nourished by an independent vascular supply which, descending from the renal side, supplies not only the ureters but the mucous membrane about its orifice, where it forms an anastomotic connection with the vessels of the vesical trigone. This is a most reassuring fact. In addition to this, the danger of ultimate stricture from cicatricial contraction of the ureteral orifice is certainly obviated by Maydl's operation in a manner not equaled by any other operation. Krynski's, Martin's or Fowler's operations, which are the next best, not excepted. But, finally, more convincing than anything else, is the real test of merit and value, the accumulated evidence of the clinical test, which indisputably demonstrates that no other operation has thus far succeeded in overcoming the risks of renal infection with more certainty and success than Maydl's procedure.

We have purposely left out of consideration the question of intestinal and rectal intolerance, because it has been abundantly demonstrated that the rectal and colonic mucous membrane will readily adapt itself to the conditions of a urinary receptacle.

Personally, my attitude toward the cure of exstrophy of the bladder by the radical method has been most conservative, and, furthermore, my conservatism has not been influenced by the recorded experience of others, but chiefly by the results of my own experience. My disgust at the unsatisfactory functional results of the classic autoplasmic operations as observed in my own practice, has kept my interest ever alive to the possibilities of other methods. I have now two cases of exstrophy in which I would have long ago attempted Maydl's operation had it not been that my lack of success with ureteral transplantation in dogs made me timid and kept me from attempting the operation on the human subject. In 1896 I read Boari's communication in the *Policlinico* of Rome, in which the application of his ingenious buttons, devised for ureteral anastomosis, was presented in a seductive manner. I immediately sent to Italy, to the author, for a set of models, and proceeded to experiment with them without delay. I followed the technic as faithfully as possible, on two dogs, but both animals perished promptly from acute ascending renal infection. The technic was simple and beautiful, but the results were bad. This convinced me that the direct anastomosis of the ureter into the bowel without providing for a valvular arrangement was untrustworthy and should be rejected. In 1897, I undertook to perform Maydl's typical operation on two dogs; the bladder was extirpated in each and the ureters, with the elliptical flange of the vesical trigone, were sutured to the rectum. Both dogs died, one in twenty-four and the other in thirty-six hours after the operation. In both the vesico-ureteral grafts were perfect; there was no sloughing, and there was no urin-

ary or fecal leakage; in both, however, there were evidences of septic peritonitis, caused no doubt by infection from the bowel during the course of the operation; in the dog that survived thirty-six hours there were also evidences of a very intense hyperemia of the kidneys. I am fully convinced that the operation is much more simple in the human subject and less likely to be followed by septic infection, as contamination from the bladder or bowel can be much more efficiently guarded against—especially if the sigmoid mesocolon is long enough to permit the bowel to be dragged out of the median incision.

I would summarize my impressions as follows:

1. All autoplasmic methods proposed for the cure of ectroxy of the bladder are unsatisfactory and, at best, simply palliative.

2. Of all the radical methods which involve an excision of the bladder and a transplantation of the ureters to the rectum, Maydl's operation is by far the most complete, rational and satisfactory, from the technical point of view.

3. Maydl's operation offers the best conditions for the complete correction of the associate epispadias.

4. Notwithstanding the comparatively large number of successful cases accredited to this method, its relation is not yet fully ascertained, though the ratio, as obtained from published cases—over 13 per cent.—establishes the superiority of this method above all others from the prognostic point of view.

5. Notwithstanding the apparent theoretic simplicity of its technic, Maydl's operation is a difficult, laborious, and in many respects a dangerous, operation and should only be undertaken by those who have thoroughly familiarized themselves with its difficulties by special training in abdominal surgery, supplemented, if possible, by experimental work.

6. It should not be applied indiscriminately to all cases, but only to those patients whose general condition is such as to warrant a long tedious operation likely to be attended by serious shock; and whose eliminating organs, especially the kidneys, are normal and capable of effective elimination.

DISCUSSION ON PAPERS OF DR. ALLEN, WHEATON AND MATAS.

DR. J. RILUS EASTMAN, Indianapolis.—In the Doctor's case there has been no resulting proctitis. This has been the chief objection. Dr. Allen deserved the honor of being the first man in America to make successful the Maydl operation; it is not rational to make the operation; circumstances tend to combine which contraindicate this method. Sonnenberg of Berlin dissects the ureters out behind the peritoneum and stitches them in the tip of the penis. My case was one in which both kidneys were more or less disorganized—one side a pyonephrosis and on the right a chronic nephritis. I did not implant these ureters; my boy was exsanguinated; he had not the strength to stand such a heroic operation, so I applied the method of Sonnenberg. Before I made the operation, however, I removed the left kidney, which was in a condition of pyonephrosis and was emaciating the boy and would have killed him. I brought the ureter on the right side and stitched it into the tip of the penis, grooved it with an incision and stitched the right ureter into this, so the boy can now wear a urinal. I have made an aluminum tank which fits around his thigh, not over three-eighths or a quarter of an inch in thickness, and which is connected with the tubes by a rubber tube with a pneumatic collar, and into which the penis—the little clupepadiac penis—with its ureter will fit, and which I hope will give him some relief. When we bear in mind that this boy lived for twelve years in a most pitiable condition, the mother changing his diapers three or four times an hour, he being helpless for ten years, one can appreciate the amount of relief obtained; still it cannot be gainsaid that the Maydl operation is one of choice. Certainly this operation would indicate it, as it removes all this dribbling of the urine and the horrors of having to change diapers three or four times an hour.

DR. W. J. MEANS, Columbus.—We are all agreed that the Maydl operation is the one, and all are proud to see the ex-

emplification of this operation by an American surgeon. This boy was certainly a pitiable object when he was brought to the Protestant Hospital. He was 15 years old, and it was a question whether he was a boy or a girl; he was excluded from society. We sent him home, as you see, dressed up like a young man, true to his belief that the operation, while only palliative, will be a source of relief to him that will justify any experience he may have gone through. The operation in his case is not yet fully complete. I had intended to make a urethra that would have extended out to the glans, but you will remember that this operation was only made on the 13th day of April and I have just now gotten the parts entirely healed up. There is one trouble in making these operations. You always have plenty of water and you have to provide a way for it. You will notice that the cleft in the pelvis is at least three inches. I leave it to your judgment whether such a cleft should be closed with any degree of safety to this boy's condition, or whether it can be remedied by such an operation.

DR. D. P. ALLEN, Cleveland.—The thing is the necessity of preserving the mucous membrane about the openings of the ureters; the safety of the operation depends on it and prevents infection of the kidney. That question must depend on statistics; quite a number of cases have been observed for three, four, five and six years, without any infection of the kidney. As to work on the ureters, it seems to me that it is most hopeful. I succeeded the other day in making an end-to-end anastomosis in the case of a horse-shoe kidney, and I think if we can do that we can do a great deal with the ureter.

THE PROCESSUS VERMIFORMIS.*

ITS ANATOMY AND BIOLOGY.

BY G. G. EITEL, M.D.

MINNEAPOLIS.

The older writers on human anatomy make no especial mention of the processus vermiformis, as a separate anatomical entity, and this omission on their part probably has its explanation in the fact that this small offshoot of the intestinal canal was not looked upon by medical men generally as the cause or seat of any disease until a period so late as to be within the memory of comparatively young members of our profession to-day. It is a study, both interesting and instructive, to note the various expressions of opinion that have been advanced on the probable utility, etc., of this process by authorities on anatomy, biology and evolution. It is the purpose of this paper to invite attention to some of these writers who have devoted more than a mere casual word on the troublesome little body situated in the right iliac region.

Deaver stated, in his work on appendicitis, that the vermiform appendix in man is the undeveloped, true cecum of some of the lower animals.

Harrison Allen states that the vermiform appendix is of unknown function, that it is found only in man, in the man-like apes, and in a marsupial animal, the wombat. It retains the embryonic characters of the large intestine, and is probably a rudiment of the enormous cecum of quadrupeds of the rodent type. Although thus structurally insignificant, its possible lesions may give rise to important clinical questions, and it is not infrequently a factor in retroperitoneal abscess. As a rule, the appendix is bent once upon itself, or twisted. It may be concealed beneath the cecum, or may hang down in the cavity of the pelvis, where it has been known to effect adventitious adhesions with the pelvic organs, and even to perforate the bladder. Rarely it is lodged under the ascending colon, or deflected so as to be in contact with the abdominal wall. Cruveilhier records an instance in which it was contiguous with the liver. Other writers have mentioned the possibility of the appendix being caught in the mesentery, or forming an ingredient of inguinal hernia.

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

Leidy refers to the cecum as the broadest portion of the colon, and says it is a capacious sack, two or three inches in length and as wide as the greater length. It is pouched, like the rest of the colon, and at its inner back part is extended in a cone which is abruptly prolonged into a vermiform appendix. This is usually from three to six inches long, about the thickness of a goose quill, commonly turned upward, and after a variable flexuose course terminates in a blind, free, rounded end. At birth it is less abrupt at its commencement, and appears more evidently a continuation of cecum. It is peculiar to man and some of his nearest allies, the higher apes, but exists also in the wombat, an animal at the opposite limit of the same class. It is regarded as a rudiment of the greatly elongated cecum of most herbivorous mammals. Sometimes it is short, and rarely it is altogether absent. The cecum occupies the right iliac fossa, to which it is closely or more or less loosely attached. In the former case, it is covered in front and on the sides by the peritoneum reflected to the fossa, and is attached behind by areolar tissue to the investing fascia of the iliac muscle; in the latter case the peritoneum invests the cecum to a greater degree, and attaches it behind by a doubling called the mesocecum. A fold of the peritoneum also extends from the vermiform appendix to the adjacent extremity of the cecum, serving to retain it in a more fixed position.

Wiedersheim of Freiburg describes the processus vermiformis as a feebly developed organ which lies at the end of the short cecum, and possesses a considerable morphological interest. In man, its average length is 8.5 cm., but it may be but 2 cm., or on the other hand some 20 to 23 cm. long. Considerable variation also occurs in its width and disposition, and in the folds of mucous membrane, which bound its ostium. Indeed, everything points to the retrogressive character of this appendage, and justifies us in concluding that the total length of the alimentary tract was formerly greater than it now is. The great variations in the form and size of the cecum also support this view. According to the best authorities, the processus vermiformis at different ages measures as follows:

At birth.....	3.4 cm.
Up to 5th year.....	7.6 cm.
5 to 10.....	9 cm.
10 to 20.....	9.75 cm.
20 to 30.....	9.5 cm.
30 to 40.....	8.75 cm.
40 to 60.....	8.5 cm.
Over 60 years.....	8.25 cm.

In embryos and new-born children on the one hand, and in adults on the other, the vermiform process varies in length in proportion to that of the rest of the intestinal canal; and since it is a degenerating organ, it is not surprising to find that it is most strongly developed in fetal times, and does not grow at a rate proportionate to advancing age. In the embryo, its length in proportion to that of the large intestine, is approximately 1:10, and in the adult 1:20. Further light is thrown on these facts by Ribbert's interesting discovery of the frequent occlusion of the vermiform process. He found it either partially or totally closed in 25 per cent. of the cases examined, with accompanying very decidedly regressive changes—pathologic cases excluded—in the related tissues; actual pathologic obliteration nevertheless occasionally occurs at the end of the vermiform process. The occlusions which result, and which are probably always due to inflammation, are less frequent than the typical obliteration. I cannot in this connection refrain from referring to the coincidence of the existence

of vestigial organs and the tendency to disease caused by them.

Taking only adults into consideration—i. e., omitting individuals under 20 years of age, in whom variations are comparatively rare—out of 100 vermiform processes, 32 were found partially or wholly closed. Complete occlusion throughout the whole organ was found in a very small number—about 3.5 per cent. Partial occlusion is much more frequent, all degrees being found, from the first narrowing to the complete closing of the lumen. In rather more than half of the cases the occlusion affected a quarter of the length; in nearly half of the remainder its extent varied between one-quarter and three-quarters, and in only a very small number did it affect more than three-quarters, or close the tube.

This process of occlusion is equally marked in both sexes, and the statistics concerning its occurrence at different ages are very striking. They make it clear that there is a marked increase in the frequency of its occurrence in advanced age, as will be seen by the following table:

OCCLUSION OBSERVED.

1st to 10th year.....	in only 4 per cent.
10th to 20th year.....	in only 11 per cent.
20th to 30th year.....	in only 17 per cent.
30th to 40th year.....	in only 25 per cent.
40th to 50th year.....	in only 27 per cent.
50th to 60th year.....	in only 36 per cent.
60th to 70th year.....	in only 53 per cent.
70th to 80th year.....	in only 58 per cent.

It follows from the foregoing table, that in more than 50 per cent. of people over 60 years of age, there is degeneracy of the vermiform process. In new-born children, on the other hand, this phenomenon has never been observed, and the youngest child in whom it has been found commencing was 5 years old. Total occlusion is also similarly connected with age, though not in nearly so marked a manner as partial closure. It has never been observed before the thirtieth year; and while it was not found once in individuals between 50 and 60 years, it was most frequent in those whose ages range from 60 to 70. Among these, nine out of twenty-one cases recorded show complete occlusion; and since, besides them, there were seven just on the point of closure, we may conclude that more than 50 per cent. were thus affected. A relation has further been proved to exist between the length of the appendix, and its degeneration. The longest appendices—21 to 15 cm. long—kept their lumen throughout; in those 14 and 13 cm. long, commencing obliteration of the lumen was observed in four cases, and in those 12 and 11 cm. long, it was not found. From this point, however, occlusion again increased as the length decreased. If we leave out of account individuals under 5 years of age, in whom occlusions have not been observed, we find that it occurs as follows; viz:

LENGTH OF APPENDIX.

20 cm.....	34 per cent.
9 cm.....	18 per cent.
8 cm.....	32 per cent.
7 cm.....	40 per cent.
6 cm.....	30 per cent.
5 cm.....	70 per cent.
4 cm.....	66 per cent.
3 cm.....	100 per cent.

Although this connection between length and frequency of occlusion is, as the table shows, somewhat irregular, we may at least conclude that, as a rule, the shorter appendices show occlusion more frequently than the longer.

Richard Owen shows the striking resemblances existing among a large variety of animals. Speaking of the water-vole, he says that here the ilium terminates at the

base of the sacculate cecum, the slender termination simulates a vermiform appendage; the colon begins by a pair of large sacculi, but quickly contracts to the caliber shown. Two oval patches are here, as usual, situated on either side of the ilio-cecal valve. In the *Leporidae* they are lodged in a special pouch; the vascular mucous membrane of the cecum in these herbivorous rodents is agitated by being produced into a broad fold, disposed spirally to near the slender termination of the cecum, which is glandular, like the vermiform appendage in man. Speaking of the aye-aye, and describing the intestinal canal he further says that the small intestines are rather more than three times the length of the body; the cecum is about one-fifth that length; measuring two inches and seven lines; for the first inch it is 10 lines in diameter, but suddenly contracts to a diameter of three lines, terminating rather obtusely and resembling an appendix vermiformis, but this is not marked off by any valvular structure from the wider part of the cecum, and it is continued, as in the human fetus, directly from the end of the wider part, or cecum proper. This type of cecum is repeated in *Stenops javanicus*, with a larger and narrower vermiform termination. Again; in *Hylobates*, the vermiform appendage reappears; it is terminal, and in some species short; but is more differentiated as such by its glandular tunic and marked commencement than in *Lemuridae*; the appendix is terminal, but is long and convolute in the orang; in the chimpanzees there is a more marked constriction between the appendix and the cecum. The colon is sacculated and moderately long in all *Catarrhines*; it is loosely suspended by a broad mesocolon, and only in tailless apes does the cecum begin to adhere, through an incomplete peritoneal investment to the right hypogastric region. Again: in a binturong I found a cecal projection, probably a vermiform process, of half an inch in length at the beginning of a large intestine, two feet in length; the small intestines are seven feet long; the length of the animal, exclusive of tail, was two feet.

Gray says that, starting from what was originally the apex of the tube, the inner and back portion of cecum, usually 1.7 cm. below the ilio-colic opening, is a famous narrow, round part of the intestine called the appendix ceci, or, on account of its worm-like appearance, appendix vermiformis. This is first seen low down among the mammals, in the marsupial group, in the wombat. No sign of it again appears until the ichneumon and pig are reached, but not then is it a proper appendix. It is next seen in the lemurs and higher apes, as chimpanzee, orang, gibbon and gorilla. Finally, in man, it is present as a functionless and dangerous structure. It attains its greatest length between the twentieth and fortieth years. Its length, compared to that of the large intestines, is 1 to 10 in the new-born, 1 to 20 in the adult. There is no relation between the size of the cecum and the length of appendix. The appendix has no set position. Treves considers it to pass most frequently up from behind the cecum to the left, behind the ilium and mesentery toward the spleen. Others regard this position as nearly abnormal.

Turner of Russia finds it hanging into the true pelvis in 51 out of 83 cases, and transversely across the promontory in 20 more of these cases. Berry gives the order of frequency as: 1, pelvic position; 2, retrocecal; 3, intestinal cecal—toward spleen; 4, variable.

The order of frequency found in this country by Joseph D. Bryant was most often inward; then behind the cecum, downward and inward, into the true pelvis.

According to Ribbert and Zuckerkandl, the cavity of

the processus vermiformis tends to undergo obliteration, not as a pathologic process, but a physiologic one. In children the lymph follicles of the appendix are very numerous and close. After the twentieth or thirtieth year, it is normal for them to atrophy.

Obliteration of the process occurs to some degree in 99 cases out of 400, or 25 per cent.; total obliteration in 3.5 per cent. (Ribbert). Or obliteration occurred in 23.7 per cent., total obliteration in 13.8 per cent. and partial—distal half most common—in 9.9 per cent. (Zuckerkandl). It never occurs in the new-born. After 60 years of age, more than half are obliterated. It occurs more often in a short process, 5 to 6 cm. long. One can never tell by macroscopic appearance as to the presence of obliteration. There are four authentic cases of absence of the appendix on record.

Charles Darwin, speaking of the rudiments, says: "With respect to the alimentary canal, I have met with an account of only a single rudiment, namely: The vermiform appendage of cecum. The cecum is a branch or diverticulum of the intestine, ending in a cul-de-sac, and is extremely long in many of the lower vegetable-feeding mammals. In the marsupial koala, it is actually more than thrice as long as the whole body. It is sometimes produced into a long gradually tapering point, and sometimes constricted in parts. It appears as if, in consequence of changed diet or habits, the cecum had become much shortened in various animals, the vermiform appendage being left as a rudiment of the shortened part. That this appendage is a rudiment we may infer from its small size, and from the evidence which Professor Canestrini has collected of its variability in man. It is occasionally quite absent, or again is largely developed. The passage is sometimes completely closed for half or two-thirds of its length, with the terminal part consisting of a flattened solid expansion. In the orang this appendage is long and convoluted; in man it arises from the end of the short cecum, and is commonly from four to five inches in length, being only about a third of an inch in diameter. Not only is it useless, but it is sometimes the cause of death, of which fact I have lately heard two instances; this is due to small hard bodies, such as seeds, entering the passage and causing inflammation.

Of course at the time this was written, it was the common opinion that appendicitis was always caused by the presence of some foreign body in the lumen of the appendix.

[The foregoing is one of a series of six papers on Appendicitis. The discussion will follow the last paper of the series.]

"In December, 1890, I objected to two imported Guernsey cows being placed in a stable where 28 milch cows and calves were kept. This because I suspected tuberculosis. In December, 1891, I stood by and saw 22 of the 28 slaughtered, and shown to be tubercular." (Letter from J. E. Storey.)

THE UTERUS.*

SPONTANEOUS RUPTURE OF ITS BODY DURING LABOR.

BY HENRY D. INGRAHAM, M.D.

BUFFALO.

Rupture of the body of the uterus during labor, for any cause whatever, is fortunately of rare occurrence, at least in this country.

Garrigues estimates it as occurring in the ratio of 1 in from 3000 to 5000 cases; Harris as 1 to 4000, and Lusk as 1 to 6000 cases. In Continental Europe it is reported as occurring more frequently, for Winckell found it in the proportion of 1 to 666 cases. This average is above that given by many writers, however.

Charpentier, in his "Cyclopedia of Obstetrics," estimates that in more than 3,000,000 cases of labor reported by thirty different writers, rupture of the body of the uterus occurred once in from 2000 to 4000 labors. As all cases of rupture may be classified either as traumatic, that is, resulting from manual or instrumental injuries, or as spontaneous, that is, occurring without any such injury, it would be of interest to know in what proportion of each Charpentier's cases are divided, but this point he does not state. No doubt many cases of rupture are not reported, and it is very natural that a smaller proportion of the traumatic cases should be reported than of those which occur spontaneously.

In investigating this subject, by making inquiries of several of the more prominent obstetricians of Buffalo, I find that in an aggregate of about 48,000 cases of labor, 12 cases of ruptured uteri have occurred, 5 of these being traumatic, and 7 spontaneous; that is, rupture from any cause occurred once in 4000 cases, while spontaneous rupture occurred once in 6857 cases of labor.

Most of the cases of traumatic rupture of which I have any knowledge occurred in the practice of midwives, and were due to their efforts to deliver the patient when the child's position was abnormal. In two cases the midwife attempted to deliver in a shoulder presentation by pulling on the child's arm; while in two other cases the rupture followed attempts at version without chloroform. In all these cases physicians were finally called, but the patients were either dead or moribund.

But the scope of this paper is to deal especially with those ruptures which have occurred without interference from anyone, that is, those which have been designated as spontaneous. In illustration, I would call your attention to the cases somewhat in detail.

CASE 1.—This case occurred more than thirty years ago, in the practice of Dr. John Hauenstein. Being a young man not long in practice, and having more faith in the instruction of teachers at that time than he had in later years, he drove six miles to attend a confinement without taking his forceps. The patient was 40 years of age—a primipara. Labor progressed slowly but naturally for several hours, when the pains became severe and somewhat irregular in character. The head not engaging, the doctor sent for his forceps, but before he could get them the uterus ruptured and the patient died in a few minutes from hemorrhage. From that time Dr. Hauenstein always took his obstetric forceps with him and was as skilled in their use as any obstetrician who has lived in Buffalo. This case, the only one of the series ever reported, appeared in the *Buffalo Medical and Surgical Journal*.

CASE 2.—This case occurred in the practice of the

*Presented to the Section on Obstetrics and Diseases of Women, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

late Dr. Storck. The patient was 38 years of age—a multipara, whose three previous labors had been normal, but protracted. In this case labor progressed slowly, with pains moderate for several hours, then gradually increased in strength, becoming severe, but making little progress, owing to the fact that the head did not engage. Dr. James Smith, who was sent for to assist, answered the call at once but just before his arrival rupture took place and the patient died almost immediately. With the exception of one foot the entire child was expelled into the abdominal cavity.

CASE 3.—Twenty years ago Dr. Earl was engaged to attend Mrs. M., Irish, 40 years of age, with her seventh labor. Five of her six previous deliveries had been by forceps, and one was a craniotomy. At about 8 p. m. he received an urgent call, as the patient was in very severe pain, and had been for some time. On his arrival he found a man in attendance and was told that he was a friend of the family—a druggist. He said that he had neither given any medicine nor examined the patient; and left soon after Dr. Earl's arrival. The doctor found the cervix well dilated, head engaged, and pains strong, though irregular. Suddenly all pain stopped. The patient did not complain of anything unusual, the pulse and appearance were normal. The doctor applied the forceps, and easily delivered a healthy living child. The placenta was soon expelled—the uterus contracted well. By this time Dr. Earl learned that the family friend, the druggist, had been there all day, had made several examinations, some of the latter ones giving the patient severe pain, and had given more than an ounce of fluid extract of ergot. Dr. Earl remained with his patient an hour after delivery, and left her cheerful and apparently in a normal condition. Soon after he went home he was recalled, as the patient was "very bad." When he reached the house the woman was dead, although no signs of either internal nor external hemorrhage could be discovered. This sudden, unexpected and unexplainable death caused much comment, doctor and druggist blaming each other. Two or three days after burial the body was disinterred, and upon post-mortem examination a transverse rupture of the uterus just above the utero-vaginal junction was found, but no internal hemorrhage. All other organs were normal. Suit was brought against Dr. Earl, but the profession came to his rescue, and he was fully exonerated. The druggist left the city during the trial, and has never returned.

CASE 4.—This case occurred in the practice of a midwife. The patient, a Pole, 35 years of age, multipara, had been in labor several hours. Prof. P. W. Van Peyma was called, but when he reached the house the patient was dead from a profuse external and internal hemorrhage. Although the Doctor immediately opened the abdomen, at the request of the attending priest, the child was dead when delivered. The midwife said she had not given ergot, nor attempted version, nor interfered in any way. Dr. Van Peyma knew her well and considers her truthful.

CASE 5.—This case also occurred in Dr. Van Peyma's practice. He was called by a midwife to see a Polish woman about 32 years of age, a multipara, who had been in labor several hours, the pains being especially severe for some time. It was a vertex presentation, and after careful examination the Doctor decided to do a version, but found it necessary to get a physician to give the anesthetic. During his absence the patient got up, walked about, suffering from very severe pains. Upon his second examination, Dr. Van Peyma found that the

head, which he was unable to move before, had receded and was now freely movable. Immediately applying the forceps he delivered the patient of a living child, and then introducing his hand to remove the placenta he found a rent in the uterus, through which at least one-half of the placenta had escaped. This case occurred in the early days of the use of bichlorid of mercury, and the doctor washed out the uterus with a 1-2000 solution until he found that it was entering the abdominal cavity. On the second day the patient complained of considerable abdominal soreness and tenderness, and there was a slight rise in temperature. However, the Doctor was told that she did not wish further medical attention, so that he personally did not see her again, but one week from the day of her delivery he sent the assisting physician to inquire how she was. The patient, who was out of doors, told him that she was perfectly well.

CASE 6.—This case was reported by Dr. Schroeter. About four years ago he was called by a midwife to see a Polish woman, 30 years of age, who had been in labor for several hours. The pains not accomplishing much, the midwife had given considerable ergot, how much the Doctor could not learn, but enough to cause irregular contractions. The woman had previously given birth to three children, each by forceps delivery. Before the Doctor's arrival the woman had a sharp, severe abdominal pain and lost a large amount of blood. Upon examination he felt the child's head high up and freely movable. He easily delivered a dead child with forceps, but when examining the placenta he discovered that the larger part had escaped through a tear of the uterus into the abdominal cavity and could be felt externally. This was extracted after some little difficulty, and the hemorrhage ceased. The patient died the next day.

CASE 7.—On the morning of Nov. 6, 1896, the writer was sent for by Dr. F. A. Harrington, with the request that he bring his long forceps, and also the instruments necessary for abdominal section. The patient was an Italian, 23 years of age, rather short and stout, the mother of two children, both of whom had been delivered by Dr. Harrington after normal but tedious labors. On November 4, the Doctor was called at 8 p. m., but finding the pains slight and cervix very little dilated, he gave $\frac{1}{4}$ grain of morphin and went home, instructing them to call if necessary. On the 5th, after calling several times, he went at 1 p. m., and remained. The pains from this time on were severe. It was a right occipito-anterior presentation, but even with complete dilation, the head did not engage. Neither patient nor friends would allow forceps to be used until 5 p. m., when the doctor refused to wait longer. While he was in an adjoining room sterilizing his instruments the patient got out of bed and sat over a pail of hot water to relax the parts. Just as Dr. Harrington entered the room she gave a scream, put her hand over the right iliac region, became pale and vomited. She would have fallen had she not been assisted to the bed. Upon examination the doctor felt the head, but higher than previously. Attempting to apply the forceps he could not feel the child's head. Introducing his hand still further, he could only find a foot. He immediately sent for Dr. Willoughby, who agreed with Dr. Harrington that a rupture of the uterus had occurred, with escape of the child into the abdominal cavity. There was no external hemorrhage, nor any symptoms of internal bleeding. Under stimulation the patient rallied, and it was advised that she be removed to a hospital. To this proposal both the patient and her friends objected, an Italian midwife strongly insisting

that if she were alone she would be all right; that she had had similar cases, all of whom had recovered. The patient was given two doses of morphin, $\frac{1}{4}$ grain each, during the night, and was fairly comfortable. When I saw her at 9 a. m. on the 6th, she had an anxious expression of countenance, pulse 150, weak and feeble, respiration 40, and temperature 101; not in much pain, with pupils contracted, showing her to be under the influence of the morphin. Upon examination, one foot of the child could be felt in the uterus, and through the abdominal walls the rest of the body could be found in the right inguinal region. It was evident that an operation was useless, but to prevent having any one called who might from her condition blame her medical attendant it was suggested that she be freely supported with strychnin and whisky, and if she were in condition we would operate in the afternoon. The friends were, however, given to understand that there was little hope of improvement and that they were criminally negligent for refusing operation immediately after rupture. A little before 3 o'clock that afternoon the patient died. Although objecting to a post-mortem, the friends wished us to make an incision and remove the child. It was a male weighing about ten pounds, and normal in shape. In the abdominal cavity just under the child were the placenta and membranes, with not more than two ounces of blood. The uterus was firmly contracted and the tear quite short; two-thirds of it was on the right of the median line, the left end being a little above the uterovesical junction and the other end curving slightly upward toward the fundus. The intestines and the peritoneum were dark in color, the vessels much engorged, showing that the inflammatory process had been unusually active during the twenty-two hours since the uterus ruptured. Although the pubic arch in this patient was slightly flattened, yet she had previously given birth to two children of about the same size and shape as this one, with neither instrumental nor manual interference. For the past few months she had increased in flesh, so that it is possible that there was a fatty degeneration of the uterus.

An analysis of the above cases shows that both mother and child died in all the traumatic cases, while in the spontaneous variety this mortality was 86 per cent. of the mothers and 71.5 per cent. of the children; also that rupture occurs more frequently in our foreign-born than in our native population. Only two of the cases reported were born in this country, and the birth of one of them was soon after her people came here. Doubtless this is partially accounted for by the fact that a large proportion of the foreign-born population of this country employ midwives. Although the American population of Buffalo is larger than the foreign-born, yet the birth-rate among the foreigners is much greater than among the native. We have quite an Italian population, and a very much larger Polish settlement, and nearly all these people, as well as the Germans, employ midwives, so that more than one-half of the births of the city are attended by them. Another very probable cause is the greater frequency of contracted pelves among the foreign-born element.

No doubt some of the cases of sudden death after confinement when the cause is unknown are due to ruptured uteri. Case 3 is an example. While others who die in a short time from septicemia may have a rupture of the uterus as the predisposing cause, the condition, however, is less frequent now than formerly, owing to the advances made in obstetric technic. Most of the cases reported occurred years ago. It is a fact well known to the older members of the profession that the

practice of obstetrics has changed greatly in the last twenty-five or thirty years. Now a physician does not leave his obstetrical bag at home, for fear that he will not be able to resist the temptation to use the forceps before he ought; and when labor is not sufficiently rapid to suit his convenience he does not give ergot freely until the contractions become severe and irregular. It was fortunate for the comfort as well as for the safety of women that much of the ergot formerly used was inert. Perhaps the same may be said of that in use to-day.

Had ergot not been given, and had forceps been applied at the proper time doubtless a majority of the cases mentioned might have saved.

DISCUSSION.

DR. JOHN M. DUFF, Pittsburg.—I think perhaps in the past we have had more cases of rupture of the uterus than have been reported, and undoubtedly it is so at the present time. Last year I was called to see a woman about the ninth day after confinement, and, unfortunately, when I arrived she was dead. I succeeded in getting an autopsy. A complete rupture of the uterus was found, so that my hand passed through it readily.

About six months ago I was telegraphed for one morning to come to the office of a physician. I went as soon as I could, and arrived there about one o'clock in the afternoon. The Doctor was upstairs in bed at the time; he came down, and I asked him the nature of the case he had, and he said he believed it was a case of rupture of the uterus. The woman resided several miles from the home of her parents; she was afraid to trust the Doctor there, and came to this town to have her baby. The Doctor was called at nine o'clock the night before, and found a breech presentation. The pains were violent. Several attempts were made to extract the child, but failed, and a prominent physician in that section of the country was sent for. Dr. No. 1 gave the anesthetic, and Doctor No. 2 made an attempt to deliver the body of the child, but after delivering the body he found the child was headless. He had attempted to deliver the head with forceps, but could not do so. Dr. No. 2 did a craniotomy to deliver the head, and it was said that the placenta came away immediately after the delivery. The woman was put to bed, and the Doctor made his visit in the morning and on examination found some coils of intestine in the vagina. It was then that they telegraphed for me. I examined the woman and found a coil of intestine in the vagina. I could not do anything for the case there, and said it would be necessary to have the woman taken to a hospital. The family objected, and so did the woman. The patient said she felt first-rate, but I insisted on her being taken to a hospital. She went to the hospital; I opened the abdomen and found several feet of dead intestines, which I removed, and put in a Murphy button. Continuing my examination, much to my surprise I found the uterus had been torn off and cut from the vagina and completely absent. There was no hemorrhage; the woman was in good condition apparently; I washed out the abdomen, and as one of the sponges was not found immediately, I began to feel around to see if I could find it in the abdominal cavity, and I reached under the spleen, felt something, pulled it down, and it was the placenta. It was the uterus that came away immediately after the head instead of the placenta. I have narrated this to you, believing that it is worth reporting, and you will understand why I do not use names. The woman died twenty-four hours afterward.

DR. JAMES F. BALDWIN, Columbus—I have seen four cases of rupture of the uterus in consultation. Of the four cases three were native-born, the other being a foreigner, who had a contracted pelvis. In one case, separating the point of rupture was a small fibroid, this case seemingly being the least hopeful of all of the cases on account of sepsis, the woman having been in labor for a week. The other three women promptly died before the day of operation. One was a case similar to that narrated by Dr. Duff, except that the uterus was not torn away, the woman having died before she was sent to the hospital. I saw the report of a case operated on by Dr. Branham, in which prompt recovery followed, although the woman was almost moribund at the time of operation. In one of my cases I believe if the woman had been brought to the hospital earlier there would have been a possible chance for recovery.

DR. INGRAHAM, closing the discussion—I believe rupture of the uterus occurs very much more frequently than we are led to suppose. I am pretty sure it does in Buffalo. More than half of the obstetric cases attended by midwives, after severe

labors, seem to die in a mysterious manner, and we do not know why. No autopsy is made, and I have no doubt many patients die of rupture of the uterus.

THE SUSPENSIO-UTERI LIGAMENT*.

ITS STRUCTURE.

BY J. WESLEY BOVEE, M.D.

Fellow of American Gynecological Society; Member of Southern Surgical and Gynecological Association; Professor of Clinical Gynecology and Gynecological University; Gynecological Surgeon to Columbia and Providence Hospitals, etc.
WASHINGTON, D. C.

The subject of uterine displacements has already caused a wonderful amount of discussion, and to this day it is as prolific of animated debate as any subject in gynecology. This paper does not deal with the causes and milder forms of treatment of such malpositions of that organ. Nor do we intend to compare the different surgical measures for relieving such conditions further than to say that ventro-suspensio-uteri and ventro-fixatio-uteri leave an exceedingly small field, indeed, for all other major operations in the treatment of the posterior variety of uterine displacements. After employing them in a few hundred cases and resorting to other operations in a smaller number of cases, the writer is forced to this deduction.

As ventrofixation and ventrosuspension are to-day practiced their difference is only one of degree. It is simply a matter of combat between the resisting property of the new ligament or attachment and the forces combined against it. The habits, customs, mode of living and other conditions in the lives of the patients have a very strong bearing upon the results of these operations. And the conditions vary from ventrosuspension for mild retroversion to firm ventrofixation for exaggerated uterine prolapse.

History.—Attachment of the uterus to the anterior abdominal wall by means of suture was done thirty years ago. Dumoret¹ says that Koeberle first did hysterectomy in 1869 for retrodeviation, and that Kaltenbach fixed the uterus to the abdominal wall in 1876 for prolapsus uteri. In 1877 Koeberle² removed the uterine appendages, raised the uterus from Douglas' pouch, and successfully sewed the appendage stumps into the abdominal incision. In his most excellent paper on this subject, Charles Carroll Lee³ says: "In February, 1880, Mr. Lawson Tait operated on a case of ovaritis complicated by persistent retroflexion, in which after removing the appendages and while closing the wound, he passed a stitch through the fundus uteri and fastened it up to the abdominal wall." And further, of Tait's work, he quotes, "In another similar case of chronic interstitial ovaritis complicated by fundal metritis and retroversion he repeated the same experiment, April 9, 1880. Both patients recovered and in both the uterus remained in situ."

To Professor Olshausen is due the credit of first urging ventral attachment of the uterus for vicious displacements of that organ.

In his paper⁴, read in Berlin in September, 1886, he recited cases he had operated on and so strongly urged the operation that it was soon adopted by other Germans. One of his operations was for excessive prolapse and the other for retroflexion and adhesions. Both had resisted all known methods of treatment, and the operation in the case of prolapse failed as well. In the discussion of his paper it was found that a number of surgeons had been doing the same work. Bardenheuer had done several in 1880. Olshausen advised the use of several sutures to

* Presented to the Section on Obstetrics and Diseases of Women, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-8, 1886.

affix the uterus to the abdominal wall, passing them either through the cornua of the uterus or through the broad ligaments in such manner as to cause them to encircle the round ligament—and the Fallopian tube as well, if after the menopause. This multiple suturing was employed by all his immediate followers. Terrier² and many others sutured from the fundus down to the bladder in ventrofixation, using coarse buried silver wire and silkworm gut. Some surgeons in this country were at this time fixing the fundus to the abdominal wall when removing the appendages. The methods employed by these operators were nearly as many in number as were the surgeons operating, so that for seventeen years ventrofixation, primary and secondary, was practiced to a greater or less extent, and all these operations had in view the firm permanent attachment of the uterus to the abdominal wall.

It remained for Dr. H. A. Kelly, in 1885, to devise an operation for temporary ventrofixation of the uterus that permits this organ to acquire its normal mobility, and position or plane in the pelvis, thus removing the feature that caused trouble in the pregnant state. This operation was correctly named by him "Ventrosuspensio uteri." Even here considerable modification has been made by him regarding the points of the uterus to be attached to the abdominal wall. The plan he has finally adopted is to pass the sutures through the posterior wall of the uterus slightly below the level of the junction of the round ligaments and uterus. The writer believes this to be the best possible position. The result is that the uterus, after some months—the time varying according to the degree of primary fixation and the future conduct of the patient—drops downward to its normal distance from the abdominal wall and remains attached by a strong ligamentous cord. Kelly says: "The distance between the uterus and the anterior abdominal wall is about one or one and a half inches. The organ is attached by a strong fibrous cord which contains the sutures close to the abdominal wall." He objects to passing the sutures to much depth in the uterine wall, but this point is not followed by all operators.

The writer has been anxious to have this new cord microscopically examined and a suitable case presented itself last year. Dr. Kelly had operated for "falling of the womb," as the patient expressed it, in 1894, and I had to do a section for other conditions four years later. The case history is as follows:

Mrs. A., white, 28 years of age, living apart from her husband and in very bad company, consulted me in October, 1898, offering the statement that she had bad health, said to be due to falling of the womb, and had been operated by Dr. Kelly in 1894, he doing some kind of abdominal operation. One year later she had a child without unusual difficulty and remained well until less than a year ago. She admitted having lived a rather fast life during the past year and had suffered from pelvic trouble, which had confined her to bed a considerable part of the past two months. Upon her person were found a hypodermic syringe and several morphia tablets, the admission was secured of her being addicted to taking grain doses of that drug, self-administered with the syringe. On her abdomen, just above the pubes, was found a scar of a former median incision about two inches in length, and an examination revealed a large fluctuating mass filling the pelvis. Operation was done October 24, 1898, assisted by Dr. W. C. Borden, major and surgeon, U. S. A. Double pus-tubes were removed, and cystic ovaries, severely lacerated in

separating their adhesions, were also removed. The section was made through the right rectus muscle and when the pelvic contents were exposed to view about the first structure to attract my attention was a round, red cord about one-eighth of an inch in diameter and about two inches long, attached to the uterus, approximately half an inch below and the same distance to the right of the junction of the uterus and left Fallopian tube, and to the lower end of the scar of the former abdominal section. This structure, undoubtedly the result of a former ventral attachment of the uterus to the abdominal wall, was continued through the parietal peritoneum into the fascia. It was removed for examination and at the ends a piece of the uterus and of the abdominal wall. The wounds in the uterus and belly wall were sutured and ventrofixation done. Dr. Borden took the specimen for examination and his report follows. Dr. Kelly has since advised me that his operation was ventrosuspension:

Macroscopic Appearance.—The ligament was 4 cm. long, of greatest diameter at the ends, the center being about 3 cm. in diameter.

Microscopic Appearance.—Longitudinal and transverse sections showed an exterior peritoneal covering, subperitoneal connective and adipose tissue, central bands of connective tissue and blood-vessels.

The peritoneal covering resembled in every way the serous coat of the peritoneum. The subserous connective and adipose tissues were small in amount and extended inward between the central bundles of connective tissue. Small blood-vessels ramified in this connective tissue. The major part of the interior of the ligament was made up of quite large, longitudinally disposed bands of white fibrous tissue, with longitudinally placed, spindle-shaped nuclei. No nonstriated muscle fibers could be discovered.

I was disappointed that a few fibers of involuntary muscle were not found in the uterine end of the ligament—not alone that there was some use for it in this ligament, for the permanency of the structure would be more likely with a few bundles of muscular tissue, but during the latter months of pregnancy its yielding would be more satisfactory, as would its involution during the same change in the uterus. As this operation is comparatively an experiment we do not yet know its results after a long term of years. The ligament is not like the others of the uterus. In some cases it has been found to have reached the length of several inches within the first two years after operation. In these instances, however, the operation was probably abused, as the ligamentation of the uterus or the pelvic floor was very faulty and such faults were not corrected. In this way improper cases were selected for this operation, and the selection and not the operation was faulty. Such cases, nevertheless, serve to demonstrate the stretching property of this ligament—a property not relatively compensated for by its elasticity. It is by no means certain that it returns to its former dimensions after full-term labor. In a few cases we have found it has done so and in the one herein reported it had not suffered by the labor of pregnancy. In some others we have found it quite slack after labor. However, its use is not for all time, and often, no doubt, its existence is necessary for but a few months, the natural uterine supports regaining their function in the meantime. The absence of muscular tissue from the suspensio-uteri ligament is, probably due to that kind of tissue having greater resisting power than fibrous tissue. As the operation is, properly performed the parietal peritoneum and a certain amount of the fascia are sutured to the serous covering of the uterus, the sutures passing slightly into the muscular tissue of that organ.

These sutures are constantly pulled downward, and

the abdominal attachment gradually yields, thus forming the structure known as a new ligament. The uterine muscular tissue does not yield to the continuous tension, and consequently none of it enters into the formation of this cord. The inclusion of a very small amount of the muscular tissue of the recti abdominales in the fixation sutures would convert the structure of this ligament to nearly that of the normal ones of the uterus. I am by no means sure that this is a reliable procedure, or would be at first, but comparative permanency of the ligament would be insured in this way, and its utility would be prolonged to any desired extent. During the past few months the author has adopted this plan in a number of cases, one of which was in early pregnancy and in danger of abortion from posterior displacement with fixation.

CHOLECYSTECTOMY.*

BY CLINTON CUSHING, M.D.

WASHINGTON, D. C.

For the purpose of this paper it will be assumed that the gall-bladder is not necessary to the health or well-being of the individual, for many cases are now upon record where the gall-bladder has been removed and the patients remain in perfect health.

That this should be so is quite reasonable when the anatomy and physiology of the bile passages are examined. The liver secretes in a person of average size about forty-two ounces of bile in twenty-four hours, or in other words, as much bile as urine. This bile passes off into the pylorus through the hepatic and common ducts, while a very small quantity, possibly half an ounce, backs through the cystic duct into the gall-bladder. So far as I am aware, no one has shown that the gall-bladder performs any physiologic function.

Bireh and Sprong report, in the *Journal of Physiology*, that in two patients upon whom the operation of cholecystotomy had been performed, a fistula forming as a result of the operation in each case, they were able to collect what appeared to be the normal secretion of the gall-bladder. In amount the secretion was something over 20 c.c. in twenty-four hours; it is usually quite clear and contained no bile at all, owing to the occlusion of the cystic duct.

The reaction was distinctly alkaline, and the exhaustive chemical examination showed that the secretion of the gall-bladder contains no bile salts, or biliary pigments. Physiologically it was shown not to have any diastatic or emulsifying action.

It cannot, therefore, be of any digestive value. On the contrary, in certain animals—the horse, the deer, and the elephant—the gall-bladder is normally absent. It would appear then, that, like the vermiform appendix, whatever may have been the importance of the gall-bladder in the animal economy, evolution has so altered its function as to make it no longer necessary.

My first cholecystotomy was made fifteen years ago, and was done in the usual manner; the gall-bladder enlarged, inflamed, and bound down by adhesions was, after separation of adhesions, drawn up to the abdominal incision and stitched there; a small handful of gall-

stones were removed through an incision in the bladder, an inch in length; a drainage-tube was introduced and recovery was uneventful.

At the end of two years a return of the symptoms necessitated the reopening of the abdomen, the removal of more gall-stones and the removal of the gall-bladder itself; after which the patient remained well. In all my other operations for cholelithiasis, six in number, I have removed the gall-bladder by ligating the cystic duct, removing the bladder, and treating the stump as after removing the appendix vermiformis. All made easy recoveries, except one, who had a slight biliary fistula for ten days, and which closed without trouble. So far as I have been able to follow the histories of these cases, subsequent to the operations, no untoward symptoms have developed, except one, a woman over 50 years of age, on whom I operated in January, 1898. I recently received a letter from her, detailing her symptoms, and it is probable that malignant disease is developing in the region of the liver. Should this prove to be so, it is doubtless a coincidence.

The indications for a surgical operation upon the gall-bladder or the biliary passages has been very ably set forth by Mayo Robson, in the *London Lancet*, for May, 1897. He says: 1, "recurring attacks of biliary colic, with or without jaundice, and whether the gall-bladder is enlarged or not;" 2, "enlargement of the gall-bladder, whether there be pain or not;" 3, "persistent jaundice which was preceded or accompanied by pain in the region of the gall-bladder, with or without paroxysms resembling ague;" 4, "empyema of gall-bladder, or peritonitis in gall-bladder region;" 5, "abscess in region of gall-bladder;" 6, "rupture, fistula or wounds of gall-bladder."

In any one of the above conditions where there is serious danger to life, or marked suffering, the question of an exploratory incision should be considered, for a positive diagnosis is difficult, or impossible, in a large proportion of cases, until the abdomen is opened, for the gall-bladder, unless decidedly enlarged, cannot be palpated in its normal position.

The diagnosis of a diseased gall-bladder, then, will depend upon the existence of local pain and tenderness, reflex pain in right shoulder-blade, coupled with the existence of gastric troubles and jaundice, where there is obstruction of the hepatic, or the common duct of the liver. As all are aware, gall-stones may remain in the gall-bladder for years without producing any symptoms, but I doubt not they cause cholecystitis much oftener than is generally believed. What leads me to this conclusion is the fact that in two of my seven cases, the bladder walls were greatly thickened; in one case fully one-fourth of an inch, and contracted firmly about a row of gall-stones up the center like peas in a pod. In another, in addition to thirty gall-stones, the bladder was so distended by the secretions of the viscus that it felt like a piece of wood and was of a dark red color. In still another, in addition to firm adhesions, clearly the result of peritonitis, there was a considerable deposit of cheesy material on the adjacent peritoneal surface.

In two of the cases the abdominal incision was partly exploratory. Both patients had been under careful and intelligent management for several months, but had irregular fever and chills, gastric pain, indigestion and marked emaciation; the symptoms finally leading to the conclusion that there was somewhere in the body a collection of pus, probably about the pelvis. In both cases the abdomen was opened below the umbilicus, and with the hand and arm in the abdominal cavity, every organ was thoroughly and carefully examined. Noth-

*Presented to the Section on Obstetrics and Diseases of Women, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

ing abnormal was found except the cholelithiasis and some local peritonitis. The opening below the umbilicus was closed and an opening made parallel with the lower edge of the ribs, and the gall-bladder with its contents removed. The fever and other symptoms at once disappeared, and the patient afterward remained well.

If, then, the gall-bladder is so seriously diseased as to warrant a surgical operation for its relief, it is better practice to remove it in toto, than to leave it as a place for the further accumulation of gall-stones, or as a point for the setting up of new inflammations. Like the vermiform appendix, the gall-bladder is a cul-de-sac, and having been once diseased, if the patient lives, is likely to become diseased again, unless removed; indeed, the same argument applied to the Fallopian tube, for when the fimbriated extremity of the tube becomes closed by inflammation, it constitutes a cul-de-sac opening into the uterus and is prone to the formation of pus, or mucopurulent material.

When we open the abdomen for the relief of salpingitis, a pyosalpinx, or an appendicitis, do we leave the diseased organs in situ? Certainly not. There is one condition in which the gall-bladder should not be removed. If for any reason the common duct or the hepatic duct below the junction of the cystic duct becomes strictured, or obstructed by morbid growths, or otherwise, so as to prevent the passage of the bile into the intestines, then it might be possible to attach the gall-bladder to the pylorus and thus utilize the cystic duct and the gall-bladder to carry the bile into the intestine.

Misleading Statements and Illustrations in School Physiologies, Physics, and in Text-Books on Diseases of the Eye.

KANSAS CITY, July 21, 1899.

To the Editor.—If parallel rays of light focus on the retina and the image is inverted, why is the image not reinverted in myopia where the rays cross before they reach the retina; does the image of objects focus at a point as it seems to do in Figure 1; and if the crystalline lens brings rays of light to a focus on

the manner in which rays of light reach the retina, and many that are incorrect.

As far as I know Figures 1, 2, 3 and 4 are the ones used the world over to illustrate errors of refraction, and they are all incorrectly drawn, and consequently misleading to teachers and students. I am of the opinion that the above illustrations ought not to appear in any text-book. If errors of refraction were represented as in Figures 5, 6, 7 and 8, writers would not be tempted to make use of the expression that parallel rays of light focus on the retina.

It can be readily seen by such illustrations that parallel rays do not focus on the retina, that the image is always inverted, no matter what the refractive error may be, and that the images of objects are not focused at a point, as represented in Figure 1. It would be well to represent astigmatism, as in Figure 8, where rays of light which strike the cornea in the perpendicular meridian are focused the farthest back, and those striking the horizontal meridian would be focused nearest to the cornea while those striking the oblique meridian, lines marked 45, would focus between the two points. Students would not then get the impression that in astigmatism rays of light focus at two points, but between two points.

the retina where would they focus if the lens were removed, and would the image be inverted? These are the questions students ask after seeing the statements and illustrations in the various text-books.

Most text-books contain an illustration correctly showing

Rays of light should be represented as coming to a focus from the cornea instead of the lens. It is more correct to represent it so, for it requires a lens of 40 diopters to bring rays of light to a focus at one inch, and the lens has only the converging power of 10 diopters. Readers would not then be led to think that rays were scarcely refracted at all, when the lens was removed. Would it not be well to represent a highly myopic eye and one where the lens had been removed, as in Figures 9 and 10, to show that in such eyes rays of light focus near the retina where the lens is removed?

Figure 11 represents rays of light coming to a focus at a

little more than an eighth of an inch back of the retina in a normal eye where the lens has been removed—which is the condition after a cataract has been extracted.

The text-books on physiology and elementary physics, used in the public schools, also teach that parallel rays of light focus on the retina in the normal eye, in front of the retina in myopia and behind it in hyperopia. Students believe the statements in their text-books to be true and the illustrations correctly drawn. They can come to no conclusion other than that the images of objects are made to focus at a point, and, according to the illustrations, the image is sometimes inverted on the retina and sometimes not. If writers of text-books were more accurate in their illustrations, which necessitates incorrect statements to describe them, we would not teach so much that is not true.

 8. **Lupus Erythematosus.**—After some remarks on the pathology of this disorder, Pardee describes a case in detail and the experiment of inoculating, with a piece of diseased skin, a guinea-pig which was allowed to live thirty-five days and then killed. It showed no traces of tuberculosis in any of its organs.
 9. **Lumbar Puncture in Cerebrospinal Meningitis.**—Cuthbertson reports three cases of cerebrospinal meningitis occurring in the First Illinois Cavalry, during the late war. In two cases lumbar puncture was performed and the patients survived. There were 6 cases; 3 were punctured and recovered; three were not and succumbed. He thinks the facts, so far as they go, speak strongly for the therapeutic value of this procedure.
 11. **Nasal Inhalations of Oxygen Gas.**—Beck describes a method of giving oxygen by nasal inhalations, which he claims has great advantages over the ordinary method of inhaling it by the mouth. A patient who underwent this treatment also remarked that inhalation in the recumbent position was much easier, and its invigorating effect much more quickly obtained.
 14. **Streptococci in Scarlatina.**—Page has made cultures from the throats of twenty-four scarlet fever patients, and found a streptococcus in the primary cultures in all cases but one, but failed to isolate it in five cases. The principal point in his paper is the variation they show in acid products from sugar, which he thinks may be of importance in separating the varieties of this organism which have such different actions on the system and the existence of which prejudices the value of antistreptococcus serum.
 15. **Effects of External Temperature on Circulation.**—The authors conclude their preliminary notes as follows: The results of our experiments would seem to show that at times there is a rise of capillary pressure going along with arterial constriction—effects of marked cold—and that at other times capillary pressure remains constant or shows only a slight rise when there is pronounced arterial dilation. In other words, capillary pressure is dependent on some other factor or factors than the amount of arterial tone. I should like to suggest that all our results are explained by supposing that the muscular coat of the small veins may be the other factor in question; if this constricts and dilates with the constriction and dilation of the arterioles we could have fairly constant capillary pressure with great variations in the amount of blood flowing through an organ; the inconsiderable changes in capil-

lary pressure, which at times accompany the marked arterial dilation produced by exposure to heat, would be because of concomitant venous dilation, which permits an easier egress of blood from the capillary region: the rise of capillary pressure, which at times accompanies the arterial constriction produced by exposure to marked cold, would be due to the excessive concomitant constriction of the venules, which hinders egress of blood from the capillary region. May it not be that while the muscular coat of the small arteries regulates the amount of blood flowing to an organ, the capillary pressure is regulated by the simultaneous action of the muscles of both arterioles and veins?

18. **Diplococcus of Scarlet Fever.**—In this preliminary report Page states that he has made cultures from eight more cases of scarlet fever and in five of these found a large diplococcus resembling that described by Class. He is confident that he saw a similar large one in a number of primary cultures of the twenty-four cases above reported. He has attempted to cultivate this organism in agar-agar mixed with garden earth, as suggested by Class, but his results are not yet conclusive. He remarks that if the organism described by Class proves to be the cause of scarlet fever, numberless problems suggest themselves to be worked out. An important one will be the effect of increasing percentages of carbolic acid in the culture-media on the virulence of the organism, to see if there is any rational basis for treatment of the disease by large doses of carbolic acid—5 to 30 grains per day in five doses, freely diluted—as recommended by Dr. A. Wigglesworth of Liverpool.

19. **Edema of Nasal Mucosa.**—Noticing first the slight reference to the subject in rhinologic literature, Gradle reports three cases of edema of the nasal mucosa involving the entire nasal lining and absolutely occluding the passage. The cases he reports are the only ones he has met with in many thousand patients, and in all three it developed after an acute inflammatory attack; whether a simple coryza or influenza could not be determined. No local lesions existed, to which to attribute it. In none of the three was there any suppuration. The treatment was with cocain tampons, applications of silver nitrate, carbol-glycerin, sprays of Seiler's solution, of menthol vaselin. In one case a vascular hypertrophy was removed with a snare. All three cases were cured, though some had been of rather long duration.

20. **Dyspnea.**—Johnson reports a case of obstinate dyspnea from laryngitis and tracheitis, of unusual severity, relieved by intubation and steam inhalations with lime water. Another case is reported that occurred in the practice of another physician. Both were young women about 26 years old, and each was six months pregnant.

21. **Hemorrhage Following Adenoid Removals.**—Martin reports three cases for the benefit of statisticians, as he states, of severe hemorrhage from removal of adenoid growths. He had been operating on these growths for seven years before he had any such unpleasant experiences, and had begun to think that his methods were more careful and better than those of physicians who had had them.

24. **Moderate Altitude in Phthisis.**—In this paper Anderson discusses the advantages of different degrees of altitude for consumptives, the high altitudes having, as has been recognized, superior advantage to the average individual. In many cases, however, the expected relief from the change does not occur, and he has found with a certain proportion of this class that benefit has followed change to a lower altitude; for a number of years he has urged such cases to temporarily go to an altitude of from 3000 to 4000 feet above sea-level and remain until improved. His attention was called some eight years since to the Mesilla Valley in New Mexico, and he has been much aided by his acquaintance with this locality. There are combined the important essentials of a maximum of sunshine and dry air together with only a moderate elevation. He finds that many patients, after spending two or three winters in this valley, find themselves able to endure the higher altitude and to continue their improvement there. It is impossible, he admits, to absolutely foretell the results in all cases and he notes a striking case where, against all his prophesying, the patient apparently recovered and died years later of a different disease.

25. **Hydrotherapy in Insomnia.**—Hance reports five cases of insomnia treated by hydrotherapy, in the form of hot-air baths, circular needle spray, douches and static electricity, with successful results. He thinks that the static electricity has an important part in the treatment, and that hydrotherapy and its together are more powerful and beneficial than either one separately.

26. See abstract in *JOURNAL*, April 29, p. 941.

27. **Organotherapy in Gynecology.**—After noticing some of the reports on facts in the literature of gynecology of thyroid treatment, Dorland reports six cases in which this medication was used. He concludes that the thyroid, in addition to its general effect on metabolism, exerts an inhibitory action on the pelvic genital organs, and the uterus in particular, especially marked in this there is a retardation of hemorrhage from the uterine mucosa, which is directly antagonistic to the effect of ovarian secretions. Thyroid therapy is especially indicated in hemorrhagic affections of the uterus and all forms of pelvic congestion, notably in uterine fibromata, hemorrhagic endometritis, metropausal hemorrhages and chronic tubal diseases. The best results are to be expected in fibromata and recently developed pathologic conditions. The more chronic cases are more resistant. It also produces an increase in tissue changes of the mammary glands, and is therefore indicated in cases of insufficient lactation. Owing to the tendency to thyroid intoxication, it is well to discontinue the use of the drug for a week or ten days, at intervals during the course of treatment. Thyroid treatment is contraindicated in tuberculosis, which it seems to stimulate, and in serious heart disease, and it should be discontinued on the appearance of tachycardia. He also reviews the facts as to the use of mammary and parotid glands. Shober has reported a decrease in the size of tumors treated with mammary gland, which he thinks acts on the uterine muscles and connective tissues somewhat similarly to ergot. It has never given rise, in his experience, to any unpleasant symptoms. He has also had gratifying results in the use of parotid gland in ovarian disorders, inflammation, congestion, neuralgia, etc.

28. **Treatment of Pneumonia.**—In treating pneumonia Hare divides the disease into three stages and asks: "What means shall we employ in the onset? As regards the use of sedatives, they are applicable to but few, but with robust individuals he would use hot foot-baths and compresses and give veratrum viride tincture in 3-minim doses every fifteen minutes for three doses, and some Dover's powder to allay cough and pain. All depressing measures, however, should be discontinued after the first twelve hours. As regards venesection, it may be useful in some cases. It is a rather severe treatment and its effects are too permanent to make it commonly advisable. When consolidation has taken place, four conditions are to be looked after: 1. Fever, which he would combat by cold sponging, ice-bags over heart and head. Antipyretic drugs, he thinks, are seldom needful; cold is sufficient. 2. The second indication is to aid the circulation if it needs it. Digitalis has been our standby, but should be given rightly. Its action is so slow that in pressing cases 10 to 20 minims of the tincture or 1 to 2 minims of a physiologically tested and standardized normal liquid digitalis should be given hypodermically, and then need not be repeated for many hours. If the pulse be gaseous and relaxed, 5 to 10 minim doses of belladonna may be useful, given every four or five hours. Strychnia, he thinks, often employed improperly, and if kept up causes more harm than good, though for combating sudden collapse it is invaluable, especially if combined with atropin. For prolonged collapse or tendency thereto, coea wine may be used. A good old brandy often agrees with patients of advanced age with feeble circulation. Nitroglycerin is invaluable if arterial tension is high; if low, it is useless, and in venous engorgement it is only a very indirect means of producing relief when a much better and more direct one is venesection. The value of oxygen gas is problematic. He uses it when respiration is difficult, and it generally seems to make the patient more comfortable: it may be partly by the mental effect. The stage of resolution is not discussed, as much had already been said on the subject. In conclusion, he remarks on the necessity of treating the cases individually; no one plan can be invariably followed.

30.—This paper was printed in *THE JOURNAL* of June 3.

31.—See abstract in *JOURNAL*, July 15, p. 164.

33. **Malaria in an Infant.**—Clark reports a case of malarial fever in an infant ten and a half months old. The case is illustrated with a diagram. Quinin was given by suppositories, after finding the parasite, 5 grains twice a day, but without effect. He then had to give the plain sulphate of quinin, 1 grain in fluid extract of licorice every two hours, beginning with 12 grains a day, and gradually reducing it until the temperature became normal. He asks how the child became infected, and suggests that it might have been from absorption from sewer gas by the milk.

42. **Internal Remedies in Surgery.**—Manley calls attention to the importance of recognizing the value of internal remedies as making it possible in some cases to avoid surgical operations. As a striking example of this he notices juvenile tuberculosis, affecting the joints, and shows that of late years not one operation is performed where formerly ten were for this condition. The use of the bitter tonics, cod-liver oil, preparations or combinations of mercury, iodine, phosphorus, creosote, salol, etc., have made this possible. While malignant disease still defies us, and surgery is in most cases a palliative, yet much can be done with local remedies. Many cancers have been thoroughly removed by escharotics. Venereal disease in nearly all its form yields often to internal remedies, and in many cases when the diagnosis is uncertain those latter both clear it and bring about a cure. Surgery cannot progress much farther, but there remains a wide chasm to be filled up in the domain of internal medicine.

43. **Thyroid Glands in Obesity.**—In this article Wood points out the usefulness of thyroid in reducing corpulence, and notes the objections, such as an occasional cardiac disorder. In most cases, however, there are no unpleasant effects from its use. The greatest disadvantage is the lack of permanence of its effects, and if we have succeeded in reducing the superfluous weight of an individual, the treatment must be continued by abstemious habits and regimen, a point on which the originator of the thyroid method, Yorke-Davies, laid great stress.

44. **Potassium Iodid in Cerebrospinal Meningitis.**—The apparent increase of cerebrospinal meningitis is noted by Moody, and he gives an account of several cases of the fulminant type and also of a local epidemic in which the iodine treatment recommended by Tanner was strikingly successful. His conclusions were as follows: In the fulminant or apoplectic form of cerebrospinal meningitis no known treatment offers any hope of cure. In the ordinary form, commonly known as "spotted fever," potassium iodid is the only drug which has shown any power to modify the disease. That drug should not be depended on alone, but any means known to therapeutics should be employed whenever it renders the patient more comfortable or aids him to resist the exhausting conditions of the disease. The contagion can, at least in some instances, be readily communicated to those exposed, provided the environment is the original focus of infection; the identity of environment is not apt to be found except at the point where the epidemic first appears. The disease is seldom communicated in any other locality than that first infected, but identity of sanitary conditions might be a source of danger of its further propagation. Finally, the writer does not consider the known influence of the iodid on absorption a sufficient explanation of its usefulness in the disease, but thinks it more likely that it either has some quality that acts as an antidote to the toxins secreted by the pathogenic organisms, or is unfavorable to their development.

45. **The United States Pharmacopœia.**—Forrest points out certain defects in the present edition of the "Pharmacopœia" in make-up, text, index, etc., and notices the propositions that have been offered by the committee on its revision.

46. **Value of Complete Diagnosis.**—Maass emphasizes the importance of a complete as compared to a simple correct diagnosis of the chief disorder, that is, taking in every possible condition of the patient that may complicate or affect the disease. His article is made up largely of cases in his experience, illustrating the advantage of thorough investigation.

47, 48 and 49. **Puerperal Sepsis.**—In this symposium on

puerperal sepsis, the symptomatology is discussed by Whinery, and he points out the possibility of either septic infection or a putrid intoxication, the latter being less grave than the former, and constituting about 75 per cent. of all cases. He suggests the value of blood examinations in dubious cases on account of not only the demonstration of microbes, but also the clinical data offered by the blood elements. In well-marked sepsis there is a diminution of red cells. In cases of moderate severity there is marked leucocytosis, which is not nearly so marked or is absent in mild and in very severe and rapid cases.

Longyear discusses the medical treatment, especially the use of serumtherapy with streptococci and other infections. His summary is as follows:

Local Treatment.—Early recognition and destruction of pseudomembrane by topical applications is of great importance. Iodin, carbolic acid and chloral mixture is a safe and efficient application for this purpose. The intrauterine douche, frequently applied, is of most value in the cases of infection unattended by the formation of a pseudomembrane, but is useful also in connection with local applications. The vaginal use of peroxid of hydrogen is useful in all forms of infection. Frequent packing of the vagina, previously dried, with iodoform gauze is especially useful in cases attended with pseudomembrane. Inspect infected cases daily with the speculum. Some uncomfortable surprises may thus be avoided, and the local treatment will be made understandingly.

General Medication.—Quinin in large doses twice daily; whisky and strychnin to support the heart, if indicated; nuclein and protnuclein in all cases; mercurial and saline cathartics at first in all cases, then as indicated: serumtherapy to be applied in all cases when the Klebs-Loeffler bacillus or the streptococcus can be demonstrated by bacteriologic examination to be present, and also in all other cases when such examination has not been made, but in which these specific varieties of infection are probably present. Streptococcus antitoxin serum is to be used persistently to prevent pus formation and symptoms of systemic infection, even if local symptoms and high temperature persist.

The surgical treatment is discussed by Alvord and, according to him, consists in thorough curetting of the cavity of the uterus followed by antiseptic irrigation and drainage. The use of Marmorek's serum is suggested for certain cases where complications have arisen, and, in case all these measures fail, the sole chance of life will be to perform hysterectomy.

50.—See abstract in *JOURNAL*, April 22, p. 876.

51.—*Ibid.*, February 25, p. 439.

54. **Blood Examinations.**—Bryant calls attention to the importance of blood examinations in various diseases, with leucocytosis or not, as an aid to diagnosis, and reports a case of pernicious anemia in which the diagnosis of typhoid was corrected in this way. The patient's red blood corpuscles had been reduced to 800,000, and the white to 4000. He rapidly recovered under the use of arsenic and bone marrow.

58. **Suggestive Therapeutics.**—Eckard reports four cases suffering from various pains and aches, treated by placebo, and believes that if these were used more we would discover more hysteria and use less morphia than we do.

60. **Skin Grafting.**—The method here advocated by Wiggins is the one suggested by Hodgen in 1871, of using a graft of the exuberant epidermic cells from the sole of the foot. The method as he reported it consisted of sprinkling the unprepared epidermic cells over the granulating surface. These suggestions were so completely ignored that Wiggins only learned of its existence after nearly completing this article. The method he advises is to have the foot prepared by a thorough scrubbing, and remove the outer layer of epidermis, which must necessarily be full of organisms. This is followed by bathing in strong bichlorid solution, and the foot is then covered with moist boric acid dressing overlaid with rubber tissue, which serves, by reason of heat and moisture, to loosen the deeper and more vitalized layer of cells. After twelve hours this dressing is removed and the surface thoroughly scraped with a dull knife. The cell mass thus obtained is placed in a mortar, which in turn is placed in a water-bath with a temperature of 110 to 115 F., and stirred until thoroughly desiccated. The object of this is: 1, to permit of trituration and to further separate particles, and, 2, to divest them of all moisture so as to influence

the adhesion of the cells to the moist surface of the ulcer, thus facilitating union by exosmosis. Where in the ordinary method we have a single graft, by this we may have 1000, and the chances of their living is increased. The dangers of this graft thus applied are: 1, excessive secretions of the surface detaching the particles; 2, insinuation of exudates between graft and granulation. To avoid these he either covers the granulated surface with perforated rubber tissue, or puts strips of this over the surface, dusted with the grafts, filling the center of the ulceration with strips of gauze and applying the ordinary dressings. Each of these methods has its advantage, the latter by fencing off the field from the secretions of other parts which are absorbed by the dressing, and the former by affording little islands of greater vascularity in the perforated spaces, thus affording the better chance of life for the new tissue. When the granulated surface is small, not covering more than 1½ or 2 inches, neither of the above methods is necessary. His results by this method have been most satisfactory.

63. **Failure to Find Appendix.**—Why surgeons fail to find the appendix is attributed by Scott to the previous occurrence of appendicitis obliterans totalis, rather than to any possible congenital absence of the part. He analyzes five cases, observed in the dead body, of reported congenital absence, and finds that in none of them was there such thorough examination made as would absolutely confirm the opinion that the appendix never existed.

64. **Gout and Uric Acid Diathesis.**—The theories of uric acid diathesis are here discussed, and the usual conclusion arrived at: that according to the best modern data we can now hold that uric acid is a physiologic product, and as such is indifferent; that when the system can no longer produce it the alloxur bases are formed, and that these bases are poisonous. The diagnosis of what we call uric acid diathesis is no longer guess work, as the examination of the urine and blood will show the characteristic changes. In the former the alloxur bodies are always increased, as they are in leucocytosis and leucemia. To differentiate from leucemia, a glance at a blood specimen is sufficient and blood examination is necessary to differentiate leucocytosis which may coexist with uric acid diathesis. In gout, the destructive metabolism of the nuclei of the cellular elements is morbidly increased, and the disintegrated nuclein is formed into uric acid as long as the organs for its formation are normal and the processes of oxygenation sufficient. We do not know, however, what produces this morbid destruction of the nuclei.

68. **Hemorrhoids.**—Martin describes an operation for painless removal of hemorrhoids by means of a new form of clamp which he illustrates. The clamp is in the form of a hollow cone introduced into the rectum. The pile is received and clamped in an opening near its base. It blocks the field against any invasion of the feces or other matter. Local anesthesia with cocaine renders the operation painless.

75. **Cardiac Injury.**—Remarking that his practice has included some cases of non-fatal cardiac wounds, and that some one has said that about 12 per cent. of these injuries recover, Wyman assumes that in this estimate pericardial as well as cardiac lesions are included, and he goes over the symptoms of cardiac wounds and concludes that most of them, in which the patient lives long enough to ask the services of a physician, are limited to the pericardium. The disordered action of the heart in these cases may be due to the presence of blood or air in its sac, encroaching on it and impeding its movements. He would advise the operator who opens the pericardium or enlarges a wound to use the utmost caution as regards infection, and objects to any extensive probing or exploration with the fingers. If blood clots are present, their release would give immediate relief. In case the blood continues to flow and is not from an intercostal or mammary artery, the heart should be explored and the source found and ligated. No one should take the chances of an intercostal or mammary artery pouring its contents into the pericardium. Sutures should be cut short that they may become absorbed or encysted. To close the pericardium and chest wall, interrupted sutures are the best, and should include both. Gauze or cotton dressing, or, better, adhesive plasters should be applied to the external wound. The bowels should be freely opened with calomel or salines, to guard against pericarditis and endocarditis. In enlarging a wound

which one has cause to think involves the pericardium, care should be taken not to open the pleura if it has not been already opened. When the wound of entrance is in the chest or abdomen at a point remote from the pericardium, it had better be opened by an incision in the fourth intercostal space commencing near the sternum and extending upward for three inches. The fourth costal cartilage may be divided close to the sternum and pulled upward to give more room. If the third costal cartilage must be divided, an incision should be made parallel with the sternum, one inch from it and at nearly right angles to the first incision. The included soft parts may be divided with scissors. Retractors may be used to hold the wound open so that access may be had to the heart. The index-finger should be passed between the apex to raise it up and steady it while the bleeding point is embraced by a curved needle carrying a ligature. This curved needle, smooth and round, held in a needle holder, is not liable to unnecessarily wound the heart tissue.

78. Intestinal Perforations from Within.—Hadra's paper treats of perforation of the intestines by foreign bodies, which he suggests may take place very gradually and a considerable time after the original ingestion. He reports several cases of abdominal abscess which he believes were caused in this way; in one of which the corpus delicti, a small bone, was found imbedded in indurated omentum. In conclusion, he calls attention to these perforations as occurring in the rectum, especially in that form which occurs just above the so-called pelvic diaphragm, say above the line of the coccyx. These cases reveal themselves as chronic proctitis with inflamed hemorrhoids, rectal ulcers, etc., and a correct diagnosis is not always easy.

79. Tonsil Clippings.—The writer considers the following topic: Follicular tonsillitis, peritonsillar abscess, hypertrophy of pharyngeal tonsil.

80.—This address was printed in full in the *JOURNAL* of June 10.

83.—See title No. 29, p. 214.

84.—*Ibid.*, No. 27.

89.—See abstract in *JOURNAL*, June 3, p. 1254.

90. Hepatic Abscess.—According to Grant's view, hepatic abscess is more common than has been generally accepted, is frequently infected by way of the ducts, and is not necessarily connected with tropical dysentery. He notes the symptoms as described by Johnston and Fontan: pain, indigestion, nausea, intestinal disturbances, irregular temperature, occasional jaundice, the enlargement which is usually palpable etc. The use of the aspirator after the tumor appears, though not approved by some authorities, is advised by Grant, and he thinks its dangers are slight and the indications it gives valuable. It is unwise to allow the abscess to enlarge, as is often advised, because it increases the suffering and renders multiple abscess more probable. He has had no experience with the subphrenic abscess located in the spaces about the stomach below the diaphragm. Its causes and symptoms, however, are much like those of acute septic abscess in the liver substance, and the diagnosis and treatment are less difficult. Recognizing, therefore, a chronic slow-growing and an acute septic form of liver abscess, the former characteristic of the tropical variety, the latter much more rapid in its course and following an attack resembling typhoid, he advises treatment, after diagnosis, by incision down to the liver, stopping at the surface of that organ until the existence of firm adhesions is made out. If there are none, wall off the cavity and follow the aspirating needle into the abscess cavity with a bistoury, wash out and drain. A still better plan, however, is to pack the wound when the liver is reached and wait thirty-six hours until further adhesions have formed, and then incise and perhaps curette and drain in safety. The hemorrhage, if the cavity is deep, may be troublesome, but yields to suture or packing. If the abscess is single, the operation will be successful in a large percentage of chronic cases, though in the acute septic form the prognosis is not so good. Perhaps 60 per cent. of abscesses are more accessible through the diaphragm and can be reached, after the use of the aspirating-needle, by excising a part of the eighth or ninth rib, and if the pleura cannot be peeled off the ribs and diaphragm, carefully incising it and sewing the costal to the diaphragmatic portions, thus shutting it off from infection, then

incising the liver from the diaphragm and, if possible, stitching the liver wound to the diaphragmatic opening; after this irrigation and drainage. In multiple abscesses a recurrence of the symptoms will indicate pockets that have not been reached, and if the accumulation can be found, the same rational surgical treatment is indicated. Such cases, however, are usually resistant to any surgery. He believes that the prognosis in single abscess without severe sepsis and with prompt and careful treatment is favorable for recovery in at least 75 per cent. He briefly reports five cases, one secondary, probably to disease of the small intestines or colon, one undoubtedly a direct infection, most likely from typhoid fever, and two apparently traceable to appendicitis. In one the source of infection was not clear.

91.—See abstract in *JOURNAL*, June 3, p. 1255.

93. Hip Disease.—After noticing the principal causes of hip-joint disease, which in practically all cases are either syphilitic or tuberculous, the author discusses its diagnosis and treatment, the principal new point of which is the description of a special form of splint devised by the author which he illustrates.

94.—See abstract in *JOURNAL*, July 8, p. 101.

95.—*Ibid.*, May 27, p. 1180.

100. Liquid Air.—Campbell White, after describing the properties and behavior of liquid air and noticing the fact that it is not antagonistic to the lower forms of life and therefore is in no sense a germicide, gives results of his therapeutic experience with this agent. He has employed it in varicose ulcers, chancroids and in some specific ulcers, and he believes, from the results of his experience, that we have nothing at our disposal that will so quickly, thoroughly and painlessly clear up the edges and stimulate the surface to granulation as does the proper application of liquid air. The applications should not be too frequent, as it is not desired to break down the new granulations. After one or two applications to a varicose ulcer, a repetition once a week is generally sufficient. A chancre or mixed sore will be disposed of at one application, generously applied. A "beefsteak" chancre requires two or three applications three or four days apart. All ulcerations thus treated seem to do better with dry dressing instead of ointment. An ulcer, boil, carbuncle or bubo in its early stage is absolutely aborted with one thorough freezing. If more advanced, several applications at intervals of twenty-four hours are required. When pus has formed in large quantities, it is best to open, under anesthesia, with this agent. In advanced bubo or carbuncle it is unnecessary to curette if liquid air is thoroughly applied to the base of the abscess after incision. He has also used liquid air in sciatica, herpes, intercostal and facial neuralgia, obtaining permanent relief by applying the liquid air to the spinal end of the affected nerve. He thinks the prospects of the use of liquid air in lupus are very encouraging. As regards the treatment of carcinoma, he cannot express any positive opinion for want of experience. One reason why it acts so well he credits to its being a natural application. Air that is in liquid form is the same as the air which envelops the tissues normally, the only difference being its extreme cold, and the tissue destruction from its actual application is less than from handling the glass tube containing it. He applies it with a cotton swab or by the spray.

101. Shock in Modern Surgery.—The principal feature of this article is a protest against too much delay in operation as favoring the occurrence of shock. Quickness of operation is not at all incompatible with carefulness, and the author objects to manipulations and elaborateness of technic requiring the expenditure of time. The special sensitiveness of the nerves supplying certain parts of the body is to be considered in this connection, and he also alludes briefly to the dangers connected with certain positions: the semi-recumbent, Sims and Trendelenburg positions, as contributing to shock.

102. Hemostasis in Intrapelvic Surgery.—Heffner's paper is a discussion of the condition and details of preventing hemorrhage in intrapelvic surgery, and not easily abstracted.

103. Exercise Treatment in Tabes.—This article gives the author's report of the results of seven months' experience

in the exercise treatment introduced by Frenkel for tabes dorsalis. He reports three cases, in all of which ataxia was pronounced and in which this symptom has been greatly relieved. His method does not require complicated apparatus as used by Frenkel, but simple appliances such as can be found in any doctor's office or constructed by the patient himself. The different movements are not enumerated here. He commences the treatment first in bed, in a recumbent position, then sitting up in a chair and, lastly, in walking and moving about, each case, however, being treated individually, according to its needs. As regards other symptoms of the disease, they are not mentioned or discussed here, ataxia alone being considered.

104. **Hydrophobia.**—Kinnear advocates the use of the "Buisson" method in the treatment of hydrophobia, claiming that this is more efficient than the Pasteur method. It consists especially in hot air and vapor baths, and he has collected a number of testimonials of its value.

107. **Serum Treatment.**—Biggs' paper is continued and will be given in abstract form completed.

108. **Light and Air in Phthisis.**—Gardiner calls attention to the climate of Colorado as affording the conditions of light and air, altitude and dryness that best suit the outdoor treatment of phthisis, and tent life, he thinks, comes nearest to the ideal condition for a certain number of patients. The tents he would use, however, differ from the ordinary ones and are described in detail, all conditions for ventilation, cleanliness, heating, etc., being met. Such a tent can be occupied in Colorado at 6000 feet altitude for at least eight months of the year, and could be transported to a milder climate farther south for the remainder.

110. **A Study of Delirium.**—Noticing first the lack of agreement among medical writers as to the conception of delirium, Hirsch thus formulates his own definition: "Delirium is a physical state characterized by an abolition of self-consciousness, by an incoherence in the chain of conceptions, and by the appearance of symptoms of sensory and motor irritation." Dreaming is its physiologic analogue. He then points out the differential diagnosis between this and similar condition: mania, melancholia, hallucinatory confusion, etc. In mania there is rapidity of the formation of ideas and paralysis of the higher psychic inhibitory apparatus. The manic is compared to a man observing the landscape from a rapidly moving train, where scenes pass too rapidly before him to give him any ordinary impression of their nature. The delirious patient, on the other hand, receives no ordinary impression, because he is in mental darkness. The mania may remember his actions; there is no absolute loss of consciousness. Melancholic frenzy is distinguishable by the unmistakable, dominating presence of fear, hallucinatory confusion by the presence of hallucinations. The clinical picture in all these forms will serve to distinguish the condition. Delirium may ordinarily occur under various conditions. It means a state of inanition and demands stimulation. The writer goes over the various conditions in which it may occur and calls attention especially to the importance of its recognition and early treatment. In general the therapeutic treatment is indicated by the underlying disease when that is recognized. The fact, however, of exhaustion, must be kept in mind and treatment be instituted accordingly.

111. **Early Diagnosis of Tabes.**—After some remarks on the newer pathology of locomotor ataxia, Pritchard states his conviction that if recognized with sufficient promptness, before secondary sclerosis has appeared, it may become practically a curable disease. He calls attention, therefore, to certain points, the early recognition of which he thinks would be of the greatest practical importance. Bearing in mind the usual etiologic features and the legitimate deductions from the new facts and theories in regard to this disorder, he thinks any nervous disorder, especially if sensory, occurring in a man between 30 and 45, who admits or exhibits evidence of previous syphilis, and whose occupation involves exposure or overexertion, should excite suspicion sufficient to at least demand an investigation of the knee-jerk, the pupil and the functions of the genito-urinary apparatus. If in such there appear evening headaches with insomnia for the early part

of the night and usually an excessive fatigue out of proportion with previous powers of endurance, the condition should be looked after. He then goes over the symptoms: those of common sensation; disorders of the sensibility; pain anesthesia; and ocular symptoms such as strabismus and ptosis without pain, described by Moebius as characteristic; Argyll-Robertson pupil; optic atrophy; genito-urinary symptoms; the reflexes; trophic symptoms, and visceral crises are noted in detail, thus covering the larger portion of all the symptoms of the disease.

113. **Calomel in Diphtheria.**—Judd first refers to a paper read two years ago, at the session of the American Climatological Association, in which he recommended the heroic use of calomel in diphtheria. The present article continues the same recommendations. Calomel has been his main stay in the treatment of pronounced cases of the disease. Its use does not do away with the necessity of faithful and intelligent nursing. As regards antitoxin, he admits the usefulness in the doubtful, mild and early stages of the disease, but does not feel so sure of it in the advanced condition.

114. **Atropin in Epilepsy.**—Wachenheim reports a case of the treatment of epilepsy with combined usage of atropin and potassium bromid. He considers epilepsy in idiopathic cases, such as the one he describes, as due to an auto-intoxication, producing an abnormal irritation on the part of the cortical cells. According to his theory the mechanism of the treatment is as follows: The bromids diminish the sensibility of the cortical cells, which have become hyperesthetic to variations in the blood-supply; atropin stimulates the vasomotor centers, thereby making the blood-supply more uniform. In the early stages of treatment bromids are useful to dull the irritability of the cortex until the proper vascular tonus is established. When that point has been reached, they are of less importance and may be reduced or withdrawn. Neither the bromids nor atropin can in any way meet the casual indication. If the disease depends on a passing intoxication, these drugs will suspend the destructive action of the epileptic seizures until the *materia peccans* has ceased to act; if there is a permanent cause, as seems to exist in the majority of cases, such treatment will naturally be at best only a palliative.

116.—See abstract in JOURNAL, May 6, p. 1000.

118. **Right-Angle Continuous Intestinal Suture.**—The right-angle continuous suture here described is a modification of the Kirschner or the continuous Lembert. Its advantages are that it can be applied more rapidly than any other suture, with scarcely an exception. It can be interrupted at any point if desired, and then reinforced by another superimposed if thought necessary. If the suturing is properly done, no reinforcing is necessary. He describes the technic in detail, with illustrations, and sums up its advantages as follows: 1. The suture does not involve the mucous membrane. 2. The intestine is closed by a suture which acts so that the greater the tension to which it is subjected the closer is it drawn. 3. It can be inserted very rapidly and easily. 4. The closure of the intestine is impervious and efficient. 5. Its technic is simple. He reports briefly some results of its use in the hands of other surgeons.

119. **Blood Examinations.**—In the conclusion of Hewes' paper, he points out the general lines of usefulness of blood examination in clinical work. In the first place we are thus able to diagnose the existence of anemia, to estimate its severity and determine its type. The appearance of degenerative changes in the red corpuscles proves the anemia. The extent of these changes, the appearance or non-appearance of 'blasts' aid us in determining its severity. The characteristics of the blood in pernicious anemia are: 1, marked poikilocytosis, with tendency to increase the size of red corpuscles, and, 2, the presence of "blasts," more particularly megaloblasts. If we do not find a megaloblast, we have a secondary anemia. The evidence of anemia found in many cases consists in the presence of achromia with some distortion, with the number of corpuscles normal. As a rule there is a reduction of hemoglobin; a very mild anemia may sometimes be discovered by this hemoglobin estimation when it is not apparent from the stained specimen. Anemia is not therefore to be ruled out except by

the hemoglobin estimation—specific gravity. In the second place, this blood-staining method may reveal the existence of a leucocytosis and determine its type. "Thus by finding a neutrophilic leucocytosis with a considerable proportion of myelocytes we may diagnose myelogenous leukemia, a marked basophilic leucocytosis, lymphatic leukemia.

"If we find an unmixt neutrophilic leucocytosis we know that we have present one of the conditions with which this leucocytosis is associated and we can rule out all conditions which do not have a leucocytosis. Such finding may help us in a given case to differentiate pneumonia from phthisis, suppuration or pyemia from malaria, appendicitis from typhoid, scarlet fever from measles, to diagnose the existence of suppuration, hemorrhage or certain acute infectious diseases, to rule out typhoid or malaria.

"If we find an oxyphilic leucocytosis we are led to consider some condition thus accompanied, as trichinosis, leukemia.

"If our blood-slide leads us to suspect an increase in the number of leucocytes, and we wish to estimate the exact number, we can make a white count. Where the number appears normal we gain our knowledge without this trouble.

"In the third place, we may discover by this method the presence of blood parasites, the plasmodium malarie, the filaria sanguinis hominis, the spirillum of relapsing fever. It is customary to look for these parasites in the fresh specimen, where they are seen alive. But it is perfectly possible to discover them in stained specimen."

British Medical Journal, July 8.

Description of New Pathogenic Microbe of Sewage; Bacillus Pyogenes Cloacinus. E. KLEIN.—The author describes a new bacillus obtained from sewage matter, with strong pathogenic action, which he has called bacillus pyogenes cloacinus. It is a minute non-motile bacillus, staining slightly in Gram's solution. Minute doses injected into guinea-pigs lead to fatal results in from twenty to twenty-four hours. Culturally, it resembles Loeffler's bacillus suiscepiscus to a certain extent, but the action of the latter on rodents is quite different.

Plastic or Croupous Bronchitis. THOMAS OLIVER.—Noticing the rarity of these cases, Oliver reports two in detail, giving illustrations of the molds of the bronchial tubes thrown off. Discussing the disorder, he does not think it specially related to tubercular disease. Its pathology is obscure and its treatment is divided into: 1, the methods used to loosen and dislodge the membrane, and 2, to prevent their recurrence. In his cases inhalation and sprays were generally unsatisfactory, and he does not speak with special favor of the use of emetics. The internal use of iodid of potash with or without expectorants gives as good results as anything. Ewart recommends the intratracheal injection of oil or a mild solvent such as lime water or trypsin. To prevent recurrence the writer knows of nothing better than attention to general health; healthy, bracing atmosphere, good food and tonic medication.

Some Points Connected With Sleep, Sleeplessness and Hypnotics. JOHN BUCKLEY BRADBURY.—This lecture treats of the physiologic and therapeutic action of chloralose, urethanes, sulphones and vegetable hypnotics of which only opium and its alkaloids are taken up.

Cases of Septicemic Infection Treated With Antistreptococcus Serum: Rapid Recovery. J. MITCHELL BRUCE.—This paper reports two cases of septicemic infection treated with antistreptococcus serum. From the first of these the author deduces that serum may succeed in septicemia after all ordinary methods fail, and that its action may be extremely rapid. From the second, which was of the cerebrospinal type, the conclusion was the same, but he also found that when one serum had failed another might succeed. The practical lesson is not to be content with the trial of a single serum, if it fail.

Lancet, July 8.

Tracheotomy in Diphtheria. GEORGE THORNTON.—This is an analysis of 151 cases of diphtheria, of which 49 died. It covers the period since the introduction of the serum treatment in the Fountain Fever Hospital, Tooting. The causes of death in the 49 cases were: toxemia in 8 cases; in 16 asphyxia from extension of the membrane; 5 from hemorrhagic diphtheria, always a fatal form of the disease; 9 deaths resulted from the occurrence of broncho-pneumonia; 2 from late respiratory

paralysis and the accumulation of mucus in the bronchial tubes; 3 deaths were due to acute tracheitis and bronchitis, no other cause being found; 1 patient, a baby, died from the late development of marantic thrombosis of the longitudinal sinus; 5 were due to a combination of cardiac and gastric symptoms, put down as gastric crisis. The use of serum in staying the disease and modifying the mortality was very striking. In not a single case was the trachea or bronchus affected after the operation and the mortality was very striking. In not a single case was the trachea or bronchus affected after the operation, when the serum had been used. Injection on the second day of the disease gave 21 cases with 2 deaths; on the third day, 47 with 16 deaths; on the fourth and subsequent days, 83 cases with 31 deaths. He believes in giving the serum freely in fairly large doses.

After-History of Excision of Entire Breast. J. E. SIMPSON.—In this study of the report of 90 cases operated on for malignant disease of the breast it appears that 70 were alive one year after operation; 47 two years; 33 three years; 19 four years; 14 five years; 8 six years; 4 seven years; 3 eight years; 3 nine years; 3 ten years, and 1 survived eleven years after operation. These figures would seem to disprove the claim that any case which remains free from recurrence for three years may be considered cured.

Chinosol in Phthisis. ALEXANDER MACGREGOR.—The author reports six cases treated with chinosol—oxyquinolin sulphate of potash—given in doses from 3 to 5 grains three times a day, all with decided improvement. In the out-patient treatment by the author, some patients seemed to derive no benefit, but the difficulty of observation was greater. He thinks that it is a valuable drug in the treatment of phthisis.

Glasgow Medical Journal, July.

Position of Gravid Uterus at Onset of Labor With Rigid Latero-Flexion and Rotation. ALEX. MACLENNAN.—The author has investigated the position of the gravid uterus in patients presenting themselves at the Glasgow Maternity Hospital during his term of residence as in-door house surgeon, and gives here the results, which are summed up in the following conclusions: Right flexion with right rotation is by far the commonest deviation. No case of the converse was met with. Flexion is caused by purely mechanical conditions, and it will tend to produce rotation to the same side. Flexion has no relationship with presentation or position of the fetus. Rotation is due to laxness of the uterine ligaments, and possibly to irregular contraction, but not to an irregular arrangement of the muscular fibers. It may replace latero-flexion as an attempt at accommodation. One case, No. 7, showed in the first three days, first symmetry, then rotation to the right, and finally rotation to the left. Only two cases of flexion without rotation occurred and they were complicated by contracted pelvis. An absolutely symmetrically-placed uterus is more common in primiparæ, but one medianly placed, if accompanied by rotation, is more common in multiparæ.

Annales de Dermatologie (Paris), June.

Lesions and Nature of Indurated Erythema. G. THIERMIEGE.—The conclusions of this article can be summarized in the statement that indurated erythema, the ulcerous variety studied by Hutchinson as well as the non-ulcerative described by Bazin, should be classed with cutaneous tuberculosis, or, to be more exact, should be included among the cutaneous manifestations of tuberculous infection caused by the Koch bacillus. It thus takes its place beside tuberculous gummata, with which it presents the greatest clinical affinity.

What Are the Limits of Syphilitic Infection?—DE BEURMAN AND DELHEM.—The absence of syphilitic antecedents in so many cases of tabes is explained by these writers as due to the frequency of syphilis occurring unrecognized or ignored. If the truth were known, they state, the subjects hitherto considered refractory to syphilitic infection would be recognized as being already syphilitized. They demonstrate that it is impossible to fix a moment when the subject escapes from the syphilis of his progenitors; also that in spite of the clinical truth of the classic doctrine of non-infection a large number of syphilitics may be and are infected while they still bear the imprint of an anterior or ancestral syphilization. It would be very important, if we could determine at what moment and under what conditions a syphilitic, a heredosyphilitic or a dystropho-syphilitic could be inoculated with a new syphilis, but this seems to be impossible at present. The large number of cases

of ignored, misunderstood or latent syphilis largely compensates the insufficiency of statistics in respect to the specific origin of tabs, general paralysis and aneurysms. It would be interesting, they add, to learn whether this class of syphilitics is infected lightly by the second infection when they contract syphilis, or whether it may not be this class that, on the contrary, is most predisposed to the severest affections of the nervous system, such as tabs and general paralysis.

Bulletin Medical (Paris), June 24.

Perforation and Abscess From Ascarides PAUCHET.—A slow and insidious abscess with perforation of the intestines was operated on in a man of 61, but a fistula persisted for six months, with pus occasionally exuding, until a lumbricus was observed in it and extracted with two others, about 15 cm. long, when the fistula healed at once without further trouble.

Presse Medicale (Paris), July 1.

Masculine Osteomalacia. P. BERGER.—Radiographs of the case reported show that almost the entire skeleton was affected, but especially the extremities, which had grown very much shorter, with an almost incredible twisting and contortion of the bones, too soft to spontaneously fracture. The patient, a young man of good circumstances and habits, of a healthy family, appeared first for treatment of a double green valgum. One limb was operated on as usual, but the trouble persisted and the general affection developed, which leads Berger to warn against green valgum developing suddenly with pain and difficulty in walking out of proportion to the extent of the deformity, especially if there is lateral mobility of the knee on either side. The painful cramps, contractions and trembling which accompany the earlier stages of osteomalacia pass away later and are relieved by immobilization in a Bonnet splint. The conclusions of a careful study of the chemistry of the case are easier to state than to carry out in practice; namely, that therapeutic treatment must aim to improve the evolution of the insufficient ternary substances, increase the oxidation of nitrogenous substances and modify the disassimilation, that is, augment the fixation of lime by the bones and promote the phosphoric interchanges. Double castration was recommended but refused by the patient. Berger considers castration no more empiric or irrational for men than for women in the treatment of osteomalacia. Why should not the removal of the testicles in man accomplish the same as the removal of the ovaries? We know that Truzzi has reported 83 per cent. cured out of 97 women with osteomalacia; Polgar 6 out of 7, and Busche 5 out of 6.

The Blood in Erysipelas. A. CHANTEMESSE AND E. REY.—The blood affords earlier and more delicate indications in erysipelas than any other clinical manifestation, and is a certain basis for the prognosis before any symptoms of recurrence appear. A number of typical curves are graphically portrayed, from which it is evident that the polynuclear leucocytes gradually decrease in number from the third day of the disease to complete recovery. The number of large mononuclear leucocytes is not materially modified, sometimes increasing at the approach of defervescence, to return soon to normal. The lymphocytes, on the other hand, rapidly increase as the fever falls and convalescence is confirmed, their accumulation the evidence of recovery. The eosinophiles, generally absent during the febrile period, also accumulate as recovery approaches. This combination forms a characteristic scheme.

Semaine Medicale (Paris), July 5.

Disturbances in Walking in Hemiplegia Studied With the Kinetograph. G. MARINESCO.—A series of fifty-two cuts shows the peculiarities of the gait in hemiplegia, and brings out certain hitherto unnoticed characteristics, among them the elevation of the pelvis and a deep fold in the skin of the lumbar region on the paralyzed side, and a deviation of the spinal column with the convexity towards the healthy side. Marinesco extols the kinetograph as a means of observing progress in cases under treatment and for teaching classes, showing with projections the abnormal characteristics of all diseases affecting the gait, gestures, etc., long after the subjects have disappeared from sight.

Archiv f. Exp. Path. u. Pharmacologie (Leipzig), xlii, 2 to 4.

Theory of Alcohol Narcosis. MEYER AND BAUM.—Dubois noticed that certain plants exuded droplets of moisture over the surface when exposed to the influence of chloroform, ether,

benzin and alcohol. He considers the process an indication that the vapors penetrated the protoplasm of the plant tissues and forced out the water, taking its place. Meyer bases a theory in regard to the effect of narcotics in man on the observation of this phenomenon, suggesting that certain substances in the protoplasm of the cell, the lecithin, etc., so important to the healthy functioning of the cell, are dissolved out of their normal proportions of solution and combination in respect to the other components of the cell, the water, salts, albumin, etc., by the tension of solubility between them and chloroform, alcohol and other narcotics, analogous to the effect of salt in the organism. If this theory is correct, then all chemical substances which dissolve fat and bodies resembling fat—lecithin, protogon, etc.—must produce a narcotizing effect on living protoplasm, and the effect would be most marked on the cells which contain the largest proportion of these substances; the nerve-cells. The effect would also depend on the mechanical affinity of the narcotics for the other constituents of the cells besides the fatty matters, especially the water, and also on its coefficient of division in a mixture of water and fatty substances. A large number of tests are reported which indicate, in fact, a narcotizing power for a number of chemically indifferent bodies of the aliphatic series, the cause of which can not be ascribed exclusively to the splitting or saponification caused by them. Baum also reports experiments which support the theory and confirm in particular that the narcotic effect is in direct proportion to the coefficients of division determined by a mixture of oil and water.

Simple and Accurate Method of Determining Amount of Mercury in Urine SCHURMACHER AND JUNG.—After destroying the organic matters with hydrochloric acid and potassium chlorate, the mercury is precipitated and then evaporated by heating in a "gold asbestos" tube. The weight of the tube before and after indicates the amount of mercury.

Oxybutyric Acid and Its Connections With Coma Diabeticum. A. MAGNUS-LEVY.—"Beta oxybutyric acid occurs in severe cases of diabetes in amounts up to 20 to 30 grams, and during coma this amount increases to 160 grams eliminated in the urine." Such an enormous amount can not all be derived from the albumin, and Levy ascribes its origin to the fats or to some synthetic process. The conception of coma as an intoxication with some acids has always been refuted by the inefficacy of alkaline therapeutics. But Levy asserts that this is due to the insufficient amounts employed. He advises daily doses of 200 grams of sodium bicarbonate, part injected into the veins in a 3 per cent. solution, the rest ingested, commencing and concluding with 60 to 100 grams a day. He succeeded in saving one very severe case by this means, but three others succumbed in spite of it.

Origin of Edema of Skin. R. MAGNUS.—Artificial hydropsia alone, Magnus states, is not sufficient to cause edema of the skin; there must also be some lesion of a vessel, such as he produced experimentally by intoxication with arsenic, chloroform, ether, chloral hydrate and phosphorus. Edema can be produced by flushing dead animals and also by removal of the kidneys or tying the ureters. In the latter cases the endothelium of the vessels is injured by the action of the urea retained in the blood.

Berliner Klinische Wochenschrift, June 26.

Tabetic Attacks Accompanied by High Fever. P. K. PEL.—Tabetic attacks with fever have never been recorded before (See JOURNAL, xxxi, p. 1161), but in this case a glass polisher, 41 years of age, with typical tabs dorsalis, has had five attacks during the last few months, in which the vasomotor and heat regulating centers were evidently irritated, followed by irritation of the inferior and then of the superior spinal roots, then of the vomiting center and finally of the trigeminal fibers. The last attack is described in detail. The temperature rose abruptly with the pains, reaching 40.2 C.; pulse 150; vomiting, profuse sweating and, invariably, herpes labialis the next day; pains in the eyes, photophobia, lachrymation and congestion in the head. There were no morbid conditions aside from the tabs to account for the fever, which fell to normal in twenty-four hours, as abruptly as it rose.

Deutsche Medicinische Wochenschrift (Berlin), July 6.

New Method of Narcosis. J. GERTNER.—This method is based on the principle of supplying a small amount of concentrated chloroform carefully measured, with the surrounding air

mixed just as it is inhaled. The gasometer is used as with the Bert-Dreser method, but without the disadvantages of the airtight mask and the necessity for the assistance of an expert to manage the gasometer. Two volumes of chloroform to one of ether are poured into a long cylinder fastened to the side of the gasometer, and are forced out into a connecting bulb as the piston within, connected with the gasometer above, sinks in the tube. The chloroform mixture in the bulb is vaporized by a gas jet below, and the fumes rise in a short tube which opens into the tube, bringing the compressed air from the gasometer. The combination of air and anesthetic flows onward in the tube with the regularity of a stream of gas, and the amount passing is accurately determined by a graduated stop-cock. The tube ends inside the usual mask, a short distance from the nose and mouth, and the surrounding air combines with it as it is inhaled. Instead of a large amount of a weak solution, Geppert uses a small amount of a strong solution, the dose precisely determined by the regulating faucet. The apparatus is illustrated in detail. Ether in this combination is not explosive and does not ignite readily.

Protracted Remittent Fever in Tertiary Syphilis. CAMO.—A case is described in which a remittent fever lasted six months and led to severe cerebral disturbances in a miller, 42 years of age, otherwise apparently normal. He was treated for tuberculosis and then for malaria, with no effect; there was nothing to suggest syphilis except a record of slight syphilis in youth, promptly cured with energetic treatment. When specific treatment was at last commenced recovery soon followed. The patient had consulted several of the most prominent German physicians, but all had erred in the diagnosis.

Automatic Lifter for Patients in Bed. MANDOWSKI.—A frame fits over the bed with a strong, soft cloth stretched over it, on which the patient lies, a hole cut out for the seat. A wide belt at each end of the frame passes over a pulley above and the frame is lifted by turning a crank without disturbing the patient. The entire contrivance costs but \$6 to \$10.

Archiv f. Gynakologie, iviii, 2.

Experimental Production of Impermeability of the Fallopian Tubes. L. FRAENKEL.—The research reported establishes that it is impossible to produce certain impermeability of the tube with either ligatures, partial resection, thermocauterizing or severing the tube. "The only reliable means to prevent conception is the complete ablation of the tube by a wedge-shaped excision out of the uterus and careful suture of the peritoneum."

Prager Medicinische Wochenschrift, 24 and 25.

Subcutaneous Injections of Brain Matter in Tetanus.—L. ŽUPNIK.—The severe epidemic of tetanus last winter in the Prague Maternity, which caused the institution to be closed, failed to show any evidence of benefit from injections of Behring's serum. A case of puerperal tetanus that occurred recently in Příbram's clinic was therefore treated with 4 grams natr. brom. and 1.5 grams chloral a day, a treatment which has a record of 53 per cent. recoveries. Besides this, 21 grams of calves' brain substance were injected subcutaneously in four days, at a concentration of 1/12 to 1/5. The tetanic symptoms were much improved, but the patient died. It was impossible to determine the cause of death as the kidneys were found the seat of serious acute and chronic lesions.

Wiener Klinische Rundschau, July 2.

Hemorrhagic Myositis. H. SCHLESINGER.—An observation reported from Albert's clinic tends to prove the existence of an abortive form of polymyositis hemorrhagica. The hemorrhagic infiltration of the muscles was limited to one leg, and in the course of a year and a half only spread to the other gastrocnemius, while typical polymyositis affects nearly all the muscles and is rapidly fatal. The anatomic and clinical manifestations were similar to those in the latter, also the severe occasional cardiac symptoms, absence of fever and of suppuration, etc.; bacteriology negative. No traumatic origin could be discovered, except slight varicose troubles.

Wiener Klinische Wochenschrift, June 29.

Deceptive Pericardial Peritoneal Friction Sounds. N. ORTNER.—In four personal cases a friction sound was noted over the heart, accompanying the contraction of the organ or the action of the diaphragm, which the autopsy disclosed was not of pericardial, but of peritoneal origin. The rhythm is the

same as a pericardial sound, either like a locomotive or systolic-diastolic or exclusively systolic. It occurs as the consequence of accumulations of fibrinous exudations or tuberculous nodules on the liver, or on a portion of the intestine in contact with the diaphragm, and the corresponding part of the latter. This pseudopericardial peritoneal sound usually occurs loudest or exclusively over or to the left of the lower portion of the sternum, while the true pericardial sound is more distinct at the base of the heart. The peritoneal origin is indicated by the coexistence of tuberculous peritonitis or subdiaphragmatic perihepatitis, which were found in the five cases in which the sound has been noted to date, while the pericardium was practically intact.

Gazzetta degli Ospedali (Milan), July 2.

Early Hereditary Syphilis of Larynx in Infants. J. ARSLAN.—The symptoms first to attract attention are the alterations in the voice, disturbances in the respiration, cough and coryza with the absence of general acute symptoms. The affection seems to be more frequent in boys and can be divided into two classes, the hyperplastic and the ulcerative. In the latter the stenosis is more apt to be intermittent.

Laughing as an Aid to Expectoration. A. AUFOLLO.—The writer states that inducing a convulsive laugh by tickling is an excellent means to promote expectoration. It is usually followed by a coughing spell which expels the secretions in the alveoli dislodged and loosened by the contortions of the tickled subject.

Bolnitschnaya Gazeta Botkina (St. Petersburg), 2 to 4.

Diazo-Reaction in Scarlet Fever and Measles. J. LOWE.—From the study of 900 examinations the writer concludes that the diazo-reaction is not pathognomonic of any affection, but merely an indication of the severity of the affection. In doubtful cases it indicates measles. The earlier the reaction appears after the eruption, the more severe the disease. The more pronounced and the more frequent it appears in scarlet fever and measles, the greater the chances of a fatal termination. Variations in the temperature and injections of serum have no effect on its appearance. The urine of convalescents and healthy persons does not produce the reaction.

Russky Archiv Path. Klin. Med. e Bacteriologii, vii, 3 and 4.

Morphologic Changes in Blood With Liver Affections.

G. VLAEV.—The writer has been studying this subject for years and announces that the nature of a liver affection and also its character can be determined by examining the blood. In the pernicious anemia of severe liver affections the reds fall below a million; nucleated reds appear and the number of whites increase to 50,000 to the c.c. The absolute number of lymphocytes or transition forms decreases, while the number of neutrophiles shows marked increase. These changes are less pronounced with cirrhosis of the liver; the whites do not rise above 20,000, the lymphocytes average 671; the transition forms, 511, while the neutrophiles increase to 11,300. No decided change occurs in the blood with catarrhal icterus or echinococcus. With pernicious anemia without any liver affection, the number of reds also diminishes and nucleated reds appear, but the whites diminish also and the above morphologic alterations do not occur. The blood also differs with the affections of the spleen. With leucemia, for instance, the number of lymphocytes is increased, and also the transition forms and the eosinophiles, but the number of neutrophiles is much diminished.

Crystal Formation in Gelatin Cultures. S. BARTOSHEVITCH.—"The crystals that form on the surface of bouillon-peptone-gelatin plate cultures as they dry vary with different bacteria and are characteristic of each species." With the anthrax bacillus the crystals are in the shape of isolated balls or flat slabs; with the staph. pyogenes albus, they form sheaves of three cornered prisms; with the bacillus subtilis, coffin-shaped crystals, etc. He considers that this fact indicates that bacteria which liquefy gelatin do not all derive the same substances from the culture-medium, and that this circumstance deserves special regard in the study of the bacterial metabolism.

Influence of Cold Baths on Number of White Corpuscles in Health and Disease. LAPINSKI AND SVENSSON.—Three-minute baths at 22.3 C. were tested in a very large number of cases of various diseases and the blood examined beforehand and at short intervals afterward. It was found that the baths

induced a transient accumulation of both reds and whites in the peripheral vessels, with consequent increase in the number of each, in the specific gravity and in the amount of hemoglobin. This condition soon subsided to normal, and the absolute leucocytosis claimed as the effect of the baths has no existence in reality.

Societies.

Chicago Neurological Society.

Regular Meeting, April 25, 1899.

DR. RICHARD DEWEY, the president, occupied the chair, and announced the subject for discussion to be

BRAIN TUMOR.

DR. HENRY M. LYMAN opened the discussion, saying: While sitting here this evening I have been thinking of various experiences and observations in the past, and I have been especially impressed with a remark that I once came across in one of Hughlings Jackson's lectures. In speaking of diseases of the brain, he said: "It is a great misfortune, but it is a fact, that the more experience a man gets in the matter of diseases of the brain, the less certain he feels in his diagnosis." The laity show a certain lack of respect for the conscientious observer who has the ability to confess his uncertainty or his actual ignorance with regard to the condition of the patient presented to him; but nevertheless such is the fact, and the more a man learns about the subject of diseases of the brain, the more uncertain he feels as to diagnosis in obscure cases. This is especially true of cerebral tumors.

The whole subject of tumors of the brain introduces us to one of the most variegated pictures of disease that it is possible to imagine, and when we consider for a moment how that may be, we realize that tumors of the brain vary in their origin, in their nature, in their seat, and give rise to various symptoms in consequence of their existence, their growth, and their encroachment upon the organs of which the brain is composed. We all admit the brain to be a vast congeries of subordinate structures, each one of which has its own definite function which is influenced by disturbances in other adjacent organs; consequently, the symptoms that result from the existence of tumors must be numerous. In many cases the existence of a brain tumor is not revealed by any sensory, motor, or focal symptoms, and it is in this subdivision of the subject that the greatest amount of obscurity probably exists. When we have a focal lesion, such as that produced by a tumor encroaching upon one of the cranial nerves, or developing, as in the case shown tonight, probably in the oculomotor nerves, or in the optic nerves, when we have definite symptoms that are easily recognizable and can be more or less accurately traced to their location, their cause and probable nature. In a case like this, it is probable that disturbance—although the history is not clear on that point—is due to the development of a tumor or tumors in the optic tracts. Sometimes it is impossible to determine where these tumors have been developed, whether in the optic commissures, in the optic tracts, in the corpora geniculata, or in the corona radiata of the brain substance itself. Even in the cortical structure we have the development of these new growths, which have a certain particular character, but are different entirely to those due to syphilis, tuberculosis, cancer, or anything of that kind developing in any portion of the optic nerve tract; yet they are likely to produce disturbance of vision, and if they develop in certain localities we have disturbance of nutrition of the optic nerve or of the retina. It is not impossible for the tumors of multiple sclerosis to develop in that portion of the brain which we call the retina; so that an example of brain tumor affords the greatest variety of locality, of effect, and of disturbance of the brain functions. But to speak of those brain tumors which exist in portions of the brain where there are no sensory or motor disturbances to be produced by their growth, they may exist for a considerable length of time, and may result fatally; yet before a post-mortem section is made there is nothing to indicate the fact of the existence of a tumor.

Dr. Bristow of London a few years ago read an interesting paper on certain cases of this kind that had come under his own observation. I believe he reported three such cases in which

the only symptoms before death were those of a hysterical character. There was no paralysis, no sensory disturbance, the only disturbance being of an emotional nature of a very obscure character; and after death it was discovered that there was cerebral tumor. I have now forgotten the exact location of these tumors, but they were in the neutral portions of the brain, where no motor or sensory disturbance was caused by their presence. I will not enlarge upon this subject, because it is familiar to you all, but will merely describe, as a sort of starter for other speakers' thoughts, a case of very great interest that came under my notice some years ago.

A man came into my office one afternoon with the story that he had been attacked during the previous night with convulsions. He was not an epileptic patient; he had never had convulsions before, but said that at one o'clock in the night his wife aroused him by shaking him, and he found her manifesting great alarm when he came to himself. He told me that he had had a fit; he had another one before morning. He had some difficulty in moving the left arm; he could walk well enough and could talk very well; his mind did not seem to be affected. He described to me his condition, as far as he was able to do so, and appeared anxious to know what was the cause of these nocturnal convulsions. He had never had an experience of that kind before. I examined him carefully and told him there was evidently some disturbance in that portion of the brain connected with his left arm. He came to see me occasionally for a number of weeks; the arm became more and more paralytic, the same condition extending gradually to the lower extremity, till at last it was difficult for him to walk about, and he ceased to come to see me for a time, so that I lost sight of him. One day I was requested to see him at his home. I did so, went to his house, and found him in bed, wasted to a skeleton. It seems that he had had a surgical operation performed, and I was told he had been under the care of an aurist; that for some reason or other he found his hearing affected, and he consulted an aurist and, so far as I could learn, from his description of his case, it was a supposed mastoid abscess upon the left side on which a surgeon had operated. It was plain enough from all the symptoms which developed, that the disease was progressing. There was headache, vertigo, vomiting, convulsions occasionally, and increasing loss of power until the whole left side was affected. He was now approaching death, and died a few days later. An autopsy was made, but I was unfortunately not notified of the fact, and did not see the specimen, but I was told by the physician who had the autopsy in charge that a large sarcoma was discovered in the right hemisphere of the brain occupying the ascending frontal and parietal convolutions. This explained all the symptoms that had developed; beginning undoubtedly in the arm center, gradually extending to the leg center, and finally by pressure and by a modification of the nutrition that comes from the development of these tumors resulting in the ordinary phenomena that are observed in classical cases of tumor of the brain.

Another case of interest that attracted my attention a few years ago was that of a boy, 5 years of age. He was brought to me from the country, and was suffering from pain in the head, with progressive loss of vision, vomiting, and unsteadiness in gait, so that he was obliged to stand and walk with the feet wide apart. It was perfectly clear that he was suffering from a tumor of the brain, and he died a few weeks after he had returned to his home. The physician was kind enough to send me the results of the post-mortem. An osteosarcoma was found springing from the base of the cranium and crowding upward until it involved the optic nerve-tracts. As nearly as I could learn from the description, which was not very exact, the tumor was a little behind the chiasm, so that it compressed the chiasm as well as the optic nerve-tracts. The diagnosis in such cases is comparatively easy, especially if the cases are under observation for some time. On the other hand, there are some cases that are exceedingly puzzling and obscure.

A few days ago a case was brought to me of this nature, a child suffering from vague and very commonplace symptoms. The only thing that seemed peculiar was that these symptoms had continued for a considerable period of time. The little patient had been taken to some of the best diagnosticians in the city, and the statement was made by the last one that there was a tumor in the posterior part of the brain. I could not discover any symptoms that would enable me to make any such

definite statement as that. If it was a tumor of the brain, it was one of those obscure growths which do not disturb sensation or motion, only declaring itself by persistence and the vaguest of cerebral symptoms.

EXHIBITION OF BRAIN TUMOR.

DR. A. F. LEMKE—This is a brain from a patient who died at the Kankakee Insane Asylum. The patient was admitted to the asylum with a diagnosis of general paralysis, this diagnosis having been made by several physicians who had sent her to the institution on account of dementia. It was my custom to examine the eyes of all new patients with the ophthalmoscope, and while going through the ward for this purpose I discovered accidentally that this woman had a double choked disc, which was very marked. I questioned her carefully and learned that the symptoms were those of brain tumor. She had had several attacks of vertigo and vomiting; and had had disturbance of vision for some time. She located her headache in the frontal region. When I first saw her at the hospital, all the reflexes were exaggerated. She had no focal symptoms; she had a very peculiar twitching of the face, which was bilateral. This occurred at intervals of a few seconds throughout the day. She finally had several convulsions, vomited a great deal, and after having been in the institution for about a year and a half she died. A post-mortem examination was made and this brain tumor removed. You can see the tumefaction of the left frontal lobe. The hemispheres were separated. On the right hemisphere in the frontal lobe you will notice an excavation made by the tumor. The tumor does not seem to have involved or infiltrated the brain structure, because we have been able to shell it out of the brain tissue without any difficulty whatever. It is about the size of a small orange, decidedly irregular and rough, made up of a good deal of connective tissue, and the microscope shows it to be a sarcoma with much fibrous tissue.

The interesting feature of the history in this case is that a tumor as large as this seems never to have created what we could consider focal symptoms, and for that reason the tumor was not located ante-mortem.

I presume it is not out of place to speak of the possibility of this tumor having been removed surgically. It shells out of the left frontal lobe so easily and readily that some surgeons have expressed an opinion to the effect that it might have been removed surgically with very excellent results. Had this been done, it would have left quite a defect in the brain, but the woman's mental condition was about as bad as it could be, and, at any rate, a surgical operation might have been attempted if the tumor could have been located.

DR. HUGH T. PATRICK—I distinctly remember examining Dr. Lemke's patient when she was practically blind. I was unable to make out any focal symptoms. She then had optic nerve atrophy following an optic neuritis. I remember, too, that she had an anxious, careful, wide-footed gait, which, although rather natural for a blind person, was also somewhat suggestive of cerebellar disease. There was some inco-ordination of gait, and, while in frontal tumors this has been attributed to polar pressure on the cerebellum, my opinion is that it is not necessarily dependent upon cerebellar pressure, but is due to general motor interference by pressure.

DR. SYDNEY KUH—What was the nature of the mental disturbance?

DR. LEMKE—Merely a dementia.

DR. KUH—Any exaltation?

DR. LEMKE—None whatever.

EXHIBITION OF SPECIMENS OF BRAIN TUMORS.

DR. HUGH T. PATRICK—I have here three specimens of tumor of the brain, each one of which seems to have a separate item of interest, and all go to show more or less the truth of Dr. Lyman's inferential statement that the typical cases of brain tumor are the atypical ones. Most of them really are atypical. I will take my cases in chronological order.

This is the brain of a girl who was 16 years of age when I first saw her, in April, 1895. In July, 1894, she had two prolonged convulsions, another one in October, and up to the time when I saw her, it was supposed to be a case of hysteria, because of the peculiar character of the fits. After these general convulsions which she had in July and October, she began to complain of pain in the right side of the head and right eye, and a little later—in December—she had a number of local fits.

She worked in a store, and every few days she would have a clonic spasm of the left arm, which, after a short time, involved the face. The arm would jerk and twitch in a peculiar way so that she would try to hold it with the other hand, and the other girls would laugh at her. When I saw her she was confined to bed with headache of the right side of the head and right eye, left hemiparesis and strabismus. There was diminution of sensation on the left side; muscular sense was much impaired and there was the inco-ordination which ordinarily accompanies this symptom. She had double optic neuritis.

On account of her age and lack of evidence of syphilis, on examination, I advised operation at once, as the girl seemed to be in a critical condition. She could walk, but clumsily, and as I had seen not long before this a case of tumor with a sudden apoplectic termination, I advised immediate operative interference, rather than to await the results of syphilitic treatment. I had a talk with Dr. Senn before the operation was done, and said that the growth would probably be a flat sarcoma which sometimes spreads out on the surface, or it would be a deep-seated, subcortical growth on account of the extent of the paralysis. It did not seem to me that a small tumor in the cortex could account for the symptoms. The patient was accordingly operated upon, a large opening being made over the arm center. Nothing was seen; although the intracranial tension was great, and the brain pulsed perfectly; by palpation through the dura nothing could be felt. Surgical considerations aside, I was in favor of making an incision into the brain, but Dr. Senn thought he would surely get an enormous cerebral hernia, and so this was not done. The operation, however, relieved the girl completely for at least three months; that is, the optic neuritis nearly disappeared, the strabismus disappeared, as did practically her hemiparesis. She regained her normal disposition, which, before operation, aside from mental hebetude, had been irritable; she became cheerful and happy and was quite herself. She had no treatment of any kind for about three months following the operation, when the headache returned and she was put upon iodids with some temporary relief. Again, her headache returned, and she did not come back to me. The next thing I heard was that Dr. Fenger was going to operate for the removal of this tumor. I went to see the operation, but it was decided to put the patient on specific treatment, namely, iodids and mercury, which relieved her for about three months. The patient then drifted from one physician to another, until one surgeon, doubting the diagnosis of brain tumor, aspirated supposedly the lateral ventricle, with instant relief. The headache disappeared, but soon returned. Aspiration was again resorted to a number of times, and this being so successful, the apparent conclusion was that aspiration with injection of iodoform emulsion would effect a cure. This was done and the patient died in a few hours.

When the brain was removed, nothing was seen on the surface, but on bisecting the right hemisphere a large, soft growth, broken down and cystic in the center, was seen. It occupied about half of the hemisphere, was subcortical, but had become so nearly cortical that in handling it before it got into my hands the very thin layer of cortex covering the tumor was broken through. The point that broke through was exactly in the arm center. The tumor is a glioma. The case illustrates how brain tumor may, for a time, simulate hysteria, how a subcortical growth may cause typical Jacksonian attacks, what an enormous neoplasm will sometimes be tolerated in the brain and what marked relief may be afforded in cases of non-specific tumor by the administration of large doses of potassium iodid.

This is a brain taken from a patient whom I saw several times, having been called in consultation with Dr. Babcock. He will remember her general medical history a good deal better than myself, as my notes have been mislaid, and I shall have to give it largely from memory. As nearly as I can remember, the first symptom of brain tumor in this case was a typical Jacksonian fit affecting the left arm. She was carrying something at the time and was about to open her door, when she had a convulsion limited to the arm. Soon after, she had another, attended with loss of consciousness. After this the fits were confusing; they were often of the general character of a petit mal, and after she was under observation for some time and we obtained a more distinct and clear history of these fits, it was found that they sometimes began

on one side, and sometimes on the other. The patient was about 40 years of age. When I first saw her I thought it was more likely a case of brain tumor than anything else, and that was about all anyone was justified in saying. There was at that time a little difference in the deep reflexes of the upper extremities. I saw her again some time later, and was reasonably sure that choked disc was developing. This woman had distinct mental symptoms; after a short time her memory became impaired; she had more or less mental hebetude; was nervous and depressed. How much the epileptoid attacks had to do with the mental deterioration I do not know. But she finally died. Dr. Haven of Lake Forest obtained a post-mortem examination, and sent the brain to me.

The tumor is a little smaller than the last joint of one's thumb, and it was a question when the brain was cut whether it was a tumor at all. It has been examined microscopically, and it is a glioma. It is subcortical, and located not in the arm center, but in that for the leg, or perhaps comes down to the junction of the leg with the arm center in front of the fissure of Rolando. I had located it behind the fissure of Rolando. It has not reached the surface. Could it have been located during life and operated upon, I believe the tumor could not have been recognized by an incision in the brain. It was with great difficulty that it was recognized post-mortem, the appearance being as much like a slight echymosis as anything else. In structure and consistency the growth was scarcely to be distinguished from normal gray matter of the cortex, and with the hemorrhage inseparable from an operation, I am convinced no difference could have been seen. From this little tumor at the vertex the patient's condition was very like that of brain syphilis; there was a sort of hebetude; she was sleepy and dull; she could be aroused and would answer rationally, or sometimes a very little at random, a condition so frequently found in syphilis of the brain. She was given large doses of iodid and mercury, to no purpose, and this may have contributed to her great prostration, but medication was withdrawn some weeks before death. It is incomprehensible how a small tumor like this could cause pronounced symptoms for a long time and finally death.

There is another interesting point connected with the case. Here is a small tumor of the convexity which has infiltrated the brain substance, and has caused no displacement, and it is not easy to see how it could cause increase of pressure, yet the patient had optic neuritis. I could compare this, for instance, with a tumor case in which I missed the diagnosis, largely on account of the absence of optic neuritis, and also because of the known fact that the man had had syphilis with unmistakable skin lesions. When, with other brain symptoms, he began to have typical Jacksonian fits, the supposition was that he had syphilitic trouble near the face center, the face and tongue being more affected, sometimes exclusively. But he was treated with heroic doses of specific remedies to no purpose. He then returned to another city, whence he came to see me and where he had been treated for epilepsy by antipyrin, with some benefit. One day he fell dead on the street, and at the post-mortem examination a tumor the size of a hen's egg was found in the face center. This man had no optic neuritis, and yet when I saw him he must have had a tumor not only four or five times as large as this one, but located much nearer the base of the brain, the optic tracts, where it would be much more apt to cause choked disc.

The present case also shows how a tumor located directly in the motor area may cause no appreciable paralysis and may give rise not only to general epileptoid attacks, but to fits being distinctly on the same side of the body.

The third brain I have to present was removed from a patient whom I saw Dec. 15, 1898. The history of the case is that of a middle-aged traveling man, who first noticed in the summer of 1898 that he was a little more nervous than he should have been, that he was a little dizzy at times, and particularly that he had trouble in making out his reports accurately. In sending in accounts and orders and in making up papers of any kind or in keeping books, he was apt to make errors. When his physician related the case to me I concluded that it was probably one of general paresis, and it comes in very nicely with Dr. Lenke's case, because there was a history of a little dizziness, some nervousness, impairment of memory, inaccuracy in

making up accounts, and finally, the patient had several fits. He had, at first, what appeared to be fainting spells, and finally general convulsions. For two or three months previous to the onset of these convulsions he had trouble in reading and writing. On examination, several interesting conditions were found; among them weakness on one side of the body, homonymous hemianopia, word-blindness, motor aphasia, and double choked disc. Vision was rather poor, which might have been ascribed to the optic neuritis, but the difficulty in reading was clearly due more to word-blindness than to failure of vision. When I saw him the motor aphasia was more pronounced than the sensory (visual) aphasia, which led me to make a mistake as to localization. I got the Wernicke sign, and from this, with the motor aphasia, I concluded that he had a tumor in the temporo-sphenoidal lobe, deep in, but near enough to the base to compress the optic tracts. This was a mistake. At the post-mortem a subcortical tumor was found in the parietal lobe, extending back as far as the parieto-occipital fissure, and forward almost as far as the operculum. If I had paid more attention to his word-blindness, and less to motor aphasia, I would have located the growth a little farther back. Dr. Herzog has made a microscopic examination and it, like the other two, is a glioma.

I have seen two cases in which a diagnosis of general paresis was made by eminent men until the ophthalmoscopic findings made it necessary to re-examine, when other symptoms of brain tumor were found. At least two cases of brain tumor have come under my observation in which there was mental exaltation, such as goes with general paresis. One was a girl with a frontal tumor—the diagnosis being made ante-mortem—on the right side. She has no delusions of grandeur, but she had the flippancy, happy, elevated, pseudo-witty manner of the general paretic. I have still under observation a man who undoubtedly had, and now has the remains of, a right frontal glioma. He was very optimistic regarding his condition, his future, and particularly regarding an invention on which he was working, or claimed to be working, and still shows somewhat this mental elevation, with a tendency to joke and laugh without sufficient cause. In frontal tumors this has been noticed by Oppenheim, Williamson, and one other author, whose name I cannot at present recall.

I saw last winter a case of brain tumor which for a time closely simulated general paresis, in a man who peddled soap to grocers. He first noticed that he could not keep track of his route. He forgot his customers; he forgot to deliver orders, and became absent-minded. The family then remarked that he would start for the stable or another part of the house and forget his object. Not long after, he was found unconscious in his wagon, having evidently had a fit. In a word, that is the history of general paresis; gradual mental failure and a fit of some kind.

I might mention another point in connection with the girl who exhibited mental exhilaration. I saw the case about two and a half years ago at the clinic of the Northwestern University Medical School. She became worse during the short time she was under observation, and began to have slight fits, which she had never had before. I told her aunt, whom she was visiting, that she might as well be sent home, as nothing more could be done for her, and that she could not live long. A couple of months ago I wrote the parents asking to know of the further course of the case, and when the girl died, and I received a letter from them saying that she was not dead; was, indeed, somewhat better, but was having severe fits.

In connection with that case, as also illustrating the occasional slow course of tumor, I will mention that of a man who first came under my observation three years ago in January. He presented himself with a history of severe headaches for the last four years. I do not know whether the headaches were caused by brain tumor or not, but they apparently were. At any rate, he gave sufficient symptoms to warrant a diagnosis of brain tumor, including intense double optic neuritis with homonymous hemianopia. Since under observation, he has presented no localizing symptoms other than hemianopia. He never has had any paralysis. The knee-jerks, although they could be obtained only with reinforcement, were always thus obtainable. His headaches, although very intense, were relieved for a considerable period by potassium iodid, notwithstanding that there was no evidence of syphilis. He passed

from observation, and I supposed he was dead until he walked into my clinic a few days ago. He is now blind, optic atrophy having succeeded the choked discs. I believe there is a tumor in the man's brain which has been latent for three years. He has had no headache during this time, but now it is beginning to return.

While I was lecturing on him at the Policlinic, I was hurriedly called to see a case that offers a striking contrast to the two just mentioned. There was a history of severe stomach trouble for a few weeks; vomiting; headache; coated tongue; high-colored, scanty and exceedingly acid urine; foul breath; no appetite, and general prostration, and as these symptoms had followed upon a period when the patient had been eating and drinking more than usual for him, it was natural to conclude that his was a gastro-intestinal trouble. The headaches required morphin on one or two occasions to relieve them. Suddenly he became comatose, and a few hours later, before bedded, double optic neuritis was discovered, and then it was learned that for several days his wife had noticed that one arm and hand were clumsy and noticeably disabled, and that in getting out of bed the leg on the same side had given way several times. The attending physician also recalled that for about a week the patient had been somewhat changed mentally, being rather in-consequent, indifferent, and unconcerned about his condition. The supposition is that this was a case of brain tumor which shows, in contrast to the other cases, how exceedingly rapid the course may be.

I spoke a moment ago of apoplectic termination in a case of brain tumor, aside from death due to sudden heart failure. About four years ago I saw such a case in a man who gave a history of slight numbness on the right side which had existed for about three months; this was followed by headache and vomiting, and then a sudden right hemiplegia, and it was when the last came on that I saw him. He then had homonymous hemianopia, undoubtedly due to extensive thrombosis. He had intense double optic neuritis. On that symptom with a history of progressive numbness on one side and headache following and some vomiting, I made a diagnosis of brain tumor. The hemiplegia, which was very pronounced and accompanied by complete aphasia, did not improve materially as long as he was under my observation, nor did it grow worse, and I believe that the thrombosis shut off the blood-supply to the tumor, and that consequently it remained latent.

A word regarding operations for the removal of brain tumor. The cases presented illustrate how futile surgery is. My personal experience is this: In over 35 cases seen in four and a half years, in which I made a diagnosis of brain tumor, I have advised operation in only two for the removal of the growth. The first was the girl whose brain I first showed this evening; the other was a case apparently very favorable for operation, and in that case operation was declined, and I now learn from Dr. Church that the patient is alive, three years afterward, so that as far as my own limited experience goes, the operative treatment of brain tumor does not hold out much hope, 1, from the fact that so few cases can be operated on; 2, the results are poor in those cases that are operated on.

DR. SYDNEY KUH—I would like to report, very briefly, a few cases which illustrate the difficulties we encounter when we attempt to make a diagnosis of brain tumor. The first patient was an old man, whom I did not see until the post-mortem was made. He was under the observation of Professor Vierordt, in the Policlinic at Heidelberg, for quite a while. A diagnosis of tumor of the liver was made, and there were absolutely no symptoms indicative of a cerebral lesion. The patient had violent pain in the region of the liver; the diagnosis was that of secondary carcinoma of the liver, the primary lesion being thought to be in the stomach. It was necessary to give hypodermics of morphia to relieve the pain. Gradually the morphin lost its effect, and one day, when an unusual dose was given, the patient became comatose, which was attributed to the injection, and within twenty-four hours he died. Post-mortem examination revealed no lesion in the stomach and a number of small tumors in the liver. Besides this, a tumor, very nearly the size of a hen's egg, was found in the cerebellum, which had destroyed all of the vermis superior of the cerebellum with the exception of a layer, which was not thicker than ordinary cardboard. Here was a case in which the very part of

the cerebellum was destroyed, the destruction of which is supposed to give rise to cerebellar symptoms. Up to twenty-four hours before the man's death there was not a single symptom of brain tumor, though the tumor must have existed for a long time.

Another interesting case I mentioned briefly at a meeting of the Chicago Medical Society a few weeks ago. It was that of a boy of 13 years, who was brought to the physician by his parents on account of short attacks of mental disturbance, which were followed by violent headaches. As far as I can remember, he had three attacks before I saw him. I had occasion to witness one of the attacks, and they were as typical as anything could be of mental epilepsy. During the attack which I saw, he had hallucinations, and the things he saw were mostly in red—a supposed characteristic of the epileptic hallucinations. A diagnosis of epilepsy was made, and some time afterward we were very much surprised to find symptoms of brain tumor, from which the boy died. It proved to be a gliosarcoma of the brain.

A third case of some little interest is one of a child, 4 years of age, who came under my observation in the late stages, and no accurate history of development of the disease could be obtained. At the time I saw the child secondary atrophy was well developed and all the other general symptoms of brain tumor. The skull, which had been of normal size, was very much larger than the normal, and one could place his fingers into the sutures, they having all opened up again. But the most striking feature about the case was Jacksonian epilepsy, which affected the right side of the body. In that case a post-mortem was made, and a large tumor was found, which had destroyed the greater portion of the right hemisphere of the brain, so that we had here Jacksonian epilepsy on the side of the tumor. The explanation for this peculiar state of affairs was probably this: that the tumor on the right side of the brain pressed upon and irritated the left hemisphere, and in that way caused Jacksonian epilepsy.

Dr. Patrick has called our attention to the fact that in one of his cases a small lesion had caused death of the patient. I recall the case of a man, about 33 years of age, who had for some time suffered from the general symptoms of brain tumor. He died within a day after I had first seen him. At the post-mortem a cyst not larger than a small cherry was found in one of the hemispheres of the cerebellum. There was absolutely no sign that it had developed recently. A pathologist examined the brain macroscopically, but I do not know whether a microscopic examination was made or not. He was of the opinion that the cyst was congenital, and the fact that so small a cyst of 33 years' existence should cause sudden death is difficult of explanation.

In speaking of the surgery of brain tumors, there is one symptom which I think is of some importance in determining whether there is any probability of giving relief by means of an operation or not, and that is the occurrence of headache. Where headache in tumors of the brain is a late symptom, it is certainly more probable that the tumor is deep in the brain. Where the headache occurs at an early stage, it is more probable that the tumor is either cortical or subcortical, the pain not being due to any change in the brain proper, but to irritation of the membranes of the brain. I know of one case in which Jacksonian epilepsy occurred and an operation was not performed because of the late occurrence of the headache, and in this case the post-mortem showed that the refusal to operate was justified, the tumor being very deep down.

In regard to the case of Dr. Lenke, Dr. Patrick mentioned the fact that he noticed something similar to cerebellar ataxia. It is about ten years since Bruns reported cases of tumor of the frontal lobe with cerebellar ataxia. Since then so-called cerebellar ataxia has become a well-recognized symptom of tumors of the frontal lobe.

Cases of brain tumor with symptoms of hysteria, such as Bristow published some years ago, are rare. I recall one case, published by Schoenthal in the *Berliner Klinische Wochenschrift*, in which a diagnosis was made of hysteria, and which seemed well established until the patient died and a tumor of the brain was found post-mortem.

(To be continued.)

Chicago Society of Internal Medicine.

Meeting held May 25, 1899.

The subject for informal discussion was

PROPHYLAXIS AND MANAGEMENT OF APOPLEXY.

DR. N. S. DAVIS, JR. opened the discussion, and said: The causes of apoplexy, almost uniformly, are thickening, and hardening, and brittle condition of the arteries. This condition is usually not confined to the cerebral arteries, but is common to many arteries in various parts of the body, although the lesion is frequently more marked in the cerebral than in other arteries. The exciting cause of rupture of an artery is change in blood pressure. It may be the result of sudden physical exertion; sometimes it is produced by intense mental strain or by overaction, usually temporary, of some of the viscera, as of the digestive organs. Occasionally a change in posture is the exciting cause of increased blood pressure. Unquestionably, in some instances, distension of the bladder has an influence, particularly in old people. A very considerable distension of the bladder increases it, and the recumbent posture heightens it still more. Frequently the occurrence of apoplectic attacks at night can be explained in this way. In very many instances patients first discover that they are paralytic when they are awakened by an inclination to make water. I speak of the milder cases which are met with every now and again. Brittleness of the arteries, or permeability, or easy rupture of them may be caused in other ways. Miliary aneurysms of the cerebral vessels are common. These are usually due to the same cause or causes as ordinarily produce thickening, hardening and brittleness of the arteries generally, and are only a part of the atheromatous state. They, however, occur also as a result of syphilitic poisoning, and less frequently from other infections. With these facts before us we can to some extent, reason as to prophylactic measures.

Prophylaxis is rarely applied to the sclerotic changes in the arteries, for these lesions are fully developed, as a rule, when a patient consults his physician. Abstemiousness—diet, in mental and physical work, will help to prevent the growth of the lesions. The iodids can be given to lessen arterial tension, and to some extent, to influence the fibrotic changes that are taking place in the arteries throughout the body, but they exert only a slight influence on the fibrous or atheromatous change; indeed, it is so slight as to be not demonstrable in many instances. The long-continued use of the iodids, which is so often recommended in such cases, is useful because of their influence on arterial pressure, more than on the fibrous or sclerotic changes in the arterioles. Although the underlying arterial changes can be influenced only slightly, blood pressure can be to a considerable extent. Unusually high arterial tension must be lowered. Patients should be cautioned against over-exertion, either physical or mental, and against overloading and overtaxing the digestive organs; they must also be cautioned to maintain regularity of bowel movements, as high arterial tension is often produced by constipation, and by overloading the gastro-intestinal tract. By dietetic restrictions, and by instructing patients with reference to the importance of emptying the bowels regularly, we can to a considerable extent prevent continued ill-effects which may be produced by the absorption of toxic materials from the intestinal tract. These toxins are believed by some to be the immediate cause of the arterial changes. It is, therefore, very important to maintain cleanliness of the gastro-intestinal tract in order to influence arterial pressure and to prevent absorption and the ill-effects of toxic agents on the arterioles generally.

Aside from these hygienic measures, we can also help to prevent the high arterial tension by the use of such drugs as the nitrates and the iodids. The nitrates usually produce a fleeting effect on arterial tension. They are to be used temporarily when the results of high arterial tension are particularly threatening—I mean when there are symptoms of pressure on the brain, or when there are symptoms connected with other organs of the body, showing that there is increased arterial tension, possibly persisting for some days. It is during this time that the nitrates can be advantageously used. The nitrates must be rather frequently administered, or else we get very temporary effects from them. The effects are so transitory that they can hardly be regarded as producing much of a prophylactic influence.

On the other hand, the iodids produce very much less influence on arterial tension, but what effect they do have is much more prolonged; they are therefore decidedly better for persistent use. In almost all cases in which it is desirable to lower arterial tension, they are the drugs to be preferred. Of the iodids, unquestionably the iodid of soda is the best for long-continued use. It is necessary in some cases to give the iodids in doses of considerable size; in others moderate doses will produce the desired effect; by moderate doses I mean from 8 to 10 or 15 grains at most.

In giving the iodids, it is generally recommended, by therapeutists, to give them for long periods of time, and for the particular purpose of reducing arterial tension they can be continuously given for weeks. An intermission of from one to two weeks should be advised, every four to six weeks, and during the intermission, if it is necessary to use anything for the control of blood pressure, use the nitrates. The iodids should not be employed so continuously that the digestive organs are deranged by them.

DR. CHARLES W. PURDY—The prophylaxis of apoplexy may be summed up in "measures to lower tension." Of those means we might take the hygienic, and under that head would come clothing. We know that the skin contains a large amount of blood ordinarily, and a sudden chilling of the skin throws quite a volume internally which goes to swell the circulation in the larger vessels, and an equable temperature of the skin is, therefore, a very important point in the hygienic treatment, as it tends to equalize the circulation. The regulation of the bowels is a very important matter, and nothing tends so quickly and so sharply to withdraw the blood from the cerebral vessels as a purge. When there is reason to believe or to fear that apoplexy is impending, the best remedy is a sharp purge. But that comes more properly, perhaps, under the head of medication. The condition of the stomach and the quality of the food are very important in their hygienic relationship. For instance, it is very important that all foods that tend to increase tension should be cut off, mostly the animal foods and nitrogenous vegetables. The amount of exercise should be regulated. A patient should not be allowed to exert his full strength at anything. Anything calling for sudden efforts he should be cautioned against. With regard to meals, it is an excellent plan to have frequent ones. Rather than large meals, there should be more frequent ones, perhaps four meals a day instead of three, and food should be strictly limited in quantity. These patients should get up from the table feeling they can eat more. Under no circumstances should they eat heavily, and, above all, they should not eat bulky foods, soups, etc.

There is one point Dr. Davis did not mention, which is an accompaniment of apoplexy, and statistics will show that it runs up in some instances to 60 or 80 per cent., and that is uniform enlargement of the left heart. We can understand why this is. With a powerful left ventricle, with atheromatous or degenerated vessels, we can readily see how blood tension must be enormously increased. Such hearts should be treated, and it is surprising how frequently and rapidly the left heart can be influenced by dietary treatment. It is not at all uncommon to find a left ventricle that measures 12 cm. from mid-sterum to the left border, taken down on a non-nitrogenous diet in from four to eight months, so that it will measure 9 or 9.5 cm. We should invariably inquire into the condition of the left ventricle, because it underlies a large number of these cases, and the diet should be arranged accordingly.

The medicinal treatment, as Dr. Davis very practically and concisely states, is limited to the vasodilators, of which the iodids in moderate doses are perhaps the best for continued use. The nitrates are evanescent in their effects, unless they are frequently repeated, and the doses frequently increased. In these conditions I give the iodids after meals, preferably the iodid of sodium; about an hour after iodids I give nitroglycerin.

It is important that we should bear in mind certain things we should not give to patients with apoplexy, and among those I would mention digitalis and that group as being exceedingly dangerous. The patient should be cautioned regarding their use. Those drugs should not be taken under any circumstances. The same may be said of opiates.

There is one more point that may be said with reference to

drugs, namely in the use of bromids. Bromids have an excellent effect on the nervous system. We know the nervous system influences tensions very much. It does more than that; I believe full doses of the bromids lessen the actual volume of blood in the head. Alcoholics should be absolutely avoided.

DR. HUGH T. PATRICK—Do not know whether I correctly apprehend the subject for discussion, but as I take it, we are talking about the clinical appearance or syndrome that is called apoplexy. The first point which I wish to make, and which I consider to be exceedingly important, is this: that in the current understanding of practitioners, which understanding I think has cropped out so far in the discussion, apoplexy is taken to be synonymous with cerebral hemorrhage. The term may be used in that sense, which is certainly a false and unjustified sense. The term apoplexy means a sudden attack involving consciousness more or less, and accompanied by more or less paralysis, generally of the hemiplegic form. If we take this general and proper acceptance of the expression, then the more frequent cause of apoplexy, taking the grave and lighter cases together, is not hemorrhage. When we speak of apoplexy as due to thrombosis, vascular occlusion or vascular rupture, a primary and fundamental distinction must be made clinically as well as pathologically, because the prophylaxis and the management of the state itself must be radically different in the two conditions. To begin at the beginning, the premonitory symptoms of apoplexy have been alluded to. There are no premonitory symptoms of cerebral hemorrhage, properly speaking. Cerebral hemorrhage is caused, in the vast majority of cases, by the rupture of a miliary aneurysm, and a miliary aneurysm causes no symptoms whatever. Therefore, the premonitory symptoms of cerebral hemorrhage, properly speaking, are *nil*. They belong to the condition of the heart and of the kidney, and not to the condition of the cerebral vessels. When there are marked premonitory symptoms, aside from those of uremia, and hypertrophy of the heart, etc., they are indicative of vascular occlusion, i. e., of thrombosis, and not of hemorrhage. That is a distinction which I think is exceedingly important clinically. On this distinction must be based the prophylaxis. The prophylaxis of cerebral hemorrhage has been exceedingly well dealt with. We cannot often predict a cerebral hemorrhage before it occurs, but we can anticipate thrombosis in many cases because the premonitory symptoms are frequent and numerous. For instance, vertigo, of which Dr. Purdy spoke, is exceedingly rare as a premonitory symptom of cerebral hemorrhage, aside from its occurrence as a symptom of chronic Bright's disease, which exists in a person who is going to have a hemorrhage. A vertigo caused by the local circulatory changes which precede cerebral thrombosis is exceedingly frequent, and in such cases we frequently get a history of repeated attacks of vertigo; perhaps an attack of aphasia, then an attack of numbness, with weakness in one extremity, perhaps more frequently an arm, possibly affecting the face and side of the tongue, which subsequently becomes more marked, and a complete hemiplegia develops. This is a case of thrombosis, not hemorrhage. Such a history is typical of thrombosis. In the prophylaxis of thrombosis two things are to be considered: 1, the weak heart, and slow circulation which generally exists; 2, diminished caliber of the cerebral vessels. Common sense will indicate what is to be done in most of such cases.

To go back to the original point, the practitioner must be clear in his mind whether he has a case of cerebral hemorrhage or of cerebral thrombosis. Of the two affections, probably thrombosis is the more frequent. Alcoholics may not only be given, but should be given. In more than one instance have I seen a patient with thrombosis, apparently very imminent, who had been dieted, taken off of meat and put on restricted diet, and his arterial tension lowered when it was already too low, improve considerably on rather liberal libations in the form of beer, and on remedies which increase arterial tension and increase the rapidity of the arterial current and strengthen the heart. Those are also the principal considerations in the management of the apoplectic state itself. The great majority of cases I see are in consultation with other physicians, and I was almost tempted to say that I have yet to see the first case in which a diagnosis of thrombosis had been made: that would not be true, but it would be nearly true, because in almost

every case of apoplexy which I see with other physicians, a diagnosis of hemorrhage has been made, simply because it has been a more or less pronounced attack of apoplexy. I believe the majority of cases are not due to cerebral hemorrhage, but to thrombosis, with an occasional embolism, which is rare. Here, again, the treatment, based on a faulty diagnosis, has been faulty. The head has been raised; cold has been at once applied, sinapisms, and active purges, etc., to lower arterial tension, especially in the brain. In other words, every possible means has been employed to favor the formation and continuance of the clot which has already formed in the vessels. I am convinced that many a mild case of apoplexy, due to thrombosis, has been aggravated by treatment directed to the misunderstood symptomatology, and that many a patient with impending thrombosis has had the process hastened and brought about by remedies directed to the prevention of cerebral hemorrhage. This is not the time to make up the diagnosis either before or after the fact, but in my opinion it is exceedingly important to make a trenchant distinction, because such cases of thrombosis, as well as cases of cerebral hemorrhage, are, and ought to be classed as apoplexy.

DR. M. L. GOODKIND—I agree fully with the remarks made by Dr. Patrick. In those cases in which arterial tension is very high and hypertrophy of the left heart is marked, I have found aconite a very useful agent. Where nitroglycerin has been given in a similar manner, and in solution, where the amyl nitrite or iodid of potash has been used and failed, patients have frequently responded to aconite.

DR. JOHN H. HOLLISTER—I desire to endorse the view expressed by Dr. Patrick, that it is entirely essential for us to determine the nature of a condition before formulating treatment. The condition in which we have incipient vertigo, gradual increasing arterial pressure and increased action of the heart, incompressible pulse and lividity of countenance is essentially different from that in which almost the opposite condition prevails, and in which we have evidence of a sudden, perhaps slowly progressive, paralysis, resulting from embolism. I recall a case of very pronounced hemiplegia which recently came under my care, and from which the patient is now slowly recovering. It was the result of embolism. The patient had previously suffered severely from inflammatory rheumatism; there were vegetations on the valves, and, as near as I could diagnose the case, there was not only retarded circulation, but there was a slight cerebral hemorrhage resulting from it.

With reference to cases in which immediate, and, what we may call heroic, treatment is demanded, particularly in those of severe blood determination to the head and great pressure, I recall the time when the ruling instruction was venesection. I have on several occasions, in emergencies, when my lance was not at hand, placed the patient as soon as possible under the influence of tartrate of antimony. Its sedative influence on the vagus is pronounced, and it answers the purpose admirably if not carried to the point of emesis, and one can guard against it if accustomed to the use of antimony, by holding it there for a period of from twenty to twenty-four hours. I recall three or four cases in which blood pressure was lessened by the administration of tartrate of antimony, and the patients were brought to the point of nausea, kept in that condition, and the pulse being reduced to 45 and 50 per minute. I consider tartrate of antimony preferable to either of the articles that I have heard mentioned to-night in cases of emergency.

In regard to the other cases in which we have miliary hemorrhage, they need sustaining treatment, lessening the volume of circulation by catharsis and by a general course of treatment. As has been stated, there are many cases in which we need to sustain the patient rather than produce a depressing influence on the nerve-centers.

With reference to persons of sedentary habits and those who are constipated, men who are actively using their minds day after day in intellectual work are making a fearful mistake in this country. I think we are witnessing direful results very frequently by the rapidity with which that class of men are taken off. We had an instance of this in one of our noted politicians not long since, a great statesman, who, after having made a speech, went to the Palmer House, and died that evening of cerebral hemorrhage, as was verified by autopsy. This

class of men and those who are following them should change their course of life in some respects. While intellectual labor is essential, there must be more periods of rest; and not only that, we are making a great mistake when we do not require of our active business men more manual exercise. There should be a systematic training of the muscular system so as to equalize the circulation throughout the different organs of the body. Our intellectual men should adopt a systematic form of manual exercise so as to avoid collapse at the age of 60 or 70, diverting the blood from the nerve centers and notably of the brain. If the circulation was improved by massage of the viscera, by a series of exercises well directed to the activities of the body, we would in another generation change the mode of living, which is certainly becoming a marked feature of the conditions of our intellectual men. I have had this impressed on me within the last ten years as to the many eminent men who have been taken off within from five minutes to five hours, due largely, I think, to the fact that their methods of living have been erroneous in this respect.

DR. HAROLD N. MOYER—I would like to emphasize a few points made by Dr. Patrick. There is no question but what apoplexy includes a number of conditions. It is very essential to a correct diagnosis, that we differentiate between them. From the remarks of Dr. Patrick, one is perhaps led to the inference that the diagnosis is easy.

DR. PATRICK—Oh, no! I did not mean that.

DR. MOYER—The diagnosis of thrombosis and embolism is one of great difficulty, and, as Dr. Patrick points out, the treatment of those two conditions is diametrically opposite. What is suitable for one is generally unsuitable and improper for the other. Take, for example, hemorrhage. If it is present, we should elevate the patient's head in a semi-upright position. On the other hand, if he has thrombosis he should lie in the prone position, so that in cases of doubt regarding the diagnosis between the two conditions, I should feel inclined to split the difference and put them half way up, so that it comes near fitting both conditions. There are forms of cerebral hemorrhage that are strikingly like thrombosis, and I would not agree with him that a case of cerebral hemorrhage is wholly devoid of premonitory symptoms. I now speak of those symptoms which belong to the progressive apoplexies in which there is a slow effusion of blood, and in which the diagnosis between the two conditions is practically impossible.

The point raised by Dr. Hollister, regarding intellectual labor in its relation to brain troubles, is one of interest, and yet statistics, so far as they can be applied to such a subject, rather show that intellectual activity and intellectual occupation protect one from disease of the brain. The gross forms of brain disease as well as degenerations are exceedingly common among the agricultural people, who largely use the muscles and to a great extent neglect the use of the brain. The circulation of any organ and its nutrition are improved by proper use, so that great mental activity is consistent with long life and good health, provided that the cells of the part and the small blood-vessels are not poisoned. The value of exercising muscles comes not so much from the fact that the blood is diverted from the brain, but is rather due to more perfect oxidation; we have a more perfect metabolism by which certain poisonous products are eliminated from the system, or are not formed. In this way we prevent auto-intoxication, which is the chief cause underlying cerebral hemorrhage, and to a large extent cerebral thrombosis. They are generally due to auto-intoxication.

DR. N. S. DAVIS, JR.—I should like to add a word or two to my previous remarks. Unquestionably the word apoplexy is commonly applied to cover both cerebral hemorrhage and thrombosis and embolism. It is unfortunate that it is so, but not strange, because of the difficulty of making a diagnosis between the hemorrhage and thrombosis or embolism. A diagnosis can often be made, and when it is possible a clear distinction should be made between the two affections. As to the applicability of the word apoplexy to both of these conditions, I doubt it, for pathologists teach us that the word apoplexy, implies a hemorrhage. We know of cerebral apoplexy, pulmonary apoplexy, and renal apoplexy. It means a hemorrhage only.

DR. HAROLD N. MOYER—I do not think Dr. Davis has correctly stated the genesis of the word apoplexy. It was used by Hippocrates, and its correct etymology signifies, literally, I strike down, or to strike down, and in that sense it was applied to a sudden fall and loss of consciousness from whatever cause. When anatomic studies in the early part of the last century were begun, it was found that many of those persons who had a stroke had an effusion of blood into the brain. The result was that the word, although etymologically incorrect, was associated with cerebral hemorrhage by expansion. The same term was used to designate hemorrhage into the liver, kidneys, or other internal organs. That, I think, is the true genesis of the word apoplexy. The earlier writers were perhaps more correct in the use of the term; certainly, they were etymologically.

I would call attention to the point made by Dr. Patrick in regard to alcoholics. He distinctly mentioned beer. Dr. Davis has in mind some of the stronger alcoholic preparations. The effect of beer and of the more concentrated alcoholics is very different. Beer contains a large proportion of vegetable nutrient, besides alcohol, and its effect on the pulse and circulation is different from the more concentrated alcoholics.

DR. S. A. MATTHEWS—In administering alcohol in concentrated form, the first effect is to cause a rise of blood pressure. This I have repeatedly demonstrated on animals, by taking kymographic tracings. But following this rise, the blood pressure begins to go down so the main effect of alcohol is to lower blood pressure. With regard to giving these patients beer, a patient taking a glass will get a certain percentage of alcohol, probably a dram, which will have a characteristic action. The large amount of water that is imbibed by the tissues after drinking beer causes a rise in blood pressure, and on that account it would be of benefit in thrombosis or in conditions where we want a rise in blood pressure. It is absolutely incorrect to say that there is no increased arterial tension from the administration of alcohol. There is; I have taken hundreds of kymographic tracings in cases where alcohol was given, and the initial dose always caused a rise in blood pressure, the after-effect being a lowering of blood pressure.

DR. EDWARD F. WELLS—I am a little surprised at the statements made by our neurologic friends, to-wit, that the vast majority of cases of apoplexy are of thrombotic, rather than of hemorrhagic origin; in other words, that such cases are very much more frequent than hemorrhagic apoplexies. Personally, I have seen comparatively few cases in which I have felt competent to make a diagnosis of apoplexy due to thrombosis. Occasionally I see a case in which it is difficult to differentiate cerebral hemorrhage from embolism, although, as a rule, I do not consider such diagnosis very difficult. Almost always, in embolic cases, we have evidences of mitral narrowing with roughness of the mitral valve. Under these circumstances we may reasonably infer that the symptoms of apoplexy are due to embolism. It may be granted that, in apoplexy, thrombosis is often the lesion, especially in those cases in young or middle-aged persons in which recovery ensues in a very large proportion of cases, unless death is sudden. But I believe that physicians engaged in general practice see a much larger number of cases of apoplexy, evidently due to rupture of blood-vessels within the brain; this not only from a clinical standpoint, but from a post-mortem point of view as well. I have had opportunities of seeing a larger number of post-mortem examinations in cases of death from apoplexy, and the lesion in such cases has been, almost always, a hemorrhage, and, as Dr. Patrick pointed out, there is not only a hemorrhage, but evidences of miliary aneurysms in the brain as well.

As to the treatment of apoplexy due to hemorrhage, it is certainly reasonable to consider the prophylaxis, and this should begin a great many years before hemorrhages occur. I have been impressed with the theory that lithemia is responsible for many of the vascular changes which lead, ultimately, to arteriosclerosis, enlarged left ventricle, increased arterial tension, interstitial nephritis, miliary aneurysms and cerebral hemorrhage. The means of prophylaxis, as is well known, are to be found in the diet and regimen of early middle life, as pointed out by Dr. Davis and Dr. Purdy.

I would like to ask Dr. Patrick, what measures, if any, can be taken to prevent the formation of a thrombus.

DR. HUGH T. PATRICK—I seem to have been misunderstood by the vast majority of the speakers. In the first place, I did not say that the vast majority of cases of apoplexy were due to thrombosis. The great discrepancy is not in the proportion of cases, but in the proportion of diagnoses. My observation is that a diagnosis of hemorrhage is made practically always, whereas, taking all cases together, the grave with the slight, and with-out premonitory symptoms, thrombosis is the more frequent. The preponderance is not great. Taking the fatal cases alone, cerebral hemorrhage preponderates; there is no doubt about that. The majority of cases of a single sudden stroke, with death occurring within a few hours or days, are due to hemorrhage, while taking the slight with the grave cases, the majority are due to thrombosis. I have especially considered embolism because it stands by itself. A sudden hemiplegic attack with heart disease is considered to be the result of embolism; that is really about as nearly as we come in making a diagnosis of embolism. Dr. Purdy, I think, misunderstood my statement, when he says that there are premonitory signs of hemorrhage. There are premonitory signs, but they are such as are connected with the circulatory system, as determined by sphygmographic tracings and the condition of the heart. Those are hardly to be considered premonitory symptoms of hemorrhage itself. They are not referable to the cerebrum; they do not belong to the same class of symptoms; there is no premonitory slight weakness, dizziness, etc.

Dr. Moyer is right about the term apoplexy. The word, as originally used, meant a stroke. Then Galen amplified it and it was applied to those cases in which there was complete loss of consciousness and complete loss of power, except that respiration remained intact. Later the exception was made to include the circulation; there was a complete inhibition of faculties except the respiration and circulation. In the neighborhood of a hundred years ago it was discovered—I think by Rochoux—that nearly all of the fatal cases of apoplexy were due to cerebral hemorrhage, and although some time following this there were half a dozen men—especially Requin, and Rostan in his work on cerebral softening, 1819—who showed that this condition was due to other causes, still that discovery has remained to bias the medical mind to this day. I am glad Dr. Wells announced the subject as he did, because in my opinion a correct apprehension of the subject is very important, and the fact that the expression "apoplexy" has led to misapprehension and confusion in this Society, the highest medical court in this city, shows that it ought to be cleared up in some way. In the minds of practitioners at large, a sudden stroke means a cerebral hemorrhage. If the members will simply consult authorities, the men who have investigated this subject and are supposed to know what they are writing about, they will find my statement substantiated, possibly sometimes qualified. Gowers, I think, says, taking all cases together, there are probably more of thrombosis than of cerebral hemorrhage. If we take the slight with the severe cases, then thrombosis predominates. Thrombosis rarely kills the first time; but hemorrhage frequently does. The idea that a man must have two or three hemorrhages is a great delusion.

With reference to treatment, I wish to say a word about tetrinitrate of erythrol, which apparently has a future in the treatment of these troubles, but its price at present is such as to almost prohibit its use. I have obtained excellent results with it, and have given it as long as the patients could afford to pay for it, but in some instances I have stopped giving it because they objected to the price. It is an extremely useful agent, because its action is so much slower and so much more prolonged than that of nitroglycerin.

Colorado State Medical Society.

Twenty-Ninth Annual Meeting Held in Denver, June 20-22, 1899.

(Continued from Page 227.)

THE RATIONAL TREATMENT OF GLEET.

DR. J. M. BLAINE advocated the use of tonics and electricity. He uses a weak galvanic current, 1 to 1.5 milliamperes. The application should be repeated once a week. In strictures of moderate age and medium size he uses galvanism from the start. He finds that where galvanism is used it leaves the

surface smooth and destroys all granular tissues, which are sure to be found back of the stricture.

TETANUS TREATED WITH ANTITETANUS SERUM.

DR. T. G. TAYLOR reported the following case: Mrs. J., mother of two children, gave a history of a long series of miscarriages, and stated that for several days she had been flowing excessively, and something had passed, but was destroyed without examination. She strenuously denied having in any way induced an abortion. The vagina was tamponed with an antiseptic solution, and next morning she complained of stiffness of the neck and jaws, not being able to separate her jaw muscles more than a half inch. She complained of soreness in the thoracic muscles; temperature, 99.5; pulse, 95.

The uterus was curetted and irrigated with a solution of bichlorid, 1-4000, and 4 c.c. of P. D. & Co's. antitetanus serum injected under the skin of the abdomen. On the following day the stiffness of the neck and jaws was found nearly gone, but she was given an additional injection of 6 c.c. of the serum. The patient made an uninterrupted recovery.

OBSTETRIC LACERATION OF UTERUS, VAGINA AND PERINEUM—SIGNS, SYMPTOMS AND SEQUELS.

DR. JESSE HASTES, considering the gynecologic and obstetric aspect of the subject embraced in the above title, referred to the psychologic correlation existing between the sexual organs and conjugal love. The condition of the sex organs, he said, markedly modify the sexual instinct, and through the sexual instinct and appetite modify conjugal affections. Healthy normal sexual organs under the influence of a chaste normal mind are a portion of the human organism designed to express the manifestations of love. He would urge on physicians to recognize this relationship.

THE USE OF SALICIN IN ACUTE RHEUMATISM.

DR. J. W. CLINE gives large doses of salicin, with invariably good effects. He gives 30 grains every hour, till pain lessens, and then every two hours until all pain, fever and most of the swelling has disappeared, which occurs as a rule in from twenty-four to forty-eight hours.

PROBLEMS IN RURAL SANITATION.

DR. J. TRACY MELVIN has adopted the following contrivance whereby ashes can be used for the purpose of disinfecting and deodorizing the contents of the outhouses in rural districts: An ordinary-sized brick vault is built and cemented on the inside. The total depth should not be over four feet, half above ground and half below. A frame with drop door about sixteen inches by three feet is built into one side of the vault above the ground, to enable its contents to be removed. Upon this vault the ordinary outhouse structure is built. Attached to the rear, on a platform placed at the height of the top of the vault, is built a brick ash-chamber, four feet square, with a cover. An opening four inches by four feet is then made between the ash-chamber and the outhouse, opening about six inches below the seat-board. A board of the same size as the seat-board, with openings corresponding to those of the seat-board, these being closed on the under side by trap-doors fastened with strong spring hinges, is fitted into the space beneath the seat-board on a level with the floor. This brings it two inches below the opening from the ash-chamber. Ashes now poured into the ash-chamber can only pass down to this false bottom, and when this is covered two inches deep, or to the level of the opening, ashes will cease to flow, even if the ash-chamber is filled to the top. Any deposit now falls into this bed of ashes immediately over the trap. A sash cord fastened to the free edge of this trap, and passing backward over a pulley and up to a handle above the seat-board, enables one to quickly drop the ashes and deposit to the bottom of the vault, the spring hinges close the trap, ashes will automatically flow in, up to the former level, and all is ready for a repeated use. This false bottom should be covered with zinc and an ordinary fire-hook should be kept to assist in spreading the ashes, should they for any reason become clogged.

PREVENTION OF CERTAIN COMMUNICABLE DISEASES IN COLORADO.

DR. G. E. TYLER, secretary of the State Board of Health, gave the following reasons for the existence and spread of smallpox throughout the state during the last fourteen months: 1. The cases as a rule have been imported, principally from

New Mexico. It is also known that Colorado has suffered at the hands of the Philippine Islands, Texas, Kansas, Missouri, Nebraska, Utah and Massachusetts. 2. Neglect of vaccination. 3. Failure to recognize the disease in its early stages. 4. Failure to report every suspicious case to those legally responsible for its control. 5. Failure of health officer to rise to the situation. Such failures may probably be ascribed to one of the following causes: a. The influence of environments. County and town officials are often reluctant to spend the money necessary to quickly stamp out a threatened outbreak. b. Lack of executive ability. c. Lack of knowledge of his legal powers.

Unless all signs fail, Colorado is likely to have more serious outbreaks next winter than she has so far experienced. She need not have, however, if physicians, health authorities and the public do all in their power to prevent it.

Health boards all over the state should take the following measures:

1. Urge all citizens to be vaccinated and revaccinated. Parents should be urged to have infants vaccinated during the first year of life, and children should be revaccinated at 5 years of age.

2. School boards should be induced to secure the vaccination of all pupils.

3. Contractors should be induced to secure the vaccination of all employees.

4. Outbreaks should be anticipated by providing places to be used as quarantine and detention hospitals.

5. Failure to report cases of smallpox should result in vigorous prosecution of the offender.

6. Disinfection should be most thorough with reference to tuberculosis.

Dr. Tyler cited statistics proving that the number of cases of tuberculosis contracted in Colorado is on the increase. The means of prevention he summarized as follows: Every tubercular patient should be given an educational leaflet on the subject. In the larger cities and at resorts every case should be reported to the health authorities, and a register kept. All apartments recently occupied by tubercular patients should be disinfected by the health authorities. The spitting nuisance should be abated by posters, and in certain places by ordinances. All herds supplying milk should undergo examination. Tubercular and non-tubercular inmates of public and other institutions should be kept separated from each other.

VACCINATION.

DR. R. K. HUTCHINGS warns against the dressing of vaccination with vaselin, or any other ointment. The best results are obtained by keeping the sore perfectly dry from start to finish. He puts a small pledget of cotton over the sore after the lymph is dry, and over this an adhesive strap. Occasionally a lump forms at the site of the inoculation. This lump is spongy, about the size of a pea, red, and at times covered by a small scab. It generally remains a week or ten days, then dries up, leaving no scar. The patient is not immune. He has never been able to ascertain the lump formation and found no mention of it in any records consulted.

FOREIGN BODIES LODGED WITHIN EYEBALL.

DR. EDWARD JACKSON said in part: The patient's account of his injury is always defective, and often misleading. A foreign body having entered deeply does not cause the sensation of something in the eye, and the patient, impelled by hope, is often very positive that nothing is lodged there. Every detail of the accident should be minutely investigated: the body that inflicted the wound, whether rough or smooth; the relative position of the point from which it flew; the exact attitude of the patient; the direction in which he was looking. A thorough ophthalmoscopic examination at the earliest possible moment should be made. The position of the foreign body may be indicated by a streak of commencing opacity in the lens, or air bubbles, or shreds of hemorrhage marking its track. We must also consider whether it may not have passed entirely through the eyeball and lodged elsewhere. Where the exact location of the foreign body cannot be made out by examination under oblique illumination, or with the ophthalmoscope, the X-ray should be used. Making two negatives, with the tube placed in different positions, with some known fixed point the shadow of which can be used as a point of reference for the shadow of

the foreign body, it becomes possible to determine the location of the latter with great exactness. Unfortunately, very small foreign bodies do not give any perceptible shadow. He has had a case in which many trials with the X-ray failed to give an evidence of the presence of small particles of steel, although it was clearly visible in the fundus with the microscope.

In considering the prognosis and treatment it is best to divide the cases into three classes: 1, those lodged in the iris or anterior chamber; 2, in the lens, or 3, in the vitreous or fundus. Among twenty-five successive cases, the location of the foreign body was in the iris and anterior chamber in three, in the crystalline lens in four, and in the vitreous and fundus in sixteen. In one case it was partly in the iris and partly in the lens, and in one a foreign body, apparently simply lying on the iris, extended back through the zonule and into the vitreous.

When a foreign body is lodged in the iris or anterior chamber it should be removed as soon as possible.

Powder grains are occasionally lodged on the iris or in the lens. The finely powdered charcoal that remains of such a grain is not likely to ever cause any irritation. A foreign body lodged in the crystalline lens causes traumatic cataract. There is little liability to serious inflammation. It is proper, therefore, to allow the cataract to develop, and then to extract it in the ordinary way. He has seen a chip of steel hanging in the remains of the lens beginning to cause serious inflammation twenty-eight years after the original injury, the eye having, according to the patient's statement, remained quiet all that time.

A foreign body entering the vitreous, retina, choroid or ciliary body, if not promptly removed will set up such inflammatory and degenerative changes as to render the eye functionally useless. Smooth and aseptic particles are less likely to set up chronic degenerative changes and small particles firmly fixed in the fundus are compatible with useful vision.

He would insist that with the foreign body should be removed all badly damaged or probably infected tissue, the track of the foreign body through the vitreous and the bed of the tissue in which it lies. This can only be accomplished through a free scleral incision, made, if possible, through the point of entrance. Half the vitreous may be lost without serious consequence. We can save two or three times as many useful eyes by a surgical operation as by extraction of a foreign body with the magnet. To make a chip of steel jump from the wound with a giant magnet would seem a very brilliant operation to the bystanders, but it is a very useless one to the patient, if it leaves a track of inflammation with the eye. Surgery has no place for successful operations that work no permanent benefit for the patient.

VERTIGO.

DR. H. T. PERSHING gave the following classification of vertigo:

1. Vertigo of organic intracranial disease.
2. Degenerative disease of the central nervous system; a, lobes; b, disseminated sclerosis; c, parietic dementia.
3. Disease of cerebral vessels; a, arteriosclerosis; b, syphilis; c, endarteritis.
4. Organic disease of brain membranes or vessels absent; a, concussion; b, mechanical vertigo; c, toxic vertigo; d, labyrinthine vertigo; e, ocular vertigo; f, gastric; g, nasal vertigo; h, active or passive hyperemia and cerebral anemia; i, neurasthenia; j, essential vertigo.
5. Vertigo occurring as part of periodic nervous attacks; a, epileptic vertigo; b, migrainous vertigo, and c, hysteric vertigo.

EXTRADURAL SPINAL MENINGEAL HEMORRHAGE.

DR. S. D. HOPKINS reported a case under the above title. J. M., while shoveling coal, experienced a peculiar sensation throughout the body. It was not painful. His lower limbs became paralyzed twenty minutes after the beginning of the peculiar sensations. When seen on the third day of his illness he was suffering from pain in lower portion of trunk and thighs. The motor power of the left leg was good in every direction, but he was unable to make the slightest movement with his right. Sensation was present throughout the body. The right knee-jerk was absent, the left increased; ankle-clonus absent; deep reflexes of forearms normal; masseter reflex absent. Plantar reflexes: right slight, left absent. No ataxia,

no paralysis of arm; special senses normal; intelligence not impaired; girdle sensation and incontinence of urine and feces. The following day the patient was in the same general condition, excepting that nausea was added. During the evening he made a sudden movement, suffered severe pain in the back, and in a few minutes had a general convulsion in which he died. The diagnosis of spinal meningeal hemorrhage was confirmed at the autopsy.

CURED CASE OF HYSTERO-EPILEPSY.

DR. MINNIE C. T. LOVE reported the following case: S. M., aged 14, family history negative, from her 8th to 13th year, had suffered from chorea. The chorea suddenly disappeared some eighteen months ago, and she suffered instead from what her numerous physicians designated epilepsy. She had rosy cheeks, clear skin, and weighed 130 pounds. Menstruation was prolonged, excessive and painful. Dr. Love saw her during one of these attacks. She had a vacant stare, worked her fingers, and the facial muscles were much distorted. Her memory was getting very defective, so that she had to give up school. Electricity gave but slight benefit. Digital examination showed the uterus strongly flexed anteriorly and dislocated downward; pelvic viscera very sensitive. Curettage was performed and a stem pessary introduced. She menstruated afterward with ease, and felt better. Two months afterward she again had a nervous attack more severe than usual. Her eyes were found considerably astigmatic, and this was corrected. The nervous attacks have not recurred since. Her memory has improved, and she is practically well.

TRACTION PLASTERS IN LIEU OF THE MURPHY OPERATION.

DR. CHARLES DENISON exhibited traction plasters which he devised for the purpose of controlling thoracic movement on one side, thereby confining respiration to the unaffected lung. The plasters consist of two long strips of muslin, to the widest end of which adhesive plasters are attached, and a soft ring or collar. The plasters are applied to the chest, crossing each other in the axilla, and the front and back ends of the muslin strips are tightly drawn and firmly pinned to the collar placed on the opposite shoulder. This method, the author claims, is a perfectly, evenly and easily applied means to nearly annul the use of one lung, and, therefore, temporarily a suitable method to arrest pulmonary hemorrhage when from a known localized source; also to control ordinary or tubercular pleurisy, complicated or not with adhesions and pneumonia, or to limit and contract a pulmonary cavity, especially if located low down in the lung.

San Francisco County Medical Society.

July Meeting.

UNUSUAL CASES, ILLUSTRATING CO-OPERATION BETWEEN GENERAL PRACTITIONER AND OCUList.

DR. F. B. EATON, in his paper on this topic, said that the relations between general practitioner and oculist should be more close and friendly than they are, in order that the patients of both may derive the most benefit from their medical attendant. In many conditions the general practitioner is indebted to the specialist for his diagnosis, or for light on a doubtful case, and in return the specialist should often turn over a patient who consults him, to the hands of the general practitioner, the patient's trouble being but some eye symptom of a condition of general disease which demands general rather than special attention. To illustrate his point, Dr. Eaton cited several conditions, and a few cases of the conditions referred to.

The first case mentioned by the doctor was one of traumatism followed by malingering, and an attempt to mulct the proprietors of a store in heavy damages. The patient, a woman, was one day in a book store when a number of heavy books fell on her head. She was not, apparently, much injured at the time, but later went to bed, claimed to be paralyzed in the left arm and leg and to have some disturbance of the left eye and vision. Dr. Eaton was asked by her and by her physician to make an examination, and did so, finding the woman to be myopic, the pupil of the left eye dilated and not responsive to light stimulation. The vision did not appear to be disturbed. Subsequently Dr. Eaton, who concluded that the eye symptoms were

hysterical, was interviewed by three reputable physicians, retained by the defendants in the suit for damages which the woman had begun, who stated to him that they thought the whole matter but an attempt to get money from the defendants. Dr. Eaton was inclined to agree with them, at least in holding it to be a possible case, and decided to go with the patient's regular physician, entirely unannounced, for another examination. At the time of the second, unannounced examination, he found the patient entirely free from any eye symptoms whatever. The pupil was normal and reacted normally to light. Dr. Eaton was summoned as a witness, and largely on his testimony the suit for damages was lost. On the day following the loss of the suit the patient had entirely recovered from her paralysis and was seen walking about the streets. In Dr. Eaton's opinion homatropin had been used, perhaps with the connivance of the plaintiff's physician, to temporarily dilate the pupil of the left eye at all times when an examination was expected.

The second case referred to by Dr. Eaton was of a somewhat different nature. This patient, a man of about 40, had been thrown from a car, striking on his left side, hand and body. He was unconscious for about three-quarters of a hour, subsequently recovered, but ten days later developed peculiar eye symptoms. When examined, about ten days after the accident, the distance vision was normal, but there was total loss of accommodation and retinal anesthesia—or retinal fatigue—manifested on examining the field of vision for red and white. There was no organic trouble, but the diagnosis of traumatic hysteria seemed justified. The patient is really a sufferer and needs the care and attention of his general physician. He has been unable to do any work for the past five months, but will in all probability recover in time.

Locomotor ataxia is frequently first diagnosed by the oculist, and here again he should be in the most friendly relations with the general practitioner, for these cases are best dealt with by him alone. As an illustration, Dr. Eaton cites the following: A man called for his professional service, stating that about a year before he had noticed a slight dimness of vision and had gone to an optician, who had fitted him with glasses, which for a time helped him considerably. Again the sight failing, he called on Dr. Eaton. Tabes was at once diagnosed and the patient referred to the general practitioner. By going to an optician in the first instance, rather than consulting a regular oculist, the man had lost a whole year, during which time he might have been benefited by the attention of a regular practitioner.

Dr. Eaton then called attention to the fact that some general practitioners object to sending their patients to an oculist, and have indeed been known to actually consult with opticians in regard to the visual defects of their patients. He read the resolutions endorsed by the AMERICAN MEDICAL ASSOCIATION at its Columbus meeting in regard to opticians.

Another condition was illustrated by the history of a case presented in the person of a woman of 23, who consulted him for failing vision. She had headache, on the left side of the head, and nausea; and when rising after having been seated for a while, things got dark to her. There was a family history of migraine. The face and mucous membranes were pallid and the optic nerves were found to be inflamed, with swollen vessels. The case was a rare one, but the diagnosis of chloroanemia was easily made and the patient turned over to a general practitioner for treatment. Liberal iron tonics soon relieved the condition to a marked degree, but the disc of the left eye remained whitish; the vision of the right eye had increased to twice its former quantity, while the vision of the left eye was about the same as when first seen. There were no cerebral symptoms and so no intracranial trouble was considered.

The importance of the early recognition of gonorrhoeal ophthalmia was then touched on, attention being called to the fact that here it is almost always the general practitioner who first sees the case, and who should make the diagnosis and see that the patient is at once properly treated. It sometimes occurs that the septic ophthalmia develops first as a slight catarrhal discharge, with but trifling inflammation, the extreme active process being delayed for some days. A case in point was as follows: A patient, who had had a slight discharge from the urethra for two days, was referred to Dr. Eaton, by his general practitioner, for a trifling catarrhal in-

inflammation of the conjunctiva of one eye. The doctor was a bit suspicious and asked that the mucopus from the inflamed eye be examined microscopically. This being done, gonococci were found and silver at once instilled into the eye. The conjunctival inflammation disappeared rapidly, but the urethral trouble developed into a most obstinate case of gonorrhoea.

Dr. B. ISAAC JONES said that the question was a very broad one and could be looked at from many points of view. Ocular disturbances from general internal diseases are very common, and it behoves the oculist to be a good general practitioner, at least in so far as ability and training go. In his opinion the oculist had insufficient knowledge of general diseases; the adoption of a specialty should be at the latter end, rather than at the beginning of a man's professional life.

Dr. JOHN WAGNER had much intercourse with specialists, and in his experience benefit was always to be derived from such family relations. A case of malingerer, after a trifling accident from a car, was fresh in his mind, and in this case the examination and the testimony of the oculists defeated the dishonest attempt of the plaintiff to secure damages. In his opinion gonorrhoeal ophthalmia was not so common as generally supposed. In a somewhat extended career as a general practitioner seeing many cases of gonorrhoea and doing a good deal of confinement work, he had met with but one case of the affection.

Dr. V. H. HULEN said that the general practitioner and the oculist should always be on the best of terms, but he knew that this was not always the case, for some physicians were in the habit of consulting opticians rather than referring their patients to a regular oculist. It might be urged, he thought, by these physicians, that they did so for the reason that their patients could not pay the oculist's fee. In his opinion no oculist would refuse to retract or examine any case referred to him by a general practitioner, for nothing, if the physician stated the patient's position and his inability to pay.

Dr. M. KROTOSZYNER thought that the oculist was indebted to the general practitioner to a large extent, not only for patients but often for diagnosis. He mentioned several cases in point, where the correct diagnosis of a case that had been treated by an oculist for some time was eventually made by the general practitioner. One patient of this sort had been treated by an oculist, stated Dr. Krotoszyner, for some time, but without benefit. On consulting him he suspected kidney affection, and found, on examination, casts in the urine and an albuminuric retinitis. This should have been diagnosed by the oculist at first. He urged the necessity for the general practitioner to study the use of the ophthalmoscope. In many cases this is absolutely essential that the fundus of the patient's eyes be examined, and unless he is able to make such an examination, the general practitioner is often left in ignorance of the true condition of his patient. He recalled a patient who had consulted him some time previously, giving a history of symptoms which he thought purely hysterical. After a prolonged course of treatment the patient did not improve. One night she died very suddenly, and on post-mortem examination a large glioma near the optic chiasm was found. Had an ophthalmoscopic examination been made early in the course of the treatment, the true diagnosis could undoubtedly have been made.

Dr. PHILIP MILLS JONES called attention to the reverse of the picture painted by Dr. Krotoszyner, by recounting the history of a patient who had been referred to him by a general practitioner a short time ago. The patient, a young woman, was sent for examination, with the statement that her sight had been failing for a short time, and the condition was probably a serious one. Vision was found to be greatly reduced, but careful inquiry elicited the fact that the patient had but just recovered from an attack of diphtheria. Three or four weeks' good tonic treatment with a trip to the country entirely relieved the eye symptoms. In his opinion there could be no question that the general practitioner who was guilty of sending his patients to the optician for refraction was doing not only the oculist and the patient great wrong, but was also injuring himself, for sooner or later many of these patients find, when too late, that they have lost their sight through the ignorance of the true condition on the part of the optician. The man who is sent to an optician for refraction by his physician when he is suffering with dormant glaucoma, will not feel kindly disposed to that doctor when he finds himself blind and knows that it is largely owing to his physician's fault. So, too, with the patient who has progressive myopia, and is handed over to the tender mercies of the optician for a refraction which will mean ultimate blindness.

Alumni Association of Medical Department of University of California.

LEUCOCYTOSIS: ITS HISTOLOGY AND PATHOLOGY.

Dr. H. A. RYFKOGEL discussed this subject and first reviewed the ground so successfully turned over during the past few years, and mentioned the advances in the study of the blood permitted by improved methods of staining. By means of these new stains the fact that five distinct forms, or better stages, of the white blood corpuscle, or leucocyte, could be recognized. Of these five forms—the young, the older, the full-grown or adult cell, the eosinophile and the myelocyte, the third or adult cell, the common leucocyte, is the most common. It may vary somewhat in size and shape, and its nucleus may vary within considerable limits; it stains, however, with a neutral stain, and may be easily recognized and differentiated from the other forms of the white cell. The leucocyte does not have amoeboid motion until it reaches the stage of development of the third variety or form, which form is found in pus and in round-celled infiltration, as well as physiologically after a meal. This question of the physiologic increase of the leucocytes after food digestion has been found an important one in investigating the truth of the statements of certain malingerers. If the statement be made that no food has been taken for some long period of time, and if the blood count shows an increase of the leucocytes with no pathologic condition or clinical symptoms that would account for the increase, it is good presumptive evidence of a misstatement on the part of the would-be-patient. Dr. Ryfkogel has found this of value.

The difference between leucocytosis and leucemia was touched on and he stated that in leucemia the myelocyte first appears, it not being found in normal blood; it persists and later the neutral leucocyte appears in increased numbers and also remains in larger number than normal. In true leucocytosis this form of the white cell does not appear, but the other forms are found, especially the third, or neutral form, which is found to occur in greatly increased numbers, the amount of the increase depending on conditions of disease infection and individual resistant power of the patient; the increase may be from 100 to 1000. It is the increase of this third form of the white cell which is of diagnostic importance in many affections, and while the other forms of the cell may be also increased, especial value is placed on the count of the adult leucocyte which stains with the neutral stain. The relation between the virulence of the infection and the resistant strength of the patient is a peculiar one, and of much importance in the diagnosis as well as the prognosis. If the patient be particularly strong and resistant and the infection virulent, there will be an unusually marked increase in the number of white cells found in the blood. The indication is that of a particularly fierce struggle going on between the infection and the individual's resistant power. If, on the other hand, either the infection or the resistant strength be out of all proportion to the other factor in the problem, the increase in the number of white cells may not be very marked. Where the clinical symptoms show the infection to be severe and the blood count shows but a trifling increase in the leucocytes, the diagnosis is not so good as when the number of white cells is larger, for the count of the cells shows that resistant strength of the patient is not great, and that the disease may conquer more easily than if the strength of the patient more nearly equaled the strength of the infection. In this way the blood count may be used as a prognostic aid of no mean value. Leucocytosis is found to be present in all infectious diseases, save typhoid, unless in the presence of an abscess or peritonitis—tuberculosis and malaria. It may occur in these cases if there is also a complicating condition which would give rise to an increase in the white cells, as in the exceptions to typhoid fever, above cited. In a case of supposed appendicitis, for instance, if the blood count shows a largely increased number of white cells, it is safe to presume that pus formation has commenced.

The various theories suggested to account for the increase in the number of white cells in leucocytosis were next reviewed, the conclusion he seemed to accept being that recently advanced to the effect that in the system were acting two tendencies or forces, one a repellent tendency, by means of which the white cells are led to accumulate in the deeper viscera, the other being an attractive tendency which seems to draw the cells to the periphery and away from the deeper organs; there is also an actual increase other than the apparent increase due to the aggregation of the cells in the superficial circulation.

Dr. TERRY asked whether any significance could be attached to the presence of eosinophile cells, except in the condition of trichinosis.

Dr. RYFKOGEL, in reply, said that that was the only condition in which the eosinophile cells seemed to play any part.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

These new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, JULY 29, 1899.

GENERAL PATHOLOGY AND THERAPY OF DISTURBANCES OF CIRCULATION IN ACUTE INFECTIOUS DISEASES.

At the height of infection the resulting disturbance of the circulation is clinically characterized by softness of the pulse and diminution of the blood pressure, not necessarily connected with feebleness of the heart's action. These changes are to be separated from those which develop in the further course, the defervescence of, and convalescence from, the febrile disease, when the heart may be dilated, abnormally rapid or slow, occasionally irregular.

No characteristic anatomical changes are necessarily connected with the first kind of disturbance. In many cases, especially in diphtheria and typhoid fever, there are, it is true, important parenchymatous changes in the heart's muscle fibers; in other infections, with acute clinical symptoms, such changes are entirely absent. It is quite generally accepted that an acute infectious myocarditis—Romberg—accompanies the symptoms of cardiac weakness characteristic of convalescence from many acute infectious diseases.

Experiments bearing on the nature of the mechanism of the circulatory disturbances at the height of infectious diseases have not as yet been such that the results could be applied to the conditions in the human patient.

In the "Festschrift für Feier des 100 jährigen Bestehens der Medicinischen Klinik zu Leipzig,"¹ this problem is considered quite extensively by Romberg and associates. In order to reach some insight into the action of infections on the circulatory system, they inoculated rabbits with pure cultures of the pneumococcus, the

baecillus pyocyaneus, and the bacillus of diphtheria. The circulatory phenomena were studied carefully and at various stages the animals were sacrificed and carefully examined. These three micro-organisms were selected because of their pathogenic actions being quite similar in man and in rabbits; these bacteria also represent the principal forms or types of bacteria invasion.

Without entering into details, which would be quite impossible here, it was found that the pneumococcus, the pyocyaneus, and the diphtheria bacillus affect the circulation of the rabbit by paralyzing the vasomotor center in the medulla. The vasomotor paralysis leads to a fall of the arterial pressure and disturbances in the distribution of the blood in the body; the splanchnic vessels are overfilled, the vessels of the skin, muscle and brain underfilled. The heart need not necessarily be involved in the above disturbances; secondary degenerative changes may develop in consequence of insufficient blood-supply of its flesh; embolic pyocyaneus abscesses would enfeeble the heart's power, and the slowing and irregularity of the pulse observed in pyocyaneus and diphtheria infection are the result of the direct action of the infection of the heart's muscle. Romberg and his collaborators believe that these results are applicable to human pathology because of analogy.

The action of the human heart is not always enfeebled when the pulse is weak. At the height of acute infections the paleness of the skin, the drawn expression, the coldness of the extremities are often marked. Dyspnea, cyanosis, passive congestion and other symptoms of heart weakness, such as dilatation of the heart, are not necessarily present. Hence vasomotor paralysis accounts well for the most marked circulatory symptoms of the period of intense infection. Not heart weakness, but vasomotor weakness, not cardiac paralysis, but vasomotor paralysis, is the principal cause of the circulatory failure in acute infectious diseases. At the same time the importance of secondary and complicating changes in the heart's muscle remains unquestioned, especially in the later changes and in the period of convalescence.

Naturally the development of circulatory failure forms one of the prominent therapeutic indications in the acute febrile diseases. Assuming, as indicated above, that vasomotor paralysis plays an essential role in the productions of the enfeeblement of the circulation in the acute critical stages, how is the physician to best meet the threatening vascular paralysis?

Passler contributes an experimental investigation toward the solution of this important problem. The course of the disease in the infected rabbits—pneumococcus and bacillus pyocyaneus—was carefully watched until symptoms of fall of vascular tonus appeared, when different medicines were administered and their effect on the blood pressure noted. It was found that digitalis, by its support of the heart, for a time only exercises a favorable influence on the pressure. Subcutaneous injections of ether and intravenous injections of alcohol or cognac were without much, if any, ef-

¹ Deutsche Archiv. f. Klin. Med., 1899, vol. lxxiv.

fect. The action of vasomotor stimulants was much more favorable than that of heart tonics. The best results as to vasomotor stimulation were obtained by the combined use of caffein and coriamyrtin; their influence was stronger, of longer duration and more constant than that of camphor. Strychnin and ergotin increased the pressure only in fatal doses. Infusion of salt solution appeared to be harmless and of some favorable influence. How far a similar human therapy will yield like results must be left to clinical observations.

In no case were any of the substances used in the experiments able to maintain intact the function of the vasomotor centers for any length of time. Clinical experience has shown that in human infections the dangers to be avoided may be transitory; if success crowns the effort to support the circulation during the critical period, it is possible that life may be maintained until the infection has passed its course.

While death during the height, or the acute period, of diphtheria infection may be attributable to vasomotor paralysis, the much-feared sudden post-diphtheritic death depends on other causes. According to the studies of the Leipzig clinic, as presented by Hallwachs, the last mentioned form of death depends on myocarditic changes. These changes usually develop after the acute period of the infection, but they may complicate the vasomotor paralysis. Similar events may occur in other infectious diseases. In diphtheria Hallwachs observed that the severity and the course of the clinical symptoms—changes in the cardiac rhythm, slowness and irregularity of the beat, feeble heart's action—corresponded closely with the degree and stage of development of the anatomic process—degeneration of the muscle fibers, round-cell infiltration, connective-tissue formation. The myocarditis begins as early as in the second week of the disease and may rapidly reach a dangerous extent; in favorable cases healing results, sometimes leaving no evidences of the changes, at other times scars and diffuse sclerotic areas. Here we have a striking example of the second possibility in which an infection may injure the circulatory system, namely by the production of an anatomic disease of the heart muscle, but it is to be emphasized that this occurs after the acuteness of the infection has subsided.

RECURRESCENCE OF BARBARISM.

In the old barbaric days, while physical prowess was the chief quality that determined the survival of the fittest, it is in evidence that moral cowardice, as shown in treachery, assassination, and the torture of the defenseless, was the rule rather than the exception. At the present time the revelations of moral turpitude in France, coupled with the clear evidences of savage disposition, make it plain that but a brand is needed to light the fires of another Commune and to initiate a fierce civil and religious war. The Dreyfus case is but a humiliating picture of moral cowardice from the beginning to the present stage. In our own country, to the

thoughtful, who must by no means be confused with the pessimistic, the signs of this form of degeneracy are all too evident. The signs are most obvious in our crowded cities where the environment departs farthest from nature and where, by close association of the criminal with the ignorant, lawlessness readily assumes the contagious form. These remarks are prompted by the terrible scenes enacted of late during the street-car strikes in various cities. The degenerate cowards, who operate under cover of darkness, have no compunction in endangering and even taking the lives of innocent men, women and children, so long as their insane desire for vengeance of real or supposed wrongs is satiated by attacks on the inanimate property of the companies. There have lately been scenes enacted on the streets of New York, Brooklyn, Cleveland and other cities that would have caused thrills of joy to run down the yellow spine of Robespierre. Cars have been stoned and blown up with high explosives, the pillars of elevated roads have been blown out, and many blameless human beings have been disabled by overwhelming assault of numbers, by direct injury from explosions, and by the terrible nervous shock resulting in those of delicate nervous organization from unwitting presence or participation in these tragedies. Because our country receives in its steady tide of immigration a constant proportion of the degenerate and unsuccessful from the lowest parts of the most unruly populations of Europe, a good part of this violence and crime may be laid at the doors of others than native-born Americans. Perhaps we should also not forget that this class, being accustomed from childhood to have the first sign of rioting on their part met with the stern hand of a well-trained military, misses the habitual repression in the proverbial laxity of American officials charged with the preservation of domestic peace.

But there are other evidences of native cowardice which can not thus be readily shifted on the backs of convenient Europeans. In what city paper can it not daily be read that some luckless individual has been run down by the reckless "scorching" bicycler, who in abject cowardice jumps on his wheel and flees ignominiously, leaving others to repair the damage he has done and "some person unknown" to bear the blame? So it is with that driver of horses who runs down the bicyclist or pedestrian. Usually the papers say that he whipped up his team and disappeared before he could be identified. Among our politicians courage is rapidly becoming the rarest of all virtues. Success is the all-important goal. If incidentally success may be attained by seeming to evince moral courage, there will be a show of it; but if the contrary holds, no thought is given to its absence. The thoughtful can supply endless and more apt illustrations of this unfortunate tendency to cowardice in our national life. Pessimism is, however, far from being the mainspring of these remarks. There is happily, even in the midst of this wave of turbulence and degeneracy, clear indication of the rise of a better spirit, or to speak more correctly there is hope that courage

is again becoming popular and reappearing brightly from under the cloud behind which it has been so darkly hidden. The popularity of the writings of Rudyard Kipling, that so often paint in bright colors courage and the other manly virtues, is a highly encouraging sign. Of still greater significance and of great hope for the future is the undoubted popular admiration for the two chief heroes of the late Spanish war, who beyond all doubt clearly exemplify to the public mind the combined virtues of physical prowess and moral courage. This popular worship of honesty and bravery can not do otherwise than give rise to healthier ideals of private and public virtue. The ignorant can only be reached through the emotions, with them reason per se is powerless. Admiration and reverence for real heroes have always marked the best that is in the Anglo-Saxon. Hero worship is not indeed an unalloyed good, but in the present condition of depraved social and personal ideals it may prove to be of immense utility in the development of our American life toward purer goals. In any event its simple existence shows the persistence among us of a great solid substratum of the keen common sense that has kept our race from so many of the pitfalls that have beset the path of the other European peoples. While it is not to be expected that the uncultured can ever admire the abstract virtues of courage and manliness, it is always possible for the personification of those qualities, which mean so much for social stability, to become a popular idol. Therein lies much of hope for our national evolution.

While the ever-present soldier of Europe is little to be desired among us, it is on the other hand true that we as a people are much too lax in dealing with violence. Even as corporal punishment is not infrequently necessary in the correction of the waywardness of childhood, so it is best that mob violence should always promptly meet the stern hand of the force of the law-loving classes. We must never forget that a large portion of any people are still, at best, but in a stage of advanced childhood, and can not be dealt with as can the fully developed man. True courage is the greatest of all virtues because its existence presupposes the possession of nearly all others. Let us insist that our teachers shall constantly instill in the developing minds of the children of our nation a reverence for manliness even were it, as it is not, at the expense of intellectuality.

PSYCHIATRY AND SENSATIONALISM.

"How Shall We Instil Correct Ideas of Insanity into the Public Mind?" is the title of a paper announced to be read before the coming meeting of the British Medical Association. This is a question that remains to be answered here as well as in Great Britain. There is no lack of desire for information, but the only kind that seems to be absorbed is the imperfect and erroneous, and the more erroneous and imperfect the more readily it is apparently absorbed. The problem of how to enlighten the public is therefore a difficult one, even more

so than many other medical problems in regard to which the public takes an interest. A description of an asylum will be more readily believed if it is portrayed as conducted on the plan of an ill-managed poorhouse, than if facts are stated as they really are. The same is true as regards insanity itself. There is no statement too extravagant to be accepted by the laity, and even plain truths, plainly told, are too often accepted in a distorted form. There is such an opportunity for sensationalism that newspaper reporters in particular are rarely able to keep their imagination in restraint and the average literature they produce on the subject is about as thoroughly untrustworthy as it can well be. The physician who unguardedly allows himself to be interviewed on any remarkable incident or phase of the subject is liable to have to repent it, and this is well illustrated by a recent occurrence in New York. The Sunday edition of the *New York Herald*, June 11, contained a long article purporting to give the opinions of Dr. Van Gieson of the New York State Pathological Institute, and his conclusions that the day of asylums is nearly past and that they are to be replaced by psychopathic hospitals which are to treat insanity in its beginnings and thus forestall the necessity of these accumulations of human misery. The article implied the claim for Dr. Van Gieson and his assistants that this great advance would be due to their labors, which were especially illustrated by a case recently under their care and the publication of which is to make a profound sensation in the medical world, and to revolutionize present systems of the treatment of insanity.

The case itself as described in the *Herald* is not a remarkable one to an alienist either in its symptoms or its outcome, though one well suited for a sensational write-up by an active reporter. While less elaborately studied and reported, more or less similar cases have often been successfully treated in ordinary hospitals for the insane. They are only exceptional enough to afford no basis whatever for such generalizations as are made in the article referred to. Insanity is not proved curable by one such case any more than it would be proved incurable by the occurrence of a case of paresis, were the latter actually as rare as it might seem to be from the statistics of fifty years ago. As for such remarks as those attributed to Dr. Van Gieson by the reporter: that "insane asylums will become almost obsolete;" that the more perfect and effectual methods used in the case of Rev. Mr. Hanna "will revolutionize the whole system" of psychiatry; that they "mark the pioneer departure from the old school and the establishment of a more logical and perfect system for the treatment of the insane," we would prefer to assume that he never uttered them any more than that he characterized workers like himself as "psychopaths," though that is inferable from a passage in the same quotation marks. It would seem eminently proper, nevertheless, for him to make some public repudiation of the statements here credited to him, but though we have been watching for

something of the kind, it has not yet come under our observation. It is sometimes a question whether silence is the best policy in such a matter, but it is generally safest for the party involved to give the benefit of the doubt to an open declaration of the unauthorized misstatement of his remarks.

Even if through want of caution there had been something said that might be thus misinterpreted, the better course would be to admit it and make the correction. As it is in this case, the uncorrected impression given the public thus far is that the workers in the New York Pathological Institute by this one cure have made the great discovery of the age in the treatment of insanity, and are willing to publish it in this sensational form in a lay journal. The use of alleged quotations from Dr. Van Gieson, implying all this, and necessarily with it a disparagement of his fellow workers in psychiatry, makes the appearance still more unfortunate and the more imperatively demands some explanation. And without such explanation the inference is justifiable that eminent ability as a pathologist is perfectly compatible with gross ignorance of clinical psychiatry and a condemnable ethical recklessness.

SCIENK'S THEORY IN PRACTICE.

A Chicago chemist has been trying Schenk's rules for the production of sex, with what he considers a successful result. He and his wife desired a male child, and the expected infant's sex turned out accordingly. Considering the fact that the chances of this being the case were about 104 to 100 in the natural order of events, this case seems hardly conclusive, but it appears to have excited enough local interest to call in the reporters and bring out one or two interviews with physicians, who are judiciously noncommittal. If important succession or even dynastic contingencies depended on this birth, it might have received less attention, and perhaps we may consider it an evidence, gratifying rather than otherwise, of the popular interest in a scientific theory.

RECIPROCITY IN MEDICAL LICENSURE.

State medical examinations should be so conducted that the license granted by the examining board of one state, to practice medicine within the boundaries of the state, should carry with it, under proper supervision and scrutiny, the license to practice medicine also in other states. A step in the fulfillment of this desired end has recently been taken in Delaware, where the medical council will hereafter, in compliance with an amendment to the state medical law passed by the last legislature, recognize the certificates of license to practice medicine issued by the New Jersey State Board. It is to be presumed that like legislation has been or will be enacted by the State of New Jersey. The organization and administration of state medical examining boards has accomplished much good, and the time has come for a national medical examining board in order that those who have qualified in one state and desire to remove to another, or to others successively, need not be compelled to submit to examination with each change of residence.

THE AMERICAN VOICE.

The American voice is a common subject of criticism, though the critics are to a great extent guilty of the fault of estimating the whole by a part, and that it may be only an insignificant fraction. Taking as its text a paper by Dr. John W. Farlow, read before the American Laryngological Association, the *British Medical Journal* indulges in some characteristic remarks on the "mangled and outraged" English tongue in this country, and the bad habit of speech "which will never be corrected because patriotic Americans look upon it as one of their national institutions." We should infer that the editor has had but little intercourse with the better class of Americans, or that he has been a very poor observer and a rash and superficial generalizer. Admitting all our faults and that we have, perhaps, as a nation, a higher-pitched and less agreeable speech than the best English practice, and that there is abundant room for improvement, we can honestly deny the greater mangling and outraging of the English tongue here than in its native seat, or that we patriotically look on any of our bad habits as a national institution. The editor of the *British Medical Journal*, in indulging in such assertions, is cultivating a bad habit of writing, which is worse in its way than one of speech. The peculiarities of the American voice are probably largely due to climate, but they are also to be found in certain parts of Great Britain. Before the War of 1812, when British men-of-war were impressing alleged English seamen off American merchantmen, it is traditionally reported that many a characteristic Yankee twang was claimed as proving its owner a Cornishman. There may be in it something hereditary after all, just as many of our alleged Americanisms are proved to be only archaic English of Shakespeare's or Cromwell's time.

WOMEN'S CLUBS AND PATENT MEDICINE.

That the disgraceful, immoral and disgusting advertisements of patent medicines and appliances for the alleged cure of diseases peculiar to women have been allowed to go on without protest on the part of the women themselves is astonishing. That the claims made by advertisers of this class of nostrums are false is probably not easily recognized by women, but their indecency certainly is plain enough. We are pleased to see that at least one of the women's clubs of the country has had the courage to take action in the matter, even if it goes no farther than to pass resolutions. We gladly give space to these and suggest to our readers that they call the attention of the "clubwomen" among their patients to the action of the women of Worcester, Mass., as contained in the resolutions passed by the Worcester League of Unitarian Women:

Resolved, That the Worcester League of Unitarian Women observes, with regret, the increasing offensiveness of advertisements of proprietary medicines claiming to cure the special diseases of the sexes. We consider them a hindrance to the work of social purity.

Resolved, That we appeal to respectable journals to combine in refusing all medical advertisements which contain indecent details of diseases.

Resolved, That we urge self-respecting women to condemn these printed indecencies, to avoid correspondence with firms which so offend, to withhold patronage

and to influence others against dealing with them, whatever the merits of the remedies they offer.

Resolved, That we request the press generally to publish these resolutions, and urge women's clubs throughout the land to take similar action, in the hope that by concerted effort we may secure redress of a great wrong, and overcome a mighty obstacle to moral progress.

CYSTICERCUS OF THE FOURTH VENTRICLE.

According to Hensen's cysticercus cysts in the fourth ventricle may cause the following anatomic changes: Extensive proliferation of the ependyma and marked internal hydrocephalus in consequence of closure of the sylvian aqueduct and the foramen of Magendie, as well as compression of the vena magna galeni; no changes are produced in the immediate vicinity, except those due to general compression. There are cases which run their course without any symptoms, but more frequently they develop evidences of increased intracranial pressure; headache, vomiting, dizziness, convulsions, enfeebled visions—all due to the internal hydrocephalus. Occasionally focal symptoms develop: on part of the medulla diabetes; referable to the cerebellum and crura cerebri, such as marked dizziness, cerebellar ataxia, indications of forced movements and positions. The kind of headache and the position of the head may point to the localization of the lesion in the posterior fossa. The features especially peculiar to cysticercus cyst of the fourth ventricle are the intermittent course and the rapid, eventually fatal exacerbation of the symptoms on account of its being free and spontaneously movable. In Hensen's own case the diagnosis lay between tumor of the cerebellum and hemorrhagic pachymeningitis. In all likelihood only a probable diagnosis of cysticercus in the fourth ventricle can ever be made during life because the general symptoms force those peculiar to the cysticercus into the background. Intermittent course and sudden death on account of paralysis of the centers of respiration may lead to correct diagnosis, although after death. It will be recalled that in the case of cysticercus cellulose of the brain and spinal cord, reported by Diamond², the epileptoid symptoms were referred to the irritation of the cysts.

RETENTION OF LIFE.

The possibility of the retention of life and consciousness for any time after complete severance of the body above the hips, has not been much raised in medical literature, and naturally observations of such an occurrence are rare. Not long since there appeared a sensational paragraph in the newspapers in regard to a young man surviving hours after having been cut in two by a train. As our confrère, Dr. Gibbon's name was mentioned in connection with the case, we wrote him in regard to it, and received the following report

CHARLOTTE, N. C., July 18, 1899.

To the Editor:—The patient, a young man of about 20 years, from the western section of North Carolina, attempted to board a passenger train in rapid motion. Losing his hold he fell across the rail, and the wheels of several trucks passed over his body, completely crushing the pelvis and lower portion of the abdomen, and the

right arm above the elbow. The accident occurred at night, about twenty miles north of Charlotte, and the unfortunate man lived about thirty minutes after reaching this place, surviving his injuries about one hour. When seen by the writer, in a crowded passenger station, the man was perfectly sensible, answered all questions and complained bitterly of thirst. His face was expressive of the greatest anxiety and restlessness, and he was entirely pulseless. There was no hemorrhage, although the mangled muscles of the lumbar and gluteal regions hung from the side of his cot.

The situation being unfavorable for a minute examination of the extent of his injury, I am unfortunately unable to confirm what was afterward told me by the trainmen, that the lower extremities were completely severed at the pelvic brim, from the remainder of the trunk. The undertaker has also assured me that he placed first the upper portion of the body in the coffin and then the legs attached to the pelvis. My own examination of the man, while living, however, showed that the wheels of the car had passed directly over the lower part of the abdomen, of course crushing everything to pulp, though I did not suppose at the time that the section of the body was complete. I have no reason to doubt, however, that such was the case, and greatly regret that I did not insist on a removal of the body and a post-mortem inspection of the injury.

Very truly yours,

R. L. GIBBON, M.D.

Other instances have been reported where a few minutes were stated to have elapsed between complete severance of the trunk and death, but this interval is the longest we have seen as yet reported. A crushing injury such as is produced by being run over by car wheels may possibly so occlude the blood-vessels as to prevent too extensive hemorrhage at once, and if collapse and death do not at once occur, life may continue until the slightly later effects of the injury have appeared. Such cases, however, rarely survive long enough to come under medical observation. As Dr. Gibbon says in his letter, accompanying the above report, it makes really little difference whether the parts were completely severed or still held together by shreds of tissue, but the sensational character of the accident depends on the former being the case.

GENERALIZED VACCINIA OF ERUPTIVE TYPE.

There is yet wanting unanimity of opinion as to the exact relation between smallpox and cow-pox, and the question has not been decided whether the two are expressions of the same disease modified by the soil in which they are implanted, or are really distinct diseases. However this may be, it is certain beyond peradventure that inoculation of human beings with cow-pox affords protection from and does not give rise to smallpox, and while vaccination is occasionally attended with noteworthy constitutional symptoms, it is rarely accompanied by any other than the local exanthem. Cases have however, been placed on record in which vaccination was followed by a generalized eruption, and only recently Tyson reported such a case to the Philadelphia Pediatric Society. A most striking instance of the same sort has also been reported by D'Espine and Jeand¹. The patient was a girl 11 months old, who was inoculated on both arms, with lymph that was also employed

¹ Deutsch Arch. f. Klin. Med., 1899, 64, p. 635.

² Journal A. M. A., June 17, 1899.

¹ Archiv für Kinderheilkunde, B. xxvi, H. 5, 6, p. 367.

in the vaccination of two other children in whom the vaccinia pursued a normal course. In the child in question moderate fever set in four days after the operation, and in a day or two later, simultaneously with the pustules on the arms, several similar ones appeared on the trunk and face. After another day the eruption became much more profuse, while the temperature remained slightly elevated. Gradually the eruption extended over the entire body, although the constitutional manifestations remained mild. The exanthem everywhere presented the typical appearance of vaccinia, and subsided in the course of four or five days, although subsequently a few new vesicles made their appearance. The inoculated points on the arm pursued the ordinary course of vaccination. A calf was inoculated with some of the lymph from pustules on the leg and foot on the eighth and ninth days, with a positive result. With the contents of the pustules thus developed a second calf was inoculated, also with positive results. An attempt later to inoculate the first calf with active vaccinal lymph proved unsuccessful. The case was believed to be one of generalized vaccinia rather than one of mild varioloid, because the eruption failed to pursue the regular course of variola; and the general symptoms of this condition were completely wanting; while the possibility of direct or indirect transmission of smallpox could be entirely excluded. There was, further, no conveyance of variola to any one in the neighborhood of the child, although many of these had not been vaccinated since childhood. Finally, the positive results of inoculation of the calves rendered certain the conclusion that the condition was one of vaccinia. The occurrence of the condition is explained as a reversion to an original type, as a result of which a non-contagious exanthem is made to occupy a position intermediate between the localized eruption of cow-pox and the contagious generalized eruption of variola.

PHASES OF "CHRISTIAN SCIENCE."

Under the new medical act "Christian Scientist healers," etc., are, for the first time, given a legal status in Illinois. The act contains the following clause explicitly prohibiting interference with them: "This act shall not apply to any person who ministers to or treats the sick or suffering by mental or spiritual means without drugs or material remedy." Under this act the "Christian Scientist" has full right to practice without supervision or control by any authorities. Whatever may be said about this backward step in medical legislation, it must be admitted that unrestricted practice of "Christian Science" and faith healing is likely to have some queer developments. One phase, interesting from the veterinary standpoint, has lately occurred in Paterson, N. J. The "Scientist" failed to make a diagnosis in the case of a cow that was in extremis when he arrived. After "three sittings of profound meditation" the cow, however, so completely recovered that she chased the "Scientist" twice around the barnyard, and he was only rescued by a hired man with a pitch-fork. The *Chicago Chronicle*, which from time to time exhibits the usual newspaper iatrophobia against non-advertising physicians, is nevertheless rather skeptical about certain phases of this cure. The "Scientist," it remarks, undoubtedly

maintains in common with other professors of his philosophy that matter is non-existent. Why then, it asks, did he rush around the barnyard to escape the cow, which, being matter, was non-existent? Why, moreover, did he treat a non-existent cow? The occurrence suggests that "Christian Scientists" are likely to demonstrate, as did the Paterson healer, that the line of the non-existence of matter has to be drawn at enraged animals, especially since these cannot be "faith cured out of existence. It is to be hoped that "Christian Science" will take to veterinary practice and thus extinguish itself. Unfortunately, however, those who have embraced this cult do not call in "Scientists" to treat their domestic animals, their face or their hair. Another phase of the same subject is illustrated in the way that some of the "Christian Scientist" judges who disgrace the bench deal with the question of mental shock in producing injuries. These, in their decisions, deny the legal right of mental shock to produce such diseases as chorea, while at the same time smuggling into legislative acts clauses favoring "Christian Science," similar to that of the Illinois medical practice act. It is not strange to find the sexual element cropping up in connection with these aberrant religious ideas, the relation between sensual practices and religious delusions among the insane having long been known to alienists. This relation explains the frequent sexual aberrations displayed by many fanatic sects. The prophets, John of Leyden, Knipperdoling and the Oneida community—the original "Christian Scientists"—exhibited these very strongly in their acts. This tendency has long been recognized as occurring among people of average normal condition by sincerely religious people. Mr. Spurgeon, in a sermon two decades ago, said: "Let us not forget, too, that excess of spirituality is by a strange but certain law, placed next door to sensuality." This phallic phase of religion naturally crops up in "Christian Science" literature. A recent issue of a Chicago medical journal contains a "Christian Science" article on marital hygiene, by one Ida E. Chaddock, which to the phrasology of the "Christian Scientists" joins directions which resemble those given to the priestesses of Aphrodite. It is to be expected that this literature will appear in greater quantities now that "Christian Science," so far as Illinois is concerned, is freed from any restriction.

Medical News.

THE NEW wing of the Tacie Harper Hospital, Long Branch, N. J., was dedicated July 19.

THE *Tri-State Medical Journal and Practitioner* is to be issued under the title of *Inter-State Medical Journal*.

THE Duke of Westminster has presented to the Royal Alexandra Hospital of Rhyl, Wales, the sum of \$50,000.

PROFESSOR BRISSAUD has been appointed to the chair of history of medicine and surgery at the Paris Faculty of Medicine.

FIRE in the pathologic laboratory of the Kankakee, (Ill.) Hospital for the Insane, July 20, destroyed many valuable specimens.

DR. J. CARDEN COOPER of Philadelphia, left July 27 for Europe, where he will attend the International Con-

ference for Prophylaxis of Syphilis and Venereal Diseases, at Brussels, in September.

BY THE will of Miss Sue M. Bryson, a sufficient sum has been left the St. Joseph's Hospital of Lancaster, Pa., for the endowment of a free bed for children.

THE NEW French Minister, de Galiflet, mentioned so often in connection with the Dreyfus case, still wears a silver plate in his abdomen to cover a defect caused by a cannon ball at the siege of Puebla.

DR. F. T. STEWART, of the Pennsylvania Hospital, Philadelphia, is quoted as saying that he has recently treated five cases of tetanus by the administration of antitoxin, but in each instance the patient died.

THE WIDOW of a respected citizen of Riga, who died recently, has applied to the court for permission to resume her maiden name on the ground that the husband with whom she had lived for twenty years was a woman.

DR. JUDSON DALAND, Philadelphia, is in California. Before returning home it is his intention to visit the Yellowstone National Park, and he will read a paper before the Rocky Mountain Medical Society, in Salt Lake City, July 25.

THE SUGGESTION is offered, in a Paris exchange, that physicians in cities and small towns might obtain change of air and scene with the minimum of loss and expense, by merely exchanging their practices, offices, etc., for a short while.

LONDON cablegrams of July 22 announce that the bubonic plague has spread from Hongkong and Mauritius to Reunion. There were thirty-six cases at Mauritius during the week ending July 20, of which twenty-nine resulted fatally.

BY THE will of the late Robert L. Rea, Chicago, Northwestern University, Evanston, Ill., receives \$10,000 for endowment of the "Rea Professorship of Anatomy." The College of Physicians and Surgeons, Chicago, receives \$5,000.

THE PASTOR of St. James Methodist Episcopal Church, the Rev. Dr. Robert McIntyre, has announced that a hospital for incurable consumptives will be erected by a citizen of Chicago at an early date. The name of the donor has not been made public.

THE ALVARENGA PRIZE of the College of Physicians of Philadelphia, amounting to \$180, for the year of 1899 has been awarded to Dr. Robert L. Randolph of Baltimore, for an essay entitled "The Regeneration of the Crystalline Lens: an Experimental Study."

DOYEN, the "champagne millionaire," "lightning operator" of Paris, received quite an ovation from the students at Kiel recently, when he exhibited his cinematographic reproductions of his operations at von Esmarch's clinic, at the request of Emperor William.

FIFTEEN druggists, confectioners and manufacturers of "fruit syrups" have been arraigned in New York City charged with selling impure syrups for soda water and ice cream. The analysis showed no fruit juice present and that the coloring was produced by aniline dyes.

A LEMBERG, Austria, paper recently reported that a portrait of the late Empress, in the possession of a certain citizen for many years, had commenced to drip blood from between the glass and the frame. A local scientist attributes it to the "reddish secretions of the bacillus prodigiosus."

ACCORDING to the *British Medical Journal*, the members of the Continental Anglo-American Medical As-

sociation will follow the precedent set last year in Edinburgh, and lunch together during the meeting of the British Medical Association next week. The chair will be occupied by Prof. Osler of Baltimore.

A FATAL case of hydrophobia in a child 3 years of age is reported from Columbia, Mo. The child was bitten June 12, and the first symptoms were noticed July 10, death occurring a few days later. Such cases are of interest as occurring at too early an age to possess the hysterical element claimed by some to be the basis of the disorder.

A CIRCULAR has been issued by the physicians of Finisterre, the French province most ravaged by alcoholism, emphasizing its pernicious consequences to public and private health and national interests, and announcing that they can no longer remain impassive spectators of the catastrophe. The effect of their crusade is already extending beyond their local influence.

DR. G. ALDER BLUMER, superintendent of the New York State Lunatic Asylum at Utica, has been elected superintendent of the Butler Hospital, Providence, R. I., and will assume his new duties early in September. Dr. Blumer has made himself an enviable reputation during his nineteen years' service at Utica, and the trustees of the Butler Hospital are to be congratulated on their having secured his services.

HEERMAN, the inventor of the postal card, is now urging the Austrian authorities to introduce the "telegram card," or "telegram letter," and the proposition is under consideration. The special card to be sold for the purpose is deposited in the mail as usual, but when received at the postoffice, the contents are to be immediately telegraphed or telephoned to the addressee. Such a card might prove a desirable means of communication between patients and doctors in many instances.

DR. LASSALLETTÉ of Pau was condemned last year to two months' imprisonment for "homicide par imprudence," as a pair of forceps was found in the abdomen of a woman who had died a few hours after he had operated on her for removal of a large fibroma. After completing his term he produced evidence that the patient's death was not due to the fact cited, but that she had been poisoned with nux vomica. The case is now in the hands of the experts according to the *Gaz. Méd. de Paris*, July 8.

THE average monthly death-rate in Santiago, Cuba, under the Spanish régime is said to have been 250, but under improved sanitary measures carried out since the occupation by American troops, the mortality has decreased to 112 per month and is constantly growing less, notwithstanding that a small epidemic of yellow fever has affected that district. Previous to July 19 no new case of yellow fever had been reported for a period of five days.

UNDER DATE of May 18, 1899, Manila Bay, P. I., Lieutenant and Asst.-Surgeon Eugene H. Hartnett, U. S. A., reported an outbreak of measles among the troops on the transport *Warren*, on her passage from San Francisco, Cal., to Manila, P. I. Five cases were developed before reaching the Hawaiian Islands. These were left at Honolulu. After leaving this port fifty-five cases were treated, although every effort was made to restrict the spread of the disease by isolation and disinfection. No fatality occurred from the disease.

IT is a curious instance of the irony of fate that the electric exhibition at Como, in honor of Volta's discovery of the electric pile, should have been destroyed by an insubordinate electric spark. The loss is com-

plete and includes the original models of all machines and instruments invented by Italians, as well as the priceless Volta relics, his machines, letters, etc., and specimens of all the latest and most improved appliances of electricity to medicine, surgery, and every art and industry.

ONE of the last acts of the late Czarevitch, as we learn from the newspapers, was to publish a set of rules for consumptives. Himself a victim, he followed these rules most rigidly; the fear of imparting his disease became almost a mania with him, and none of his attendants were allowed to be on duty with him over two hours a day; the rest of the time they were obliged to spend looking after their health. He had collected, it is said, an extensive library on the subject of tuberculosis, which seems to have been the subject that most occupied his attention.

DR. L. L. SEAMAN, of New York City, has offered \$100 in gold or a medal of equal value, as the successful competitor may select, for the best thesis on "The Ideal Ration for an Army in the Tropics." The competition is under the direction of the Military Service Institution of the United States, which has its headquarters on Gouverneur's Island, New York Harbor. Col. Weston, acting commissary general; Lieut.-Col. Charles Smart, deputy surgeon-general, and Lieut.-Col. Wm. E. Dougherty, 7th U. S. Infantry, have been asked to act as a board of awards. The theses must be submitted by March 1, 1900.

ACCORDING to report the officials of the New Jersey experiment station have for a number of years had under observation several cows in which reaction had been given with tuberculin and were pronounced tuberculous. These animals found to be infected were isolated and have been closely watched, and from time to time examinations of the milk have been made but no tubercle bacilli have been found. The statement has also been made that, because no bacilli have so far been found, it does not absolutely prove that bacilli have never been present, and further that at this time the apparatus used is not as accurate as it is hoped to make it at some future day.

PHILADELPHIA is making an earnest effort to determine the extent to which adulteration of foods is being practiced in that city. Not only the retailer, but the wholesale dealer as well, will come in for his share in this investigation. The grand jury for July has five bills of indictment charging defendants with violation of the food laws, most of them being dealers in oleomargarin. Since January fifty-two persons have been indicted for selling oleomargarin for butter. During the same period twelve have been charged with selling adulterated milk. Five true bills have been found against retailers charging them with selling coffee adulterated with chicory.

THE ANTIVACCINATIONISTS will find food for thought if they will investigate the latest reports concerning smallpox in Germany during the last decade and a half. For the ten years previous to 1895 the average death-rate from smallpox was 116, the greater of the total number occurring in the early period of the decade. In 1895 there were 27 deaths, in 1896, 10, and in 1897, 5. In Germany the law requires vaccination and revaccination, and the law is carried out. In no other country is the value of vaccination more evident than in Germany, and in no other country is the preventive method more thoroughly carried out.

SINCE the large number of deaths from tetanus pro-

duced by injuries from the use of toy pistols, the coroner of Philadelphia has been looking up the law as it applies to the sale of firearms in general. Several additional deaths from tetanus have occurred in the city during the past week and that has probably given a greater impetus to the crusade against these firearms. An act of the Assembly, passed June 11, 1881, makes it a misdemeanor to sell firearms or any explosive substance to boys under the age of 16 years, and the offense is punishable by a fine not exceeding \$300. Under this act a dealer in toy pistols has been arrested and after being censured severely, by the coroner, is now held to await the action of the district attorney.

THE ENTIRE sewage of Paris is used for irrigating and fertilizing the formerly partly barren tracts of land at Achères and Pierrelay, where the cabbages, etc., now grow in rank profusion. The last great intercepting sewer emptying into the Seine was formally closed with appropriate ceremonies, July 8, and the black flood diverted to the pumping works where it is raised to a height of 35 meters and then distributed, the water finally draining clear and odorless into the river. In the addresses delivered a glowing tribute was paid to several physicians, Bourneville, Cornil, Proust and others, who in the Senate Chamber and City Hall so materially forwarded the great work now brought to completion.

THE CRUPPI bill to regulate medical expert testimony, already mentioned in the JOURNAL, has been passed by the French lower house, but so enlarged in its scope that it now applies to all expert testimony in all criminal cases. It provides for a list of experts to be prepared each year, by the authorities, to include among others all the various faculties of medicine, pharmacy, and sciences, and physicians, surgeons and pharmacists connected with hospitals and asylums, classified according to specialties. From this list the judge appoints one or more experts and the accused an equal number, who are to study and confer together and in case of impossibility to agree, to select a third, or he can be selected by the court. The expenses are to be included in the court costs. The House passed a resolution independent of the bill urging that more attention be paid to legal medicine in the medical colleges.

SPONTANEOUS GANGRENE IN CHILDHOOD.—It is not always possible to ascertain the causes that lead to the changes in the vessels that are responsible for the development of spontaneous gangrene. In those of mature and advanced years vascular degeneration may be considered as a more or less physiologic process, constituting a part of the process of senescence. Pathologically it may occur also earlier in life. Under such circumstances we naturally look for an infective or toxic origin. The condition is obviously rare in early life, and when it does occur one is naturally inclined to attach greater importance to hereditary predisposition, alone or in conjunction with acute infectious disease, than to any other possible single cause. A unique case of spontaneous gangrene occurring in a child a year and a half old, has been placed on record by Goebel (*Deutsches Archiv. f. Klin. Med.*, 63 B., 1. und 2 H. p. 94). The parents were healthy; two children were well, and one had died of convulsions during dentition. The patient had been nourished artificially, had its first tooth at four months, walked at fifteen months, and had off and on suffered from catarrh of the respiratory passages, of which there had been an aggravation four weeks before coming under observation. Fever set in, with severe

cough, prostration and anorexia. After eight days the child dragged the left leg, although it presented no physical abnormality. There was no knowledge of traumatism. After another week the tonsils became enlarged, and a rash appeared over the whole body. The child was not severely ill, was free from vomiting, and had but slight fever. The eruption disappeared in the course of a few days, although the condition of the leg meanwhile underwent no change. The child, however, became peevish, restless, and sleepless, with mild delirium at night. It coughed a good deal, ate scarcely anything, asked only for water and lost perceptibly in flesh. Finally the extremity became marbled in appearance, strikingly cold, slightly swollen and within a short time entirely blue. Examination of the blood disclosed a slight increase in the number of leucocytes. The spleen was small, and the urine contained neither albumin nor sugar. A diagnosis of occlusion of the anterior tibial artery was made, and this was confirmed by the formation of a line of demarcation in the upper third of the leg. The parents refused to permit surgical intervention. In the course of a few days more signs of pneumonia made their appearance, together with albumin and tube-casts in the urine. The throat became red and edematous, and a mucoid deposit formed on the tonsils. Death finally took place amid septic symptoms. The autopsy disclosed necrotic destruction of both tonsils and catarrhal pneumonia, especially in the left upper lobe, with purulent bronchitis. The heart was dilated, its musculature firm, its cavities and valves free from thrombi and deposits. The spleen was enlarged, the liver pale, the kidneys cloudy. The aorta from the origin of the renal arteries was occluded by a thrombus, which on the left side extended to the division of the popliteal artery and projected into the anterior and posterior tibials. On the right the clot extended to the origin of the deep femoral artery. The veins were empty. The thrombus was brownish-red in color, without lamination, and nowhere presented appearances suggestive of an embolic origin. The only abnormality discovered from histologic examination was a local endarteritis at the bifurcation of the popliteal artery.

The hydrozone may at first produce acid sensations in the stomach, but as the irritated gastric surface improves in tone under its influence this will pass away and sensitiveness to its action will subside. When necessary the amount of hydrozone

may be reduced until the stomach becomes more tolerant to it.

—H. T. Webster.

G. Hayem prescribes in the hyperpeptic form, with abundant secretion without dilatation, a course of Carlsbad water, unless there be heart disease or phthisis or the subject be feeble or aged. A formula for an artificial Carlsbad, for home use, is the following:

R. Sodii sulph.	gr. xl	2 60
Sodii bicarb.	gr. xl	2 60
Sodii chlorid.	gr. xvi	1 04
Aqua destil.	ʒxxxiii	1026 30

Sterilize or consume while fresh.

GASTRIC NEUROSI.

R. Morphin hydrochlor.	gr. iiii	20
Cocain hydrochlor.	gr. v	32
Tinct. belladonna.	ʒi	3 90
Aqua amygd. amar.	ʒv	19 50

M. Sig. Ten to fifteen drops (.5-.75 gm.) every hour. When pains are very severe, three doses of ten drops (.5 gm.) each within an hour.

R. Codein phosph.	gr. ¼	016
Bismuthi subnit.	gr. v	32
Sacchari lact.	gr. iiii	30

M. Sig. A dose, every two hours.

—Ewald.

Treatment of Hepatic Insufficiency.

According to the *Medical Review of Reviews*, Gilbert and Weil have recently studied two cases of "lesser diabetes" in which there were present an enlarged liver, digestive glycosuria, urobilinuria and hepanozoturia, together with indicanuria, a picture suggestive of hepatic insufficiency. All these symptoms disappeared under the administration of hepatic extract. In another case a consumptive with enlarged liver had no other symptom than indicanuria which was persistent. Under the use of hepatic extract this symptom disappeared to return when the extract was discontinued.

Local Treatment of Pneumonia in Children.

The *Medical News*, May 20, refers to Chase's observations on the efficiency of external applications in the treatment of pneumonia in children. The forty-five patients studied lived in tenement-houses, in unfavorable surroundings. All but two were over a year old. Of thirty-nine who had lobar pneumonia, thirty-eight recovered. Six had bronchopneumonia, and of these four recovered. The effect of poultices was especially noted. These were made light, of flaxseed and cheese cloth, and covered with oiled silk or paraffined paper, and weighed not more than six ounces (186.6 gm.) They were placed on the affected part while the child was in bed, and removed in 30 or 40 minutes. Rarely were more than six or eight applied in twenty-four hours. Observation convinced him that poultices diminish pain, and have a soothing effect, often producing sleep; that they relieve dyspnea and reduce the number of rales; that they are rarely opposed by the children, and by adding to the comfort of the patient they maintain his strength and so facilitate his recovery.

Subacute or Chronic Bronchitis.

The following prescription is recommended by Crinon:

R. Terpin hydratis.	gr. lxxx	5 20
Glycerin.		
Spiritus aa.	ʒiiss	77 70
Mellis despumat.	ʒi	62 20
Tinct. vanille.	m. lxxv	4 67

M. Sig. Two to four tablespoonfuls a day.

Treatment of Angina Pectoris.

The best remedy during the attack is the inhalation of amyl nitrite. This should be administered in glass capsules, to be crushed in a handkerchief held to the nose. The beginning dose is four minims (.24 gm.) which must later be increased to eight minims (.48 gm.) If the attack is prolonged, trinitrin should be given per os or subcutaneously, as in the following formula:

R. Spts. glonoini (1 per cent.)	gtt. xi	155
Aqua laurocerasi.	ʒiii	11 70

One or more syringefuls may be injected, or three drops (.15 gm.) of trinitrin in water, increased to six drops (.3 gm.). Between the attacks regulate the diet and forbid alcoholic drinks. White meats, eggs, vegetables, and as drink, milk, mineral water, and tea should form the chief diet. For medication digitalis, caffeine, and especially the iodine preparations are important. Potassium iodid should be administered for one month, followed by sodium iodid given for two months, as in the following formula:

R. Potass. iodid.....	3iiss-5v	9 175-19.50
Ext. thebaice.....	gr. iii	20
Aqua destil.....	ʒx 3ii	

M. Sig. Teaspoonful three times a day. Continue course for two to four years.

R. Sodii iodid.....	3iiss-3iiss	5 185-9.75
Sodii arsenit.....	gr. i	065
Aqua destil.....	ʒxxxxvss	138 45

M. Sig. A tablespoonful three times a day. —Huguenin.

Dysmenorrhœa.

R. Antipyrin.....	3iiss	9 75
Ammonii bromid.....		
Potassii bromid. āā.....	ʒi¼	4 87
Ext. viburni prunifol.....	ʒv	19 50
Spts. vini gallici.....		
Syrup aurantii, āā.....	ʒx 3i	39
Aqua destil.....	ʒxxxx	79 95

M. Sig. A teaspoonful four or five times daily. —Cushing and Cunston.

DYSMENORRHEA AND OVARIAN NEURALGIA.

R. Ext. belladonna.....		
Ext. stramonii, āā.....	gr. 1/5	012
Ext. hyoscyami.....	gr. ¼	016
Quin. sulph.....	gr. ss	03

M. Ft. pil No. ii. Sig. One repeated in two or three hours if necessary.

—Steer.

Tinct. cannabis ind.....	m. x	60
Syrup chloral hydrate (P.B.).....	m. xx	1 20
Glycerin.....	ʒi	3 90
Aqua camph. q. s. ad.....	ʒi	31 10

M. Sig. One dose to be taken at the commencement of pain. A second dose may be given in three hours, but no more until the next day.

—Bedford Fenwick.

For nervousness and general malaise, especially at the period of the menopause.

R. Ammonii bromid.....	ʒi	7 80
Sodii bromid.....	ʒiv	15 60
Spts. ammon. aromat.....	ʒvi	23 40
Aqua camph.....	ʒvi	186 60

M. Sig. Teaspoonful every four hours. —Parvin.

Vaginismus.

R. Zinci valerianati.....	gr. 5/6	05
Quinin valerianat.....	gr. iss	095
Ext. opii.....		
Ext. belladonna, āā.....	gr. 1/6	01

M. Ft. pil No. i. Sig. From three to six pills daily.

Locally:		
Ext. krameria.....	gr. iss	095
Morphin hydrochlor.....	gr. ¼	008
Ol. theobrom.....	ʒi	3 90

—Tourcnaint.

Sexual Atony in Women.

R. Ext. cannabis ind.....		
Ext. nucis vom. āā.....	gr. xxx	1 95
Ext. aloes aq.....	gr. vii	46

M. Div. in pil No. c. Sig. One three times a day.

Taste of Potassium Iodid Disguised.

Dr. F. E. Ferre of San Francisco, Cal., writes: "It gives me pleasure to forward you a formula for the administration of potassium iodid. I have given such a mixture to many of my medical friends who are more than pleased with it. One teaspoonful readily disguises the taste of ten grains of the iodid:

MIXTURE YERBINUS COMPOUND.

R. Saccharin.....	ʒiii	11 70
Ft. ext. orange peel.....	ʒii	7 80
Ft. ext. yerba santa.....	ʒii	7 80
Ft. ext. ginger.....	ʒiv	124 40
Aqua.....	ʒiv	1920

Mix. Add ʒi (31.1 gm.) MgCO₃; shake; let it stand for twenty-four hours; filter. Color red with ʒi (31.1 gm.) fl. ext. udebear, if desired.

Book Notices.

Electro-Hæmostasis in Operative Surgery. By ALEXANDER J. J. SKENE, M.D., LL.D., professor of gynecology in the Long Island College Hospital, etc. New York: D. Appleton, 1899.

This work is a monographic statement of the construction and uses of the author's electric hæmostatic forceps, which appears to be a very valuable addition to the surgeon's armamentarium. It is profusely illustrated, the descriptions are clear and readable, and the author's success with his method appears to have been very satisfactory in quite a wide range of operations. The cuts, though evidently made from elaborate drawings, are largely schematic, and, therefore, the more intelligible and illustrative of the text. The concluding chapters are devoted to the description of the author's approved methods of surgical antiseptis and asepis, including hospital construction and disinfection methods.

Albuminuria and Bright's Disease. By NESTOR TIRARD, M.D., F.R.C.P., physician to King's College Hospital, etc. With original illustrations. London: Smith, Elder & Co., 1899.

This latest addition to the text-books on kidney disease and albuminuria seems to have the merit of being a clear, practical monograph of the subject, especially in its purely medical aspects, as, while it includes also the kidney affections that sometimes call for surgical measures, these are left for the student to refer to in especially surgical works. It is also brief in its mention of the usual urine tests, and, as a text-book, perhaps more might have been said as to these. In other respects it seems a valuable work both for the student and the practitioner, and one that can be heartily recommended.

BOOKS AND PAMPHLETS RECEIVED.

Acknowledgement of all books received will be made in this column, and this will be deemed by us a full equivalent to those sending them. A selection from these volumes will be made for review as dictated by their merits, or in the interests of our readers.

Manual of Bacteriology. By Robert Muir, M.A., M.D., F.R.C.P.Ed., and James Ritchie, M.A., M.D., B.Sc. Second edition. Illustrated. 8vo. Cloth. Pp. 564. Price, \$3.25. Edinburgh and London: Young J. Pentland. New York: The Macmillan Co. 1899.

A System of Medicine by Many Writers. Edited by Thomas Clifford Allbutt, M.A., M.D., LL.D., F.R.C.P., F.R.S., F.S.A. Vol vi. Octavo. Cloth. Pp. 944. Price, \$5.00. New York: The Macmillan Co. 1899.

Mechanics of Surgery. Comprising Detailed Descriptions, Illustrations and Lists of the Instruments, Appliances and Furniture Necessary in Modern Surgical Art. By Charles Truax. Large Octavo. Cloth. Pp. 1024. Chicago: 1899.

Pulmonary Tuberculosis. Its Modern Prophylaxis and the Treatment in Special Institutions and at Home. Alvarenga Prize Essay of the College of Physicians of Philadelphia for the year 1898, revised and enlarged. By S. A. Knopf, M.D. (Paris and Bellevue, N. Y.), physician to the Lung Department of the New York Throat and Nose Hospital; former assistant physician to Professor Detweiler, Falkenstein Sanatorium, Germany; vice-president of the Pennsylvania Society for the Prevention of Tuberculosis; Fellow of the American Academy of Medicine; laureate of the Academy of Medicine of Paris, etc. With descriptions and illustrations of the most

important Sanatoria of Europe, the United States, and Canada. Octavo. Price, \$3.00 net. Philadelphia: P. Blakiston's Son & Co.

Principal Poisonous Plants of the United States. Svo. Cloth. Pp. 60. Published by the Illinois State Board of Health. 1899.

Transactions of Southern Surgical and Gynecological Association. Vol. xi. Eleventh Session, held at Memphis, Tenn. Octavo. Cloth. Pp. 516. Published by the Association. 1899.

Pyrorrhea Alveolaris and Its Relations to General Medicine. By John Fitzgerald, L.D.S. Small Octavo. Cloth. Pp. 62. London: The Medical Publishing Co., Ltd.

Mineral Waters of United States and their Therapeutic Uses. With an account of the various Mineral Spring localities, Means of Access, etc. By James K. Crook, A.M., M.D., adjunct professor of clinical medicine and physical diagnosis at the New York Post-Graduate Medical School, etc. In one octavo volume of 580 pages. Cloth, \$3.50, net. Philadelphia and New York: Lea Brothers & Co. 1899.

Deaths and Obituaries.

W. N. Alsop, M.D., Shaw, Miss., formerly of Louisville, Ky., was called to see a patient at Cleveland, Miss., July 12, and there murdered. . . . S. H. Boyd, M.D., Tolu, Ky., was thrown from a cart and instantly killed July 1. . . . Joshua A. Brown, M.D., McConnellsville, Ohio, died July 7, aged 85 years. . . . Clarence Chapman, M.D., Medina, N. Y., died July 8, aged 84 years. . . . Byron S. Coleman, M.D., Rochester, N. Y., July 15, aged 38 years. . . . A. J. Davis, M.D., Pittsburg, Pa., July 19, aged 73 years. . . . S. N. Guice, M.D., Meridian, Miss., July 7, aged 60 years.—John M. O'Byrne, M.D., Ocean View, Cal., July 10, aged 39 years. . . . David Rosenthal, M.D., Chicago, July 18, aged 70 years. . . . Charles J. Siglinger, M.D., Philadelphia, July 12. . . . John T. Stafford, M.D., San Francisco, Cal., July 3, aged 30 years. . . . William R. Wood, M.D., Scotland Neck, N. C., formerly superintendent of the insane asylum at Raleigh, July 12, aged 75 years. . . . Burrows Burdick, M.D., Stoughton, Wis., June 30, aged 76 years.

HENRY TUBBS, M.D., Kirkwood, Ill., ex-state senator, president of the First National Bank of Kirkwood, First National Bank of Alexis and National Bank of Monmouth, died July 16, after a brief illness.

PAUL JONES, M.D., who for several years has been connected with the department of biology in Vanderbilt University, Nashville, Tenn., was drowned at Wood's Holl, Mass., where he was doing special work in biology, July 1. He was 31 years of age.

C. W. CRAM, M.D., Davenport, Iowa, died July 13, aged 65 years. In 1857 he entered Starling Medical College, and later served as house surgeon of the hospital at the Ohio State Penitentiary for several years, afterward becoming superintendent of the hospital.

GEORGE W. BARCOCK, M.D., Chelsea, Mass., died July 14, aged 84 years. He was one of the founders of the Massachusetts Society of Medical Examiners.

KATHARYN N. NORTHROP, M.D., Women's Medical College, Philadelphia, 1893, formerly of the Warren, (Pa.) Asylum, and for the past three years resident physician of the South Mountain State Insane Asylum, died in Reading, Pa., July 15.

RUSSELL STURGIS, M.D., Harvard, 1881, of Boston; died there July 18. He was a son of Major Russell A. Sturgis and a grandson of the Russell Sturgis of Haring Brothers, London.

JAMES S. GEARY, M.D., Bellevue, 1892, coroner's physician Borough of the Bronx, New York city, died in Moot Haven, N. Y., July 18, aged 30 years.

CYRUS N. LAWRENCE, M.D., Vermont Medical College, Wood-

stock, Vt. (now extinct), 1850, died suddenly July 18, at a sanitarium in Jamaica Plains, Mass. He was mustered in as surgeon of the Tenth Massachusetts, in June, 1861, and was in charge of the hospital establishment at Gettysburg after the battle. Afterward he was transferred to the South Street Hospital, Philadelphia, in 1863, and in 1864 became medical inspector of the First Army Corps.

CHARLES HOWARD HILL, M.D., Philadelphia, died July 18, aged 85 years. Dr. Hill was a graduate of the Jefferson Medical College, and was in active practice for a period of nearly sixty years. In early life he took considerable interest in politics and was at one time a member of the state legislature.

ORIS B. BEXBROOK, M.D., formerly of Natchez, Miss, died July 14, aged 29 years. The Doctor received his degree in medicine from Tulane University, New Orleans, in 1893, returning to Natchez, where he was connected with the hospital for some years. In 1897 he removed to St. Joseph, La.

Miscellany.

Systolic Mitral Murmurs: Correction.—In Dr. Horace D. Arnold's article on this subject in the *JOURNAL* of July 15, on page 143, line 13, column 1, read: "We can not find a dividing line between the so-called anemic murmurs and the mitral murmurs."

Hernia of the Diaphragm.—There are 433 cases of hernia of the diaphragm on record, but seldom of such extent as the case of a new-born male infant who showed no external indications of the condition. The left pleural cavity contained, in a hernial sac, almost the entire contents of the abdomen, with the heart and large thymus pushed entirely over to the right.—*Wien. Klin. Woch.*, 24.

Traumatic Aural Affections.—Radzich reports several instructive cases which emphasize the importance of examining the ears in case of traumatic injury to the body. Symptoms of a traumatic lesion of the inner ear are chronic hyperemia of the deeper segment of the meatus externus and of the tympanum. The temperature-curve is also an indication in catarrhal otitis with a subacute course.—*St. Petersburg Med. Woch.*, July 1.

Philadelphia Mortality Statistics.—The number of deaths for the week just closed was 510, an increase of 28 over last week and a decrease of 13 over the corresponding week of last year; 211 occurred in children under the age of 5 years. The following were the principal causes of death: apoplexy, 11; nephritis, 26; cancer, 17; cholera infantum, 73; tuberculosis, 69; diabetes, 2; heart disease, 24; pneumonia, 17; appendicitis, 4; suicide, 1; sunstroke, 3; tetanus, 7.

Chronic Ankylosis of Spine.—N. Schatalow describes three cases of this rare affection. He notes that the pains disappear when reclining and are more intense when the patient moves about. He considers these pains due to the compression of the nerve roots as well as the affections of the bones. This compression explains the other nerve symptoms noticed. The affection begins gradually and may be due, he suggests, to a congenitally defective development of some segments of the connective tissue and skeleton, with premature sclerosis.—*St. Petersburg Med. Woch.*, July 1.

Specific Toxic Properties of Tuberculin Acid.—Ruppel isolated from the tubercle bacillus a specific nucleic acid, and Behring announces that this acid alone is fully as effective, to say the least, as any other preparation yet produced for the treatment of tuberculosis. It also retains its specific properties much longer. With the help of this tuberculin acid the degree of toxicity of any tuberculin product can be regulated as desired. His communication in the *Berlin Klin. Woch.*, No. 25, describes his methods of testing, on animals, the specific

toxicity of preparations of tuberculin, for which he considers cattle better adapted than goats.

Parishes Must Pay for Keeley Cure.—The supreme court of Louisiana holds that article 202 of the constitution of 1870, while properly construed to mean that the taxing power was to be exercised by the general assembly for state purposes, by parishes for parish purposes, and by municipal corporations for the purpose of such corporations, is also to be construed with article 163 of the same constitution, which provides that "the general assembly shall make it obligatory upon each parish to support all infirm, sick and disabled paupers residing within its limits," etc., and, when so construed, did not affect the power of the general assembly, by the adoption of Act No. 157 of the Acts of 1894, to require the parishes to pay the expense of treatment at the Keeley-Cure Institute of persons contemplated by said act, and as therein provided. Moreover, it holds that the plaintiff, in *Webster vs. Police Jury of Parish of Rapides*, had the right, being a poor man, etc., to place his brother in the institute for treatment, and to look to the parish to pay the bill; and if, as between himself and the institute, and in order that the purpose of the law might not be defeated, he borrowed the money and paid the fee required by the institute in advance, he still had the right to look to the parish to pay the bill.

Hydrophobia and the Pasteur Treatment.—The Chicago Pasteur Institute gives a summary of the results of the preventive inoculations against hydrophobia attained since its inauguration, July 2, 1890. During this time 750 patients received the antilymphobiotic treatment. Of these 789 were bitten by dogs, 29 by cats, 26 by horses, 7 by skunks, 5 by wolves, 2 by cows, 1 by a calf, 1 by a rat, 1 by a mule, 1 by a pig, and 3 by hydrophobic human beings; 377 persons received severe and multiple lacerated bites on the hands and wrists, 92 on the head and face, 110 on the arms, 173 on the legs and thighs, and 28 on the trunk. Following the role of Pasteur, the patients treated have been classified as follows: 1. Persons bitten by animals recognized and ascertained to be rabid by the first experiment made in the laboratory or by the death of other persons or animals bitten by the same animal; of this class 268 were treated. 2. Persons bitten by animals recognized to be rabid by the symptoms of the disease shown during life; of this class 378 were treated. 3. Persons bitten by animals strongly suspected to be rabid; of this class 161 were treated. Only three deaths have been reported, thus giving a mortality of 0.38 per cent. Before the discovery of the Pasteur treatment the mortality was as high as 88 per cent. for the bites of the face, 67 for bites of the hands, and 20 to 30 per cent. for those of the limbs and trunk. All patients tolerated the treatment perfectly well. The treatment consists in hypodermic injections of a specially prepared virus of different gradation of strengths for a period of fifteen, eighteen or twenty-one days, according to the severity of the case. The method used is identical with that used in Paris.

Army Medical News from Manila, P. I.—Reports from Chief Surgeon Henry F. Hoyt, Second Division, Eighth Army Corps, detailing the movements and engagements of his division during the month of May, 1899, have been received at the surgeon-general's office. An engagement with the insurgents took place May 3, at the Santo Tomas railway station. The troops suffered greatly from heat and thirst, as their canteens became empty early in the day and the water found in the locality was brackish. The wounded were sent to the rear, on hand-cars. Filipino prisoners were made to propel the cars as our own men were so prostrated by the heat. After being cared for at the dressing stations the wounded were immediately sent to Manila by train. On the 24th another engagement took place west of San Fernando. The wounded, including some Filipinos, were treated at the field-hospital and sent to

Manila on the same day. The casualties for the month were 6 killed and 52 wounded. On May 25 a division field-hospital was established in San Fernando in five adjoining buildings. Major Guy L. Edie, brigade surgeon volunteers, in charge. The capacity of this hospital is 200 beds. Diarrheal troubles were so greatly on the increase during the month that recommendation was made to regulate and restrict the sale of fruit. Major Hoyt's recommendations for change in the ration to meet the conditions of service in the tropics are that the rice of the field ration should be increased to six ounces. Company commanders should encourage its use and see that the cooks prepare and serve it in palatable form. The canned corned beef of the travel ration has been generally disliked by the troops of this division. In place of it boiled sliced ham or a sausage, three parts beef and one part pork, is recommended. In place of beans a nutritious vegetable soup is proposed. These articles and the tomatoes of the ration should be put up in flat cans, as being more convenient to carry than those of the present shape.

Influence of Borax on Nutrition.—In a recent number of the *Am. Jour. of Physiology*, R. H. Chittenden and William J. Gies of the Sheffield Laboratory of Physiology, Yale University publish the results of their experiments in a study of the influence of borax and boric acid on nutrition, with special reference to proteid metabolism. In view of the wide-spread use in commercial food preparation, of boric acid and borax as a preservative, as well as the general interest recent inquiry into food adulterations has awakened, their conclusions are of special interest. The experiments were conducted on full-grown dogs, whose nitrogenous equilibrium was well determined before the experiments were begun; the animals were suitably caged that all excreta, both liquid and solid, could be collected. During the experimentation the animals were fed on a properly-balanced mixed diet composed of lean beef, cracker-meal, lard and water. Great care and accuracy was resorted to in the preparation and administration of this food, which was served twice daily, the boric acid or borax being usually given with or immediately following the meal, enclosed in a gelatin capsule. Three distinct series of experiments were perfected and carried on. In the first borax was administered, in the second boric acid, while in the third both drugs were used. The conclusions were that the administration of moderate doses of borax, that is, up to five grains per day, even if continued over a long period, does not influence proteid metabolism, nor exert any special influence on general nutritional changes in the economy; under no circumstances does borax tend to increase body weight, or to protect the proteid matter of the tissues. Large doses of borax (5-10 grams daily) directly stimulate proteid metabolism, and, if continued, lead to increased excretion of nitrogen through the urine, also of sulphuric and phosphoric acid. Boric acid, on the other hand, in doses up to 3 grams per day, is without any practical influence on proteid metabolism and on the general nutrition of the body. Borax, in large doses, somewhat retards the assimilation of proteid and fatty foods, the feces are increased in weight, and in both nitrogen and fat. Large doses produce some increase in mucus and diarrhea. Boric acid, contrariwise, in large doses is without such influence.

Right to Appoint Substitute.—A contract in writing for the employment of a county physician provided that he should perform all the duties of health officer for the county, and should also "take care of and give all poor person or persons who may be a proper charge upon the county, giving the same proper medical attention and care, furnishing all medicines, surgical dressings, and appliances," etc. Finally his bill for one quarter was disallowed. During that quarter his wife had been seriously ill for much of the time, so that it was necessary for him to remove her to a city hospital for treatment, and he

himself was quite ill for a number of weeks. To meet this emergency, he had made an arrangement with another reputable physician of the county to attend to all of his practice, both for private individuals and under the contract with the county. Upon this, however, the Board of County Commissioners relied to defeat a recovery of his bill, contending that the contract called for the personal services of the plaintiff, and that he could not substitute another physician for himself, and maintain his claim for compensation against the county. But this contention, the court of appeals of Colorado thinks, was without any force. Under every reasonable construction of the contract, it holds—Appeal of Board of Commissioners of Prowers County vs. Bedell—it did not call for the personal services, in all cases, of the plaintiff (Bedell). All that it required was proper medical attention, medicines, etc., and there was no effort to show that the substitute physician was incompetent or inefficient. Furthermore, even if the contract had specifically called for the personal services of the plaintiff, the court holds that it would be unreasonable to claim that in case of his sickness or temporary absence he could not furnish the services of another physician without forfeiting his contract, provided that such other rendered proper services. Nor does it consider that there was any error in excluding evidence that the board had early in said quarter appointed another physician county physician and health officer, under a similar contract to the above. This, the court of appeals says, was entirely irrelevant to the issues in this case, and had no bearing whatever on it. The only question, it declares, was whether the plaintiff had complied or failed to comply with his contract. Then, the Board contended that this evidence was admissible, because the contract was in part for the services of the plaintiff as health officer, and that under the statute the Board had the power to remove that officer at pleasure. But, assuming this to be true, the court holds that, under the terms of the contract, it would not prevent the recovery by the plaintiff of the compensation agreed on, if he had fulfilled the obligations of his contract, for his services as county physician.

San Francisco.

THE MEDICAL COLLEGES.—Some friction has arisen between the medical department of the State University and Cooper Medical College on the one hand, and the recently incorporated College of Physicians and Surgeons on the other, over the distribution of the wards at the City and County Hospital. The two first named colleges have been on the most friendly footing at the hospital for some years, but the introduction of a new element into the question seems to be a disturbing factor. The superintendent of the hospital, Dr. Sussdorff, states that the representatives of the new college tried to run things with a high hand and decide for themselves, without regard to the Board of Health or the other medical interests, what they would have. Dr. Sussdorff objected and the matter was adjusted by the Board of Health itself, not altogether to the satisfaction of the new college. The College of Physicians and Surgeons is not regarded with great friendliness by the other colleges. The reason the older institutions give for this lack of cordiality is that they do not consider the standard of the newly incorporated school high enough for a modern medical school. The young rival of the older schools has been in existence but three or four years, has lower tuition fees than either of the others, and has already a goodly number of students on its rolls.

SANITARY REGULATIONS OF TROOPS.—Very stringent sanitary regulations have been formulated for the protection of the men of the Oregon regiment who have recently returned from Manila. The camp at the Presidio is to be placed under the direct charge of a regular army surgeon and all precautions taken to guard the men and the other troops camped at that post from introducing any contagion. Strenuous efforts are also being made to protect the returned soldiers from the rigors

of the climate, as San Francisco weather is a most decided contrast to that which they have experienced for nearly two years past. Whether the men themselves will aid in the carrying out of the wise orders as to the wearing of overcoats, not riding on the outside of cars, being in bed early, etc., remains to be seen. As yet, however, very little sickness has developed among them, in spite of the fact that since their return the weather has been particularly bad, cold and fog prevailing most of the time.

London.

THE death of Sir William Henry Flower, the past week, has not only deprived English zoology of the last of that generation of giants, to which Darwin and Huxley were the standard-bearers—and out of which Alfred Russell Wallace has done his best to read himself, by his amazing relapses into spiritualism and antivivisection—but also the medical profession of one of its former heroes and ornaments. Like Huxley, he was not only trained, but actually began life in practice as a surgeon, in the army instead of, like his great colleague, in the navy. Educated first at University College, London, and later at the Middlesex Hospital, at the age of 23 he went out to the Crimea as assistant-surgeon to the Sixty-third Regiment. Through the entire campaign he served, to the permanent detriment of his health, but with such distinction as to receive two medals at its close. Returning to London he became demonstrator of anatomy and assistant-surgeon to the Middlesex Hospital, and in 1861 was appointed curator of the Hunterian Museum of the Royal College of Surgeons, in which position he won a world-wide reputation, and which he only relinquished to accept the directorship of the Natural History Department of the British Museum, twenty-three years later. This he held for fourteen years, until failing health compelled him to relinquish it, about a year ago. So that, although chiefly famous as a zoologist, he was intimately connected with medicine throughout the greater part of his life. He was knighted, in recognition of his high scientific attainments, in 1887. Prof. Flower will be longest remembered by his excellent monograph on "The Horse," and his superb works, "Mammals Living and Extinct," and "The Osteology of the Mammalia." Although only 67 years of age he had been in failing health for many years, said to be due to a glycosuria, dating from the strain and hardships of the long Crimean campaign, which was even worse managed from a sanitary point of view than ours at Santiago.

OUR homeopathic brethren in London have been treating themselves to a celebration this week, on the occasion of the fiftieth anniversary of the Homeopathic Hospital. Their position here is much weaker and less prominent than with us. In the first place they all have to pass precisely the same examinations and take the same M.R.C.S. and L.R.C.P. degrees as the regular practitioner, so that the source of a man's diploma is no guide to his "school." Then they, none of them, place the name "homeopathic" on their door-plates or signs, or if they do they are decidedly looked down on by their brethren, so that often only their patients and their regular neighbors know that they are homeopaths. They are a mere corporal's guard in point of numbers, compared with our large and noisy army, although, as their orator on the recent occasion seemed to think, they may have some reason to congratulate themselves on the percentage of the increase in seventy years, from one lone representative in London in 1827. They seem actually proud of the fact that their only hospital had 11,000 patients in 1850, and 19,000 in 1898, an increase of 70 per cent. in forty-eight years. They are vaguely hopeful of a school, in connection with the coming University of London, but if they are content to wait for such a "Greek Kalends" sort of a date as this, regular medicine has little to fear.

THE Royal College of Surgeons is preparing to celebrate its centenary next year by (as noted in the JOURNAL, July 22, p.

235), among other things, an application to the government authorities for a supplemental charter. In this the Council has already determined to ask for power to confer an honorary fellowship on distinguished members of the profession, who are not members of the College, said honorary Fellows not to exceed fifty in number at any one time. Now the Members of the College, who have been clamoring for recognition, and representation on the Council, are taking advantage of this proposed change to urge that a clause giving them this simple and long-refused justice should be added to the new charter. As it stands at present, the election of the Council and entire control of the affairs of the College, its library and museum is in the hands of the Fellows only, and as not more than a small percentage of the Members can afford either the time or the heavy fees required to secure the higher degree, it results in the great majority of those actually forming the College being ruled absolutely and without recourse by a small minority. Indeed, this was the frank intention of the original charter, and the tacit determination of every Council, and of most Fellows until quite recently, and although the Members have been organized for years past, and held enthusiastic and excited meetings every year to demand this right, the Council has always been able to shelter its own selfishness behind the charter and the alleged difficulty of getting any alterations made in it. Now, however, that they are actually proposing a new charter, for some of their own amendments, this excuse will no longer hold water, and it hardly seems possible that the Council can in decency refuse this act of simple justice much longer.

The charity bazaar, organized by certain ladies of title, in aid of the building fund of Charing Cross Hospital, has proved a great success, netting the handsome sum of \$75,000. There is nothing your true Briton will pay more handsomely for than an opportunity to shake hands with, or receive a smile from, a duchess. If he—or she—can only render himself interesting to such an exalted personage for a few minutes, as an object of plunder, he will be happy for a month, and submit to almost any amount of bleeding with Spartan stoicism, nay, even with enthusiasm. We suppose that it is justifiable to play on even the weaknesses of humanity in a good cause, at least so the professional keepers of our ethical ideals, the clergy, have always taught us by their example, but the spectacle of patrician dames hawking pamphlet "souvenirs" about a bazaar, at whatever price, from \$3 to \$50, which they could inveigle plebeians into paying for them, in the cause of medical education, is not one of which a great and influential profession can be especially proud, or regard as a dignified and appropriate means of securing funds for such a purpose.

The tropical expedition of the enterprising, young Liverpool school is to start early in August, and consist of Major Donald Ross, Dr. Annett and two student assistants. Its destination is the west coast of Africa—Sierra Leone—and its object the most interesting one, experimenting on the possibility of exterminating the malaria-bearing species of mosquitoes from a certain limited district, or districts, by draining the marshes, covering the pools with petroleum, and other methods recommended. The heads of the expedition will return in October, but it is hoped to leave some of its members to continue the investigation, and that Major Ross will return early in the coming year. This certainly ought to stimulate us to see that similar experiments are carried out this summer and fall, on some of our smaller river-bottoms, or mosquito-infested "summer resorts."

THINGS "do moobe" in London at times and the time-honored fog is having a serious attack made on it at last. Sir William Richmond's vigorous crusade against the smoke nuisance has finally penetrated the judicial skull-cap, and magistrates are beginning to impose really serious fines on all factories, hotels, etc., where their chimneys are complained of, warning them

that since smoke-consumers have been shown to be practical, unless they put one in at once they will be fined again on the next complaint. The big Charing Cross and Strand Electric Co. have just been made examples at two of their stations, and the effect will be most salutary.

A CURIOUS illustration of the truth of our quaint western saying, "it's dangerous to be safe," has just been afforded by a fatal bicycle accident at night, due to the excessive brilliancy of the acetylene lamp carried by the machine. A business man, returning home from a meeting at about 10 o'clock in the evening, was run into by a triplet while attempting to cross a broad street, and received a fracture of the skull base, from which he died in a few hours. The accident was seen by several witnesses, who were unanimous in testifying that the unfortunate man was perfectly sober, that the cyclist had given ample warning by sounding their gong, so that he seemed to be fully aware of their coming, and that the accident was entirely due to his becoming confused by the brilliant and dazzling rays of the huge acetylene lamp, so that in trying to spring out of its way he threw himself right in front of it. It is really time that our profession, members of which are aware of the curious confusing effect of the sudden appearance of a brilliant light at night, as illustrated by the way migrating birds dash against lighthouse windows, and moths plunge into lamp and candle-flames, amounting to an apparent fascination, should emphatically protest against the absurd and dangerous brilliancy of the newer lamps, which the whim of the cyclist is leading him to affect. They are no addition whatever to his own safety, for the brighter they are the more narrowly they limit his view, and the blacker the shade into which everything outside of their beam is cast, and they are a serious menace to the foot passenger. Indeed, it is seriously to be doubted, and needs testing by careful experiment, whether after all the carrying of a lamp at all is really a protection or a danger to both cyclist and passenger. It certainly is much more difficult to estimate either the position or the rate of approach of a lighted than of an unlighted wheel, for the simple optical reason that the slight overlapping, or non-correspondence of the two retinal images, by which we estimate distance, is entirely eliminated, as we can see nothing of the approaching cycle but a black shadow behind a brilliant luminous point. All who have had experience, either as riders or walkers, in cities like Buffalo, N. Y., which require a bell but not a light, will testify that the streets are both pleasanter and safer, for both parties. The constant stream of fire-fly lights is so annoying and the difficulty of estimating their distance to fifty yards or so, is so great that the nervous strain of crossing a street is nearly trebled, while cyclists are almost unanimous in testifying that obstacles of all sorts are much better seen and more easily avoided without a lamp.

Queries and Minor Notes.

BACTERIOLOGY IN HIGH SCHOOLS.

ATHOL, MASS., July 8, 1899.

To the Editor:—Will you kindly tell me whether there is any book published on bacteriology or germ life that is suitable as a text-book for an elementary course in high schools? Do you know of any high schools where such a course is adopted? What is your opinion of the value of such a course? Yours truly,

H. H. B.

ANSWER:—We know of no work especially adapted for high schools and doubt whether there is any general practice of teaching bacteriology in these institutions. So much depends on actual practical knowledge of the technic, that it appears to us doubtful whether any but the most general theoretic knowledge could be imparted in them. There are some small popular works, like Pruden's "Story of the Bacteria," and Conn's "Story of the Germ," but these are mere primers and hardly suitable for systematic instruction except of the most rudimentary kind. It would certainly seem to be a good thing if some general instruction on the subject, even if only rudimentary, could be imparted to the schools.

ACCREDITED MEDICAL COLLEGES.

GWAZALES, TEXAS, July 11, 1899.

To the Editor:—Will you kindly send me a list of the accredited reputa-

the medical colleges in the United States? What do you know of the diploma-mill in Chicago by the name of "The Independent" or "Collectum Independentia," or some such style? Respectfully, J. J. E.

ANSWER:—The "Appendix to the Twentieth Annual Report of the Illinois State Board of Health" contains a list of institutions recognized by the board. A copy of the list can perhaps be obtained from the secretary, Dr. J. A. Egan, Springfield, Ill.

The Independent Medical College of Chicago has no standing among reputable institutions, but is exclusively a diploma-mill. It has been proceeded against by the attorney-general, and under the new law it will undoubtedly soon be extinguished.

MEDICAL JOURNALS FOR DONATION.

CAFFEINE, ILL., July 6, 1899.

To the Editor:—I have complete files of the following medical periodicals: Phila. Med. and Surg. Reporter, 1870 to 1898; St. Louis Med. and Surg. Jour. 1867 to 1898; Obstetric Gaz., Cincinnati, first ten years; St. Louis Jour. of Med., 1885 to 1888; Chicago Med. Exam., 1863 to 1875; Va. Med. Semi-Monthly, 1889 to 1893; Compend Med. Sci., 1883-84-85; Annals of Surgery, 1888; "Breithwaite's Retrospect," several vols. These I will donate to any medical library, if any such can be found which will pay freight on them. I have them all properly filed and in good condition. Very truly yours, W. H. C.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including July 23, 1899:

Charles H. Alden, colonel and asst. surgeon-general, U. S. A., to represent the Medical Department at the meeting of the Association of U. S. Military Surgeons at Kansas City, Mo., in September next.

Carl H. Anderson, acting asst.-surgeon, from Washington, D. C., to San Francisco, Cal., for duty in the Department of California.

Guy G. Bailey, acting asst.-surgeon, from Mackinac Island, Mich., to San Francisco, Cal., for temporary duty in the Department.

William Bowen, captain and asst.-surgeon, Vols., assigned to the 27th Vol. Infantry at Camp Meade, Pa.

Henry H. Bradley, acting asst.-surgeon, orders directing him to report for duty with the 19th Infantry revoked; the revocation subsequently annulled.

George H. Calkins, acting asst.-surgeon, from Tonawanda, N. Y., to San Francisco, Cal., for duty in the Department.

John Ryan Devereux, acting asst.-surgeon, from Fort Hamilton, N. Y., to Camp Meade, Pa., for duty there.

F. A. E. Diano, acting asst.-surgeon, from New York City to Camp Meade, Pa., to accompany the 19th Infantry to Manila, P. I.

Douglas F. Duval, lieutenant and asst.-surgeon, U. S. A., leave of absence granted.

Richard M. Fletcher, acting asst.-surgeon, from Camp Wardner, Idaho, to Fort Harrison, Mont.

John J. Gilhuley, acting asst.-surgeon, from Bridgeport, Conn., to San Francisco, Cal., for duty in the Department.

Richard S. Griswold, lieutenant and asst.-surgeon, Vols., assigned to the 26th Vol. Infantry at Plattsburg Barracks, N. Y.

Thomas D. Ingram, acting asst. surgeon, sick leave granted.

Frank M. Kemp, lieutenant and asst.-surgeon, U. S. A., now in the Philippine Islands, is relieved from further station at Vancouver Barracks, Wash.

James S. Kennedy, acting asst.-surgeon, from Columbus Barracks, Ohio, to Fort Sam Houston, Texas.

Paul Mazzari, acting asst.-surgeon, from New Orleans, La., to Division of Cuba.

George F. Peed, lieutenant and asst.-surgeon, Vols., assigned to the 28th Vol. Infantry at Camp Meade, Pa.

Julius L. Powell, major and surgeon, U. S. A., delegated to the meeting of the Association of U. S. Military Surgeons at Kansas City, Mo., in September next.

L. B. Sandall, acting asst.-surgeon, from Au Sable, Mich., to San Francisco, Cal., for duty in the Department.

Paul F. Straub, captain and asst.-surgeon, U. S. A., now on duty in the Philippines, is relieved from further station at Camp Wrangel, Alaska.

George H. Torney, major and surgeon, U. S. A., delegate to the meeting of the Association of U. S. Military Surgeons at Kansas City, Mo., in September next.

Starling S. Wilcox, acting asst.-surgeon, to Columbus Barracks, Ohio.

Marine-Hospital Changes.—Official List of Changes of Station, and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended July 20, 1899. Surgeon Preston H. Bullbacher, to proceed to New York City for special temporary duty in the supervising depot.

Surgeon C. E. Banks, relieved from duty at Washington, D. C., and detailed as medical purveyor of the service at New York City.

P. A. Surgeon H. D. Geddiogs, to proceed to New York City for special temporary duty.

A. A. Surgeon M. J. Rosenau, detailed as inspecting quarantine officer for the island of Cuba.

Asst.-Surgeon L. D. Fricks, to proceed to the Brunswick Quarantine Station, Brunswick, Ga., for special temporary duty.

Asst.-Surgeon W. R. McAdam, granted seven days extension of leave of absence.

Asst.-Surgeon T. F. Richardson, relieved from duty at the Immigration Depot, New York City, and directed to proceed to Cienfuegos, Cuba, for temporary duty.

Asst.-Surgeon F. J. Thornbury, to proceed to Point Pleasant, N. J., for special temporary duty.

Sanitary Inspector R. E. L. Burford, granted leave of absence for seven days.

APPOINTMENTS.

Alanson Weeks, of Michigan, to be acting asst.-surgeon, U. S. Marine Hospital Service, for duty at the port of Chicago.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended July 22, 1899:

SMALLPOX—UNITED STATES.

California: Oakland, June 3 to 24, 2 cases, 1 death. Connecticut: Stamford, July 1, 1 case. District of Columbia: Washington, July 12, last two cases discharged. Georgia: Montgomery County, July 13, 9 cases. Kentucky: Louisville, July 6 to 13, 1 case. Maryland: Baltimore, July 5 to 15, 1 case. Massachusetts: Boston, July 8 to 15, 1 case. Texas: Sabine Pass, July 8 to 15, 2 cases. Washington: Almira, July 3, 9 cases; Spokane, July 1 to 8, 3 cases; Tacoma, July 1 to 8, 2 cases.

SMALLPOX—FOREIGN.

Austria: Hungary, Budapest, June 18 to July 2, 2 cases, 1 death; Vienna, June 24 to July 1, 1 death. Belgium: Antwerp, June 17 to July 1, 1 case, 1 death; Ghent, June 27 to July 1, 1 case. Ecuador: Guayaquil, June 3 to 10, 1 case. England: London, June 27 to July 1, 1 case. Egypt: Cairo, June 3 to 17, 4 deaths. France: Nantes, June 1 to 30, 1 case. Greece: Athens, June 27 to July 1, 21 cases, 9 deaths. India: Bombay, June 13 to 28, 6 deaths; Calcutta, June 3 to 10, 1 death. Mexico: Mexico, July 2 to 9, 7 cases, 9 deaths; Nuevo Laredo, July 1 to 8, 2 deaths.

Russia: Moscow, June 10 to 17, 16 cases, 8 deaths; Odessa, June 10 to 21, 2 deaths; St. Petersburg, June 16 to July 1, 34 cases, 7 deaths; Warsaw, June 3 to 24, 4 deaths.

Straits Settlements: Singapore, May 1 to June 10, 17 deaths. Turkey: Constantinople, July 9 to 19, 4 deaths.

YELLOW FEVER.

Brazil: Bahia, June 17 to July 1, 65 cases, 31 deaths. Colombia: Barranquilla, June 10 to 24, 2 cases, 2 deaths; Panama, June 27 to July 10, 17 cases, 9 deaths. Costa Rica: Punta Arenas, July 10, reported. Cuba: Santiago June 10 to 17, 6 cases, 1 death. Mexico: Mexico, July 6 to 13, 28 deaths; Vera Cruz, June 1 to July 6, 27 cases, 25 deaths. San Salvador: San Salvador, July 1, 1 case from Guatemala.

CHOLERA.

India: Bombay, June 13 to 20, 1 death; Calcutta, June 3 to 10, 10 deaths; Madras, June 3 to 9, 1 death.

PLAGUE.

Africa: French Ivory Coast, June 7, 500 deaths. Egypt: Alexandria, June 20, 42 cases to date, no deaths. India: Bombay, June 13 to 20, 53 deaths; Calcutta, June 3 to 10, 21 deaths.

Japan: Formosa, Tamsui, May 3 to 24, 318 cases, 225 deaths. Persia: Bushiro, present. Straits Settlements: Penang, January 1 to June 2, 20 cases, 17 deaths; Singapore, present.

CHANGE OF ADDRESS.

Bradley, C. H., from 9 W. 219 to 3609 4th Av. So., Minneapolis, Minn. Briggs, C. T., from City Hosp. to 191 Island Av., Minneapolis, Minn. Curtis, A. B., from Ferry to Maple City, Mich. Church, W. F., from Austin, Ill., to Delphi, Ind. Curtis, W. H., from Greencastle to Columbus, Ind. Dotterweich, F. V., from Cleveland to Ashland, Ind. Eastman, J. R., from 315 to 249 N. E., Indianapolis, Ind. Gray, G. A., from Minneapolis, Minn., to Mohawk RR., Spokane, Wash. Gallagher, M. L., from 650 Adams to 144 Oakwood Bou., Chicago. HARRISS, L. H., from Fairfield to Canandaigua, Mich. Hughes, T. D., from Arbroth to Ileria, La. Hardy, J. A., from Richmond to Kilmonach, Va. Johnson, J. M., from Omaha, Neb., to Birch Tree, Mo. Johnson, A. E., from 1744 N. Clark to 349 W. Chicago Av., Chicago. Knox, J. T., from 413 Broadway to 22 W. 7th, Cincinnati, Ohio. Kinnell, A. L., from 413 Broadway to 22 W. 7th, Cincinnati, Ohio. Kellough, G. M., from 314 N. Clark to 350 La Salle Av., Chicago. Kirby, H. W., from Pallid to Airheart Bk., Cripple Creek, Colo. Lowellen, F. W., from Brookfield, Mo., to Clarinda, Iowa. Math, E. R., from Washburn Av. and 31st St. to 709 S. Chicago Av., Chicago. Addresses.

SECTION ON LARYNGOLOGY AND OTOTOLOGY.

CHAIRMAN'S ADDRESS.*

BY EMIL MAYER, M.D.

Surgeon of the New York Eye and Ear Infirmary, Throat Dispensary;
Fellow of the American Laryngological Association and of the
New York Academy of Medicine; Member of the American
Medical Association, etc.

NEW YORK CITY.

With the advance in other branches of medicine in the past few years, otology and laryngology with their allied branches have fully kept pace. The otologist has made himself not only master of the indication pointing toward the involvement of disease in the adjoining sinuses, and in the cranial cavity, but the technics of operative procedure have been fully mastered, so that what was formerly done occasionally by the general surgeon, or more frequently was entirely unrecognized, is now promptly discovered and attended to by him.

In laryngology, intubation of a gradual nature by Schröter's tubes, or the O'Dwyer tube, has taken the place of tracheotomy in acute stenoses, while in the more chronic forms both tracheotomy and intubation may be required. In cases where a preliminary tracheotomy has been performed, the retention of the intubation-tube has been found to be frequently impossible. For such cases the ingenuity of Dr. John Rogers of New York City has come to the rescue with a most excellent and serviceable device. It consists of having a threaded opening made into the tube directly opposite the tracheal opening, and into this opening is screwed a solid hard-rubber tube which remains and absolutely prevents the tube from being coughed out. I have had most gratifying results from its use. The endolaryngeal method of removal of growths still betokens the greatest skill in the laryngologist. The curette has entirely taken the place of the cautery in the treatment of follicular pharyngitis, and the use of gargles for pharyngeal affections is shown to be rarely of avail.

In the treatment of nasal affections the greatest advance has been in the more conservative treatment of that hitherto abused organ. The various synechiae and subsequent sufferings occasioned by the indiscriminate use of saw and cautery have resulted in their practical disuse. There are many rhinologists whose saws are now accumulating the dust of time and whose galvanocautery tips rarely feel the glow of heat. The "beautiful results of the cautery of the inferior turbinate," as they have been termed, are now produced by other methods, painless, prompt, and free from subsequent discomforts.

"Many a nasal or pharyngeal mucous membrane has been practically ruined by the indiscriminate use of the cautery or knife for the relief of existing disturbances, the sole object apparently being to give space regardless

of the destruction of tissue. Had the treatment been directed toward the true cause, the nasal mucosa would have remained intact and after the relief of the congestion the individual would have left a normal secreting mucous membrane." This statement, just quoted, is from a very recent and valuable paper by one of our own members, and coincides exactly with my own experience. Whatever of good there might have been in some carefully selected cases by the use of the cautery was more than counterbalanced by the greater harm that was occasioned by promiscuous applications and in hands unskilled. Even in practiced hands it often happened that parts not intended to be touched were frequently the recipients of the sears of the cautery.

To acknowledge former errors is part of our duty and it is distinctly an advance when safer methods take the place of former crude ones. These are some few of the advances that have been made in our work; to mention all would be to review the whole literature of the past few years, a task that would be onerous to me, and also to you to be compelled to listen.

From time immemorial it has been the custom of physicians to present the results of their brain-work, whether it be in the shape of a new remedy, a new instrument or a new operation, freely to the profession, and without expectation of reward. We have come to accept these offerings quite as a matter of fact, for each of us would do the same. We are often not only indifferent, but we find fault with or try to improve on the original. Our praise, when it is bestowed, is apt to be faint, far too faint. Can we say now that we did all we should have done for our fellow countryman, O'Dwyer? His instruments and his labor will live though he has passed away; some fitting memorial will be erected to commemorate his genius and the triumph of an American physician, but how much grander and nobler it would have been had it been given in his lifetime! Since his too early demise we learn that so great a benefactor to his race, and so competent a physician, always had with him the carking load of care in the struggle for existence, and that he died practically a poor man. Oh, that we might have done better!

Wilhelm Meyer, to whom the world owes so much, had some credit in his lifetime, and a monument to his memory has been erected by the contribution of children from all over the world, and yet, so matter of fact are we that I once heard a physician say that he would not attend a certain meeting at which a paper on adenoids was to be read because someone was sure to mention Wilhelm Meyer and he was "sick of it."

It is not so many years ago that a young medical student at Vienna discovered the effects of cocaine. How much human suffering has been saved by its use, what a boon it has been to humanity, you know full well. What commensurate credit in his birthplace or in the land of his adoption has its discoverer received? None that I know of.

At a recent meeting of a large medical society, a

*Presented to the Section on Laryngology and Otology, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

speaker said that he objected to the naming of a disease or a symptom after its first investigator because it was puzzling to the student of medicine, and hence he objected to such terms as Basedow's disease, Colles' fracture, etc.

These few instances of many that might be cited give ample proof that we are far too lukewarm and too chary in our praise. In the last instance here quoted, without taking the speaker too seriously, I would say that his remarks should be positively condemned. I am not aware that the medical student seeks our solicitude, but if he does, it will be in vain, for we were able to cope with such things, nor is he any better than the student of chemistry, botany or astronomy for instance. A new chemical, a new flower or planet bears the name of its discoverer, why not an instrument or a disease?

Instead of indifference, would it not be better then if we cultivated "that most aristocratic of all virtues," appreciation? Why should we, like the proverbial republic, be ungrateful? If it were known that as a recompense for the obedience to duty that requires a medical man to give freely all that he knows for the benefit of mankind to his professional brethren, he would always receive the grateful and substantial plaudits of his colleagues, what an incentive to thorough work that would be. If, after careful investigation, it was found that his work was of such a nature that he was a benefactor to his race, a credit to his profession and to his country, some commensurate action should be taken in appreciation thereof. There is precedent enough for this.

While every soldier and sailor does his duty, yet we hail the returning hero with loud acclaim. His name is on every tongue, his deeds are sung in poetry and prose, we weave garlands to place upon his brow, we present him with swords and gifts innumerable and nothing is too great for us to do. The most facile pens describe his very action and his heroic deeds. What of the doctor? Are his deeds any the less heroic because unsung? Is his bravery any the less than that of his brother at arms who stands undaunted 'mid shot and shell? The bravery that fights the unseen foe in the most dreaded of all contagious diseases is every bit as great in him as in the other. No one is there to chronicle, and none stands ready to cheer and encourage—only duty, nothing more. Marble is enduring, and much may be placed thereon, but the eye that its words would gladden most sees it not, nor do his pulses thrill at its laudatory words, and no smile of gladness can they evoke. How much better it would be if we showed our gratitude during his lifetime. How amply rewarded such a one would feel to receive the plaudits of his brethren—the most competent of judges. What a gratification it would be if, when we acted thus, we saw how lastingly happy we had made him as we said, "Well done, thou good and faithful servant." With such incentive then, there would be no temptation to cease doing good work, for all would know that there is something still better to be had than is conveyed by the meaningless phrase, "Virtue is its own reward."

GERMANY is about to establish a school for the study of tropical diseases in Hamburg. The Medical Faculty of Berlin, led by Prof. Koch, desired the institution located at Berlin as a department of the Institute for Infectious Diseases. The Government, however, is of the opinion that from the fact that as Hamburg nearly always has patients from the tropics in her hospitals suffering from diseases which are of purely tropical nature, it would be a preferable location.

NEUROLOGY AND PSYCHIATRY.*

PROGRESS THEREIN FOR THE YEAR.

CHAIRMAN'S ADDRESS.

BY FREDERICK PETERSON, M.D.

NEW YORK CITY.

There is but one excuse to offer you for the infliction of an annual address at a Section meeting, and that is that it is a requirement of the By-Laws, from which I quote as follows:

The chairman of each Section shall prepare an address on the recent advancements in the branches belonging to his Section, including suggestions in regard to improvements in methods of work, and present the same to the Section over which he presides, on the first day of the annual meeting. The reading of such address not to occupy more than forty minutes.

I shall endeavor to fulfill the obligation thus placed upon me, to your satisfaction, by making the address a very brief one, for I shall be especially careful not to avail myself of the dangerous prerogative of occupying forty minutes should I so choose. Since I am required, in addition to presenting to you the facts of recent progress in our branch of medicine, to include "suggestions in regard to improvements in methods of work," I shall include just one such suggestion, viz., that the annual address referred to be hereafter dispensed with or curtailed to remarks not to occupy more than five minutes. I think this a very reasonable suggestion. An annual address which touches upon "recent advancements" in medicine in a general way is proper for the entire body of physicians here gathered together in one great organization, but for the Sections themselves, which are here for the summing up and discussion of the work of their members during the year, an annual address is unnecessary as well as prodigal of precious time. The chairman who would attempt to present to the members of this Section an epitome of the work done in neurology and psychiatry for one year would have a vast and wearying labor to perform, even in collecting the titles only of the many contributors in these subjects, for I am informed that there are some thirty-five hundred articles, pamphlets and books relating to our special line of work now issued yearly. Should the chairman desire to present a review to date of a somewhat new subject, such as, let us say, the cytology of the nerve-cell, he would have to examine four hundred different contributions, books and journal articles by two hundred and eighty authors, in order to write an exhaustive critique of nervous cytology.¹ I have gathered together here, however, in lieu of such an athletic study, and merely to indicate the extraordinary activity of workers in our domain at the present day, a bibliography of neurology and psychiatry and allied subjects for the year 1898 and this early part of the year 1899. I have limited this bibliography to books of over fifty pages. The innumerable pages and articles in medical periodicals are not included. I have the list here, but will spare you the weariness of hearing the titles read. Suffice it to say that there are two hundred and one books under the following headings:

Anatomy of the Nervous System, Human and Comparative	10
Anatomy and Physiology of the Nerve-Cell	12
General Neurology	48
Medical Jurisprudence	7
Criminal Anthropology	4
General Psychiatry	27
General Relation of Mind and Body	11

*Presented to the Section on Neurology and Medical Jurisprudence, at the Fifteenth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1898.

¹Bibliography of the Cytology of the Nerve-Cell. Smith Ely Jelliffe, M.D.

Aphasia 6
 Sense Organs 9
 Chronic Poisoning 2
 Special Psychology and Sexual Psychology 21

BIBLIOGRAPHY OF NEUROLOGY AND PSYCHIATRY AND ALLIED BRANCHES. JAN., 1898; MAY 1, 1898.*

* Including works of 50 pages and over. Citations which are not dated appeared in 1898, those of 1899 are so noted.

ANATOMY—HUMAN AND COMPARATIVE.

Boari, E.: Elementi di anatomia, semeiologia e diagnostico del sistema nervoso. Vol. I. Bologna, 1899, Pp. 344.
 Edinger, L.: Untersuchungen über die vergleichende Anatomie des Gehirns. 4. Studien über das Zwischenhirn der Reptilien. Frankfurt, 1899.
 Gaupp, É.: Anatomie des Frosches. I. Lehrv. vom Nervensystem. 1899.
 Davies, H.: The Cerebellum. London, 1898.
 Gegenbaur, C.: Vergleichende Anatomie der Wirbelthiere. Leipzig, Vol. I. Nervensystem.
 Koester, R.: Über das Rückenmark einiger Teleostier. Hirschwald, 1899, Pp. 88.
 Smith, G. S.: The Brain in the Edentata. London, 1899, Pp. 118.
 Flatau, E.: Atlas des menschliche Gehirns und des Faserverlaufes. Berlin, 1898.
 Flatau and Jacobsen: Vergleichende Anatomie des Gehirns der Säugetiere. Karger Berlin, 1899, Pp. 1000, c.
 Boyce, R.: A Contribution to the Study of Some of the Decussating Tracts of the Mid and Inter-brain. London, 1899, Pp. 432.
 Barker, L. F.: Structure of the Nervous System. Appleton, 1899.
 Fusari: Loc. cit. (General Relation of Mind to Body.)
 Edinger: Loc. cit. (Nervocell.)

ANATOMY—GENERAL.

Jacob, C.: Sistema nervosa. Tr. into Italian, Milan, 1899.
 Edinger, L.: Lezioni sulla struttura degli organi nervosi centrali. Italian translation. Milan, 1899, Pp. 436.

NEURVE-CELL. ANATOMY AND PHYSIOLOGY

Böhler, A.: Untersuchungen über den Bau der Nervenzellen. Wurzburg, Pp. 108.
 Deschamps, J.: Étude sur les principes et les applications de la physiologie et de la pathologie cellulaire. Paris, Pp. 104.

I am unprepared to give you even an outline of the genuine progress made in the sciences compassed by the bibliography just cited. I am inclined to single out, however, one seemingly unimportant thing from this great array of monographs for special comment. It is a book of one hundred and twenty pages² bearing the date 1899, and is a description of a psychopathic hospital in a German city, the newest and finest of them all. Many neurologists would find, perhaps, little in such a volume to interest them, but such as have had asylum experience, or are familiar with the needs of the insane, will hail its publication with enthusiasm, for it describes a method of provision for the insane and a scheme of laboratory investigation, a model psychiatric institution, which is destined to be imitated in many of our larger cities before many years have passed. I shall not dwell long upon the subject here, because I have quite recently published an address, delivered two weeks ago as the Annual Address to the American Medico-Psychological Association, in which the new era in psychiatry and psychiatric methods is discussed in detail. Suffice it to say then that this psychopathic hospital in the town of Giessen, which, modified to suit varying conditions and circumstances, is to be the model for similar foundations in all your American cities of 50,000 to 100,000 inhabitants, consists of ten or eleven cottages for some 116 patients. It is situated near the other university buildings. The central structure contains laboratories for pathologic, microscopic, chemical, photographic and psycho-physical work, besides a mechanical workshop, clinical auditorium, library and polyclinic or dispensary for out-of-door patients. The administrative offices and rooms for assistant physicians are also here. The cottages afford accommodations for each sex, and the patients are divided into private, quiet, restless, suicidal and disturbed classes in separate buildings.

There are many of these psychopathic hospitals in Germany. Indeed, only one university town is now without one. I saw them in successful operation even in my student days at Strassburg, Leipzig and Vienna. This at Giessen was first opened for patients in 1896, and deserves special mention and consideration because it embodies all that is best in this species of institution, the management having profited by the experience of all the others up to the date of its construction. The psychopathic hospital solves many problems, among them improved opportunities for collaborative study by scientific investigation in different branches of research, better facilities for clinical study, a greater diffusion of a knowledge of psychiatry among practitioners and students, and last, but not least, earlier and speedier treatment of the unfortunate patients.

The psychopathic hospital for the acutely insane lo-

cated in the midst of the city, following the precedent of general hospitals in this regard, is the ideal institution of the future for this particular class. The chronic insane on the other hand will be transferred to the country, always in the neighborhood of the city having the detention hospital, and will there be cared for in colonies, for the colony or village system has proved to be the ideal method of cure for the chronic insane. The colony will consist of a small hospital for the sick and injured, a small infirmary for the infirm, crippled, bed-ridden and disturbed cases, and a multitude of small cottages clustered about the centers of industry, where the majority of the patients will occupy themselves with agriculture and handiwork of all descriptions. This colony system or village community system is not new and I have myself seen several of them successfully conducted in other countries.

I will not occupy your time longer by entering into the minutiae of these two methods of state care of the insane, but I thought I would exercise the prerogative of chairman, in calling your attention to the psychopathic hospital and the colony as among "the improvements in methods of work" referred to in the By-Laws above quoted. A little seed disseminated in this way will take root somewhere, spring into existence, and some day bear fruit. Perhaps a few years hence some of you may describe to us here in this Section the model institutes for psychiatry you have builded in your cities and point out to us the great improvements you have made on old-world models.

APPENDICITIS.*

ITS DIAGNOSIS AND TREATMENT: A REPORT OF ONE HUNDRED AND TWELVE CASES.

BY WILL J. MEANS, A.M., M.D.

Professor of Principles and Practice of Surgery, Ohio Medical University; Surgeon in Chief to Protestant Hospital, COLUMBUS, OHIO.

As a preface to my remarks, I wish to submit a report of 112 cases that came under my observation, 82 of which were treated by operation and 30 by medicinal measures. In submitting this report I have not attempted a detailed outline of each case, as there is a sameness in many of the cases that would make such an outline monotonous. I have, therefore, grouped similar ones.

Of the 82 cases operated on there were 2 fatalities. One of these was operated on the fifth day, and had diffuse suppurative peritonitis. The other patient was one of chronic appendicitis, and the cause of death was obscure. Immediately after the operation she began vomiting coffee-ground material, and continued to do so until her death, which occurred seventy-two hours later.

The ages of the patients, grouped in decades, were as follows:

Under 10	10
10 to 20	25
20 to 30	28
30 to 40	20
40 to 50	19
50 upward	10

Of the operated cases 30 were acute and 52 chronic or recurrent. In speaking of acute cases I refer to those giving no history of previous attacks. Of the 112 cases reported, 45 cases were females, and 67 males.

*Presented to the Section on Surgery and Anatomy, at the Fiftyth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June, 6-9, 1898.

² Die Psychiatrische Klinik zu Giessen. Published by S. Karzer, Berlin, 1896.

In 9 cases the operation was made within twenty-four hours after the attack. The appendix was ruptured in 5 of these, and coprolites found escaping through the opening. In the other 4 the appendix was inflamed, the mucosa showing pathologic changes, and the surrounding tissues more or less involved. In 17 cases operated within forty-eight hours of the attack, the appendix was gangrenous in 10. This was caused from one or more strictures occluding the canal, the presence of concretions, and the intensity of the inflammation due to the virulent matter coming in contact with peritoneal surface. The omental folds were more or less adherent and gangrenous. In 7 cases the lumen of the appendix was intact, but there was inflammation of the surrounding tissues with adhesions; and in 4 cases dilatation of the proximal ends; coprolites were found in 9 of this group. Twenty-three cases were operated within seventy-two hours. In 20 of these the appendix was gangrenous in some portion. Localized abscesses existed in 20. The remaining 3 were cases of catarrhal appendicitis with more or less inflammation of the surrounding tissues. In 25 cases the operation was made after the third day, and as late as three weeks. There were abscesses in 20 of these. One had diffuse suppurative peritonitis, and died from the operation, and 5 cases were catarrhal. The mucosa of the appendix was more or less diseased, but the lumen was unobstructed. The appendix was more or less gangrenous in all the cases where there was an abscess. In 9 the appendix was not removed. It was found imbedded in the granulation tissue forming the wall of the abscess. In 16 cases operated between the attacks, the appendix was obliterated in one. The tenderness and pain in this case were due to adhesions surrounding the cecum. There had evidently been an abscess in some former attack, and the contents had passed off through the bowel. Coprolites were found in 25 cases, foreign bodies in none, strictures in 19. Fecal fistula followed in 4. These closed spontaneously in the course of a few months. Hernia, so far as I have been able to ascertain, followed in 6 cases. In every instance this sequela followed in the cases where the abscess was adherent to the peritoneal wall. The appendix was found attached to the right ovary in 5 cases; to the right Fallopian tube in 7; to the uterus in 4; in one case to the gall-bladder; in 3 cases I found the appendix attached to the sac of irreducible inguinal hernias.

I have made eighty-four operations for appendicitis, and was mistaken in my diagnosis in two. One of these was a cholelithiasis; the gall-bladder was dragged down to the ileocecal fossa, and presented a tumor with the outlines of an appendicular abscess; thirty gall-stones were removed. The other case was a pyosalpinx, with the tumor extending into the iliac region. In this case, however, the appendix was attached to the tumor, and the distal extremity much inflamed.

Of the 30 cases treated medicinally, 8 died from septic peritonitis; 12 of the 22 who recovered had recurrent attacks; of the remaining 10 cases I am unable to give any history.

An operation was advised in quite a number of these cases, but, owing to the objection of friends and the attending physician, it was not made. In 5 cases of those that died I refused to operate, owing to the condition of the patients at the time I saw them.

It has been my observation rather than my experience, that where there is profound septicemia, complete paresis of the bowel, with a pulse-rate entirely out of proportion to the temperature, an operation is useless.

The percentage of deaths in the 82 cases operated is 2.4, the percentage in those treated medicinally is 26.6.

I have tried to summarize the lessons that I have learned from these cases. Several important facts bearing upon the pathologic conditions, diagnosis, and treatment of appendicitis have been settled in my mind. I am fully aware that other surgeons have had a much wider experience than mine; but the examination of their statistics does not develop any material points of difference from the conclusions that I have reached.

As it is not my purpose to consider the pathologic conditions in this paper, I will pass from this part of the summary and take up the matter of diagnosis.

Few diseases have a more uniform set of symptoms than appendicitis. There are, however, two types of cases; one having typical symptoms, and the other atypical symptoms. The typical symptoms of appendicitis, as we understand them, are: 1, the sudden onset of attack; 2, the character and location of the pain; 3, tenderness in the right ileocecal fossa, and muscular rigidity; 4, nausea, and perhaps vomiting, with more or less febrile action.

If these symptoms were all present in a given case, there could scarcely be any mistake in diagnosis; but unfortunately they are not all present at the same time. Any one or two of them may be absent, or being present, may be due to some other disease. For instance, the sudden attack is generally characteristic of abdominal trouble. Acute peritonitis, from whatever source, may give rise to the same symptoms.

Pain is also a variable symptom, both as to location and intensity. While pain in typical cases is usually near the umbilicus, radiating over the abdomen, it may be at other points. Its location depends largely upon the location of the appendix. If the appendix extends upward toward the gall-bladder, the pain may be very easily mistaken for cholecystitis. If the appendix be behind the ascending colon, the pain may be mistaken for renal colic. In this location the pain will sometimes extend to the testicle, the same as in renal colic. Again, the sympathetic nervous system often plays an important role as to the location of the pain. Physicians are all familiar with the pain in the right shoulder in cases of peritonitis. This reflex pain may be deceptive, but if the local conditions are carefully examined the deception is easily determined. There may be an entire absence of pain. While this fortunately is not the fact in many cases, yet it is one that must be recognized in making a diagnosis. Pain does not always indicate the pathologic conditions. It has not been very long since surgeons attempted to point out how the pathologic conditions could be determined by the character of the pain. Experience has taught us, however, that this is radically wrong. I shall speak more of this, however, under the head of treatment. We now understand that pain may be indicative of gangrene, or it may on the other hand, indicate resolution.

Tenderness and muscular rigidity in the right ileocecal fossa are nearly always pathognomonic of a diseased appendix. In the onset, tenderness may exist in a large area, but in a short time it becomes limited and confined to the ileocecal region. Tenderness always varies according to the location of the appendix. As suggested when speaking of the variableness of pain, tenderness may be absent; and when it is absent, it may be due to a gangrenous condition, or one of resolution. Rigidity of the muscles on the right side of the abdomen is an important symptom. With rigidity of the muscles on the right side of the abdomen, and its absence on the left, there

can be scarcely any doubt as to the location of the trouble. Constipation usually exists, although this is not properly a diagnostic symptom. Nausea and fever go to make up the picture that completes the diagnosis. Fever is a variable symptom. The temperature may be quite high during the first twenty-four hours, and then subside, remaining low, although important pathologic changes are taking place. Nausea and vomiting may be present in the first twenty-four hours, but usually subside after that.

Tumor as a secondary symptom is important. It existed in about 35 per cent. of the cases reported in this paper. A tumor is not always indicative of pus. In a number of cases I have found the swelling due to the enlargement of the glands of the mesentery and the infiltration of the tissues surrounding the cecum and appendix. In one case the cellular tissues beneath the peritoneum were swollen to the size of a small orange. Tympanitis is a constant symptom in acute cases, and one of considerable diagnostic value.

Another important factor that has been established beyond question, is that in males peritonitis has its origin almost exclusively in the appendix; while in females the Fallopian tubes, as well as the appendix, are important factors in the production of peritonitis. These points should be borne in mind in determining the source of peritonitis in any given case. It might be supposed, if this observation is true, that females, owing to their double exposure, would suffer more from peritonitis than males. Statistics show that this is probably true. It seems that males are more prone to appendicitis than females. I have recently noted some statistics where this statement is not borne out; but from my own experience, and that of many others, the ratio is about 60 per cent. male to 40 per cent. females.

Leucocytosis is a condition that takes place in the blood in all acute inflammatory diseases. It is, therefore, of value in determining the presence of pus in appendicitis. The leucocytes increase in proportion to the destructive changes taking place. This important blood-change may also furnish valuable points in differentiating from typhoid fever, floating kidney, fecal impaction, hepatic and renal colic. In general practice, however, I doubt very much if a blood examination, considering the technical skill required, would be of much value. I have not made blood examination a routine practice even in the hospital. In cases where there existed some doubt as to the presence of pus, examination of the blood was made, and in every case where a high degree of leucocytosis existed, an operation developed pus. All the cases examined were operated, and pus was found in them. The degree of leucocytosis, according to these cases, seems to be determined by the amount of destruction going on in the abdomen.

Evidence of the existence of the disease may be determined by skillful palpation. It is best made by Edebohl's method:

"The patient lies on his back with limbs flexed at the hips. Placing three or four fingers of the right hand flat on the abdomen, we feel for the margin of the right rectus muscle, in the line between the navel and the anterior superior spine of the ilium. The fingers are introduced with a light, steady pressure under the margin of the rectus until we feel distinctly the pulsation of the common iliac artery. The appendix is felt, as a rule, just outside the artery, its insertion about an inch distant, while its tip often crosses the artery. We move the fingers slowly outward as soon as we feel the

pulsation of the artery and note with care the condition of the posterior abdominal wall—that is, the iliopsoas muscle covered with the iliac fascia. This is the point of resistance against which we compress the appendix and which makes it possible to palpate it." When there is much tenderness and rigidity of the muscles, it will be almost impossible to feel the appendix; and again, if the appendix extends upward behind the colon, it cannot be discovered. However, with experience, a skillful manipulator will be able to determine the outlines of the appendix in a large percentage of cases.

The pulse and temperature considered together are important. A high temperature with a high pulse indicate simply an acute inflammatory process. When the pulse and temperature part company, serious pathologic changes have taken place. A low temperature with a high pulse indicates a toxemia that bodes ill to the patient.

There are other points in the differential diagnosis that might be mentioned. Renal colic is perhaps one of the most difficult cases from which to differentiate. We, however, should bear in mind that in appendicitis, while the pain is constant it is progressive in its intensity, and in renal colic while the pain is constant, the intensity is not increased. In renal colic, when the pain ceases, it ceases instantly; in appendicitis it ceases gradually.

Then again, in a limited number of cases where the appendix is behind the colon, the pain may extend to the testicle, the same as in renal colic. If other characteristic symptoms of appendicitis are present and the peculiar progressive character of the pain is recognized, it is possible to differentiate from renal colic.

In gall-stone colic there is nausea and vomiting, and they usually continue for several days; in fact, the gastric disturbance is characteristic of disease of the gall-bladder. The location of pain in gall-stone colic is in the epigastrium, and it radiates toward the shoulder and scapula. The seat of tenderness is also usually over the gall-bladder, while in appendicitis it is over McBurney's point.

In the female there may be some difficulty in differentiating between appendicitis and salpingitis. In the early stage the differentiation can be made much more readily than later when pus has formed. The main points of difference are the acuteness of the attack in appendicitis, and its tendency to recurrence. The pain in appendicitis is more acute, and the location of the tenderness is different. A vaginal examination will reveal the seat of tenderness to be in the right pelvis; while in appendicitis the pelvic organs will not be tender. Chloroform narcosis may be necessary to complete a satisfactory examination.

The controversy that has been waged during the last decade as to whether appendicitis should be classed as a medical disease, a mixed disease, or a surgical disease, has been decided largely in favor of the surgeons. Some of our medical brethren still hold that appendicitis is both a medical and surgical disease, coming within the purview of the surgeon when the physician has failed to cure. I maintain that it is the consensus of opinion of the profession to-day that appendicitis is essentially a surgical disease, and should be treated from that standpoint. If there is any doubt as to the correctness of this view, a consideration of its pathology, and the entire absence of any remedial measures that will remove the pathologic conditions and bring about resolution, should be enough to definitely settle the question. There are certain remedies that may be prescribed to an advantage.

It is necessary when the pain is excruciating to resort to measures to relieve it. It may be necessary to relieve the bowels of impacted fecal matter, and to increase the action of the kidneys. Beyond this I have no confidence in medicinal measures. Remedies that simply give the patient a measure of relief without looking to an ultimate cure should not be relied upon other than for emergencies. The question settled that in surgery alone lies the hope of permanent cure in cases of appendicitis, the next question is to consider the time to operate.

Some of the leading surgeons of to-day have set forth the dictum that the patient should be operated upon as soon as the diagnosis has been made. With proper qualifications, I believe this to be the correct position. These qualifications are much the same as those that obtain in other surgical diseases. The same difference of opinion exists with reference to the amputation of an injured limb while the patient is in shock. There is no difference of opinion as to the necessity of the operation, but there is a question as to the most opportune time. This matter has largely resolved itself into one of judgment on the part of the surgeon; in other words, it is not a matter of prescribed rules, but one of surgical acumen. When a diagnosis of appendicitis has been made, the judgment of the surgeon should govern the time at which the operation should be performed. When I make the qualification that the judgment of the surgeon should point out to him the most opportune time for the operation, I mean that conditions that cannot be specified nor described by fixed rules may exist. It is my conviction, and it has grown stronger with more extended experience, that the earlier the operation the better for the patient. If the diagnosis is made within twenty-four hours of the attack, and the environments are such that the operation could be made, I believe there should be no delay. It is my rule at the present time to operate upon all cases as soon as I have made the diagnosis, if the condition of the patient is favorable, and his environments are such as to justify a surgical operation. I recognize no time limit.

It is unnecessary to describe the environments that might cause a postponement of an operation. These are obvious to every one who is familiar with modern surgery. There may be complications in the case that should be removed or corrected before operating. The conditions unfavorable to an immediate operation are not well defined. Rules elaborated a few years ago for our guidance are useless to-day. Some good surgeons advise, when the patient is seen after the third day, that operation should be postponed until after the attack, or until purulent formations, if such exist, have been walled off, and the patient is practically rid of general sepsis. I have operated after the third day, and during the attack, without any fatal results. My experience does not coincide, therefore, with this rule. During the last two years, I have not delayed operation longer than was necessary to give the patient advantage of the best possible surroundings.

General septic peritonitis might be considered a cause for delay, and, perhaps, for no operation at all. One of my fatal cases was of this type. I do not believe in last-resort operations. While they are sometimes successful, they are more often fatal. I have seen some desperate cases get well, but they were of the fibrinopurpurative type. The suppurative peritonitis is a more virulent condition, and the prognosis more grave.

There is a question as to the feasibility of operating

between the attacks of recurrent appendicitis. We are often confronted with the proposition that an operation will be submitted to after the existing attack has subsided. In the interim, if the patient is fortunate enough to recover, gratuitous advice both from neighbors and physician to wait until another attack, with the hope that it may not come, prevails, and there is another delay, jeopardizing the life of the patient. I can see no reason for treating these cases differently from those in a first attack.

Again, I do not believe the time for operation depends altogether upon the pathologic conditions we find in the patient at the time of our first visit. Some surgeons endeavor to divide the cases into classes, and to divide the time limitation for operation by the pathologic conditions found in each of these cases. When we consider that it is impossible to determine by examination the true pathologic conditions, these rules become ridiculous and unsatisfactory.

In a number of cases that I have operated on within twenty-four hours of the onset, I have found the appendix ruptured, and coprolites in the viscera, and a gangrenous condition of the surrounding tissues. Again, I have found in a large number of cases where the acute symptoms of the first twenty-four hours had subsided, with a temperature of 100 and a pulse corresponding, that an abscess had already formed. With this uncertainty as to the pathologic conditions, I cannot see the necessity, or the good judgment, of postponing an operation. Conservative surgeons (so-called) and physicians will tell us that a certain number of these cases will get well without an operation. They do not, however, tell us how many get entirely well. It is a matter of statistics that about 80 per cent. recover from the first attack. Of these we have no statistics to definitely determine the number in which the attacks are recurrent. Nor have we statistics that throw much light upon the complete recovery of the remainder. Because 80 per cent. of these cases get over the first attack is no reason why early operations should not be made. When statistics show a mortality of less than 5 per cent., with recoveries that are permanent in a large majority of the cases, there can be scarcely any question as to the feasibility of operating early. It seems to me in the light of experience and modern success, that the question of when to operate should be entirely one of surgical acumen, governed by the conditions of environment and complications.

Surgeons have exercised their ingenuity in devising methods of operating, and have established certain principles in the technic that make it an easy matter for those of less experience to select a safe and reliable method. The primary purpose is the obliteration of the appendix. The preparation of the field of operation is a matter of detail differing in no way from other abdominal operations.

The location of the incision is largely one of choice with the operator. It is my experience that no fixed rule can be followed. In some cases the incision should be made obliquely from without inward, well down toward Poupart's ligament; in others, along the outer border of the rectus muscle. It depends upon the location of the appendix and the diseased portion.

The length of the incision, while an important factor, depends upon the character of the trouble. An incision not exceeding one inch in length is sufficient for a large number of cases; but there are cases where it is necessary to make it four or five inches long. In abscess cases where the abscess wall is not adherent to the parie-

tal peritoneum, the incision should be of sufficient length to permit free access to the parts, and for packing with gauze to prevent the pus from permeating into other parts of the abdominal cavity.

The disposition of the appendix is a matter of some importance, but this depends largely upon the condition of the organ. In catarrhal appendicitis where the lumen of the organ is not constricted, it can be invaginated and carried within the bowel. The meso-appendix is ligated in several places, and cut close to the organ. With a probe or fine mouse-toothed forceps the extremity of the appendix is inverted, and pushed through the lumen into the bowel until the organ is disposed of. Three or four Lembert sutures are sufficient to close the opening. The question of the ultimate disposition of the appendix is not very well settled, but it is safe to presume that it will cause no trouble.

The next method, that of excision, is accomplished in various ways. The meso-appendix is tied off in sections, and if there are adhesions, they are broken up. The appendix and the cecum should be brought up through the incision, and gauze packed around them. The peritoneal coating is cut through about one-half inch from the cecum and stripped to the base. The appendix is then excised, and the stump inverted into the bowel. The peritoneal cuff is then inverted, and the opening closed with Lembert sutures. This is, perhaps, the simplest and safest method for ordinary cases. I have used the clamp and cautery method suggested by Dr. Eastman, but can express no particular preference for it. Where the base of the appendix is gangrenous, the surgeon must exercise his ingenuity in disposing of the opening into the cecum with a view of preventing a fecal fistula. This has occurred in four of my cases.

In cases where there is a deep-seated localized abscess, a free incision should be made. The abdominal cavity should be carefully protected with gauze, the appendix excised, and the abscess and necrotic tissues removed. In these cases I make it a rule, after carefully cleansing the cavity, to place a glass drainage-tube, which usually remains about forty-eight hours. When the abscess has approached the anterior wall of the abdomen, and becomes agglutinated, it is opened and drained. I make no effort to remove the appendix in such cases. The surgeon must of necessity have sufficient experience to comprehend the various conditions that may arise in each given case, and meet them accordingly.

In nine of the cases reported I did not complete the operation. While I believe in making a complete operation, yet in this class of cases I doubt very much the expediency of doing more than draining the abscess.

Closing the incision in clean cases is a procedure that differs in no way from that of other abdominal wounds, and therefore needs no special mention.

CONCLUSIONS.

1. An early diagnosis of appendicitis is desirable and possible if the few cardinal symptoms are understood, such as pain near the umbilicus, tenderness in the ilio-cecal region, tympanites, and rigidity of the muscles in the lower right quadrant of abdomen.

2. Too much significance should not be placed upon the presence or absence of pain, and high temperature. Both may be absent, while grave pathologic conditions are going on. They may also be present to a high degree without determining the pathologic status.

3. Appendicitis is a surgical disease, and should be treated from a surgical standpoint.

4. From the nature and location of the disease there

are no known remedies given internally or applied externally that can remove the trouble.

5. The pathologic conditions of a diseased appendix cannot be definitely determined by external examination, or from the existing symptoms.

6. Early operations give the best results.

7. The time for operation is when a diagnosis has been made, providing the environments of the patient are favorable, and there are no complications precluding the same.

8. The technic of the operation is governed largely by the taste of the operator and the pathologic conditions.

APPENDICITIS.*

ITS CAUSES, PREVENTION AND TREATMENT.

BY WILLIAM M. HARSHA, M.D.

Professor of Operative and Clinical Surgery, College of Physicians and Surgeons (University of Illinois Medical School).

CHICAGO.

Appendicitis is well characterized by Professor Osler as "the most important of acute intestinal disorders;" and it may be said further to bear a somewhat similar relation to active digestive disturbances that pneumonia does to acute bronchial affections.

The question most frequently asked by the people relates to the cause of the disease, the problem that most vexes the physician and surgeon is one of treatment, while the great frequency and fatality make its consideration of interest to us all. Among the etiologic factors is considered age—being essentially a disease of the young. The study of 157 cases occurring in some of the Chicago hospitals during the past year shows an average age of 26 years, the oldest in this number being 62, the youngest 1½ years. As showing the rarity of cases in extremes of life, but one of these cases was found under 7, and but three over 50 years. The writer has successfully operated on two patients, aged respectively 4½ and 5½ years for the past two years. The list referred to shows the influence of sex to correspond very nearly with Hawkins' tables—of 159 cases 93 were males, 66 females. The greater frequency in males is no doubt due to their greater exposure to injury, fatigue, colds and overindulgence in eating and drinking. The seasons affect materially the frequency of attacks—the greater number occurring during the summer months—more than half the cases under study occurring during the six months, June to November, or during the time when intestinal disorders most prevail. In the list considered the greatest number occurred in August; the fewest in the months of October and December.

While the disease is an infection, the infective agent is not uniform and the mechanical causation or excitement of the inflammation is believed to be the greater factor. Fecal concretions are found in nearly half of all the cases, sometimes bearing a nucleus of some hard, foreign body, such as a piece of bone, grape seed or bird shot; and showing evidence in their structure of their formation *in situ*. These concretions, by prolonged contact with the degenerate structure of the mucosa, make an atrium for infection or occlude the lumen and imprison secretions, bringing about distension and stasis followed by infection. The small size of the organ and its dependent position make congestive stenosis easy. Like the contracted cervix uteri or Fallopian tube, it may be patent most of the time; but congestion from dietetic errors or from sudden chilling of the surface, or

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

injury by fecal masses or otherwise, may suddenly occlude its lumen and directly appendicular colic results. If this stenosis is not relieved promptly the next infective and inflammatory stage soon follows.

The most frequent exciting cause, and especially in recurring cases, is believed to be errors of diet. Constipation, which is generally accompanied by a full cecum, may induce this condition of congestion and irritation at the outlet of the appendix which causes stenosis, or by extension may sooner or later involve the entire organ. Robin¹ believes a distinct form of gastric and intestinal indigestion, with what he terms coprostrasis, is responsible for most cases, and that treating this condition by castor-oil and enemata will prevent attacks. Typhoid fever, especially, and other debilitating conditions predispose to attacks. Osler cites a case where bird shot were found in the appendix. Bernays found calomel and bismuth forming nuclei of fecal concretions. From the dependent position of the appendix and the tendency of heavy substances to gravitate into the organ we may consider appendicitis—like hernia and hemorrhoids, but in less degree—a penalty imposed on man for getting on end. Traumatism and severe exertion are frequent exciting causes, as are also chilling of the surface determining the blood to the viscera.

Viewing the etiology in this light, prevention seems possible many times, although hardly demonstrable. These means of prevention apply to other conditions and have the advantage of uniform safety. The disease is so frequent and dangerous, however, that its consideration alone should lend the commonest rules of health new dignity. These are moderation at the table, careful regulation of the bowels and care in diet, prompt attention to digestive disturbances and care to avoid the ills of physical overexertion and taking colds. As Robin advises, treatment should be directed to those dyspeptic conditions attended with distension, catarrhal gastric intestinal affections or colonic torpidity. Castor-oil or salines are favorites with most physicians, and perhaps when more used in our forefathers' time prevented many attacks. Colonic flushing in fecal retention is of great value. If we shall accept the view that gastric or intestinal disturbances are possible harbingers of appendicitis, as we regard acute bronchial affections in their relation to pneumonia, we shall by timely treatment ward off many attacks. In the matter of treatment there is yet a great variety of opinion. In view of the large number of cases that recover from first attacks, and remain well, under prompt rational medical treatment, surgeons can not in my view properly recommend operation in all cases, although early operation in proper cases has lowered the mortality.

The study of eighty cases of the list referred to shows a mortality of about 10 per cent. Of cases operated on up to the fourth day all but one recovered, and that was operated on the second day. As hospital reports represent cases of more than average severity—many of the light ones being left at home—we can safely expect a much lower mortality under surgical supervision of all cases, and early operations in proper ones. If people are advised to call a physician promptly for diagnosis in cases of sore throat they should likewise be instructed to attend to stomach and intestinal disorders, as many times attacks may be warded off, or aborted after actual occurrence. In ten cases observed by the writer during the months of April and May, last past, six were distinctly attributed to, and preceded by, digestive derangements,

usually two to four days elapsing between the onset of intestinal and gastric disorders and the characteristic symptoms of appendicitis.

The treatment in these cases was in general, evacuants, salines, calomel, enemata, rest in recumbency, hot (antiseptic) fomentations. If seen at the onset, this treatment is tried for thirty-six hours; except in fulminant cases, which would be operated on at once, codein is used, if urgent, to allay pain. In four of the ten cases so treated from onset, three recovered without operation. In cases seen later, operation is advised if tumor is present or temperature or accelerated pulse continues. In the dietetic and supporting treatment where liquid diet is indicated, as it is in operative or inoperative cases, as well as in many other debilitating conditions, I have used Reed & Carnick's beef peptonoids and trophinin, and Parke, Davis & Co.'s beef jelly, with the greatest satisfaction, as many patients can not take milk. In one other case of the four mentioned operation was advised at the end of thirty-six hours, but the patient began to improve then, and recovery proceeded without operation. Two of the ten cases were recurrent and were operated on in the quiescent stage. All recurrent cases should be operated on between attacks or at onset of attack. Six of the ten were operated on, and the appendix removed in all but two, in which there were abscesses. All recovered, if we may count the two last operated on, which are practically well at this writing.

Where cathartics could not be retained I have used hypodermically, a tablet consisting of physostigmin sulph., 1-50 grain, and magnesium sulph., 1.84 grain. In twelve trials catharsis was produced in four to seven hours in five cases. The strength of the magnesium solution should not be greater than 2 per cent.

103 State Street.

DISCUSSION ON APPENDICITIS.*

DR. KEEN, Philadelphia—I am more radical than my friend, Dr. Deaver. He, if I understand him rightly, considers that general suppurative peritonitis is a contraindication of operation. This view I cannot accede to. The very fact that a patient has a general purulent peritonitis as the result of an appendicitis or from any other cause, means to me, instant and thorough operation, for the very reason that if you let such a patient alone he is absolutely sure to die. That the majority of those who are attacked with a suppurative peritonitis will die, operation or no operation, is certainly true—a large majority of them—but every one rescued is one rescued from the grave. That these cases are not without hope, I am absolutely certain, both from my reading and from my experience, for I could recount a half dozen cases in my own practice in which life has certainly been saved after a general infectious peritonitis—not saved simply by an ordinary operation for appendicitis, but by an incision on both sides, which will allow thorough flushing of the entire abdominal cavity.

Of the other paper, I wish to say a few words. Dr. Morris excuses his attack by alleging a *mens conscia recti*. I am reminded of two rival shoe stores on opposite sides of the same street, one of which placed on the sign: "*Mens Conscia Recti*." The other, not to be outdone, put on his: "*Men's and Women's Conscia Recti*."

The notice that Dr. Morris stated that he had sent to each one of the persons attacked, by some delay of the U. S. mail never reached me, and my first knowledge of it came by a verbal statement two or three days ago from a friend, notifying me that I was to be attacked. But we must remember that only a year has elapsed since the Denver meeting. He is right in saying that at the last meeting of this Section I challenged any one in the room who believed he could do a hundred abdominal sections on well patients even, and not have 2 per cent. mortality, and not a man or woman in the room

* This discussion covers a series of six papers, the other four having appeared in the JOURNAL as follows: "Best Methods in Treatment of Appendicitis," by Robt. T. Morris, July 15; "Appendicitis," by A. J. Ochsner, and "Appendical Pus," by John B. Deaver, July 22; "The Processus Vermiformis," by G. G. Eitel, July 29.

¹ International Clinics, Phila., 38, 8, 104.

responded to that challenge; not one took it up. I am perfectly well aware that several of the best surgeons can show less than 2 per cent. mortality. But, remember, we are debating here to-day not a rule for surgeons like Deaver, McBurney and Morris, but we are debating this question from the point of view of a general rule for the general practitioner—and do you mean to tell me that the doctor at a country cross-roads, in a village, the man who does a surgical operation, once, twice, it may possibly be ten times a year, who, in many cases is not familiar with modern methods of cleansing the hands, of cleansing the skin, of taking the antiseptic precautions known to you and me, is to follow a general rule that we are to lay down for such a practitioner that he is to operate indiscriminately, and then state that he will not have a mortality of 2 per cent! I protest against it! It is not true! I believe in operation. I believe the rule should be operation, but the rule is proved by many an exception, and that which is a rule for the city surgeon who is operating every day is not the rule for the country surgeon who operates only once in a while.

THE CHAIRMAN—I ask Dr. Murphy of Chicago down to the stand.

DR. J. B. MURPHY, Chicago—It is very difficult to decide just what to say on this colossal subject in six minutes. From Dr. Keen's last statement—if I interpret him properly—I understand that he believes the cases should be operated on if they were in competent hands. Is that correct?

DR. KEEN—Certainly.

DR. MURPHY—Do you believe that *all* cases should be operated on in competent hands?

DR. KEEN—No.

DR. MURPHY—Do you believe all cases in the first twenty-four hours—if seen in twenty-four hours and if a competent surgeon is at hand—should be operated on?

DR. KEEN—With exceptions, yes; not all.

DR. MURPHY—May I ask the exceptions?

DR. KEEN—Certainly. There is an immense difference in the gravity of the cases. A severe case seen in the first twenty-four hours, in the hands of any reasonably competent surgeon, should undoubtedly be operated on at once. A mild case is a very different thing, and many of these should not be operated on in the first twenty-four hours, and sometimes not at all.

DR. MURPHY—Another question. What is a mild case in the first twenty-four hours?

DR. BEVAN—I object to the cross-questioning of the witness. I direct to this method of conducting questions.

CHAIRMAN—The Doctor is in order.

DR. MURPHY—If anyone has a better spirit or a better feeling for Dr. Keen's great surgical skill than I have, I would like to see him. I love him for the work he has done. I am up here for the sole purpose of trying to arrive at some conclusion, at some line of action, at some position whereby all other great surgeons of America can say: "There is a line, and we will try and follow it"—something to guide us in this darkness, something to prevent the death and devastation that every year comes on from appendicitis—that is why I ask Dr. Keen these questions. I think you feel that (indicating Dr. Keen).

DR. KEEN—Certainly, and I quite agree with Dr. Murphy that this is a serious matter, that all want to arrive at the truth. I am just as anxious as Dr. Murphy and I quite reciprocate his kind expressions of feeling toward me, as to his own work in appendicitis. Will you kindly repeat the question?

DR. MURPHY—The question was: "What would you call a mild case in the first day of appendicitis? What would be considered a mild case?"

DR. KEEN—I have seen, and do not doubt that every one in this room has seen, cases in which even the diagnosis was itself doubtful, in which there was slight tenderness, little or no fever; it may be even by the end of the first twenty-four hours that these symptoms are subsiding, and I submit that in every such case it is not proper in all cases to operate in the first twenty-four hours.

DR. MURPHY—Thank you. With that as a basis for discussion, I can say that I might safely agree with Dr. Keen. But, gentlemen, how rarely do we find these very mild cases that remain mild cases for another twenty-four hours? No, sir. Who is the man who can say: "I feel from the course that this case is taking in the first twenty-four hours, that in the next twenty-four hours it is going to take a similar favorable course?" No one. The more frequently I operate, the more confident I am that I cannot tell from the symptoms what the course of a case of appendicitis is going to be for twenty-four hours. As I am unable to tell this, I feel it is my duty to do

what? What I feel I can do in the first twenty-four hours—remove from that patient, with comparatively little danger, his appendix, which may become a source of great danger to him within forty-eight hours from the onset of the symptoms. It is my practice, and I am becoming more firm in it every day, and I am urging it more forcibly on the doctors who kindly transfer their surgical cases to me, that their cases should be operated on within the first twenty-four hours and that all of them should be operated on within the first forty-eight hours. A case was referred to me by Dr. _____ of Chicago; I was called early in the night. In the morning it would be twenty-four hours. In the morning the patient's temperature was normal and the pulse was, as I recollect it, 86. That patient appeared in a very nice condition for recovery. I said: "This case should be operated on." What did I find? A completely gangrenous appendix, black as rubber, distended and filled with necrotic debris.

THE CHAIRMAN—I wish to say that the discussion took a rather unusual turn and I think the position the Doctor took was entirely proper. The only reason I had for having it in this way was that I do not believe that Dr. Murphy would do anything that would be out of the way, and I have known Dr. Keen for a great many years, and he is abundantly able to take care of himself. Dr. Keen will now come on the platform and have his say.

DR. KEEN—Inasmuch as I have been catechised, it is only fair that I should have a word. Now, I believe that if Dr. Murphy and I were alongside of each other at one hundred cases, we should come to just about the same conclusions. I think he would be, perhaps, a little less radical than he talks, and I would be a little more radical than I talk. I have heard my friend Deaver, for instance, and you have heard him, talk very radically, but when he gets at the bedside, as I know of him in Philadelphia, he does not always do exactly as he says. It is very difficult to lay down a rule for a case of appendicitis. It is impossible. There are certain acute attacks in which you cannot operate too quickly. There are other cases so mild that Dr. Murphy would hesitate or refuse, I am sure. There are also intermediate cases, and, therefore, though I answered categorically in the cross-examination which my able lawyer friend put me through in the beginning, "Yes," "No," the answers were not quite precisely true. There are modifying circumstances in every case. There are modifying circumstances that will lead the most radical man to hesitate, and others that will lead the most conservative instantly to push ahead.

THE CHAIRMAN—Gentlemen, the discussion is now open for you.

DR. LEWIS, Kansas City—If I should not hear another paper read, I feel amply repaid for the time and travel from my home to Columbus. This is the class of cases which, surprising as it may seem, we meet every week, and to know just what to do, when to do it and how to do it are indeed the questions. During the last three or four weeks I have seen three cases, so interesting and so much to the point that it brings me back to the proposition of: Should I or should I not? The conjuring of conditions which have developed in the right inguinal region during the last fifteen years has been marvelous. During the last few days or weeks I operated upon a case of appendicitis and what did I find? I found a large gall-stone as big as the end of my thumb in a patient of 64 years of age—nothing but a mild attack of appendicitis. In the practice of an intelligent and experienced physician, I was called some six weeks ago, two-hundred miles in the Indian Territory in consultation with several of our best surgeons to see a patient. The trouble was in the same region, and on an exploratory incision we found the ileum passed through the omentum, eighteen inches in length, where the rupture of the omentum had occurred, and it was strangulated; only thirty-six hours had elapsed since the symptoms; there were twenty-five necrotic points in the bowels which were perforated. The extensive inflammation and softening precluded the removal of this amount of bowel, and of course we lost this chance. This occurred in a stenographer.

When Dr. Keen made his statement of 2 per cent. mortality, I asked him the question: What is the mortality from the present method of his standpoint of treating the disease of appendicitis. We all know that it is more than 2 per cent. in the hands of the best men. Dr. Harshbarger, in his excellent paper, stated the most danger, and what I believe to be the most dangerous cases—the most dangerous cases—that many cases recovered without operation. That is an argument absolutely unanswerable. We are to blame for that argument. I remember saying on that occasion something that I cannot more forcibly say now; when the time comes that we can calculate our pathologic symptoms and determine in the begin-

ning that this case is going to be a dangerous or a mild one, the time has come for limiting our views and treating every case in a conservative way by the new—the eclectic—method. That time has not come; we must treat those cases from what we know; the mortality is great, but very slight if the cases are operated on. I believe that very soon cases, regardless of their character, operated on in the first twenty-four hours will show an infinitely less mortality than we have to-day. At the Denver meeting I remember Dr. Keen's challenging anybody who said that he could get a less mortality than 2 per cent. in a hundred consecutive cases. My natural modesty permitted me to rise at that time and state that I had at that time one hundred and eighteen cases of consecutive operations of appendicitis in the interval, without a death. Since that time the number has risen to one hundred and thirty-seven; that, however, does not prove. I believe that there are mild cases in which the judgment, observation and careful watching of the surgeon will permit him to carry the case through without an operation, and then he can operate, if he desires to protect his patient from future attacks. Many a time I have been called by competent physicians to operate, and have refused. I have been called in three consecutive cases, and yet I refused to operate and these cases recovered. As near as we can glean from statistics, between 85 and 90 per cent. recover, if they are operated on; but we do not know which case is a dangerous one and which is not a dangerous one.

DR. JOHNSON, Hartford—When I came in this afternoon and looked over the program and saw that there were eight articles on appendicitis, I came to the conclusion that the surgeons had gotten at an attack of literary appendicitis, from which, I think, there will be about 100 per cent. of recoveries. As my name was referred to this afternoon, I wish to state, that at the meeting of the AMERICAN MEDICAL ASSOCIATION at Atlanta, I reported one hundred consecutive cases of appendicitis, with two deaths. I want further to state that in all my operations up to date, in which I have operated before the suppurative process had commenced, I have not lost a single case, and those in that class now number a great many more than a single hundred.

DR. WAGNER, Chicago—I do not want to speak of my own favorable results, but I would like to say a few words with regard to the severity or non-severity of the attack in the beginning of appendicitis. In one case, a boy, seen one afternoon, had a temperature of 99, fever, pain in abdomen; normal next morning, temperature 102 with fever that very same day; he was operated on at 9 p. m. with perforation of the appendix and pus. The boy got well. Another case was that of a boy, who had pain in the abdomen, which passed off in a few moments; I saw the boy at noon; the mother told me that he had had pains before; I operated at 10 o'clock at night. I found a perforated appendix with foul-smelling pus. The boy walked up to the operating-table. I doubted whether I should operate on him. In the case of a girl of 17 years, who fell on the floor in the morning, the doctor came in the afternoon; she was suffering with a pain; the next day I saw her with the doctor; at 3 p. m. operated on her. There was pus, with a great big lump of omentum and a stone beneath the kidney; the stone had existed for a long time. In regard to the further question of how to decide whether to operate or not, you never know what the condition is until you operate on the case. I want to say a few words in regard to dealing with pus cases. I do not think that the operation is concluded after you have emptied the abscess. I believe you have in every case to resort to finding the appendix. I do not believe that appendectomy is completed when you have removed the appendix and discharge of pus. In a number of cases that I have shown to the hospital my method has been to break up all the adhesions and have the intestines freed from each other.

DR. D. W. GRAHAM, Chicago.—I was glad to hear the discussion and all the papers. I believe that the most experienced surgeons disregard all rules of other surgeons in the presence of individual cases of appendicitis. That is the conclusion I have arrived at. It is my method, and when in the presence of a case, I do not want anybody else's rules and experience—I want my own. I believe that every surgeon here is governed by his own experience. There is something in the face of the patient, something in the pulse, the general aspect of the case, that helps the surgeon to decide, regardless of any rule that can be put into practice. Dr. Keen, I think, struck the keynote to the whole situation when he said that some cases are so mild that Dr. Murphy would refuse to operate, and other cases can not be operated on too soon. Speeches are easily made and words are universally washed off in a meeting. I want to say, without being personal, that Dr. Murphy sometimes does not operate; he says, "I think that case is better without operation." Is that not so, Dr. Murphy?

DR. MURPHY—What was the condition? I will ask the Doctor to name the case.

DR. GRAHAM—It was a case of appendicitis, which, in my judgment, should have been operated on. Everything was ready; Dr. Murphy was called in consultation; he said, "No." I acquiesced. I had to.

DR. MURPHY—I recall the case and the consultation—except the particulars of the patients sometimes—and I think I agreed with the doctor's diagnosis.

DR. GRAHAM—That is right.

DR. MURPHY—And I think this was four or five years ago, and I think that was the position I took at the time, but I am happy to say that I have changed!

DR. GRAHAM—This was three years ago. I heard Dr. Murphy preach the same way.

DR. PLACE, Philadelphia—It is true that our first object must be to save life and we should be conservative. We must remember this: as long as the abdominal wall remains opaque and not transparent, we cannot see what goes on, and we should lean toward operation, except the case be very clear. I think with that we can have something to think about.

DR. PORTER—I wish to go on record as opposed to the statement that no case of purulent appendicitis gets well. I wish to go on record as believing truly that there are cases of general purulent affection of the peritoneum that, with timely opening and drainage, coupled with incision, relieving the tympany and letting out the intestinal contents will get well, and I believe such cases are on record, and the burden of proof rests upon the man who denies the proposition.

DR. OCHSNER, Chicago—I have nothing to say in closing, as regards my own paper, but I wish to take just one moment to speak on a part of another's paper—the very matter just spoken about. Now, I have seen a great many cases of general peritonitis. There was a time when I operated on these cases, and at that time whenever the cases proved to be general peritonitis the patient died. I have assisted in a considerable number of these operations and whenever they were operated upon the patient died. Others have succeeded in saving some of those patients, I am aware, according to the literature. I have not been so fortunate, but for the last four years I have followed another form of treatment in these cases in which general peritonitis was present, in which the condition was present that in former times I concluded to be general peritonitis, and cases in which precisely the same symptoms were present, and cases which were formerly proven to be general peritonitis. I have followed this form of treatment: I have entirely stopped the feeding of the patient; washed out the stomach to stop the vomiting; feeding the patient entirely by enema, and I have saved many of these patients. Now, I can prove that these cases had general peritonitis, because I have seen them later on for the relief of adhesions and from general adhesions; consequently I can prove that these patients had general peritonitis. I have the history of these cases.

DR. JOHN B. DEEVER, Philadelphia—I believe the cases of general purulent peritonitis believed to be cured by operators are in the majority of instances, circumscribed peritonitis and localized abscess. In early years I operated upon cases like those under discussion, but with universally fatal results. I have seen cases of what I believed to be general peritonitis recover without operation. It is my practice to treat these cases by packing the abdomen with ice, rectal alimentation absolutely, fly blisters over the epigastrium and hypodermic of strychnia. I do not for one instant think it possible to clean every nook and corner of the peritoneal cavity, therefore I do not believe that operation in the presence of universal inflammation of the peritoneum from infectious pus will accomplish a cure.

In answer to Dr. Keen, who states that Dr. Deaver does not always operate when called to the bedside of a patient, I beg to state that he is quite correct. In many instances where I refuse to operate, had I been called early enough I would. I am still of the opinion that better results will follow the removal of the appendix immediately after the initial appendiceal pain than at any other time.

Until the good Lord makes the belly walls transparent it will be impossible to do other than guess as to the progress the appendiceal inflammation is making. In the greater majority of instances the diagnosis of appendicitis is not a difficult one to make. There are cases of appendicitis, as of all other forms of disease, where the diagnosis is not only difficult but at times impossible to make.

On general principles I do not approve of breaking up adhesions between coils of bowel in the presence of infection and searching for the appendix. As to the removal of the appendix in cases of appendiceal abscess, I would go on record as advis-

ing against the procedure, the operator not being an expert in this line of work. With all due respect, I believe there are few of the many men operating for appendicitis who are capable of dealing successfully with the different cases. I know of no operation which is more difficult than some of the appendiceal cases. In the majority of instances the appendix can be taken out with safety by the expert, but not by the occasional operator or the general doctor, who operates but seldom. If time permitted I should like to refer to the varieties of abscess met with in appendicitis.

DR. MEANS, Columbus—The matter has been discussed so thoroughly and carefully that I feel it would be unwise to take your time further in discussing the points at issue. I think that there has been a general agreement upon the point I made in my paper that there should be no time-limit. My position was that I recognized no time-limit in operating upon appendicitis; that when the diagnosis was made I operated, provided that the environments of the patient were such that I could, and I believe that point has been considered.

THE DEATH-DEALING LONG-TUBE NURSING-BOTTLE.*

BY ERNEST WENDE, M.D.

BUFFALO.

It is not my intention to enter into a controversy on infantile mortality from diarrheal diseases, its deplorable rate, and the causes which are responsible for it. These latter have been carefully studied, and are, briefly: bad air, summer heat, ignorance of simple hygiene, and especially artificial feeding.

To the correction of all these possible factors have been directed the efforts of municipal authorities, the medical profession, societies, philanthropists and others. Tenement-house construction has been corrected and regulated by ordinance, the evils of the heated term mitigated by fresh-air missions, free ice and the like, maternal ignorance enlightened by educational circulars, and finally, sanitary protection has been given to milk from dairy to nursery, as has been extended to no other industry, and this largely, if not almost entirely, with the interest of infantile feeding in mind.

With regard to diet, the child should live on food provided for it—milk—the only food which contains all the principles essential to life and growth. The infant structures grow by selecting with unerring accuracy, from the blood, the materials akin to their own composition. For the first six months the child should draw his supplies exclusively from the maternal fountains. When, however, the full and finely-chiselled bust of napkins or towels, the mammary gland of the mother of today, is insufficient for the performance of its functions, we must have recourse to lacteal glands less esthetic and beautiful—those of the cow, goat, or ass—in preference to the wonderful feeding stuffs now so largely advertised in the daily and the medical journals. "An honest farmer who pastures his own cows on a healthy farm is the man to be employed to furnish milk to the poor little baby who has to seek another dairy than his mother's. And if the milk is not sweet, fresh, and pure, pathologic changes will be developed, thereby rendering the gastrointestinal tract more susceptible to irritants, and the production of cholera infantum results—when the baby gets beyond hygiene and enters the domain of medicine.

While all these causes of diarrheal disease in infancy have, as stated, been carefully studied and their influence minimized, and while also the so-called long-tube nursing-bottle has been condemned, the extent of its evil possibilities, from its intrinsic construction, has been in part elaborated.

It is almost needless to state that an infant previously enjoying an environment of continual warmth and moisture, entirely devoid of infection, that was aseptically and insensibly nourished by osmosis should not have a hose several inches in length, remarkably efficacious for the propagation and the passage of pathogenic micro-organisms, placed in direct communication with its very susceptible, excitable and over-sensitive stomach. Facility of access is the only recommendation attaching to such a plan, but this is altogether outweighed by the terrible risk necessarily involved. Decidedly its only use and adaptability to lessen the danger of infection is its employment for the flushing of the lower bowel of the child.

The object of this paper is to briefly give the perilous and untrustworthy features of the so-called long-tube nursing-bottle, and to show justification for not only interdicting it, but doing so by law. Something definite should be aimed at and done to protect and save the helpless offspring of the ignorant and indifferent. The myriads of little ones it has already slaughtered should be sufficient to inspire us to enact elaborate laws, to be administered with the greatest care and strictness, in order to prevent parents and those in charge of infants from committing a variety of acts inconsistent with duty, judgment and common sense—for there is more virtue in the power of law than in circulars of instruction or education.

The chain of protection sought to be placed against these most prolific sources of cholera infantum is no stronger than its weakest link, and this weak link has been the apparently innocent but death-dealing long-tube nursing-bottle. No factor has been more deadly, none so subtle as this device. Conceived in the interest of labor and time saving, appealing to the poor and overworked housewife, it has invaded the home under false pretense as has no other appliance, but has left in its trail a record of mortality. Its dangerous possibilities, now well known, have caused the physician to taboo it for some time, yet its convenience has been so great, and its innocence so reasonable, that its apparent merits have, in only too many instances, been considered above the warnings against it. So certain is its malignant bearing on the artificially fed infant that its manufacture, sale and use should be prohibited by law, and, recognizing this fact, it has been so interdicted by the Buffalo Department of Health.

The peculiar features of danger from its employment may be summarily stated, that owing to its construction and material, and to the use to which it is put, probably no better incubator of pernicious micro-organisms and their toxins could be easily designed, as none have proven so successful. To the details, which render this statement plausible, your attention is asked, as well as to the experimental work which has been done in absolutely demonstrating, step by step, the vicious results created by the utilization of this contrivance, and how and why it is vicious; why it should, in all communities, be condemned and prohibited. Its popularity and foothold have been so strong that it also has had a commercial significance, and its abolition in Buffalo has not been without remonstrance and even the cloud of possible litigation. With the elimination of this, the greatest source of artificial infant-food contamination in the household, with a judicious observance of sanitary care of milk in homes, as supplementary to official surveillance of possible and preventable causes, it is not visionary to expect a reduction in death-rates in proportion as efforts based on our present knowledge can be made effective.

*Presented to the Section on Diseases of Children, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

As milk is an almost universal food for bacteria, its reception in a rubber tube, acquired from a coagulum that is normally cavernous and unstable, invariably presenting surfaces that are rugose and unpolished, rendering asepsis an impossibility, must necessarily augment the conditions favorable for the growth and development of micro-organisms, and finally convert it into a nursery which produces conditions favorable to cholera infantum.

To establish, beyond peradventure, the danger of these tubular thoroughfares for the introduction of pathogenic microbes into the infantile economy, and the justification of suppressing them by legislation, I, as a health official, resorted to a series of investigations, microscopically, bacteriologically and chemically. The microscopic examinations of transverse sections, cut from unemployed rubber tubes taken from nursing-bottles procured at the various drug stores of our city, revealed the fact that they were manufactured out of rubber sheeting cemented together at their longitudinal margins to complete the tubes, and the seams thus formed were found unfaithfully imperfect in their construction, showing, throughout their entire length, elongated pits and sinuses, which, in their functions, can only be likened to our modern bacteriologic "breed ovens." In some instances, this state of affairs was further intensified in that the tubes were constructed of more than one layer, between which such enormous spaces were frequently developed, directly connected with the lumen of the tube by the numerous pits and sinuses referred to, as to more or less involve their entire circumference. Moreover, the sections likewise demonstrate that the material used in the manufacture of this tubing is exceedingly porous, and that the pores vary amazingly in size and shape. Again, pockets were often seen communicating with the inner surface of the tube, while, in several specimens, distinct channels were visible connecting similar pits or pockets with cavities in the substances of the rubber. It would, indeed, be difficult to imagine a more efficient arrangement for the propagation of germs.

By reflected light, under the microscope, the inner surfaces exhibit a view apparently made up of roughened and scraggy elevations and depressions with many openings and clefts, extending deeply into the texture. All the features of the imperfect seams, by this means, are easily discernible and can be readily traced and studied throughout their entire length. Therefore, it is obvious that any foreign material, gaining entrance to this perilous combination of pits, sinuses and porosities, cannot be removed by any of the ordinary methods of cleansing, however vigilant and faithful be the mother or nurse. Yes, it is extremely doubtful whether bacteria, when once lodged in these incubators, can be displaced or even destroyed by any known germicide or chemical.

From the bacteriologic examination of an infected rubber tubing, we were able to recognize a deposit of decomposing material coating the inner surface, being the thickest in those portions of the lumen in close proximity to the nipple and glass tubing. This debris was found, on further investigation, to consist of coagulated casein, with innumerable bacteria of varied morphology. The qualitative bacterial examination of the material demonstrated the bacillus acidi lactici to be the predominating organism. The staphylococcus pyogenes aureus and oidium albicans, with three other distinct species, two of which belonged to the non-chromogenic bacilli, the third being a chromogenic micrococcus, were present, and in addition several species not yet completely isolated.

Five decigrams of this grumous conglomeration, dissolved in 2 c.c. of sterile water and injected intraperitoneally into each of three full-grown guinea-pigs, weighing respectively 200, 254 and 261 grams, produced death of the animals in from forty-eight to sixty-one hours.

Segments of the infected rubber tubing were placed in small vials, and kept in an incubator at a temperature of 98.5 F., for twenty-one days, after the lapse of which time the specimens thus prepared were either in part softened or completely disintegrated, while, on the other hand, like pieces of the infected tubing, soaked for a few moments in a 5 per cent. solution of carbolic acid and subjected to the same temperature, were not similarly affected. The inference drawn from this experiment verifies the fact that the prolonged effect of decomposed milk on rubber will mash, mangle and disintegrate it.

In further unraveling the chain of morbid sequences, it was found, on a chemical analysis and investigation, that this process of decomposition and divulsion was due to the fermentation of the lactose of milk remaining in the tube.

An intimate part of the tubular mass consisted of zinc oxid as a filling which, in the cheaper grades, was considerable in amount. This component substance, under the influence of the bacillus acidi lactici, and probably some other bacteria, supplied one of the conditions favorable for the continuous production of lactic acid, while the other condition was the presence of stale milk in the lumen of the tube. At the ordinary temperature, these micro-organisms decompose the lactose, giving an interchange of elements as follows:

However, a certain degree of acidity puts a stop to the growth of the bacteria and to the production of acid, but if the acid is neutralized, as formed by zinc oxid, as in this case, the decomposition is a continuous one. The casein was also more or less decomposed, which gave rise to bad-smelling products that remained in solution or else passed off in the form of gases. The presence of the zinc lactate, thus formed, which was soft and hygroscopic, coupled with the other soluble casein products, rendered the rubber doughy, indicating further injury dependent on micro-organisms.

In conclusion, I must insist that there are most rational grounds for believing that this mechanical invention, the long-tube nursing bottle, should be considered as a premeditated plan for the poisoning and killing of infants, demanding special treatment by law.

DISCUSSION.

DR. F. P. NORRBY, Jacksonville, Ill.—The ordinary nipple is open to many of the objections which are applicable to the long tube. In the average nipple that is molded, after being used for some time there will be a crease running the whole length of the nipple—on a line at which the two halves are united. This is to be seen by turning the nipple wrong side out. This becomes an excellent nidus for bacteria. I have seen, in consultation, several cases of poisoning resulting directly from the use of such nipples.

DR. A. C. CORROX, Chicago—I would like to ask Dr. Wende whether he has made any microscopic examinations of the nipples as well as of the tubes.

DR. ERNEST WENDE—The nipples are subject to the same objections as the tubes. However, they can be inverted and, thus, are more easily cleansed. It is customary to recommend that two nipples be employed, same to be kept in a solution of bicarbonate of soda, and used alternately. It may be too early to speak concerning the wisdom of this ordinance, yet the death-rate in the city of Buffalo was diminished just one-half, as compared with the year previous to the enactment of the said ordinance. Our statistics are based on the number of those who died from cholera infantum, for they demonstrate that the majority of deaths occurred among those who use the long feeding-tube.

SUMMER DIARRHEA OF INFANTS.

ITS ETIOLOGY AND TREATMENT.

BY H. M. McCLANAHAN, A.M., M.D.

PROFESSOR OF DISEASES OF CHILDREN, OMAHA MEDICAL COLLEGE.
OMAHA, NEB.

While the summer diarrheas of infants vary much in their clinical manifestation and in the pathologic lesions, they are all similar in their etiology and treatment. It is, therefore, of these phases of the subject that I wish to direct attention.

ETIOLOGY.

The etiological factors are predisposing and exciting, the former are age, environment, season, character and method of feeding, and previous condition of health. Nearly all cases occur during the first two years of life. During this period the child has feeble resisting power; its digestive organs are readily prone to functional disturbances. Its nervous system has feeble inhibitory power, and the irritation that in the adult would have no effect, in the infant produces profound impressions.

The influence of environment is particularly noted in large cities where, owing to the lack of fresh air and sunshine there is induced a feebleness of constitution that increases the susceptibility of the child to morbid influences.

The method of feeding and the quality of the food is a nearly constant predisposing cause. Statistics show that about 97 per cent. of all cases occur in bottle-fed babies.

The predisposing element is undoubtedly the quality of the food, in most cases lacking in elements to symmetrically nourish the child, and, by producing an enfeebled condition, make it more vulnerable to the exciting cause. Rickets is a conspicuous example.

Again, the food may be difficult of digestion, as when it contains an excess of albuminoids. In these cases, the digestive organs are taxed beyond their capacity and a state of chronic irritation produced. It can be safely affirmed that the majority of cases of summer diarrheas are preceded by some form of indigestion due to the method of feeding. The season is so important that these diseases were formerly looked upon as thermic fevers. We now know that they are not directly induced by heat.

Modern bacteriology has taught us the true influence of heat in inducing these disease. We should not, however, lose sight of the fact that extreme heat is debilitating, that its enervating influence lessens the resisting power, that the profuse perspiration creates a thirst which leads the child to ingest excessive quantities of food, overloading the digestive organs, and impairing their functional activity. The previous condition of the health of a child is perhaps more important in influencing our prognosis than in causing summer diarrheas.

The child whose constitution is enfeebled by sickness, either acute or chronic, is not only more susceptible to these diseases, but is less able to withstand the invasion. All the conditions I have mentioned exert, either singly or together, an influence in predisposing the child to summer diarrheas but none or all together, in the true sense of the term, cause these conditions.

Summer diarrheas is an infectious disease, just as certainly and upon the same evidence as typhoid fever, with the distinction, however, that it is not due to one specific germ. The method of invasion is nearly always by the food through the gastro-intestinal tract. The poison originates in the milk, through the agency of bacterial growth.

I quote from Professor Vaughan of Ann Arbor¹:

"The child taking its nourishment directly from the breast of the healthy mother obtains its milk practically germ-free, while the one taking cow's milk receives along with this food many kinds of bacteria, some of which are very harmful. These diseases are confined to the summer months because the germs which elaborate poisons in milk require a relatively high temperature for their growth. During the hot months of summer these bacteria are widely distributed, and easily find their way into milk. They grow rapidly and produce chemical poisons. Furthermore, decomposing matter harbors and supports these bacteria at a time when the outdoor temperature is high enough to allow their growth."

The intestinal tract of healthy children contains bacteria. The two varieties constantly found are bacillus lactis aerogenes, and bacillus coli communis. As to the part played by these bacteria in normal digestion, but little is positively known.

In all forms of diarrheas these obligatory milk-feces bacteria are greatly increased in number, and are more widely distributed throughout the alimentary tract.

According to Booker's investigation, in mild types of summer diarrheas these varieties predominate almost to the exclusion of all others. Owing to their increased number they develop acids in the intestinal tract—lactic, acetic and butyric. These acids irritate the mucous membrane and are probably the direct cause of the diarrheas. More important, however, is the fact that by reason of the irritation of the mucous membrane from the increased number of these bacteria, it is made more vulnerable to the influence of virulent pathogenic germs. In the more serious types of diarrheas, however, other bacteria are present, among the most common being the proteus vulgaris.

In many of these serious cases, as post-mortem examinations demonstrate, the actual damage is the result of bacterial growth, since no lesion of the intestinal wall is discovered and no penetration of the body tissues by bacteria can be demonstrated. In this class of cases the symptoms are certainly to be attributed to the absorption of toxins. In cases where the micrococci are present there are usually found distinct inflammatory changes in the intestinal mucous membrane. It is most generally the staphylococci that are found. These bacteria may find an entrance into the subjacent tissues, and thence may be distributed throughout the body. When these cases do not terminate fatally in the acute stage, they are likely to drag along for weeks and even months. "It is the consensus of opinion among investigators that no one specific kind but many different kinds of bacteria are concerned in the causation of summer diarrheas."² Indeed, as many as forty different varieties have been detected.

A further important fact is this: chemical poisons, the result of bacterial growth, may be developed in the milk before it is taken into the stomach and these poisons may induce very serious symptoms in a short time after the milk is ingested. Professor Vaughan reports a case where symptoms of cholera infantum developed within two hours after taking the milk.

There is certainly good reason for believing that true cholera infantum is caused by toxins developed outside the body. It is important to remember that the stomach of the infant has feeble digesting power than that of the adult; that the albuminoids of milk are but slightly changed in the stomach, but pass into the bowel almost

¹ Edwards' Supplement to Keating's Cyclopaedia, p. 8.
² Keating's Cyclopaedia, Vol. iii, p. 190. Intestinal Bacteria in Children—Booker.

unaltered, hence, poisons in the milk are not likely to be destroyed or inhibited by the gastric ferments.

TREATMENT.

The first and most important principle of treatment is to stop milk and all other kinds of food. This direction should be made mandatory, because people, in mistaken kindness, will insist upon giving the child some nourishment. The reasons for this are that milk affords a pabulum for development and growth of bacteria, and therefore tends directly to increase and continue the difficulty. Furthermore, digestion is greatly impaired and the child receives little nourishment from the food. The next object is to unload the intestinal tract as completely as possible. This is done to remove the supply of poison, lessen the absorption of toxins, and prevent irritation of the mucous membrane by the contact of decomposing material. The means to this end are mechanical and medicinal.

The mechanical means are lavage of the stomach and irrigation of the bowels. In those cases where there is marked gastric irritation, lavage is an excellent mode of treatment, not only because it empties the stomach, but for the reason that it prevents vomiting. While some writers say this is entirely free from danger, yet if a serious result had ever occurred such a statement is incorrect. One fatal case has been reported from introducing the catheter into the larynx. To avoid this accident, the index finger should be used as a tongue depressor, when the catheter can be carried over the base of the tongue, and against the posterior wall of the pharynx, and thence on down the esophagus. In this way all danger can be avoided.

Irrigation of the bowels reaches directly only the large intestine, and in order to accomplish this purpose, it is necessary that large quantities of water be used, at least from half a gallon to a gallon. As the object is to flush out the colon the operation is to be continued until the water returns free from fecal matter. While irrigation is going on the abdomen should be gently rubbed. This stimulates peristaltic action of the entire intestinal tract, and favors elimination.

To unload the small intestine, drugs are necessary. Calomel is the best remedy, given in doses of from 1-10 to $\frac{1}{2}$ grain, repeated hourly until the typical spinach discharges are produced. In many cases this may be followed to advantage with castor-oil. In a majority of cases seen early, this treatment will arrest the disease.

When the disease is so arrested the next important point is in regard to the diet, because it should be remembered that these cases may easily suffer a relapse from renewed infection. It is often better to withhold milk for some days and use other varieties of food.

It is in this connection that certain proprietary articles are of service. Among these articles I would mention bovine, Fairchild's panopepton, and liquid peptonoids. Mutton broth is an excellent article of diet, and may be the sole food for several days. It should be carefully prepared and all fat removed. In children over a year of age farinaceous infusion may be employed. The following, taken from Jacobi³, answers a good purpose: 5 oz. barley water, the white of one egg, from one to two teaspoonfuls of brandy or whisky, some salt and sugar. Small quantities of this may be given every few minutes.

When a milk diet is resumed, it should be thoroughly sterilized and properly diluted. In infants under a year of age, I prefer the milk and cream mixture. The formula which I usually employ is as follows:

R. Cream	3iii
Milk	5ii
Sugar of milk	5i
Water	5x
Mix and sterilize.	

To each three or four ounces of this, when ready for feeding, one to two drams of lime water should be added. In preparing this the sugar should be dissolved in water and the cream and milk added.

This formula can easily be modified to suit individual cases. Cases that do not yield to the treatment already indicated, and this includes those that have persisted for a few days before medical advice is sought, require further attention.

Where the alvine discharges continue fetid, remedies directed to the disinfection of the alimentary tract are indicated. A remedy that has given me the best satisfaction is eudoxin. This may be given in doses of from $\frac{1}{8}$ to $\frac{1}{2}$ gr., in powder, combined with sugar of milk.

Where the discharges are acid in character, as indicated by the erythema about the buttocks, this remedy may be combined with an alkali; as subnitrate of bismuth or prepared chalk. In these cases also the bowels may be irrigated twice each day with a warm saline solution. Where there is much tympanitis, it is of benefit to add to the water bicarbonate of soda one dram to the pint.

Where the diarrhea persists the question of the use of astringents suggests itself. My own belief is that it is better to use some remedy to check the action of the bowels, because frequent movements interfere with the rest and comfort of the patient. I have never been able to see any benefit from the vegetable astringents, even in those cases where they are retained by the stomach. Of the preparations of opium I prefer either paregoric or Dover's powders. These allay irritation, arrest peristalsis, and give needed rest. A safe rule is to direct that the prescribed dose be given after each movement, thus as they become less frequent, less of the drug is given.

Where there is marked prostration, supportive measures are indicated. Alcoholic stimulants, externally and internally, are to be employed. Children bear stimulants well. Whisky is the better, as it is less likely to be adulterated than wines or brandies. For external use, equal parts of alcohol and hot water are better than alcohol alone. Where the heart is evidently weak, digitalis is an excellent remedy. I prefer the fluid extract, owing to the smallness of the dose, of which one drop may be given every two or three hours in water.

There are a certain number of cases that persist in spite of treatment. This class includes those cases where there is a true inflammatory lesion in the bowel, with a general sepsis. The discharges consist largely of mucus, epithelium, and blood. The treatment already indicated is appropriate to these cases, but often unavailing. Small doses of silver nitrate are sometimes of benefit. Sulphocarbolate of zinc is another remedy worthy of trial.

Whatever the reason may be, the fact remains that change of location is the most valuable treatment possible. I remember a case that I treated with indifferent success for five weeks and then suggested a change. The mother took the child to Spirit Lake, Iowa, and in one week, without any other general change in treatment, the child was restored to health. In another case seen by me in consultation a year ago, the disease had persisted for four weeks. The child was extremely emaciated and anorexia was complete. This patient was sent to Wyoming, where it made a complete recovery.

³ Therapeutics of Infancy and Childhood, p. 225.

CHOLERA INFANTUM.

A few thoughts upon the subject of the treatment of the acute form of this disease. After irrigation of the bowel it is of benefit to use the following: 20 gr. of tannic acid dissolved in one pint of boiled water. This is injected into the bowel and retained by pressure against the buttocks. The acid probably coagulates any albuminoids that may remain in the bowel, and prevents their absorption. This treatment, which was suggested by Professor Vaughan, I have frequently employed, with decided benefit.

As the watery discharges rapidly produce collapse, it is good treatment to arrest the action of the bowels, after they have been irrigated. For this purpose I employ the method suggested by Holt, namely, the hypodermic injection of morphin sulphate, gr. 1-100, with atropia sulphate, gr. 1-800. This will frequently arrest the action of the bowel for some hours, but should not be repeated within twelve hours.

Thirst is usually intense, but the stomach is so irritable that fluids are generally rejected. All kinds of foods should be strictly withheld. The most agreeable drink is ice-cold sterilized water containing one drop of dilute nitric acid to each half ounce.

For collapse there is nothing equal to the subcutaneous infusion of normal salt solution. The only apparatus necessary is a hypodermic needle and fountain syringe. This supplies the system with water in a manner so that it can not be rejected. When the extremities are cold the hot sheet pack is indicated. Mustard may be added to the water in which the sheet is dipped, with advantage.

Nervous symptoms are probably due to either fever, the absorption of toxins, or both, and when prominent, generally indicate a fatal termination. The ice-cap to the head can safely be employed. A solution of bromid of potassium and chloral hydrate may be given per rectum.

Coal tar drugs are seldom to be employed.

SURGICAL TREATMENT OF ACUTE PERITONITIS.*

BY A. F. HOUSE, M.D.

Surgeon to St. Clair Hospital; Consulting Surgeon to the German Hospital.
CLEVELAND, OHIO.

In presenting my paper on the surgical treatment of acute peritonitis I have not thought it necessary to review my experimental work, or to report all my cases operated upon. Neither is it possible in a short paper to enter into a discussion of the anatomy, etiology, pathology and the various clinical phases found in this formidable disease, because inflammation of this membrane may have so many different causes and assume such varied clinical aspects that it is difficult to formulate a uniform and satisfactory classification. Suffice it to say that, anatomically and physiologically considered, the peritoneal cavity may be said to be a large lymph-sac, and noted for its capacity of absorption. This capacity is not surprising when we take into consideration that in its parietal and visceral foldings, it presents nearly as large a surface as the entire integumentary covering of the body.

Idiopathic peritonitis is considered doubtful by most modern pathologists, and it has become an established

practice to search for a local cause in all cases of peritonitis. I believe in every instance, micro-organisms from some source or other have gained access to the peritoneal cavity. Wounds of the peritoneum heal with remarkable rapidity if the surfaces are kept in uninterrupted contact; in a few hours, adhesion takes place between the united parts by means of plastic material and is termed "plastic peritonitis." This is purely a regenerative process and should not be classed with the inflammatory affections.

Of the various structures of the body, the peritoneum, without question, is one of the most susceptible to septic influences, and it has become an established fact that different portions of the peritoneum present different degrees of vulnerability to sepsis. The most sensitive region is that over the small intestines. The parietal peritoneum is much less susceptible to infection. When peritonitis is developed away from the small intestinal area, it is apt to be localized. This is shown by the course of peritonitis in the iliac fossa, in the subphrenic region and in the pelvis.

Septic and suppurative peritonitis are, etiologically, identical; however, clinically they differ in that acute septic peritonitis is generally diffuse and leads to a rapidly fatal termination, while both forms are caused by a pus organism. Suppurative peritonitis is more generally local or circumscribed and more often amenable to surgical treatment. It is quite likely that the most common form of peritonitis is that caused by infection from some portion of the alimentary canal, as in appendicitis or acute obstructions and the various forms of ulceration of the bowels. The organism generally found in these cases is the bacillus coli communis. Still there are certain other infections which pursue quite as fulminating a course as those from the alimentary tract, such as for instance results from faulty technique, in which a virulent germ is introduced by instruments, sponges or fingers. We also know that the reproductive organs are often the cause of a virulent peritonitis, as in certain forms of metritis or salpingitis. It may be well also to mention here certain forms of inflammation of the liver and gall-bladder and the rupture of abscesses of various parts of the body as producing peritonitis. The micro-organism usually found in these cases is the streptococcus. In rare instances, perhaps, some of the milder pus cocci seem to have an unusual virulence. I believe, barring faulty asepsis, that peritonitis caused by infection from the intestine is the most rapid in its progress and the most fatal in its results. Whether the colon bacillus in its growth is an effect rather than a cause, I am unable to say. Its constant presence in all cases of peritonitis of intestinal origin justifies the opinion that it has at least a great influence as a causative factor. The symptoms of acute peritonitis when operative interference is advisable and not without hope may be grouped as follows:

1. Pain of varying degree; either local and becoming general, or general becoming local, according to cause. This pain is very frequently referred to the region of the umbilicus, even when the seat of infection is remote from that point.

2. Tenderness, general becoming local, or local becoming general, as a result of pain. Marked rigidity of the abdominal muscles is present, and in many instances this rigidity is more marked over the portion of the peritoneal cavity in which the infection commenced. The importance of early rigidity is a symptom of the utmost value, and my experience leads me to fear that its aid in

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

making an early diagnosis is not sufficiently recognized by many practitioners.

3. Vomiting, usually of a green ropy substance. It may be exceptionally absent, but when present is a symptom of a rapidly developing and severe infection.

4. Shock, varying in degree, is usually present in cases of acute perforation or gangrene, before paralysis of the intestine from septic absorption has occurred.

5. From two to twelve hours after infection the abdomen becomes more or less distended, this distension not only being due to a transudation of fluids but also to the accumulation of gases within the intestinal canal as a result of paralysis and arrest of the normal functions of the intestinal tract. To wait for distension in the diagnosis of general peritonitis, is in the larger proportion of cases, to postpone operation until too late. A rise in pulse and temperature is exceptionally absent. More frequently the pulse runs from 100 to 160, is thready and weak, the temperature varying from 99 to 105 or even higher within twelve hours of the first symptoms of invasion. Peristalsis is diminished.

The symptoms in fully developed peritonitis in which the wisdom of an operation is questionable, I have grouped as follows: Pain, lessened or absent. Tenderness general. Distension marked, replacing the rigidity. Incessant vomiting of green or stercoraceous material, obstinate constipation, peristaltic movements not heard, a rapid and feeble pulse, temperature may be high or low, more or less lividity of the abdominal skin; the extremities cold and the mind clear, and the body bathed in perspiration; one step more and our patient is moribund.

The treatment of peritonitis resolves itself into both medical and surgical, and while it is the purpose of this paper to treat the subject from a surgical standpoint yet a few words in reference to what the surgeon should do and what he should not do in the way of medical treatment is pertinent to my subject. The diet should consist of concentrated liquid nourishment, such as milk and the animal broths, with stimulants as indicated. When nausea and vomiting interfere with the stomach feeding, which is so frequently the case, high rectal enema may be tried, and if this fails submammmary infusion of warm water or the physiologic saline solution will frequently relieve the intense thirst which is at times so distressing.

The therapeutic indications in acute general peritonitis have not up to this time been fully settled. While opium and cathartics have been used largely in the treatment of this formidable disease, yet both fail to accomplish the desired result. The advantage claimed for the use of opium is the relief from pain and the state of rest it gives the inflamed intestinal surfaces. This theory, however, is an erroneous one. The fact is the chief danger in this disease is dependent not upon the local inflammation but upon the absorption of the products. The method of intestinal drainage, first devised by Lawson Tait, has found a general acceptance throughout the world. The free and early use of saline cathartics not only carries out these products through the intestinal canal but relieves distension, promotes absorption of the peritoneal exudates and assists in eliminating the toxins. On the other hand the use of opium not only increases intestinal distension by the impairment of its muscular wall but also hinders the absorption of exudates and the elimination of the various toxins. To condemn the use of opium in perforation peritonitis would be folly. Cathartics in this class of cases are positively contraindicated, as an extravasation

of liquid feces would likely be increased in such a case and an infection which had, up to that point, been local, might become general. Opium in these cases not only prevents peristalsis, but relieves pain and diminishes shock.

In general peritonitis, especially the septic variety, strychnin, camphor and alcoholic stimulants should be employed early and at short intervals. Should the stomach refuse to tolerate the above mentioned drugs they should be given hypodermically or per rectum. Calomel in small doses in the early stages sometimes diminishes the nausea and vomiting.

In discussing the surgical treatment of general peritonitis is it not good logic to assume that septic inflammation of the peritoneal sac is amenable to the same general laws that govern septic infection of other tissues? The indications for interference are much more difficult to determine than methods. While, perhaps, most cases of general peritoneal infection prove fatal, yet many cases are recorded where free incision and thorough irrigation and drainage have been followed by recovery. In a classical address by N. Senn, before the International Medical Congress at Moscow, in August, 1897, he says: "I have opened, drained and washed out the peritoneal cavity in many cases of diffuse septic peritonitis and I am free to confess, without a single successful result. Yet there can be no difference of opinion in reference to the advisability of early operative treatment in the management of general diffuse septic peritonitis. Without operation death is certain." Koerte⁶ believes that most of the brilliant statistics of cure of acute general peritonitis by operations are false. Frederick Trevis³ says there can be no doubt that all forms of peritonitis are septic and due to micro-organisms, and that there is no such thing as idiopathic peritonitis, and we have made great advances in the treatment of localized peritonitis but we have made but little progress in the treatment of diffuse peritonitis. Halstead of Johns Hopkins regards general peritonitis an exceptionally fatal disease. Mikulicz reports 3 recoveries in 14 cases, Koerte 6 recoveries in 19 cases. E. H. Grandin⁴, in a discussion on septic peritonitis, says that his studies have enabled him to be more hopeful in the prognosis of general suppurative peritonitis than was formerly the case. He gives a record of 40 cases of local and general suppurative peritonitis. These cases do not include instances when pus was low in the pelvic cavity and accessible by the vaginal route. Thirty-one of these cases were local suppurative peritonitis and a general suppurative peritonitis. Of the 31 cases, all recovered after incision and drainage. Out of the 9 cases of general suppurative peritonitis only one recovered. In this case multiple incisions were made, and copious flushings were practiced with saline solution, drainage was through the incisions by means of strips of gauze, and antistreptococcus serum was injected a number of times at stated intervals. After the administration of the serum the temperature invariably fell, the pulse-rate became less, and the production of pus was greatly limited. Dr. Grandin is not certain that the serum brought about a cure in this case, but thinks it quite probable and advises its use in all cases.

A paper by Robert Abbe, upon "The Prognosis and Treatment of Acute General Peritonitis," says that the grave form of acute general peritonitis is almost invariably due to the rupture of a hollow viscus—stomach, intestine, appendix or bladder. Its origin is certainly bacterial, and septic infection overwhelms the patient and is unconfined by any barrier of lymph. The virulence

of the attack varies with the nature of the material introduced. Material from the appendix is more virulent than material from the stomach and bladder. In grave cases a long median incision or two lateral ones are required. He believes that gauze packing is far better for drainage than glass tubes or rubber; that in widespread infection systematic irrigation with normal saline solution must be used, and if the intestines are distended with gas and fluid to prick them in one or two places with a knife and allow the escape of gas and feces and wash away with a stream of hot water. Through one of these openings introduce a syringeful of saturated solution of epsom salts and close the puncture.

I am fully satisfied from personal observations that a fatal issue in many of these infectious cases is due to prolonged medication, and the surgical remedy is consequently postponed until its chances of success are gone. If the abdominal cavity could be opened at the very beginning of general infection the results would be much more encouraging than they are at the present time. To sustain that which we have asserted, let us take for instance perforation of the abdominal wall with injury of its internal viscera, sudden intestinal extravasations, twists, invagination, strangulation or rupture abscess. While it is true that with some of these lesions a general infection is coincident, and in others it may appear in a few days, yet in both classes an early operation is necessary to be successful. In all acute abdominal lesions of an obscure character we are justified in making an exploratory incision.

It is not within the scope of this paper to go into all the minute details as to the locality and size of the incision or the different methods of drainage and irrigation. Suffice it to say that the incision should be made in the median line below the umbilicus, unless the primary lesion should indicate otherwise.

For simple evacuation of fluids and drainage a short incision is usually all that is required, but when the condition depends upon mechanical obstruction or paresis of the intestine, and irrigation of the peritoneal cavity is to be used, an incision at least long enough to admit the free introduction of the hand is indispensable.

Perfect drainage of the peritoneal cavity in all cases is practically impossible and especially so when the intestines are greatly distended. The material generally used is either gauze, rubber or glass. I prefer gauze wicks or glass tubes filled with strips of gauze and wrapped with the same material. Many times, in order to make drainage as perfect as possible, it is necessary to insert gauze or drainage-tube in other than the primary incision, as in one or both loins or through the lumbar region. The Mikulicz tampon or drain, first used by the one whose name it bears, has proved of inestimable value in many cases of abdominal operations.

Irrigation, like many other surgical procedures, has been freely argued pro and con. The objection that irrigation only spreads the infection holds good only in localized peritonitis where there might be danger of breaking or tearing up the adhesions. Practically it is impossible to thoroughly disinfect the peritoneal cavity, yet it is far better to have imperfect disinfection than none. Solutions of various kinds are used; those containing strong antiseptic or germicidal properties are conducive to more harm than good. Sterilized water, boric acid, Theirsch solution, acetate of aluminum and normal saline solutions may be used without fear of toxic effect. Personally I prefer the physiologic saline solution with 1-2000 or 1-3000 formalin. Whichever one of these solutions one prefers should be used at a temper-

ature of at least 105 to 115 F., as in all cases where irrigation is deemed advisable, a solution of this temperature stimulates the heart and thereby assists in relieving shock. The stream should be sufficiently large, with force enough to reach the remote parts of the peritoneal cavity. I prefer using the Kelley irrigation tube introduced into the bottom of the peritoneal cavity. The propriety of breaking up adhesions for the purpose of making irrigation more perfect is questionable, and I believe should not be done except in non-suppurative cases. The method of mopping fluids or pus from the peritoneal cavity by gauze or sea sponges is not to be advised. It is far better to turn the patient upon the side and allow the fluid to run out, after which a more thorough cleansing can be done by gauze. Death in peritonitis is more frequently caused by rapid intoxication than by inflammation. In all cases of fulminating peritonitis, inflammation of the visceral peritoneum of the intestine leads to paralysis of the muscular coat and rapid distension. To relieve this, surgical intervention has of late been advised by N. Senn, McCosh, Knowsly, Thornton, and many others, by incision or puncture of the intestine. The methods of Senn and McCosh seem to be the most practical. Senn places his patient upon the side, brings the most distended part of the intestine well forward into the wound and then makes a transverse incision of about an inch opposite the mesenteric attachment, then grasps the bowel as far as possible above and below the incision, elevates the intestine on either side of the incision in its wall and in this wise empties out its contents, after which he thoroughly cleanses the exposed intestinal surface with normal saline solution. The incision is closed with the usual Lembert sutures and the bowel returned.

McCosh's claims that his results have been much better since he began the use of saturated solution of magnesium sulphate as an intra-intestinal injection. His method is to inject one or two ounces of sulphate of magnesium through a hollow needle attached to a large aspirating syringe; the small intestine is punctured as high up as possible and the wound closed by a Lembert suture.

While my experience in the surgical treatment of acute peritonitis has been limited, compared with that of many other surgeons, yet the results have been such that I feel justified in asserting that in the early stages of acute peritonitis we are not only justified in making an exploratory incision, but it is our imperative duty. I hold that every case showing most or all of the symptoms I have enumerated should be subjected to an operation at once or as soon as the patient has been prepared. I make but one exception to this rule and that is, in cases of gonorrhoeal infection of the tube we are justified in waiting in most cases until the acute symptoms subside. I have yet to see a death that was caused by a too early operation, while I have seen many where medication was prolonged until the surgical remedy was of no avail; and the sooner the general practitioner is brought to a realization of the fact that acute peritonitis is a disease that must be treated surgically, the sooner will the mortality in this disease be decreased. My method has been to irrigate freely the peritoneal cavity with from two to four gallons of normal saline solution, after which I irrigate with one or two gallons of saline solution, containing from 1-2000 to 1-3000 formalin in all cases where no pus or seropurulent fluid is found. I use no drainage, but fill the peritoneal cavity with plain physiologic saline solution and close the wound. Drainage is always attended by danger of pu-

trfection bacilli entering into the peritoneal cavity, and, to be of service, must be limited to the evacuation of pre-formed pathologic spaces. I have no cause to regret its abandonment in non-suppurative cases. If there has been no bowel movement for several hours and evidence of intestinal paresis exists, I inject from one to two pints of normal saline solution into the intestine by means of a hollow needle attached to a glass irrigating jar and close the intestinal wound by means of a Lembert suture. In cases of localized suppurative peritonitis, after evacuation of the pus I mop out the cavity with gauze dipped in normal saline solution containing 1-1500 formalin, and drain with gauze wicks.

The after-treatment in all cases of peritonitis which have been subjected to an operation demands close attention, for all such patients are prostrated, not alone from the immediate effects of an operation, but from the disease as well, and require stimulating treatment. Strychnia, camphor and alcoholic stimulants are to be used. Dry heat externally aids in relieving shock and in restoring peripheral circulation. Partial inversion of the body by raising the foot of the bed acts as a cardiac stimulant; thirst must be relieved when vomiting and nausea are severe, by high rectal enemata or subcutaneous infusion; tympanitis can often be relieved by the use of the rectal tube or high turpentine enemata.

PERFORATION PERITONITIS.

CASE 1.—F. G., a male, age 43 years, by occupation a laborer, was found by a park policeman in Gordon Park Sunday evening, July 26. An ambulance was called, and he was sent to St. Clair Street Hospital. The history as given me by the house physician previous to his coming under my charge is as follows: The patient says he has not been feeling well for several days. During Sunday he was taken with diarrhea and vomiting, with severe pain in the abdomen and lower limbs. On entering the hospital he was given a hypodermic injection of $\frac{1}{4}$ grain of morphia every four hours, which gave him some relief from pain, and vomiting was less frequent. The patient says his bowels moved several times during Sunday evening and Monday. Tuesday at 2 p. m. the house physician observed that the patient was in more pain and that there was stercoraceous matter in the material vomited. No bowel movement had occurred during the day. I was at this time asked to see the case. I found on inspection a pinched look, anxious expression, flat abdomen and a restless patient. On palpation I found extreme rigidity of all the abdominal muscles; in fact, they were hard and board-like; tenderness was general, yet on firm pressure there seemed to be one point at the outer border of the left rectus muscle, one inch below the umbilicus, which was apparently more sensitive than any other part of the abdomen. The pulse was 126 and the temperature 99. A hypodermic injection of $\frac{1}{50}$ grain of strychnin was given and the patient prepared for an abdominal section. An incision was made midway between the umbilicus and pubis; a retractor was used to raise the abdominal wall for an intra-abdominal inspection before disturbing the internal viscera; to the left of the incision a coil of collapsed bowel some five inches in length was seen. The peritoneal cavity was walled off with iodoform gauze, the collapsed bowel brought out of the incision and laid on a sterilized towel wet in saline solution; intestinal clamps were applied, five inches of bowel were removed, and the Murphy button used. After the button was introduced into the bowel, before being closed, twelve ounces of saline solution, the bowels thoroughly cleansed and wiped with gauze wet in saline

solution and returned to the peritoneal cavity. No drainage was used in this case, yet my patient made a rapid and complete recovery.

CASE 2.—Miss S., aged 22 years, by occupation a clerk, gave a history as follows: Three weeks previous she was sick and her attending physician said she had an attack of appendicitis—which I believe was so. After recovering from her illness she says at times she still had some pain. On Tuesday morning, Sept. 8, 1898, she arose as usual. After being up a couple of hours she was taken with violent pain in the abdomen, and vomiting began shortly thereafter. Dr. Pasko was called, who diagnosed peritonitis undoubtedly due to appendicitis. At 10 p. m. of the same day I saw her in consultation. The abdomen was distended, there was general tenderness, rigidity well marked, vomiting, frequently of a green rosy substance. Pulse was 120, temperature 102.5. Peristalsis was diminished. My advice was an immediate operation. This the parents did not accede to but wished to wait and see what they could accomplish by local applications during the night. Early the following morning the Doctor telephoned me that the patient was much worse and that they had decided to remove her at once to St. Clair Hospital for an operation. Before leaving home her temperature was 103, pulse 130, the abdomen greatly distended, tenderness general and extreme rigidity of all the abdominal muscles; vomiting quite frequent. After due preparation an incision was made in the right linea semilunaris. A slight amount of odorless serum was found in the peritoneal cavity. The small intestines were thoroughly covered by and agglutinated with plastic material. These adhesions were thoroughly broken up, and whenever practicable, the lymph was removed and washed away. The appendix was removed. It contained a large fecal concretion $1\frac{1}{2}$ inches from its distal end which was necrotic and broken down. The peritoneal cavity was thoroughly irrigated with some four gallons of normal saline solution; after this thorough irrigation. The cavity was filled with the same solution and the wound closed. No drainage was used. My patient made an uninterrupted recovery.

DISCUSSION.

DR. A. J. OCHSNER, Chicago.—Dr. House has brought before us one of the most important subjects that we will have under consideration during this meeting, and this paper should certainly receive a very full discussion, because the very radical views which the Doctor has expressed should either be endorsed by this Section as good teaching, or, if our experience does not correspond with that of the author, this fact should be emphasized.

Having under my care a large surgical hospital, I have had an opportunity to observe an unusually large number of patients suffering from peritonitis, especially those in whom this condition is due to perforative or strangulous appendicitis, and others in whom it is due to infection from salpingitis. Patients are constantly being sent in with the request of the attending physician that an abdominal section be made at once, because this seems to be the only possible chance of saving the patient's life. Until about four years ago I usually complied with this request, and almost invariably the patient died. At that time I thought these patients died notwithstanding the operation, now I know that many of them died on account of the operation.

Usually the infectious material is primarily localized, either in the appendix or in the Fallopiian tubes, and this material is distributed to the other portions of the peritoneal cavity by the motion of the small intestines. If this motion is prevented in the early part of the attack the peritonitis will remain very

limited, and correspondingly harmless. The omentum naturally surrounds any infected intra-abdominal area, and the small intestines apply themselves against the omentum, but as soon as food is taken into the stomach, the peristaltic motion of the small intestines, which is always sure to occur at once, disturbs this condition and distributes any septic material with which parts of these organs may have come in contact.

On this physiologic fact is based the treatment which I now employ in these cases. These patients are given absolutely no food by mouth, not even a small amount of milk or gruel, because my experience has taught me that it requires but a very small amount of any kind of food to kill these patients. If food is given, it will simply decompose and increase the amount of septic material in the intestines; it will form gas which will distend the intestines, and favor the passage of the colon bacilli through the intestinal walls. But aside from this, the fact that it will give rise to peristalsis is alone enough to condemn the giving of food by mouth in these cases. If there is stercoraceous vomiting I wash out the stomach, and if no further food is given this will usually permanently stop the vomiting. The patient receives from three to five ounces of preigested food by enema every three hours.

Many of the patients come into the hospital with the abdomen enormously distended, a pulse ranging from 120 to 160 per minute, and a temperature ranging from 101 to 104.5 F., presenting precisely the same clinical picture that many others had shown who almost invariably died after a laparotomy of last resort, and still a very large proportion of these patients recover. I have frequently opened the abdomen in these patients later, and found gangrenous or perforated appendices, or extensive adhesions following a ruptured pyosalpinx, proving the correctness of the original diagnosis.

I believe that if this form of treatment were employed systematically whenever any form of peritonitis, not due to traumatic causes, first makes its appearance, general peritonitis would almost never occur, and I am certain that this treatment will save many patients, who would almost certainly die were they subjected to an operation under the impression that this is their only chance.

DR. J. B. MURPHY, Chicago—To begin with "I do not know where I am at" on this subject. I would like to ask Dr. Ochsner whether he means by allowing the contents of the bowel to escape to allow it to move on?

DR. OCHSNER—As long as the patients vomit I wash out the stomach. Then they get rectal feeding, three to five ounces of the liquid food, of some kind, every three hours, and absolutely no nourishment by mouth.

DR. MURPHY—That is not the question. But you said it prevented the contents of the bowel moving—being disturbed. Do you mean passing along in the canal, or what?

DR. OCHSNER—If you stop feeding them the small intestines will not churn around the septic material with which they come in contact, and no more food decomposes in the intestines because none is placed there. The decomposition products, and especially the colon bacilli, find a chance to get through the intestinal wall if food is given, because of the gaseous distension of the intestine, which does not occur if food is absolutely prohibited.

DR. MURPHY—The important factors in peritonitis are: The diagnosis. When does a patient get a peritonitis? When does he get a general peritonitis or a local peritonitis that is extending along and going to become a general peritonitis? What is the significance of the term "collapse" in connection with general peritonitis? Should we operate on a patient in collapse in general peritonitis? Do I understand Dr. Ochsner that he means this class of patients—patients that are collapsed, having the cold and clammy skin and gulping of that biliary material, if I may use the term, every ten or fifteen minutes? Is this the class of cases you stop feeding?

DR. OCHSNER—Some patients of that particular class will still get well if we stop the feeding; formerly they all died.

DR. MURPHY—The important matter in connection with general peritonitis, as I look on it, is the type of infection. What is the character of the infection? What is the course of the type of that infection after the peritoneal surface has been inoculated?—I will use that word. We know from experience and opening of the peritoneal cavity, when that contains a large quantity of pus, that cases, with a large quantity of pus, get well. We know from experience that cases with a small quantity of pus, opened and drained, will die; also that when we see a peritoneal cavity where the peritoneum is not blistered, where the peritoneum retains its gloss, regardless of the quantity of pus, patients in a large percentage of cases recover. We again know from experience, when we open the peritoneal cavity, regardless of the quantity of pus, that patients with blistered peritoneums—that is, where the intes-

tine has lost its gloss—will die. We must go back to the type of infection. I believe from cultures that we have made from these cases that the blister cases are of the streptococcus type. I believe, again, that a large quantity of pus cases are some other kind, but I leave out of consideration what the etiology is. I speak of the pathologic condition when you open the peritoneal cavity. If the peritoneum is blistered, I do not recall a single case that has not died. Where the peritoneum has not been blistered, many, many of them have recovered. Then, there is a middle class that you can not save. The infection has existed for four or five days. And it seems to me somewhat a mystery where the infection comes from. I am much more afraid of infection from the lower portion of the bowel than the other, and that sustains Dr. Ochsner's position, with a gastro-perforating abscess extending down to the peritoneal cavity, having an accumulation of pus in the pelvis from a perforating ulcer of the stomach, and I report a case where the patient had been seen but thirty-six hours and the pelvic cavity filled with pus. I washed him up with salt solution and closed him up without drainage. I believed he would get well, and he did get well.

In the diagnosis the length of time the pus is retained in the peritoneum is a very important thing. A surface covered with these endothelial cells—and these have the same functions as the epithelial cells—a material that destroys the endothelial cells and blisters the bowel, opens the lymphatics for absorption. I believe the surface of the peritoneum absorbs little more than the surface of the skin. As soon as the endothelial cells are disturbed, then absorption commences, and that is why I draw the line on appearance of cases. I believe all cases of general peritonitis should be treated in the early stage. I believe diagnosis should be made on pain, tenderness, nausea, vomiting, temperature and distension—and this is not an early symptom; it is the last of symptoms; it may not be present. You should not wait for collapse or shock. The collapse is practically the fatal condition. I do not recall a single case of collapse, of cold perspiration, that has recovered from an operation or recovered without—they have all died. I have a number of times recently refused to operate. If I would operate I would make a large opening and clean out the peritoneal cavity thoroughly with gauze or fluid.

DR. THOS. H. MANLEY, New York—What does he mean by blistering of the abdomen? He says every patient with a blister dies—those with the severe form of peritonitis with blisters die. What does he mean by that?

DR. MURPHY—I thought I made myself plain. Where the peritoneum is blistered, the endothelial cells remove from the infection of the peritoneum.

DR. OCHSNER—If this treatment is followed in the early cases there are no late cases, and, on the other hand, the conditions in which formerly I have found the blistered peritoneum and in which the patients died—the same clinical conditions—the patients get well now.

DR. JOS. H. BRANNHAM, Baltimore—This discussion has brought out a most remarkable condition of things. The idea of general peritonitis is one of infection, generally one after injury of some kind, either perforation or gunshot injury, or something of that nature, and I can hardly understand—although we know washing out the stomach and lower intestine can do something—how we can listen to teaching that keeping the patient quiet, and without food, will cure a case of peritonitis with a half-dozen gunshot wounds, through the intestine. Maybe Dr. Ochsner means some other kind of peritonitis. If it is perforation of intestine and you have infection from colon or other bacilli, we are going backward. I should say that this teaching is a long step backward, because I believe with the writing of the paper, that the best treatment of general peritonitis is operative treatment with thorough cleansing of the bowels and peritoneal cavity, added to the method recommended of thoroughly cleansing the alimentary canal above and below. A certain number of cases, especially those in which there is a good deal of fluid in the peritoneal cavity, will get well after this treatment; but in a general infectious peritonitis with a lot of pus in the peritoneal cavity, if it has made any progress, or unless the infection is caused by a mild germ—such as the pneumococcus—the patient will surely die if left without some surgical interference. On the other hand, if the alimentary canal is thoroughly cleaned from above and below—the bowels cleaned off after operation—a small percentage will be saved, and I think that small percentage with improvement in the method of cleansing will gradually be increased. I think it would be just as reasonable to leave a patient—after washing out his stomach and alimentary canal—quiet if he had a perforating appendicitis, as it would be if he had a general infectious or suppurative peritonitis, and I think that because a few have died after operation we should

not go backward to some old method—the only improvement over which is the keeping of the alimentary canal as empty and clean as possible.

DR. FLOYD W. McRAE, Atlanta, Ga.—It seems to me that, if my ideas of pathology are correct, Dr. Ochsner is wrong. The condition he described is secondary to the primary infection. This new infection that is added to the original infection, due to paresis of the bowel, is the result of fermentation and putrefaction in the alimentary canal. The general peritonium is in danger here from two sources: the primary disease, and the infectious material from the thin-walled intestines of lowered vitality. The diagnosis in these cases is of the utmost importance, because it frequently enables the surgeon to remove the primary cause of the peritonitis. By early operation, the infection can be removed before the condition described by Dr. Ochsner obtains. That is the way it impresses me. I have recently collected statistics of 601 cases of septic peritonitis, subjected to surgical intervention, with a mortality of 52.4 per cent. I believe these results are better than can be obtained by medical treatment. Dr. Van Arsdale recently reported ten cases of general septic peritonitis with six recoveries and four deaths. Surgeons operating early in this condition are the ones getting good results. In the late cases, where there is enormous distension, surgery does little good; but in these extreme conditions, I think the treatment which Dr. Ochsner recommends is the proper treatment. I have seen three cases of beginning general peritonitis get well under operative interference. By general peritonitis, we now understand that condition where the infection is not limited by adhesions, where there is nothing to prevent an extension—we rarely see a case where the entire peritoneum is inflamed. I have seen three cases get well where there was that dirty-dish-water fluid loose in the peritoneal cavity, and the whole membrane seemingly involved, due to gangrenous appendices. I do not believe they would have gotten well under Dr. Ochsner's plan of treatment.

DR. M. F. PORTER, Fort Wayne, Ind.—I wish first to emphasize what Dr. Murphy says regarding the importance of realizing the nature of the infection that is at the bottom of peritonitis. I believe that if you have a streptococcus invasion of the peritoneum, you do not have to have infection extending over a great surface of the peritoneum in order for that patient to die, no matter what you do. On the other hand, I wish to say that I have looked over as much of the peritoneal surface as it is possible to look over from opening six inches in the middle line and have seen a perfect, if you please, complete bath of all the surface in pus, and I have seen these persons get well. I do not know of any means of telling whether you have to deal with streptococcus or infection of some other sort prior to the operation. When the opening is made I believe you can. I have seen the intestines look as if they had been dipped in boiling water; I believe these patients will die. Dr. McRae has just spoken of a condition in which he says all patients die—a great distension of the bowel, and this seems to me an important point. I believe in these cases of great distension of the bowel, that the opening of the gut is of almost as much importance as is the opening of the peritoneal cavity itself for the purpose of drainage. It is true that most of these people die, but I have seen them so far distended that they could scarcely breathe—cyanotic—and yet I have seen such patients get well with opening the gut, doing just as little as you can do to get rid of your septic material for the time being and finishing the operation by and by. It is good theory and good practice; it is a nice idea to get rid of the cause of the trouble, but you can not always do this at the first operation; some of these patients are dying, not from appendicitis or peritonitis, but from the results—tympany has a great deal to do with it. Patients will be relieved if you open the gut. So I believe that the first thing to do is to stop the absorption, relieve the tympany, etc., by a quickly performed operation, simply a laparotomy, cutting a hole in the intestines, leaving it lie on the outside, letting the gas escape, and finishing the operation when the patient is stronger. Most of them will die, but you will not kill any one of them. I admire Dr. Ochsner's bravery in saying: "I have killed them." He did not save them. That is so, and most of us are in the same boat; but now and then you have one that does get well and then you know that you have saved a life.

DR. BROWN, Illinois—As a representative of the country doctor who is a listener probably more than anything else, I want to say that this discussion puts me in mind, like every other surgical treatment in treating a disease, of a story. Our magnificent surgical friends, Dr. Ochsner and Dr. Murphy, are, apparently, getting on two sides of the question, when, in reality, they are not. The story of which I am reminded is of the student who was questioned by the professor

as to what he would do in the treatment of a certain difficulty—he would do this and that, and the other thing. "If you didn't succeed, then, what would you do?" He said to the professor, "I would send for you!" The country doctor can not send for Dr. Ochsner and Dr. Murphy. I should be compelled to send for both of them, because they have two kinds of treatment. This treatment of a case of peritonitis is the treatment of an individual case. When Dr. Ochsner goes to the bedside of a patient, he will treat that individual case as he finds it, not as you discuss it here before these gentlemen present. Dr. Murphy will do exactly the same thing, and I am very much afraid that if they were both at the bedside, they would come pretty near getting the same idea when they saw the individual case. I know the treatment of Dr. Ochsner—depriving the patient of all nourishment—is a good one, but whether it will do all that he says I am willing to wait and see.

DR. MOORE, Indianapolis—I came in late, but I trust the author of the paper laid stress on the fact that peritonitis is a secondary affair; it is always secondary. There is no one thing more remarkable in the history of medicine and surgery than the fact that for centuries men of high and low degree have been making post mortems and finding cases of peritonitis without having recognized that fact which we all now recognize—that peritonitis is a secondary affair. It is always secondary to an appendicitis, to a salpingitis, to a cholecystitis, to a perforation, or to some surgical lesion. Therefore, if we get our patient early and have the evidence of general peritonitis, the mere fact that there is a general peritonitis should not direct us away from our surgery. We should treat those cases surgically. When a patient comes in with a last gasp, our medical friends very kindly turn him over to us. Then I am inclined to think that our friend, Dr. Ochsner, has a very level head. I think it behooves us to do nothing in those extreme circumstances. If I may judge from my own personal experience we will accomplish nothing but to bring surgery into disrepute; I mean in these cases coming in at the last minute. I have never seen surgery do good there, but at an early date why should we treat a patient with inflammation of the abdomen differently from a patient with inflammation in any other part of his anatomy?

DR. A. F. HOUSE, Cleveland—I want to say that while, of course, I had to cut my paper somewhat short, it is not likely that you would treat peritonitis surgically without some medical preparation. In my paper will be found what I believe to be proper preparatory treatment, as well as before, during and after an operation. I believe that the alimentary tract should be emptied, if it is possible. If you cannot do so by salines by the mouth or by fluids injected, or salines into the rectum, then we should empty the alimentary tract, not opening the abdominal cavity. I think I made mention of the fact that while no bowel movement had occurred for some time, I did not fool with a patient, and that, while there were evidences of paresis, I used a large needle-aspirating needle—for the purpose of emptying the bowel of liquid feces and gas and then injected from one to two pints of normal saline solution. I have done that with the very best results. As to peritonitis being a secondary condition to something else, I think I made mention of that. Another thing is in what class of cases to operate or when to operate, and when not to operate. I think I laid as much stress on the different symptoms as it was possible. I think, as many others do, that each and every individual case must be governed by its condition when seen. I simply wanted to lay stress on the fact that I believe that all cases of peritonitis beginning with local tenderness becoming general, with rise of temperature and rapidity of pulse, should be operated on at once, and I think I can show that by statistics. I know that had I operated early I would have saved my patients. It is not four weeks since I showed a case, five days after being diagnosed as appendicitis. It was seen by a prominent surgeon of the city forty-eight hours before I saw it. He said wait for developments and let it localize itself. He did. The next day I saw the case. He said let it localize itself and develop. He did. I saw the case within twelve or twenty-four hours afterward. I then believed that the belly was filled with pus. It was a retrocecal abscess. I recollect another case of six weeks ago, where the gentleman was taken sick on Tuesday morning going to his place of business. He immediately returned home, and called in his family physician, who diagnosed appendicitis. A surgeon was called in shortly afterward and he rather dilly-dallied and said, "Wait for developments." I saw the case on the same evening, or the evening of the same day. The tenderness was local in the morning; when I saw the case, tenderness was beginning to be general, pulse 120, temperature 103, tympanitis beginning to be marked and there was rigidity of the entire abdominal

muscles. My advice was immediate operation, not to wait until morning. My advice was not taken, because I could not promise to cure the patient. The patient was not operated upon. At the post-mortem what did we find? A belly full of pus. The man had a postcecal abscess ruptured. And what was the consequence? Death.

EPITHELIAL STRUCTURES IN THE PERIDENTAL MEMBRANE.*

BY FREDERICK B. NOYES, D.D.S.
CHICAGO.

For four or five years I have been interested in the histologic study of the peridental membrane, and during that time have devoted what time I could to the special study of certain structures found in that membrane, and called by Dr. Black, who first described them, the glands of the peridental membrane.

The work which I have tried to do on this subject is really not in shape to report, as it has not been worked out to the point where positive statements can be made

ing. I need not dwell on these technical difficulties. All who are familiar with such work will understand them. I mention them only as an apology for defects which may be noticed in the illustrations.

One man has said to me that he had never seen a specimen of tooth that would be considered technically acceptable in the study of the liver, for instance.

It is true that the technic of this study must be improved. It is almost impossible to get sections of the peridental membrane as thin as would be desirable for high power work; but, though they are harder to study, many things can be learned from thick sections; some things better than from thin ones, especially by comparison with low powers, and the use of the binocular. The difficulty of showing in photographic illustrations the things that are learned in this way is very great, however.

The diseases of the peridental membrane have attracted marked attention, and provoked an immense

Longitudinal section of the tooth, and alveolar process showing the fibers of the peridental membrane, magnified 40 diameters—35 mm. Zeiss obj. Ep, epithelium lining the gingival space and continuous with the epithelium covering the gum. D, dentine. P, pulp. Cm, cementum. Al, bone of the alveolar process. Pd, peridental membrane. Per, periosteum covering the outside of the alveolar process.

in regard to the nature of these structures. But I have reached a point where to carry through the work would require from three to six months of time, without interruption. This it has been impossible for me to do, and I see no probability that I will be able to do it in the near future. I have, therefore, decided to make this simply a report of my work, and a statement of the problem as it stands. The histologic study of this tissue is beset with the greatest technical difficulties. Situated between calcified tissues, all specimens must go through the calcifying methods, and, moreover, the character of the tissue is such that it is difficult to avoid overharden-

Transverse section of the tooth, peridental membrane and alveolar process. Magnified about 40 diameters—35 mm. Zeiss obj. M, muscle. Per, periosteum on the labial side of the process. Al, bone of the alveolar process. Pd, peridental membrane. P, pulp. D, dentine. Cm, cementum.

amount of writing and discussion. It has been a continual surprise to me to find so many of those who write most freely on this subject show so little interest in the histologic character of the tissue with which they have to deal. They usually dismiss it with a word. Last winter one man who has written much on this subject, told me that he had never had time to take up the study, and showed absolutely no interest in it; still, in a paper which I heard him read a few days before, he had indulged in arguments based on his ideas of histology of the tissue.

I am unable to understand how men can hope to arrive at a knowledge of the diseased conditions of a tissue, the normal conditions of which they do not know, and which contains structures which they do not recognize, and concerning the origin, function, or destiny of which

*Presented to the Section on Stomatology, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

they have no idea. It is impossible that anything satisfactory can be worked out in regard to these conditions, which are of so great interest to the dentist, until the problems are attacked in a more scientific and rational manner. Until then we are fighting we know not what, we know not how.

Transverse section through two teeth and the peridental membrane in the gingival portion. Magnified about 40 diameters—35 mm. Zeiss obj. Ep, epithelium covering the gum. D, dentine. Cm, cementum. Cm 2, cementum filling an absorption cavity in the dentine. Ec, epithelial structures. Ec, 2, portion shown in Fig. 1b.

The peridental membrane (Figs. 1 and 3) may be defined as the tissue which fills the space between the root of the tooth and the bony wall of the alveolus, being attached to the cementum on the one side and the bone on the other; it surrounds and is attached to the root from the border of the alveolus, to the gingival line, and supports the epithelium of the gingivus. It has been called by a number of names, of which I prefer pericementum, or peridental membrane, the two being used synonymously. This membrane belongs to the class of fibrous membranes, being composed chiefly of white, fibrous con-

Cross section of a root of an incisor showing the epithelial structures. Magnified about 75 diameters. A. A. Zeiss obj. Cm, cementum. D, dentine. P, pulp. F, fibers of the membrane. Ec, epithelial structures.

nective tissue. It is not in any sense a double membrane, and, while it has qualities in common with the periosteum with which it blends at the rim of the alveolus, it differs markedly from the periosteum in any position.

For convenience of description I have followed Dr. Black's division of the membrane into three portions. The gingival portion surrounds the neck of the tooth from the border of the alveolar process to the gingival line, and supports the gingivus. The alveolar portion surrounds the root from the border of the process to the apex. The apical portions surround the apex of the root and fill the apical space.

In transverse sections of the membrane, which have been well stained with hematoxylin, and eosin, even with as low a power as a thirty-five (Figure 4) m.m. lens,

Tangential section of the peridental membrane. x75 A. A. Zeiss obj. D, dentine. Cm, cementum. F, Fibrous tissue of the peridental membrane. Ec, epithelial structures, showing the net work.

small deeply-stained bodies can be seen lying close to the cementum, and winding between the fibers as they spring from it. With a one-half or three-fourths inch (Fig. 5)

objective and a binocular instrument, the winding of these cords of deeply-stained cells among the fibers is beautifully shown. In such observations these bodies very strongly suggest such structures as the sweat-glands. As many as 200 bits of these cords have been counted in a transverse section of the gingival portion of the membrane around an incisor of a young lamb.

Epithelial structures magnified about 550 diameters; 1 1/2 oil Zeiss obj. Ec, epithelial cords showing the cell forms and nuclei. Cb, cementoblasts. Cm, cementum. D, dentine.

In studying the arrangement of these cords they are found to form a network about the root of the tooth, extending from near the attachment of the epithelium at

the gingival line almost to the apex. In the gingival portion they form a close-mesh net, which grows more open as they pass apically. In sections cut tangentially

to the root (Fig. 6), this branching and net formation is shown, but the entire arrangement cannot be shown in photograph. This diagram (Fig. 7), made by Dr. Black some time ago, shows the plan as it is made out from the study of many sections.

When Dr. Black first described these structures, thirteen or fourteen years ago, in his "Studies of the Periosteum and Peridental Membrane," he considered them to be of lymphatic character, and there are things about them that support this idea, but from a study of the character of the cells they seem to be of epithelial order showing various forms, sometimes appearing ovoid, but usual-

Epithelial structures magnified about 500 diameters; 1 1/2 oil Zeiss obj. Ec, epithelial structure appearing to show a lumen and showing the arrangement of the e cells. Cb, Cementoblasts. Cm, cementum. D, dentine.

ly polyhedral, or cuboidal. The nucleus is always large polyhedral, or cuboidal. The nucleus is always large and conspicuous, and often shows nucleoli. (Figs. 8 and 9.)

Epithelial structures magnified about 300 diameters; D, D. obj. and No. 2 projection ocular Zeiss. Fb, fibroblasts. Ec, epithelial structures. Cb, cementoblasts. Cm, cementum showing the penetration of the fibers of the membrane. D, dentine.

The cells are not arranged into true tubules in all places (Fig. 15), though what appears to be a lumen, with a circle of cells about it, may be found in a good many positions. The structures are better described as cords of cells than as true, distinct tubules. In some

places there is a circle of cells, with one in the center. Sometimes there seems to be a central cluster and a circle around it. These appearances may be caused by a cut, which does not strike the center of the cord, or tubule, but this could hardly be the case in transverse sections. This arrangement of the cells suggests lymphatics, rather than true glands, though some of the ductless glands, as the thyroid, show alveoli solidly filled with cells.

The cords of cells lie very close to the cementum be-

tween the fibers as they spring from it (Fig. 16), swinging out from the root and back again in hoops. In many places the end next to the cementum is club-shaped (Figs. 17, 18 and 19), and comes very close to the root between the cementoblasts. A delicate basement mem-

Epithelial structure with club-shaped end close to the cementum. Magnified about 300 diameters; 4 10 obj., Bausch & Lomb, No. 2 occ. Ee, epithelial structure with club-shaped end. Cp, cementoblasts. Cm, cementum showing the penetration of fibers of the membrane. D, dentine brane surrounds these cords (Figs. 9 and 17), and in a few places a circular arrangement of fiber may be seen about the large ones. (Fig. 20.)

I have searched for something in the form of a duct for these structures, or some connection between the epithelium lining the gingival space, and the cords. Some appearances which suggest ducts are uniformly found, but it has been impossible to follow them because of the failure to obtain complete series of sections.

In the gingival portion of the membrane in transverse sections I have found a number of very perfect tubules in section, of which Fig. 20 is the best illustration I have been able to get, but that is not as good a representation of the object as I could wish. With the microscope it shows a very perfect circle of cuboidal cells with large nuclei. In the lumen are several loose cells. There is a distinct basement membrane, and a few circular fibers. Just on one side of this is a small duct made up of four cells. When these tubules have been observed, they show a tendency to swing out from the surface of the root. Figure 21 shows these duct-like structures in longitudinal section. As they pass away from the cords of cells, they swing away from the cementum, and, passing gingivally, curve farther away from the root as the gingivus is approached. The epithelium of the gingivus presents long slender projections, often of complicated form. The connective tissue between these contains small round cells. This collection of round cells is especially conspicuous on the proximal sides, and constitutes what has been called the gingival gland.

The ducts have been followed up into these epithelial legs, where they have been lost. But even in this position

Transverse section of a duct-like structure. Magnified about 1000 diameters; 1 12 oil Zeiss obj., No. 2 acc. their cell structure is very different from that of the epithelial legs, so that I would say that they do not connect with them. As far as I have been able to follow them they maintain their characteristics.

The structure referred to by Dr. Black¹ as the gingival gland (Fig. 23), and which as he states is not a gland at all, is very characteristic of the gingivus, at least in the sheep, in which I have chiefly seen it. At first I was inclined to regard it as pathologic, but it is so nearly universal in large or small form on the proximal portion of the gingivus, and has been so universally observed by Dr. Black, that it seems to be the normal condition.

The presence of these epithelial structures in the membrane is beyond question. Their nature, origin, and function can not be stated. I have showed photographs and sections of them to very many histologists and pathologists, engaged in general morphologic as well as in medical work, and almost without exception, after looking them over, they say: "On casual inspection I should say that they are probably tubular glands!" I have observed them in sections of the membrane from man, dogs, cats, sheep, pigs, about the temporary and permanent

teeth in the young and the old membrane. Like all cellular elements of the membrane, they grow less numerous with age, but they have been seen in the membrane from a man 70 years old.

The size, number, persistence, and conspicuousness of

these structures make it seem extremely improbable that they are simply embryonal remains from the epithelial cord, or external or internal tunics of the enamel organ, as suggested by the work of Von Brom, quoted by Charles Thomas², and as was suggested to me by Dr.

Huber of Ann Arbor. I have not attempted to trace the origin of them, but in the last few weeks, by the kindness of Dr. John Palmer of Chicago, I obtained some rabbits' jaws, soon after birth. I have studied them over, and have been unable to find any trace of such structure in membranes of unerupted teeth. It seems to me that these structures must be present for a purpose. What that may be I cannot suggest, and I know nothing that throws any light on the question.

In order to work out the problem to meet the requirements of the histologist, four things must be done.

1. The origin of the structures must be traced, so as to determine from what tissue they are derived.

2. Their relation to the blood-supply must be determined.

3. Their morphology must be determined, by making a complete series of sections, both longitudinal and transverse, to determine whether they have ducts or not, or other connection with the gingival epithelium; and the complete reconstruction of them from serial section. The last task is perhaps impossible, but it could be done for small areas so as to satisfy the demand.

4. Their condition in diseased conditions of the membrane must be carefully studied.

Until such a program is followed out we can but speculate as to what the origin and function may be, and speculation of this kind does not often aid in the advancement of scientific knowledge.

SYPHILIS IN SURGICAL PRACTICE.

BY ARTHUR DEAN BEVAN, M.D.

Surgeon to Presbyterian Hospital; Associate Professor of Surgery, Rush Medical College.
CHICAGO.

My father was a physician. One day, when a boy of 16, I was in my father's office when a tall, fine-looking man of 35 or 40 came in to consult him. This man was a German-American of considerable prominence. I had often met him before, and had always admired him. He was a great thick fellow, more than six feet tall, with large brown shaggy head and beard, deep-voiced, bright-eyed, the picture of physical and mental health; a fine type of the Teutonic massiveness and vitality that has relegated the Latin races to the dying nations of the world. I remember that when I read "Caesar's Commentaries," with the description of the giant Germans, who disputed Caesar's advance across the Rhine, and who died so bravely, crushed by the better arms and better discipline of the Roman legions, I thought of this man; they were his ancestors. He was a picture of what they had been. After he had left the office I drove with my father on his afternoon round of visits. We had been in the buggy, driving possibly ten minutes, when my father suddenly turned around to me and, for the first time in my life, gave me some advice on the subject of sexual intercourse. He told me of the penalties of promiscuous intercourse, the virulence of gonorrhoea, the ravages of syphilis. He drew a picture of an invalid wife, a blind child, the man with the blurred brain and the incoherent speech of syphilitic aphasia, and the staggering gait of ataxia. He was a graphic word-painter, and I remember as a boy it made a profound impression on me. And in some way I always associated this, my first knowledge of venereal disease, with the German who had left the office but a short time before. That was twenty-two years ago. Two weeks ago an old man, of great massive frame, dragging his

²Read before the Alumni Association of Rush Medical College, May 24, 1899.

right leg, shuffled unsteadily into my office; his pocket handkerchief and gloves were almost falling out of his right overcoat pocket; he could not articulate above a whisper, and even then could command but a few words. The left eye was dulled with an old iritis; the right eye was reddened by an acute attack; the pupil dilated unevenly with atropin; the hands presented syphilitic skin and nail lesions; and this wreck was my German, the German whom I had idealized; plus syphilis. With some difficulty I obtained his history, and, most interesting of all, the fact that he had always denied to the many physicians who had treated him for twenty years for various lesions, principally if not entirely syphilitic, syphilis. My father and myself, he said, were the only ones who knew that he had syphilis, because, as he stated, my father had told him at the end of two years' treatment that he regarded him as cured. My father died about that time, and he said no one then living knew that he had had syphilis, and he had a family and he could not have anyone know, and would I swear to him that I would not tell any one? You are all familiar with the picture I have so crudely drawn, the common picture of syphilis and its concealment, interesting only because of the frame of circumstances which surrounds it.

When I received my degree in medicine I accepted a contract position as acting assistant-surgeon in the U. S. Marine-Hospital service. I was stationed at the marine hospital in Chicago. My duties were to look after the out-patient department of the work. In this department we treated nearly 3000 patients annually, about one-third of these being venereal diseases, and of these 1000 venereal cases, many were cases of syphilis, representing all stages of the disease. Syphilis became the first great problem in disease with which I wrestled, and the diagnosis, the vagaries, the treatment, and the tenacity of the lesion became an interesting study, for which later five years of regular service in marine hospitals afforded an abundance of material. The sailor man is as a class easily the point of least resistance in the community to syphilis. His long voyages and enforced continence, and his drunken embrace of blear-eyed Venus during his short spree in port, make him an almost certain victim of infection, and the fact that he seldom early receives the benefit of proper and continued medication enables the marine surgeon, into whose hands the derelict finally drifts, to study often the natural history of syphilis unmodified by treatment. Many of our cases are honestly ignorant of having syphilis; some would deny and later confess to a syphilitic history, when confronted with positive evidence. I early learned to place little or no reliance on the previous history in making a diagnosis.

Since leaving the marine-hospital service, ten years ago, I have devoted my time exclusively to general surgery, and in this work I have found that my early syphilitic training has been of great service. I do not mean to pose as a syphilographer, but I am sure that I have been saved many mistakes by this training. I am sure that I have seen many cases which this training clearly branded syphilis to me, overlooked by the specialist, the surgeon and the general practitioner. On the other hand, I must confess that in a number of cases I have believed lesions syphilitic which were later proved to be of other origin. I have learned to know that syphilis is not a respecter of class or person—rich and poor, youth and age, priest and libertine, prostitute and virgin, guilty and innocent, all can and do acquire this disease. We must not be astonished in finding it

anywhere. We must never accept a negative history as definite evidence of its absence. Syphilis is more widespread than is generally supposed. It causes many an illness when it is not recognized or even suspected. Without carrying our suspicion to extreme, we should constantly be on the watch for syphilis in our everyday work.

It is not my intention to present a discussion of typical syphilis, as is done by the syphilographers, in textbooks, but believing that a broad discussion of the unusual and often unrecognized lesions of syphilis as they present themselves to the general practitioner and specialist might interest all, I will open the discussion by reviewing some of my experiences with syphilis in surgical work. I might entitle this brief paper, then, "Unusual Syphilis in Surgical Practice."

The subject of extragenital chancre will furnish the unusual form in the primary stage. I have handled about fifteen of these lesions which I can now call to mind; most interesting to us possibly are the extragenital chancres which physicians acquire in their professional work. I have seen a number of these cases; the majority of them presented none of the characteristics of chancre and were mistaken for pus infections, or tuberculous infections, and later, when the axillary lymphatics were involved and a low form of syphilitic fever was present, the axillary lymphatics were removed; the subsequent development of the secondary symptoms cleared up the diagnosis. Several of my cases have been seen by expert syphilographers, and the primary lesion positively pronounced not the initial lesion of syphilis. In one case an expert said that if it was a chancre it certainly had none of the characteristic signs, and that he had never seen one like it. In another case, seen by me with a colleague, the syphilographer staked his professional reputation that the lesion was not specific, and yet in both, the later secondary symptoms disproved their statements. In both these cases the axillary lymphatics were removed with the idea that we had a low form of pus infection or mixed infection to deal with. The lesson to be learned from such cases is that extragenital chancres of the fingers are seldom typical. An infection on a physician's hand, which is not acute, which produces enlargement of the axillary lymphatics, which persists for more than ten days, which is locally limited, which is accompanied by a slight continued elevation of temperature, is suspicious of syphilis, no matter what the size, shape, or consistency of the sore may be.

In looking into this question I find that trained nurses very rarely acquire syphilis of the fingers. Among 500 nurses observed from 1883-1898, no cases; among physicians it is much more common than is generally believed. Among the several hundred physicians, certainly less than five hundred of my acquaintance, I know of six cases of extragenital chancre. This is almost entirely preventable and shows the necessity of the observance of the simple prophylactic rules required, and evidently followed out more carefully by nurses than physicians. The primary sore of the finger may be so small and so transient that it is not recognized; the secondary symptoms following may be slight and not interpreted and the case goes on to tertiary syphilis untreated. I have seen this in the case of a physician of unusual intelligence, who, in the light of tertiary symptoms, was able to review in this new light his previous four years and could plainly recall the primary sore and the mild secondary symptoms. In the light of this case, I have no doubt that many cases of syphilis exist in the com-

munity unrecognized by the physician and unknown to the patient. Extragenital chancres of the lips are fairly common; usually the infection is carried from a mucous patch on the lip of the infector; sometimes, of course, due to sexual perversion, and sometimes due to an indirect infection from instruments in the hands of dentists or physicians.

I have had one chancre of the tonsil occurring in the case of a physician who had his throat treated by a throat specialist, the infection being carried by the instruments used. A great mass of glands on the side of the neck followed the small unrecognized chancre. Two prominent surgeons diagnosed tuberculosis of the cervical glands and advised removal. Prof. James Nevins Hyde and myself suggested the possibility of syphilis. The doctor patient ridiculed the idea, but decided to await developments. Within a few weeks secondary symptoms occurred; treatment, rapid disappearance of glands, but later, unfortunately, brain syphilis.

An unusual type of extragenital syphilis occurred in a doctor who presented himself with the history: He tripped and fell on an iron rail, cut the skin over the patella; wound slow in healing; examined and probed by a number of doctors; wound almost healed, and then after twenty days a circular hard ulcer developed at the site of traumatism; hard chancre from infected instruments or fingers.

A physician brought me to see his son-in-law, his grandchild and his wife, who he said had been poisoned by poison ivy. The man had a pustular syphilide, the child inherited syphilis of the skin and skeleton, the grandmother a history of having had a sore on the arm on which she usually carried the child. This healed slowly, was accompanied by weakness and deterioration of general health, and she was, when I saw her, suffering from a macular syphilide. The mother of the child had no symptoms and my doctor friend, the grandfather, has escaped.

When stationed in Portland, Ore., my position as marine surgeon brought me many patients from the salmon fishermen; some seven thousand were at the mouth of the Columbia River. These men, like sailors, frequently acquire syphilis. Two of them go in a boat to tend their nets and live together for many weeks and months. Sodomy is common, and as a result chancre, chancreoid and gonorrhoea of the rectum occur. I have seen several cases of chancre of the rectum among these men, but have never been able to follow out the later history of these cases to determine whether the lesion was the initial lesion of syphilis or chancreoid.

The facts to be kept in mind in extragenital chancre are: 1, its atypical character; 2, that it is common, at least that it is not a rare lesion; 3, that it is possible in any individual; 4, that we should wait for secondary symptoms before placing the patient on constitutional treatment.

The second unusual form of syphilis I desire to mention is the unusually severe constitutional symptoms called syphilitic fever. I have seen one case in which I believe that it is possible that death resulted from the profound primary syphilitic intoxication before secondary symptoms developed; history of healing, hard chancre, bubo, severe pains in limbs, high continued fever, and death at the end of ten days; no post-mortem made. I have diagnosed typhoid several times and later found that I had syphilitic fever to deal with.

I shall pass over the unusual skin lesions of secondary syphilis because I am not qualified to discuss them. I shall simply remark, in passing, that I am impressed

with the fact that they may simulate almost any skin lesion, and that I lose confidence in the dermatologist who with great emphasis affirms positively that a certain lesion cannot be syphilis because it lacks this or that characteristic of form, color, consistence, symmetry, etc., because I have seen a number of cases in which these positive statements were made turn out to be syphilis after all.

Syphilitic ulcerations of the skin and mucous membrane are common. As a rule, in the light of the previous history they are readily recognized. There is a large number of cases, however, in which the patient conceals the history, or is ignorant of the history, and in which there is no other sign to guide the physician. These cases form a large group, and they are frequently mistaken for other lesions. As types, I will cite the following cases:

Mrs. P. was sent to me by a dermatologist, to remove a small epithelioma from the nose. I found a small ulcer with hard base, about the size of a bean, which had existed for several years; it would sometimes scab over, but never heal. She was a woman of refinement, fine social position, and with no specific history. I put her on iodid in large doses, and in two weeks the ulcer healed. I have had two other cases on the nose with the same history and result.

Mrs. R. was sent with diagnosis of epithelioma of scalp or possibly lupus; mother of eight children, youngest 12 years; good social position; no specific history. The lesion was of that character in which it was impossible to state the pathology positively. Under iodid of potash the lesion healed in three weeks.

I have seen several cases diagnosed as carcinoma of the tongue heal under iodid. In fact, I believe we should make it a rule, before operating on these small ulcerations of skin and mucous membrane, to give the patient the benefit of the doubt and put him or her on a thorough course of iodids.

We will sometimes make the mistake of confounding some other lesion with syphilis. As an example, I recall a case of a man of 50, with palmar syphilide, history of syphilis, and an ulceration of the finger, the size of a copper cent, of one year's standing. The diagnosis was positively syphilis. A long course of iodids gave no benefit. I removed a section and Prof. L. Hektoen found carcinoma, which we believed began on a syphilitic base.

Syphilitic lesions of the nose and palate are common. I refer to them here because I have met with several unusual cases. One was sent by a rhinologist, with destruction of cartilage and bone; no syphilitic history, course of iodids 8-grain doses producing no benefit. On increasing to 70-grain doses, the lesion healed. A second case, positively pronounced by rhinologists as non-specific; no specific history; mercury produced no effect; lesion healed under 300 grains a day. A third case: I removed the greater part of the superior maxilla for a dentist; no specific history; wound became indurated and disease began to invade other jaw. Iodid in 40-grain doses produced a cure.

Cases of suppuration of lymphatic glands, where a specific history is denied, are often due to syphilis. As an example, a business man of 40, with bubo in groin, positively denied venereal disease. The pus was evacuated; sterile; wound healed slowly. I discovered a small ulceration on the nasal septum; put him on iodid; bubo and ulceration of nose healed rapidly. He then confessed to having had syphilis twelve years before.

The subject of large gummata which are mistaken

for malignant tumors forms a most interesting chapter of unusual syphilis. Esmarch has written extensively on this point, but the value of his work is not widely known. As types:

CASE 1.—A tumor of the breast was diagnosed carcinoma. Amputation of breast was done. A years later a similar tumor appeared on opposite breast; glands in the axilla enlarged; noticed, by accident, a palmar syphilitic. Under large doses of iodid the tumor in the breast disappeared. Evidently the first tumor was also specific.

CASE 2.—A man of 40 was sent by Dr. Frankenthal with a tumor in the thigh the size of a fist; malignant in appearance; diagnosis probable sarcoma, no specific history; removed section and found granuloma. Under iodid the tumor disappeared. The patient later acknowledged a specific history.

CASE 3.—A man of 43 presented a tumor in the breast; no specific history; diagnosed sarcoma, which was removed; wound healed, but became indurated. Iodid in large doses; induration melted away, and the patient then acknowledged a specific history.

Gummata mistaken for a variety of lesions form a mixed class. As examples:

CASE 1.—A patient of 30, male, married three years, and two healthy children; no specific history; enlarged testicle; suppurative; ulceration of scrotum; removal of the testicle and infected skin; diagnosis, tuberculosis. The wound healed. Later there were two hard masses in the penis the size of walnuts; surgeon desired to amputate penis. I removed a section of granulation tissue, put the patient on iodid and the lesion melted away; patient cured, but still denies syphilis.

CASE 2.—Medicolegal case. A brakeman, in a railroad accident, received an injury to the shoulder; paralysis of sternocleidomastoid and trapezius; threatens to sue company; sent to me for examination and report. I found a gumma in the sternocleidomastoid along the course of the spinal accessory nerve. The patient at first denied syphilis. Under iodid the gumma melted away, and with it the lawsuit and paralysis disappeared.

CASE 3.—A man of 50; pain over gall-bladder; small mass palpable; diagnosis, gall-bladder lesion or carcinoma of liver. On making an exploratory laparotomy I found what I believed to be a gumma of the liver. The patient is still under treatment.

CASE 4.—A patient under mercurial treatment for syphilis developed pain over liver; jaundice. The jaundice disappeared under large doses of iodid; probably obstructive jaundice due to gumma.

I will pass over unusual forms of syphilis of the stomach, small intestines, and colon, of which I believe I have seen examples, because of lack of positive evidence.

The so-called syphilitic stricture of the rectum is unusual only to the men who are not familiar with its frequency. Although these so-called syphilitic strictures are usually due to gonorrhoea, true syphilitic strictures occur; I have one case of syphilis of the kidney to report:

A man at St. Elizabeth's Hospital, seen for Dr. Futterer, presented a large kidney mass; explored; greatly thickened edematous capsule, both fibrous and fatty; nothing in the pelvis; two masses in the capsule which Dr. Futterer, from gross appearance, regarded as tubercular. The patient recovered from operation shortly after; admitted syphilitic history. He was put on iodid, and the kidney mass melted away; patient now well. I believe it was a syphilitic lesion of the kidney.

In order to be brief, I shall omit in my discussion any

cases of unusual syphilis of the heart and blood-vessels, but shall hope that cases of this class will be presented by our internists.

The last class of cases which I desire to present comprises cases of unusual syphilis of bone and joints. The relation of syphilis to fractures can be well shown by three cases.

CASE 1.—A man of 24, under treatment for syphilis, has a gumma on the right humerus. On boarding a street-car he feels something give way in the arm and the arm falls helpless to his side. Examination reveals no new point of motion; some swelling; no deformity; no crepitus. The X-ray shows complete fracture of the humerus without displacement. Spontaneous fracture or fracture from muscular contraction is one of the results of syphilis.

CASE 2.—A man of 25 had fracture of both bones of the leg; delayed union; at the end of three months he confided to his surgeon that shortly before being injured he had secondary syphilis. At once placed on constitutional mixed treatment, union rapidly followed.

CASE 3.—Inherited syphilis of both bones of leg; bent at right angle. I believe the case to be one of late rickets; operated; straightened limb; no union. The patient returned after several months, I operated again, and placed him on iodid and mercury. Rapid bony union followed.

CASE 4.—An unusual case of double mastoid disease, operated on at interval of six weeks between; was slow in healing; patient admitted syphilis; iodids given; rapid recovery.

I have seen cases of joint syphilis mistaken for tuberculosis and gonorrhoeal rheumatism. I shall cite but one instructive case.

A man of 23, a large, strong, robust fellow, with carious disease of the left wrist-joint was treated by iodoform injections and resection; not cured. I believed the case to be tubercular and amputated. Later a large gumma of the arm on same side, and a deep ulceration on the skin of the face appeared. He previously denied syphilis, but now admitted it. Under iodid treatment the lesions disappeared. I have no doubt but that the wrist lesion was syphilitic.

Before closing this rapid and incomplete sketch, which is meant simply as an introduction to a general discussion by the members of the Association, let me call the attention of the Association to the fact which has impressed me more and more as I accumulate experience in the use of iodid of potash in syphilis, and it is this: The fact that a granulation melts away under iodid does not prove absolutely that it is syphilitic. Why? Because we now know that at least one other form of granulation tissue is often similarly absorbed—i. e., actinomycosis, and I had a few months ago under observation a case of blastomycetic dermatitis which undoubtedly disappeared in part under iodid.

RECENTLY the Duke of Westminster's horse, Flying Fox, won the Eclipse stakes at Sandown Park, England, the purse being £10,000—\$50,000. Thus far this item is not in the least medical or of interest to our readers, but when we state that the Duke turned over the whole amount to the Royal Alexandra Hospital, Rhyl, Wales, it becomes most interesting from a medical standpoint. The *Lancet*, from which we get our information, commends this excellent example to other owners of fast horses who race for love of the sport and not for "filthy lucre."

Correspondence.

Muscae Volitantes.

LAFAYETTE, Ind., July 24, 1899.

To the Editor.—I have been very much interested in the recent articles in the JOURNAL on the seeing of the blood-corpuses in one's own retina. So far as I am concerned it has not only never been a difficult matter for me to see them, but has been a very difficult matter in microscopic work to keep the field free from them. To see them best, it is well to prepare a slide with blood for comparison. Any good microscope stand with "B" eye-piece and $\frac{1}{4}$ -inch objective may be used. Focus the instrument on the slide, to get the idea of the size and appearance of the corpuscles, then draw the tube back by the coarse adjustment until the focus is lost, when the blood-corpuses will be seen traveling across the field exactly like the corpuscles in the capillaries of the frog's foot in that well-known experiment. A bright artificial light is best, and a blue glass placed over the eye-piece as an advantage, but by no means necessary. If the tube be drawn back till the objective is at a distance of one or two inches above the table of the instrument, and the eye held very close to the eye-piece, a very much enlarged image of a small portion of the retina will be seen; the corpuscles can be seen moving, but not so distinctly as in the first method.

Any reader of the JOURNAL who has a microscope can study this new field with great profit. The blue glass used, as recommended by Dr. Norton, is an advantage, but I find no difficulty in seeing the corpuscles with the naked eye in looking at a clear blue sky.

W. H. PETERS, M.D.

Plea for Both the Tuberculous and the General Public.

FORT HUACHUCA, N. M., July 15, 1899.

To the Editor.—At last, after years of neglect, the great army of sufferers from the deadly "white plague" have had something in the way of legislation done in their behalf. All praise to the New York Legislature for taking the initial step in appropriating the money for the erection of a sanatorium in the Adirondack Mountains, for the treatment of pulmonary tuberculosis. Equally as praiseworthy was the act of the Government in turning over to the marine-hospital service, Fort Stanton, N. M., for a similar purpose. The work of turning it into a modern sanatorium is now being done, and when completed it will be used for the treatment of tuberculous sailors and marines. And if reports are true, Surgeon-General Sternberg has recently selected Fort Bayard, N. M., as a site for a similar institution where the tuberculous soldiers will be treated.

Why the tuberculous have been so long neglected and left not only to face certain death, but also to menace the health of all those around them, when a large percentage can be cured by the sanatoria method of treatment, which at the same time removes all danger to the public, is beyond all comprehension. That the example set by the New York Legislature should be followed by every state in the Union there can be no doubt.

The blind, the feeble-minded, the epileptic and the insane are being cared for by the states, and why not the tuberculous, when a large percentage, who otherwise must die, can be saved, and at the same time the general public protected from its most dangerous foe?

Tuberculosis can be cured in any climate by the sanatoria method of treatment, but the more suitable the climate the greater will be the percentage of cures. A great number have been cured in the Adirondack Mountains, and the same can be said of the mountains of North Carolina, but hardly any other part of the United States, except the Southwest, offers the suitable climatic conditions for the successful treatment of pulmonary tuberculosis. In the Southwest, namely, Arizona,

New Mexico, northwestern Texas, and Colorado, are to be found all the climatic conditions having a curative influence on tuberculosis, viz., a maximum amount of sunshine, a pure dry atmosphere, altitude and a porous soil. Land is cheap and favorable sites for sanatoria are to be found in abundance in this section. Now, why wouldn't it be feasible for states having unfavorable climates for the successful treatment of tuberculosis to secure land in the above-mentioned section and erect thereon sanatoria for their tuberculous, instead of within their own borders? Would not the greater number of lives saved, the greater number of otherwise hopeless invalids returned to the producing class, the greater security from infection by this plan more than pay the additional expense it would incur?

The tuberculosis craze is abroad, not only throughout the land, but throughout the world, and now seems an auspicious time for the profession to urge proper legislation. When the general public becomes educated to the fact that tuberculosis is a contagious and a preventable disease; when the different states provide sanatoria for their tuberculous; when the general practitioner learns to diagnose incipient tuberculosis, and becomes honest enough to tell his patients their true condition and advises them to go where they will have the best chance of recovering, then and then only will we be able to successfully contend with the greatest destroyer of mankind.

ARCH. DIXON, JR., M.D.

Exstrophy of Bladder. Correction.

INDIANAPOLIS, Ind., July 29, 1899.

To the Editor.—My discussion of Dr. Allen's paper on "Exstrophy of the Bladder," as printed in the JOURNAL of July 19, is somewhat garbled. I did not make bold to say: "It is not rational to make the operation of intestinal implantation," but did say that under certain conditions Maydl's brilliant operation, as successfully executed for the first time in America by Dr. Allen of Cleveland, might be contra-indicated. All agree that the operation of intestinal implantation of ureters should not be practiced if the kidneys are unsound.

In the case which came under the writer's observation there was on the left side a pyonephrosis, and on the right a chronic nephritis. The patient was exsanguinated and could hardly have borne such an heroic operation as that of Maydl. Therefore a method much less dangerous and requiring less exquisite skill for its performance, namely, the method of Sonnenberg, was selected.

I prefer not to go on record as one who, having realized the beggarly results of Sonnenberg's operation, would criticize the great work of Dr. Allen, to whom we all should unstintingly give honor.

Very sincerely yours,

J. RILUS EASTMAN, M.D.

A National Board of Health.

MINNEAPOLIS, Minn., July 28, 1899.

To the Editor.—An editorial in the JOURNAL (July 22, p. 234), speaking of a national department of health, refers to the endorsement of such by several medical bodies—the American Public Health Association, the AMERICAN MEDICAL ASSOCIATION, and the Conference of State Boards of Health. In connection with the latter association, it said "recommended with practical unanimity—three delegates not voting." This is a misrepresentation. The question brought to a vote at the Conference at Richmond was not, "Shall we have a national board of health?" but "Shall we endorse the Spooner bill?" Quite a different proposition. I was one of those who put myself on record as not voting, for the motion was so worded that one voting in the negative was made to appear to be voting against a national board of health. I was not willing to vote to endorse the Spooner bill. At the same time, I was not willing to appear to be voting against a national board of health;

hence the request to be recorded as *not voting*. Two others did the same, and I presume for the same reason.

From the editorial it would also seem that the National Conference vote was strongly affirmative, for the term is used, "with practical unanimity." As a matter of fact, there were probably not more than twenty voters in the room when an endorsement of the Spooner bill was called for. With a *viva voce* vote, it is hard to judge how many votes were cast in the affirmative. The few keeping silent or voting in the negative added to the three "not voting" does not leave "practical unanimity."

The Spooner bill is meant to please those who insist on state rights in quarantine, as against national rights.

We should have a national board of health established on as firm a foundation as is the army, the navy and marine-hospital service. The Spooner bill will never give such an organization.

Respectfully,

H. M. BRACKEN, M.D.

Breech Presentations.

ELGIN, Ill., July 30, 1899.

To the Editor—I have just attended a German woman in her fifth confinement. The presentation was a breech, as was the case in her former confinements. Having never heard of another case of five successive breech presentations in one woman, I take the liberty of reporting this to you for publication. The children were all boys, and three are living. Two died during delivery.

EDWARD H. ABBOTT, M.D.

AMERICAN.

- Conservative Gynecology.**—The president's address at the American Gynecological Association, at its late meeting, dwells chiefly on two points: 1, the danger of overlooking early cancer of the uterus and neglecting the essential measures to save the patient, and, 2, the controversy between active and conservative gynecology.
- Best Management of Umbilical Cord.**—Dickinson's article is a very complete review of the literature on the management of the cord, and a plea for the methods which he thinks are best. He believes that infection from the cord is a much more common cause of infant mortality than is gen-

erally appreciated, and that the common practices are not in accord with the best surgical principles. He advocates complete removal of the cord, amputation at the skin margin, and describes the methods of securing the vessels by ligature, suture and pressure. In the first case he exposes the vessels by drawing the sheath and gelatin away from the points of amputation, ligating and cutting them off short. This method is, he claims, much more sure to control bleeding than the common mass ligature usually used. In suturing the vessels the cord is drawn upward and severed through the capillary ring and the vessel seized in an artery clamp. The needle is taken in the right hand and a simple continuous stitch is run across and its ends tied together, or a subcuticular stitch (Kendall Frank) put in place. If it is desired to ligate as well as sew with the same silk, one loop of the stitch sweeps around the artery and the other around the vein. Simple pressure needs hardly to be described, but will require further testing in a long series of cases to see whether it gives rise to any more secondary hemorrhages than the older methods. He reviews the objections to complete primary amputation and thinks that with proper surgical antisepsis they hardly require argument. A rather full bibliography is appended.

- Purgatives after Abdominal Operations.**—In this article Ramsay reports the results of a series of experiments on patients, with the careful use of purgatives after operation, contrasted with a similar series where they were not used. He thinks that the results are sufficiently conclusive to make further argument on the subject of increased danger to the patient following early interference with the bowels unnecessary. His conclusions are: That it is important both for the welfare of the patient and for the comfort of the operator to attend carefully to the diet and to the thorough emptying of the bowels before any abdominal operation; that the bowels should be moved and the distension relieved soon after operation, for the comfort of the patient as well as to avoid possible dangerous complications; that in the simpler groups of operations, such as suspension of the uterus, myomectomies, the removal of uncomplicated ovarian tumors, and in uncomplicated hysterectomies, the administration of the calomel and the use of enemata on the second day is followed by a perfectly satisfactory convalescence; that in cases of beginning peritonitis, in cases where numerous adhesions have been broken up or large raw areas left, in cases where the intestines have been freely handled or long exposed, and finally in emergency operations where no previous preparations can be made, Dr. Byford's method of immediate purgation is indicated.

- Wound Infection in Insanity.**—Hobbs writes on the effects of puerperal injuries on the nervous system and in producing insanity by exciting erysipelatos inflammations and septic poisoning. He claims that in the London (Canada) Asylum they have had in their surgical treatment of such cases 30 to 45 per cent. of recoveries, and improvement in 20 to 25 per cent. He says that the fact that it is evident that septic infection is mainly responsible for these inflammatory conditions, which in turn are responsible for insanity, and the large percentage of these cases that resulted in mental recovery or improvement after removal of the lesions shows how important a factor the micro-organism is in producing mental alienation.

- Shortening Round Ligaments and Hysteropexy by Vaginal Section.**—Byford does not discuss the technic in detail but merely gives the method he has used in thirty-one cases, and calls attention to the results. He combines hysteropexy, or suture of the uterus over the bladder, with shortening of the round ligaments, which he thinks is better than either operation alone. He has followed up his cases as far as possible, and knows of but one recurrence of the retroversion, and two cases in which the uterus sank lower into the pelvis without complete retroversion. In his later cases he has drawn the ligament tighter and sutured the fundus higher over the bladder than in his early ones and has not observed any failure. He reports three cases in detail in which he later opened the peritoneal cavity and one case in which pregnancy went to term after the operation, with good results.

6. See abstract in JOURNAL, May 27, p. 1173.

7. **Vaginal Celiotomy.**—Smith reports eleven cases of vaginal celiotomy, discusses the technic and concludes that the operation is indicated in retroversion with fixation, in mild diseases of the ovaries and tubes, and small fibroids. In his experience, however, the freeing of the retroverted adherent uterus is more difficult by this method, and vaginal fixation not so reliable, in curing retroversion and relapse, as is ventral fixation. If the uterus is movable and there are no adhesions, one is not justified in opening the peritoneal cavity in any attempt to shorten the round ligaments. In such cases Alexander's operation is easy, safe, quick and more reliable. In removing pus tubes the operation by the vagina is more difficult than the abdominal operation, except where the uterus is also to be removed. When the uterus is split in half and each half removed with its corresponding tube, and when clamps are used the vaginal operation is easier than the abdominal with ligature. The vaginal route is a little safer on account of the drainage it affords, but there is more risk of injuring the ureter. Smith does not favor the removal of the uterus, even if both ovaries and tubes have been removed, on account of the bad moral and physical effects, and he dislikes clamps as compared with ligatures, on account of bruising the nerves and consequent prolonging of convalescence. For the removal of chronically inflamed ovaries and tubes, vaginal celiotomy has decided advantages in that it is less dangerous because the intestines are not exposed to handling; it is less painful; there is no telltale scar, and little danger of hernia. Much good conservative work on the ovaries and tubes can be done by the vaginal route without risk or pain to the patient, and he enumerates a number of conservative operations that can be thus performed with advantage. Tubal pregnancy before rupture, not later than the sixth or eighth week, can be readily removed by vaginal celiotomy. This operation, however, is contraindicated when the pregnancy has advanced twelve weeks or has ruptured into the abdomen. In general terms, all cases in which the trouble is small in size and located low down can and should be operated on by vaginal celiotomy, while everything large and high up should be reserved for abdominal section.

8. **Disorders of the Menopause.**—Cushing's paper discusses the various disorders attending the change of life; the circulatory, consisting in hot flashes and hemorrhage; the nervous troubles, such as palpitation, fainting and hysteroneuroses; the psychic disorders, and also the complications incident to the period of life in which this change occurs. Of the latter cancer is the most serious, and he calls attention to the necessity of care, noting all irregular and profuse hemorrhages occurring at this time and the ease of diagnosis of the condition by competent examiners, the comparative safety of the operation and its success as a rule in preventing recurrence. The next most important complications are tumors, fibroids and adenoma, and the endometritis which is liable to occur at this time.

11. **Whooping Cough.**—Taylor summarizes the therapeutics of this disorder as follows: 1. Isolation and disinfection; 2. pure air and warm clothing; 3. keep the patient up to his most perfect standard of vigor, by frequent feeding; 4. palliate by the use of antipyrin, belladonna, and bromids internally, with inhalation of formaldehyde vapor to relieve paroxysms and nervous irritability; codein, tartar emetic, ipecac, and squills for catarrhal condition, and iron, arsenic and strychnin to tone up and strengthen in convalescence.

14. See editorial, page 358.

15. **General Infection by Weichselbaum's Coccus.**—Gwyn reports what he thinks is the first instance recorded of general infection or septicaemia from the diplococcus intracellulularis. The patient was admitted to the Johns Hopkins Hospital, November 4, supposed to be suffering from typhoid fever, and died on the morning of the 6th. The autopsy revealed Weichselbaum's germ in the blood and in the inflamed joints. This throws some light on the arthritic infections of cerebrospinal fever.

19. See abstract in JOURNAL, March 11, p. 545.

20. **Tenotomy as a Preliminary to Amputation.**—Remarking first on the difficulty in muscular subjects in performing amputations, on account of the tendency of uneven con-

traction of the muscles, thus making an uneven stump, Davis pleads for a preliminary performance of tenotomy. He has not attempted to study the subject historically. Dawbarn's suggestion to cut the ham strings before amputation of the hip-joint is the first with which he is conversant. His experience is not extended to over a dozen cases, but it has been sufficient to make him view the procedure with great favor. He believes, in addition to the great ease of the operation and the improved appearance of the stump, that painful stump and conical stump would be less frequently met with. In cutting the tendons it is important to avoid dividing the large nerve trunks. If this rule is followed the nerves will draw well up above the cut stump of the muscles, and can be disregarded, as they will be out of danger of being imprisoned in cicatricial tissue.

25. **President's Address.**—The points made in Dr. Solly's presidential address are the relation of nasal disorders to tuberculosis, as observed by him in his practice. He disagrees entirely with Dr. Ingals' deductions that disease of the upper air-passages has a deterrent influence on pulmonary tuberculosis, and is inclined to believe with Dr. Freudenthal that in many cases the bacillus finds the readiest point of entrance in the nasopharynx behind the nasal obstruction. The facts and theories appear to him to indicate the importance of treating the respiratory tract as a whole.

26. See abstract in JOURNAL, June 24, p. 1440.

27. *Ibid.*

30. **Paralysis of Divergence.**—After reporting a case, Daune enters on a thorough discussion of the theories of periodic squint, and of divergence and its anomalies, and explains the pathogenesis as follows: Exophoria and divergent squint may be due to: 1. Underaction of an adduction—insufficiency in the true sense of the word—or overaction of the abductor, due to abnormalities in structure, insertion or innervation—muscular squint or exophoria; not very frequent by itself, but frequent as a complication. 2. Overaction of the diverging power—divergence-excess; fairly common. 3. Underaction of convergence—convergence-insufficiency; very frequent; may be either accommodative (in myopes) or non-accommodative. 4. One or more of the above anomalies combined—mixed conditions. Such a combination usually obtains in long-standing and marked cases of concomitant divergent squint. Esophoria and convergent squint may be due to: 1. Underaction of the abductor—true insufficiency—or overaction of the abductor, due to abnormalities in structure, insertion, or innervation—muscular squint or esophoria; not very common by itself but frequent as a complication. 2. Overaction of convergence—convergence-excess; very frequent; may be either accommodative (in hypermetropes) or non-accommodative. 3. Underaction of the diverging power—divergence-insufficiency; rare. 4. One or more of the above causes combined—mixed conditions. Such a combination usually obtains in long-standing and marked cases of concomitant squint. It is by following an etiologic classification like this that we attain the best success in both diagnosis and treatment.

31. **Haab's Electromagnet.**—Burkan reports 7 cases of extraction of particles of iron and steel from the eyeball, with Haab's large electromagnet, and sums up the results in these and in 5 cases previously reported: 3 eyes had to be removed on account of panophthalmitis, which in two cases had certainly set in immediately after the injury. In those cases the magnet did good work but against impossible odds. Eight eyeballs have been saved, 4 with very good and 4 with partial vision. One man died of delirium tremens. He has found it advisable to always enlarge the wound previous to extraction, in order to facilitate the exit of the foreign body. A meridional sclerotic section might be advantageously tried in cases of perforation of foreign bodies into the vitreous. Haab's magnet does all that the hand magnet will do, and more, but must be used guardedly. Compared with the latter it avoids destruction of the vitreous and diminishes danger of infection. It is a good and safe sidescopie.

33. **Suprarenal Extracts in Ophthalmia.**—Bates finds that suprarenal extract is a powerful astringent, having a strong effect on local and general circulation. He describes the methods of preparation of the aqueous solution, its chemical and physiologic properties, so far as known, and gives the

details of a number of cases in which it was used in ophthalmic practice. He thinks it is an astringent of great value, and during the five years he has used it he has seen no disagreeable effects. Within the limits of its sphere of activity, no other substance can take its place.

34. **Bacteriology of Conjunctivitis.**—The conclusions of Veasy's paper are as follows: It would seem that for Philadelphia and the immediate vicinity, by far the most frequent cause of acute catarrhal conjunctivitis is the pneumococcus of Fraenkel; that occasionally it is produced by the Koch-Weeks' bacillus, and that the clinical manifestations of both are so similar in severe cases that it is practically impossible to distinguish between them without a bacteriologic examination; that the experiments of Gifford showing the contagious character and its reproduction with anaerobic cultures have been fully corroborated; that it has also been reproduced by the writer with a pure aerobic culture; that it is a disease met with more frequently in young adults, but apparently may occur at any age.

35. **Sterile Salt Solution Injected into Weak Eyes.**—Knapp reports three cases in which he used physiologic salt solutions to replace the eye fluids, and concludes as follows: According to the foregoing observations and experiences, I believe I am justified in recommending the injection of a sterile physiologic salt solution—or any other sterile and indifferent liquid, for instance, boric acid solution—into the eye with a small syringe under the following conditions: 1. When from lack of vitality in old age or any other cause the cornea sinks in so that the eye collapses in such a way as to prevent the wound from closing exactly, a liquid should be injected until the globe has resumed its shape and the lips of the wound apply correctly. 2. Not only remnants of cataract, but also cholesterol and other heterogeneous substances, including perhaps some movable foreign bodies, may be syringed out of the eye with impunity and success. 3. When during the extraction of a complicated cataract the fluid vitreous escapes in such a quantity that the eyeball collapses either totally or in such a degree as to prevent the closure of the wound, liquid should be injected to refill the globe and make the wound close. 4. When from an operation or an injury the eye collapses, injection of a sterile indifferent liquid may restore the shape of the globe, facilitate the closure of the wound, and ward off infection from the entrance of conjunctival secretion into the eye. The above histories demonstrate that eyes whose chances of recovery are unfavorable may be saved by intraocular injection,—saved, I am inclined to believe, in a greater percentage than if such treatment were omitted.

36. **Euphthalmia.**—According to Knapp, euphthalmia in 10 per cent. solution is without a rival as an aid for ophthalmoscopic examination. As a cycloplegic it does not compare with sulphate of atropia and is even more unobtrusive than homatropin. It does not irritate the conjunctiva or the skin, and he recommends it for routine use to dilate the pupil in ophthalmoscopy.

37. **Holocain.**—After using it for more than a year, Knapp, thus states his experience with holocain: 1. It is as powerful a local anesthetic as cocaine, over which it has several marked advantages, in that it acts (1 per cent. solution) in much shorter time, one-third to 1 minute, and it does not interfere with circulation. It does not dry the cornea as much as cocaine. For the removal of foreign bodies it is an ideal anesthetic. It does not suck in germs that may have contaminated the foreign body. Cocaine is an anesthetic, but not a remedy, while holocain has a good influence in septic ulcers of the cornea, though he has not observed its action in this regard to such an extent as stated by Derby.

41. **Blood Changes Induced by Altitude.**—Solly first reviews the statements and theories in regard to blood changes induced by altitude, and concludes that the theory of regeneration of the blood cells proposed by Miescher, Egger and others is the correct one, being supported by the recent work of Schaumann and Rosenquist, of whose experiments he gives an account, also by those of Herrera and Lope. He briefly states some of his own experiments made in Colorado, which also support this view, and suggests that the members of the Climatological Association could aid materially in this problem by having blood examinations made of their patients or of per-

sons in normal health who will co-operate, before and after leaving sea level to try the climate of our interior plateaus. The effect on the blood, in visiting the sea shore and desert regions of moderate elevation, would also be a good subject of inquiry.

42. **The Laboratory in Stomach Diseases.**—Robin dwells on the value of chemical analysis in the diagnosis of stomach disorders, and believes the biochemical laboratory is of the greatest value in these affections.

49. **Address.**—Girard presents some thoughts concerning the recent war.

50. **Lecture.**—Simons' remarks concern The Naval Medical Corps, its duties and experience in the late war.

51. **Patholesia.**—The title of this article is a new name devised by Buckley to cover the same ground as the popularly used term, "hysteria." He offers it as a needed substitute for the older term, and as indicating etymologically the condition, a disorder of the will.

54. See abstract in JOURNAL, June 24, p. 1448.

57. **Alcohol.**—This article is a plea for the use of alcohol in medicine, and a defense, practically, of its use as a beverage, though this is not professed. The author, however, gives his conclusions as follows: Alcohol, used discriminately, at the right place and at the right time, is beneficial. Alcohol, used habitually and quite particularly in large quantities, is noxious. Alcoholic beverages are the more dangerous the worse they are, the more adulterated they are, consequently only the purest beer, the purest wine, the purest whisky is that which we should use, if we use it at all.

58. **Cerebrospinal Meningitis.**—Block's paper reports some clinical histories which he credits to cerebrospinal meningitis, and which, in his opinion, is due to the same micrococcus as pneumonia.

59. **Melancholia.**—Burnett reports two cases of melancholia attended with convulsive attacks, and refers to Clouston's description of this form of the disease. He believes that an early diagnosis of melancholia with immediate private care will almost insure a recovery.

62. **Piece of Wood in the Brain.**—Evans reports the case of a man who received a wound in the face during the Civil War, in 1862, which healed up; and who finished his term of service in the army without serious inconvenience. A year before his call on the doctor he received a blow in the face by a falling plank, in exactly the spot of the former injury. This produced an abscess, which was opened, but as the discharge continued, he came to the doctor. In probing the wound, dead bone was found, and by the free use of cocaine the ethmoidal cells and the floor of the skull were opened up, exposing the dura, which was swollen and exuded pus through a small opening. A small probe was passed, coming in contact with a hard substance which was removed by a Pean's forceps. It turned out to be a piece of pine wood measuring $1\frac{1}{2}$ inches in length and one-third of an inch in thickness, imbedded in the brain substance. Hemorrhage was severe but was controlled by packing the cavity with gauze, which was removed in twenty-four hours and the wound flushed with warm water. In a few days the cavity contracted and the flow of pus ceased. Thirteen days later the patient was seized with partial paralysis affecting the same side of the body from which the piece of wood was removed, also paraparesis and melancholia. He has since recovered from the paralysis. The duration of time in which the wood was left in the brain was thirty-two years. Evans also reports a case of extraction of a knife blade from the left frontal lobe, which had been imbedded eighteen months. Death followed removal, in eight days.

64. **That "First Hysterectomy."**—Haughton's article is a defense of his claim of having performed the first hysterectomy in the state of Indiana, which had been criticized by Dr. Mary E. Dixon Jones.

69. Published also in N. E. Med. Monthly, July. See JOURNAL, July 15, title No. 50, p. 150.

83. **Catarrh of Middle Ear, From Influenza.**—In this paper Smith treats of otitis media as a complication of influenza, calling attention to its importance, the dangers of its neglect and the method of early and timely treatment. He reports four cases illustrating his views. He believes a large

percentage of these cases might be cut short or aborted by local depletion or a little active purgation, if seen at the onset of the disease.

84. **Deformity.**—LaFerté's paper describes and illustrates a number of cases of deformity relieved by operation.

85. **Fractures of Patella.**—After general remarks on the treatment of patellar fracture, Means briefly reports six cases, some of them treated by non-operative methods and others by opening of the joint and suturing the parts, and concludes as follows: The results of non-operative methods are unsatisfactory, both as to long confinement and functional disability. The methods of maintaining apposition of the fragments by external appliances are unsatisfactory and unscientific. In open arthrotomy the fragments can be carefully approximated and sutured in such a manner as will maintain apposition and, ultimately, bony union. The operative method saves months of confinement, and gives permanent results. The buried suture material should be absorbable, such as catgut or kangaroo tendon. The field of operation should be continuously irrigated with a hot salt solution during the manipulation, and the incision closed without drainage. The massage treatment begun at an early date is an important factor in restoring the functional activity of the joint.

86. **Pneumonia in Children.**—Dickey recommends, in cases of pneumonia in childhood, the following treatment: Good ventilation; special attention to the clothing so as not to impede movement; nutritious and easily digested diet, given at stated intervals, and in concentrated form; plenty of cold water; moving the bowels in the beginning as an initial measure; special attention to the possibility of cardiac failure, strychnin being the best tonic, alone or combined with belladonna; temperature controlled as far as needed by hydrotherapeutic applications of water bags; in case of subnormal temperature, hot baths or hot packs with strychnin and digitalis. In case of delirium and high fever the ice-cap may be beneficial. As regards expectorants, he does not speak very strongly. Opium is to be avoided except when the cough is very harassing and interferes with rest. Pain can be relieved by external mustard applications. The internal remedies should be those that have germicidal or antiseptic properties, and will not depress the heart, and he thinks that salicylate of cinchonidia might, on theoretic grounds, be of advantage, but he has had no personal experience with it or other salicylates. In a few cases he has used creosote with apparent good results. He concludes with a brief mention of serum treatment.

88. See abstract in JOURNAL, July 8, p. 101.

96. **Disinfection in Typhoid Fever.**—Miner, noticing the prevalence of typhoid in North Dakota, describes the defects of sanitation along the course of the streams, especially the Red River of the North, where the same location is often the source of the water-supply and the drainage outlet. He remarks that the inhabitants of long residence along the river seem to have gained a certain immunity, but new-comers and children are very generally attacked.

92. **Bottini's Operation.**—Guitéras' paper is a very lengthy one, giving reports of twelve cases operated on by the Bottini method. In conclusion he discusses the indications of the operation at some length and states his belief that of all operative procedures so far devised for prostatic hypertrophy, this is the least dangerous and attended by the best results.

95. **Colles' Fracture—New Treatment.**—Rockey recommends, instead of the ordinary method of using splints that make pressure on the tendons and interfere with the circulation, lateral splints that prevent pressure of the flexor and extensor tendons, do not interfere with the circulation, and permit movement of the joints during the healing process. In his last case he used strips of pasteboard $1\frac{3}{4}$ inches wide and 25 $\frac{1}{2}$ long, made with four thicknesses on each side, and molded while moist, to the radial and ulnar margins, the palmar and dorsal surfaces of the wrist being entirely relieved from pressure by the thickness of the splint. Perfect reduction of the fracture is of first importance. He has used this method in twenty-five cases with good results.

98. **Tetanus Treated with Antitoxin.**—De Youna reports a case of tetanus coming on eight days after an injury, cured

promptly by tetanus antitoxin injection. In all, 280 c.c. were given in fifteen days of treatment.

100. **Modern Therapy of Tympanic Cavity.**—Goldstein's paper is a plea for rather conservative methods in the treatment of middle ear disease. He thinks that frequent use of the syringe and lavage of the auditory canal is distinctly contraindicated in suppurative cases where large perforation of the drum exists, and where free entrance of the fluid into the cavity is so easy. He says they carry infection into the attic or antrum when none has previously existed. It should be our object also to extract fluid from the sodden, boggy surface of the cavity, and not to add to it. With a viscid, tenacious and copious discharge, a gentle current of a warm antiseptic fluid may be used to clear the canal to the surface of the drum, but beyond this point it should not be used. He is also opposed to the use of middle ear syringing in any tympanum affections other than in mild cholesteatoma. He has found a small tuft of sterilized cotton on the end of a probe, frequently renewed, a much better cleanser of the auditory canal than a large current of antiseptic fluid. If a small perforation exists, not passing the cotton tuft, he employs a nebulizing antiseptic fluid with the Eustachian catheter, thus driving it out and inflating and medicating the middle ear cavity better than could otherwise be done. His fluid consists of iodin, 3 grains; carbolic acid, 4 grains, and benzoinol or abolein, 1 oz. A slight insufflation of an antiseptic powder, preferably nosophen, completes the treatment. When the discharge is profuse, he adds a gauze packing to this treatment, using narrow strips of plain sterilized gauze. He thinks that oil sprays will soon gain the upper hand in the treatment of mucous membrane of the upper respiratory tract in the ear, and he describes his methods of using them. Where the Eustachian tube is impervious, as revealed by the auscultation tube, he employs an intratympanic injection made with puncture of the drum under antiseptic precautions, with the same formula as before, and he describes in detail his methods of doing this. Another departure of his own is the use of picric acid as a desiccator and antiseptic. It can be used with weak alcohol solution, thus avoiding pain, or with glycerin. In concluding his paper he speaks of the use of cimicifuga in the treatment of tinnitus aurium. In his experience, only about 5 per cent. of patients thus treated were benefited.

102. **Odd Types of Disease.**—Pearce's article points out certain peculiar phases of tabes, myelitis, cerebrospinal palsy, chronic anterior poliomyelitis, brain abscess, cerebral edema, and traumatic neurosis. The details can hardly be given here.

103. **Typhoid Without Intestinal Lesions.**—The paper by Lartigau gives full reports of two cases, with autopsy, in which the characteristic lesions of typhoid were not met with. The clinical picture in one was characteristic, and in both bacteriologic examination revealed the typhoid bacilli. In the second case, which was operated on for ectopic pregnancy, there was also streptococcus and pneumococcus infection.

104. **Malignant Disease of Digestive System.**—Noticing the general features of cancer of the digestive tract, Einhorn lays down the following as guides to their recognition:

Esophagus and Cardia.—Gradually developing dysphagia and the presence of a stricture in the esophagus, especially if a partiele of tumor showing the characteristics of cancer has been brought up with the tube, or the above symptoms, with frequent small hemorrhages, make the diagnosis of malignant disease positive.

Stomach and Pylorus.—1. If particles of tumor are found—in the wash water or in the tube—which under the microscope reveal the characteristic picture of a malignant growth.

2. The presence of a more or less large tumor with an uneven surface, belonging to the stomach and associated with dyspeptic symptoms.

3. The presence of a tumor associated with frequent hematemesis.

4. Constant pains, frequent vomiting, isochymia, emaciation—all these symptoms being quite permanent and not extending over too long a period of time (six months to a year.)

5. Tumor and isochymia.

6. Emaciation, isochymia, presence of lactic acid.

7. Constant anorexia and pains, not yielding to treatment,

accompanied by frequent small hemorrhages of coffee-ground color.

Small and Large Intestines.—1. If by abdominal or rectal palpation a tumor can be detected which is situated in the small or large bowel, and accompanied by symptoms of cachexia and disturbances of defecation.

2. The presence of a tumor as just described, and the discovery of small particles of the neoplasm in the evacuation giving microscopically the appearance of a cancerous growth.

3. Gradually increasing disturbances of the bowel for a few months in a heretofore healthy person, accompanied by cachexia and symptoms of a beginning or already developed stricture of the bowels, and the presence of a small particle of growth in the stools giving, as above, microscopically, the picture of cancer.

He also gives the following general rules as to operation: 1. Whenever the tumor is accessible for operation, and there is the slightest hope of curing the patient, the complete extirpation of the growth should be performed. 2. If the tumor is not accessible for operation, or the entire removal of the malignant disease is practically impossible, palliative operations which serve to alleviate suffering and prolong life should be undertaken in cases requiring them. 3. Cases of malignant disease operated on, as well as those without operation, require for their treatment and management a skillful physician, who is able to lessen suffering and nearly always able to lengthen life, even under the most trying conditions. Cancer of the esophagus and cardia does not at present permit any radical operation. When the patient cannot take food, gastrostomy is indicated. Cancer of the stomach and entire intestinal tract should be removed if discovered sufficiently early. Practically the outlook for the cure of malignant disease of the intestinal canal becomes less encouraging the farther away from the anus it is situated. Cancer of the lesser curvature of the stomach and posterior wall is usually recognized too late for radical operation, and if the cardia and pylorus are not involved, only the usual palliative remedies should be resorted to. Cancer of the rectum, when recognized early, has by operation afforded brilliant results. With the tumor higher up in the intestines, its excision and resection of the intestines with end-to-end anastomosis is advised. Where total resection is impossible and enterostomy or enterocolostomy, or, if in the rectum, a colostomy, will be advisable palliatives.

105. See abstract in JOURNAL, June 17, p. 1390.

107. **Glycosuria in Cerebral Hemorrhage.**—Gradwohl reports three cases of temporary glycosuria in connection with cerebral hemorrhage, in two of which it was due to direct pressure on the diabetic center in the fourth ventricle. In the other, where there were no local lesions at these points, the general condition of cerebral pressure will, in his opinion, account for the condition.

108.—See abstract in JOURNAL, July 1, p. 37.

109. **Headache and Asthenopia.**—Cobb reports 3 cases of headache due to nasal disease, and comments on them. He thinks that many patients have headache from chronic rhinitis, with a viscid dry discharge which is due to uricacidemia and high living. Another form is caused by hypertrophy of the posterior third of the nasal turbinate. This form is not at all rare. In conclusion, he says: wish to emphasize the following points: 1. Headache may be and often is caused by intranasal disease. 2. Other diseases, aside from atrophic rhinitis, nasopharyngitis, affections of the accessory sinuses or the obstructive intranasal conditions may be the cause of headache. 3. An examination of a patient suffering from headache is not complete unless the condition of the nasal cavities has been investigated.

111. **Serum Treatment.**—Biggs's paper is concluded in this number. Having already noticed the brilliant results in the treatment of diphtheria by antitoxin, he reviews the facts as regards the serum treatment of pneumonia, in which the experimental results have been very striking, and he thinks it not improbable that the next great achievement in serum therapy will be in the treatment of this disease. He also notices the good results of cholera and plague inoculations and Wright and Semple's prophylactic inoculation for typhoid. As regards the yellow fever serum and serum therapy in streptococcal infection, he does not speak with such positive

encouragement. Leprosy and tuberculosis he throws out altogether, as regards treatment by this method.

113. **Peritonsillar Abscess.**—Cobb's paper concludes as follows: The whole number of cases examined was 44. 1. No causative relation could be proved to exist between rheumatism and peritonsillar abscess. 2. An acute inflammatory condition to the tonsil was found to exist in a sufficient number of cases to suggest that it may be the cause of the infection to the peritonsillar tissue. 3. A study of the pharyngomaxillary space shows: *a*, that its injection with wax on the cadaver may produce an appearance similar to the peritonsillar abscess as seen clinically; *b*, that its distance from the surface of the palate may account for the depth of the puncture often needed in order to obtain pus; *c*, that the cross action of the muscles covering the space seems a sufficient reason for the closure of puncture made into it; *d*, that the supratonsillar fossa and the infratonsillar space offer the space for puncture most free from anatomic obstruction; *e*, that puncture anterior to a plane passing through the posterior pillars can not injure the great vessels if the knife be kept at all times anterior to such plane; *f*, that the space is divided into two cavities by a septum formed by the styloglossus and stylopharyngeus muscles. This in most cases protects the great vessels from purulent infiltration. Failure of this septum to act explains the cases cited by Bosworth where the pus passed along the great vessels into the mediastinum.

114. **Normal Salt Solution in Septicemia.**—Edson reports a case of septicemia apparently starting from tonsillar infection, in which the use of normal salt solution injected into the subcutaneous tissues was resorted to after the patient had gotten into a desperate condition. The use of this solution was immediate in its good results, relieving pain, quieting delirium, and improving the pulse, and his cure may be said to have started from its first employment. Another noticeable feature was the ease with which large amounts of the solution were absorbed.

115. **Acromegaly.**—After reviewing the subject of acromegaly, Lackey reports a case presenting some unique features occurring in a colored male, who enjoyed average strength and health up to the age of 13. About this time he suffered with excruciating pains in the hip-joint and extremities, and was confined to bed for a period of two years, during which time the extremities increased rapidly in size, the stature also. Thirst was a constant symptom. The general nutrition of the patient was poor. Since the confinement locomotion has been impossible excepting by the aid of mechanical support. The patient is now 28 years of age; the extreme height of 8 feet 6 inches is recorded; the patient's face is repulsive, oval in outline, the lower jaw very much increased in size and length, the forehead extremely low with a thickened orbital border; the eyes small; the temporal bones indented; the nose long, large and much flattened; unlike most cases of acromegaly, the lips are thick and very prominent. The case presents special interest, in that it is undoubtedly one of the so-called giant forms of acromegaly, the enormous height being due to the lengthening of the long bones, the smaller bones of the hands and feet were found much enlarged. The heart showed hypertrophy. Spinal curvature was observed. The mentality of the patient is unimpaired.

116.—See abstract in JOURNAL, June 10, p. 1313.

117. **Corpuscular Phosis and Aphosis.**—Describing the phenomenon, Gould suggests that a day not too bright be selected, the sky filled with gray to bluish clouds. Shade the eyes with the hands, and, narrowing the palpebral borders until the aperture is about the width of the pupil, gaze steadily toward the clouds, but vacantly, i. e., without any accommodation whatever. Without winking, hold the eyes perfectly still. Within a number of seconds the field will be filled for 180 degrees, laterally, with innumerable darting points of light—phosis—moving, disappearing and reappearing in all directions without order and with great irregularity. A tinted lens being introduced, the number of bodies is reduced, but the remainder have the same general character and rate of movement. The reduction in number he describes as being due to the accommodation and fixation almost necessitated by the different lighting of the corpuscles, and the fact that but a single eye is used. By using a large piece of cobalt-glass over both eyes, and looking to a brightly sun-lit white

cloud, the aphoses are more numerous and fill a larger expanse of the field than when a single eye is used. In this way the two classes of sensations are recognized as due to the same object or causes of retinal origin, and he considers that the corpuscles are not seen directly, nor by means of the shadows they throw on the retinal end organs, but arouse sensations only when they reflect and focus on an incident beam of light on an unaccustomed and sensitive portion of the retina; and therefore expresses the firm conviction that these bright points—phoses—and the Newton aphoses are all due to reflections from corpuscles of the retinal capillaries, varying in appearance according to the method of observation and the illumination; thus differing from the conclusions of Willetts, who considered that they originated in the cornea.

118. Post-Appendiceal Abscess.—In reporting this case of abscess posterior to the appendix, discharging through the umbilicus, and refilling and causing perityphlitis and general peritonitis, Friend explains the discharge of pus through the umbilicus by presupposing a patulous vestige of the vitello-intestinal duct, and that the infection which came from the intestine first involved this duct. The abscess cavity filled and the pus followed the course of least resistance, viz., through the umbilicus. The general infection was probably due to obliteration of this exit.

119. Horseshoe Kidney.—One weighing 14 ounces is reported as a finding in posting a patient having met with a violent death in her 45th year. The organ lay at its normal height, with convexity downward, close to the spinal column and symmetric as to the two sides—measuring fifteen inches from the highest point of one extremity to a corresponding point on the other. The pelves and ureters were intact. The connecting band was composed of true renal tissue and measured $3\frac{1}{2}$ inches in circumference.

120. A Mechanical Laxative.—Liquid petroleum is recommended as a mechanical laxative, in quantities of from two to three ounces. Upson considers it absolutely non-irritating, that it does not distend the bowel, nor cause flatulence; indeed, diminishes it, and is easily taken, even by children.

122. Irritation-exostosis.—Bradford shows, by a series of skiagraphs, the more common locations in which are found the various exostoses due to irritation about the small joints of the feet. The parts where irritation from bone pressure or shoe external irritation takes place are those positions of the foot where the strain is greatest and the bone is less protected by fat, commonly the first and fifth metatarso-phalangeal articulations, and at times at the dorsal-surface articulations of the cuneiform and first metatarsal, and on the dorsal surface of the head of the first metatarsal bone, and on the prominent portions of the posterior portion of the os calcis.

123. Case of Syphilitic Fever.—In the case recorded, diagnosis was extremely difficult, and a study of the febrile course shows an average evening rise to about 101.6 degrees, with a morning fall to below normal. Attention is called to the value of a study of the pulse in doubtful febrile cases; slight variations of the pulse are at least suggestive of specific fever.

124. Antistreptococcal Serum in Puerperal Fever.—In treating these cases, besides the use of serum, Rosenthal advises a douche of sublimate, 1:8000; lysol, 2 per cent.; or creolin, 5 per cent.; curettage, with iodoform packing, which is removed after twenty-four hours. Purgatives and stimulants are to be selected, while the serum is used in quantities of 10 c.c. in initial doses, repeating the dose on the following day if fever continues, and gradually diminishing the quantity injected. Several cases are reported in which the antistreptococcal serum was used; the writer reports a mortality of 25 per cent.

126. Angioneurotic Edema.—The condition appeared in a female of 35, who had enjoyed average health. She first noticed a swelling of the right side of the face, appearing suddenly; no pain, tenderness, or pitting was present early, nor was itching or heat complained of; disappearing in twenty-four hours to reappear again on the wrist and various other portions of the body for weeks. The condition continued to involve various portions of the body, extending over larger areas, especially selecting the face and loose tissues of the neck; burning, itching at times; redness developed as the condition progressed; twice during the six months did the edema extend

beyond the pharynx, the patient becoming cyanotic and complaining of great distress in the chest; venesection relieved the symptoms at these times. Eventually the patient died of an internal hemorrhage.

127. Arsenite of Copper in Cerebrospinal Meningitis.—Kolpinski reports four cases of epidemic cerebrospinal meningitis which he treated by the following method: 1. Quiet, excluding from the sick-room as much as possible, friends, light and sound. 2. A simple milk diet with drinking water whenever desired. 3. Daily movement of the bowels by enema or castor-oil. 4. The arsenite of copper for the first and second days, every half hour when the patient was awake. With improvement in symptoms the intervals were prolonged to every one or two hours on the third day, and every three or four hours on the fourth day, and the remedy was discontinued when convalescence began to appear. With children he uses about 1/2400 to 1/1200 of a grain a dose, with the adult 1/320.

FOREIGN.

British Medical Journal, July 15.

Case of Freidreich's Hereditary Ataxia with Necropsy. GEORGE E. RENNIE.—The author reports a case of Friedreich's ataxia, with autopsy findings, in a boy aged 13 years. The lesions found were well-marked degeneration of the posterior columns throughout their whole length, in the posterior root zone, and also of a large number of posterior root fibers; much less marked degeneration in the lateral columns in the region of the crossed pyramidal tracts; scattered marginal degeneration at different levels; distinct degeneration of the direct cerebellar tract with atrophy of Clarke's column. The findings, therefore, agree quite well with those usually met with, but it is interesting to note the extent of the lesions, though the duration of the disease was stated to be only about fifteen months. The disease, therefore, is apparently a primary nervous derangement grafted on an imperfectly developed spinal cord, the imperfect development being due to unknown hereditary influence. In conclusion, the author calls attention to certain features in the clinical picture, such as the absence or rarity of sensory disturbances, lack of sphincter troubles and the condition of muscular hypotonia present in the majority of these cases.

Contribution to Study of Posterior Columns of Spinal Cord. HAMILTON WRIGHT.—This article is a discussion of the findings of the autopsy in a case of tabes, with special reference to the nerve tracts of the posterior column. The author discusses the findings with special attention to the course of what are considered the intracordal or endogenous sections. He concludes that the Marie cornu-commissural zone, Flechsig's median triangle and postero-internal root zone are of true intracordal origin, at least as regards the majority of their fibers. The comma tract of Schultz was found in a state of almost complete fibrosis, which he explains as probably due to an anatomic connection with Clarke's cells, and generally close association with the vesicular cylinders.

Some Points Connected with Sleep, Sleeplessness and Hypnotics. JOHN BUCKLEY BRADBURY.—Bradbury discusses the chemistry and physiologic action of some of the derivatives of morphin, cannabis indica, hyoscin and anhalonium, and concludes with remarks on the treatment of insomnia. After noticing the causes, toxic, psychic, and those due to changes in the mode of life, he mentions the special and general measures for its relief. In ordinary cases of insomnia, uncomplicated, he would first try the bromids as least harmful. He notices the requirements as to sleep places, diet, etc., and then specifies special drugs for particular cases. [In the main his suggestions are much the same as those found elsewhere.—Ed.]

Treatment of Malarial Fevers by Inunction of Creosote. A. O. FITZGERALD.—This article contains the report of classified cases of malaria treated by inunctions of pure beechwood creosote over the chest, abdomen, axillæ and sides, 15 to 20 minims for a child of one year, and 30 to 60 minims for an adult, mixed with an equal quantity of olive-oil, the latter being employed to counteract the tingling and burning occasionally produced by the creosote. The results as reported in his tables are certainly remarkable, and he mentions some of the cases in detail. He thinks it is an ideal treatment in malarial fevers in children and he has never seen any bad effects in any case. It seems to be also equally effective in adults.

Lancet, July 15.

Observations on Tuberculosis and Syphilitic Diseases of the Eye. LACHLAN GRANT.—The author calls attention to the comparative rarity of tuberculous disease of the eye, and offers the following as probable reasons for the facts: 1. The eye is exposed to much bright sunlight, which is fatal to the bacillus of tubercle. The movements of the eyes and eyelids tend to dislodge the bacilli, and the secretions also favor this action. He thinks there is also something in the construction of the surface tissues of the conjunctiva and cornea, which is hostile to bacilli infection. Another means of defense is the phagocytic destruction of the bacilli and he concludes that the organ may be considered naturally immune to tubercle, thus resembling the pharynx, thyroid body, pancreas and ovary. In striking contrast with this immunity is the relative liability of the eye to be attacked by syphilis, the virus of which seems to circulate throughout the entire system, probably finding in all non-syphilitic individuals a suitable nidus for its development.

Muscular Hypotonia in Epileptics. GEORGE E. RENNIE.—Three cases of epileptics are reported in whom there was a noticeable flaccidity of the muscles as one of the symptoms. The subjects were those in whom the disease had existed a long time, with very frequent fits and no long intervals of freedom. There were also in all three marked mental deterioration, and they were all young. He concludes that in this class of epileptics there may be a more or less permanent interapoxysmal muscular hypotonia due to a state of exhaustion of the cortical motor cells.

Anthropological Work in Asylums with a Practical Scheme for Conducting the Same in Adults. EDWIN GOODALL.—The degenerative stigmata in the insane have lately been noticed by various writers, especially Schmidt, Meyer, and Peterson, and Goodall here offers a scheme of anthropologic work in asylums. The chief objects of such a research in his opinion are: 1. To show whether these stigmata are more common; and more numerous in the insane—apart from cases of obvious congenital defect—than in the sane. 2. To make a division into grave and slight stigmata by ascertaining which are commoner in the more depraved types of insanity, and which in the more hopeful. 3. To ascertain whether there is such a frequent recurrence of particular stigmata in particular forms of mental disorder as to justify a correlation. 4. To ascertain the relationships between the number and nature of the signs and the degree of inheritance of neurotic disorder; where such inheritance is denied, or where the history is difficult to ascertain, a study of the physical condition may be expected to give useful information as to inheritance. 5. To obtain a guide in prognosis in persons where history raises the apprehension of mental disorder and in those who have become insane; where the insanity has supervened in an individual said by his relatives to have been previously normal, and some accidental cause for the disorder is assigned, the discovery of physical stigmata may materially alter the prognosis. The normal measurements should be made from the sane population of the district supplying the patients to the asylum, which, though difficult in places where there is a large and changing population, would be comparatively easy in others.

Journal of Laryngology, Rhinology and Otolaryngology (London), July.

Hysterical Aphonia and Ventricular-band Speech. MIDDLEMASS HUNT.—The case here reported is that of a Jewess, aged 27, who, from a nervous shock experienced in attending an Irish wake, completely lost her voice and did not regain it up to the date of being seen, excepting on one occasion when under the influence of ether, and then it was only retained for two hours. Laryngoscopic examination showed the ventricular bands brought close together on attempted phonation, hiding the ligamentous glottis almost entirely, but it could be observed that the vocal cords were wide apart. All efforts to restore her voice failed, but a gradual improvement took place within the last two or three years until she came to talk in a deep, rough but fairly powerful voice. The laryngoscopic picture remained unchanged. On phonation the ventricular bands were seen to come tightly together and vibrate, while the glottis, so far as it could be seen, remained open. The voice was evidently due to ventricular band vibration. No change occurred, and hope of restoration was abandoned

until one day last September she returned with perfect voice, it having been restored to her by a nervous shock on seeing a man thrown down stairs into the street and so severely injured that he died shortly afterward. Laryngoscopic examination showed the vocal cords closing normally, but still considerable hypertrophy of the ventricular bands. Hunt asks in what proportion of cases do we find closure of the ventricular bands on attempted phonation in hysterical loss of voice? He can recall only one other case, and did not find it described in the text-books, though Trauelp says it is not uncommon, and regards it as a transition form of neurosis between spastic and paralytic aphonia. Hunt asks, is this view correct, and is not the approximation of the ventricular bands in hysterical aphonia rather an effort of nature to make them take the place of the paralyzed cords, as we see in cases where these latter have been destroyed by disease?

Bulletin de l'Académie de Médecine (Paris), July 4.

Malarial Aortitis. LANCEBEAUX.—In this communication 21 cases of a special variety of aortitis, occurring in patches, are added to 16 previously reported. Some were accompanied by an aneurysm, angina pectoris, dyspnea or dysphagia, and terminated by rupture of the vessel or suffocation, or more slowly from cardiac insufficiency, unless the lesion was arrested and cured. Lancebeaux ascribes the aortitis to malarial infection, and insists on the importance of watching over a malarial subject, as the first acute stage, more or less intermittent and transient, is followed by a phase of sclerous and persistent lesions, frequently mistaken for syphilitic. Hydro-therapeutics is beneficial, also potassium iodid if the lesions are not too far advanced. He reiterates that he has found gelatinized artificial serum extremely successful in obliterating the aneurysmal sac, injecting 250 c. c. of a 2 per cent. solution into the buttocks every fifth to eighth day, confirmed by the experience of the Bucharest professors among others. [A. Fraenkel has also recently reported another severe case cured.—Ed.] The ascending portion of the aorta is usually the site of the lesion, which in some respects anatomically resembles the invasion of the frontal nerves in syphilitic periostitis of the skull.

Report of Delegates to Tuberculosis Congress.—The fact was especially emphasized that a condition indispensable to the success of sanatoria for the poor is the support of the family while the breadwinner is in the sanatorium; also that no patients should be admitted to the suburban sanatoria except those in the pretuberculous stage, before the appearance of bacilli in the sputa. Those with "open lesions" should be received and relieved as far as possible in the hospitals. "As many sanatoria for the people as are opened, just so many hospitals will be closed in the near future." "The rich, by founding and endowing sanatoria will protect themselves, their children and future generations against the white scourge, as the number of cases progressively diminishes."

Revue de Chirurgie (Paris), July 10.

Creation of Cleido-Humeral Nearthrosis. OLLIER.—The entire scapula and the upper end of the humerus had been removed, on account of a gunshot wound received at the siege of Metz, leaving the arm hanging loose with a deep depression instead of a shoulder. Ollier attached the humerus to the clavicle by a couple of silver wires, raising and shortening the arm 6 cm., but restoring almost complete function. A supple but very resistant fibrous tissue has developed, forming a peripheral capsule and ensuring the solidity of the nearthrosis. Radiographs show that the support does not now depend on the wires, which might possibly be removed. The subject can lift a weight of 57 kilograms with this arm, and the outline of the shoulder is normal. This case has been reported before (JOURNAL, XXXI, p. 429), but the extremely favorable functional results secured induced Ollier to describe it in detail, and insist on the principles of the disinsertion of the muscles accidentally displaced or abnormally attached, and their reinsertion on the bone which they can then move normally. "As long as the muscles are not entirely atrophied, as long as normal conditions of the nerve persist, it is possible by restoring normal relations to hope for a successful re-establishment of part of their functions. A pseudoarthrosis swinging loosely can thus be replaced by an actual articulation, endowed with active movement, and adequate resistance, if intervention occurs before the muscles

have become degenerated, and it is still possible to find the elements for a new capsule in the peripheral fibrous tissues."

Post-Anesthetic Paralysis. MALLY—"Hysterical and reflex paralysis occurring after an operation do not seem to have any connection with the anesthesia. Central paralysis from cerebral hemorrhage is a rare accident, evidently due to a vascular rupture mechanically produced by the anesthetic, but peripheral paralysis is a comparatively frequent complication, always caused by compression, and the anesthesia is only indirectly responsible, as it favors the involuntary and accidental compression of the nerve trunks of the roots of the brachial plexus. It is impossible to establish any toxic or depressing action of the anesthetic on the nervous system. Treatment of post-anesthetic paralysis should be preventive, avoiding forced elevation of the arms, and watching to see that the edge of the table or a ligature does not cut into the members or tissues. Local faradization, as soon as possible, is indicated in paralysis from compression, and passive movements of the articulation to prevent stiffness. If the electric tests disclose degenerative atrophy or severe reflex paralysis, localized electric treatment is counterindicated. In the latter case the reflex medullary irritability should be soothed with static electricity, and possibly revulsion on the spine with spark friction."

Wounds of Pericardium and Heart. E. LOISON—This tabulated description of fifty-four cases, concluded from the numbers for January, February and June, aims to establish that the prognosis is not necessarily unfavorable, that many cases have been successfully operated on, and that intervention might have been far more active than it was, as in many instances the results or autopsy findings demonstrated that surgical treatment would have been possible and would have had every chance of success. The symptomatology is no more uncertain than in cases of wounds of the peritoneum or of certain abdominal viscera, and the diagnosis is no more difficult or delicate.

New Method for Resection of Gasserian Ganglion. O. JACOB—Experiments on the cadaver have convinced Jacob that the simplest and easiest route to reach the Gasserian ganglion is by following up the superior maxillary nerve to the foramen rotundum. The external surface of the base of the pterygoid apophysis serves to locate the foramen, as it separates the round from the oval opening. This method includes resection of a part of the external wall of the orbit to expose the superior maxillary, which opens a large field for the operator, and much shortens the route. The steps of the operation are first to find the superior maxillary and to follow it to the base of the skull; then trephine the skull and seek the ganglion, isolate and extirpate it, and replace the osteoplastic flap. The incision is circular, commencing a finger in front of and above the tragus, fitting around the orbit, and continuing the circle around to a point in front of the upper portion of the ear.

Semaine Médicale (Paris), July 13.

Biliary Lithiasis, Suppurative Cholecystitis and Persistent Infection of the Biliary Passages. RENDU—A case that had been under observation for a long time, and twice been operated on, still gave evidence of latent, persisting infection, and Rendu sketches the treatment appropriate in such cases: 1. Evacuate the bile with light mineral purgatives, such as sodium sulphate. Calomel is also effective, and glycerin. Follow with mineral waters, Evian, Vittel, rather than Vichy, which does not produce a sufficiently laxative effect in this late stage. The secretion and fluidity of the bile are increased by administering 2 to 3 grains of sodium salicylate a day, or 25 to 30 centigrams of salol. The meals should be far apart, regular and not too abundant, with a little starch, meat, fat or substances rich in cholesterol, such as brains and the yolk of eggs. Green vegetables and fruits are the principal reliance, avoiding effervescent and alcoholic drinks. Plenty of exercise, out-of-door life, and cutaneous stimulants, baths and frictions, are also to be recommended.

Journal d'Hygiène (Paris), July 13.

High Frequency Currents in Therapeutics of Arthritis. G. APOSTOLI—An experience with 913 patients during the last five years, treated with d'Arsonval's application of the high frequency currents, confirms their efficacy as a thera-

peutic measure which acts on the cell itself, and powerfully modifies the general nutrition, promoting and regulating it. The clinical results are almost constantly progressive restoration of the general health, as strength, appetite, sleep, digestion, cheerfulness and capacity for work return. Tests of the urine of 469 patients showed increased activity in the organic combustions, improved diuresis and easier elimination of the excreta, while the proportion of uric acid tends to return to normal. The high frequency current is a powerful weapon against arthritic neuralgia, neurasthenia, dyspepsia, eczema, vascular congestions, and all other manifestations of arthritism, by the preventive and curative effect of general applications, combined with local for hemorrhoids. It is counterindicated in acute rheumatism, but may be beneficial in the subacute stage, and is almost invariably effective in the chronic forms, as also in gout, although it may induce a fresh outbreak in certain cases when first commenced. The static current, on the other hand, is most effective in hysteria.

Centralblatt f. Chirurgie (Leipzig), July 15.

New Operative Treatment of Varicose Ulcerations of Legs. N. BARDESCU—The latest views of the phlebo-neurotrophic origin of varicose ulcerations indicate that besides the alterations of the vessels, the lesions of the nerves require treatment, and Chipault has confirmed the writer's experience that stretching the nerve is an important factor in the cure. Two observations are related, both severe chronic cases that had resisted all treatment for four to eight years, one with gangrenous detritus. Both were completely cured in about a month, by resecting the vena saphena magna with cocaine and eucain anesthesia, and ten days later stretching the nervus peroneus communis behind the head of the fibula, under chloroform, separating its fibers with the point of the bistoury to destroy the varicose vessels of the nerve as much as possible. In future operations he intends to complete the intervention at one sitting.

Triple Bladder. A. STRAUSS—This is an observation of a man of 29, complaining of intolerable desires to urinate, and incessant incontinence, and operated on, with the result of the discovery of two supernumerary bladders in front of the main bladder debouching in the prostatic region, and of the typical bladder shape, about one-fourth normal size, but without connection with the ureters.

Deutsche Medicinische Wochenschrift (Berlin), July 13.

Fatal Acute Nephritis in Consequence of Intoxication with Wood-Sorrel. H. EICHMORST—Notwithstanding the prevalence of the custom of nibbling wood sorrel, and using it for salads, as is done in Germany, intoxication from the oxalic acid has never been noted with absolute certainty, although a veterinarian has reported a horse succumbing to it with inflammation of the stomach and convulsions. In the case described in this communication a boy of 12, after eating a large quantity of sorrel as he played in the fields, became affected with violent colic and diarrhea. The next day the right kidney region was sensitive to pressure, with 12 per thousand albumin in the urine; no fever; the fifth day unconsciousness, clonic contractions of the right arm and eyeballs twitching from right to left, pulse 84 to 92; no previous scarlet fever; received at clinic on seventh day; no oxalate crystals detected in urine; respiration ceased the eighth day, but the heart continued to beat for three-quarters of an hour longer.

Glycosuria in Intoxication from Atropin. F. RAPHAEL—An accidental intoxication with atropin induced spontaneous glycosuria: 1.8 gram dextrose in the urine the first morning and afternoon—patient a merchant 28 years old—and tests with grape-sugar ingested, showed that 13.2 per cent. was eliminated, indicating not merely a glycosuria *e saccharo*, but also an *ex amylo*. Experiments with rabbits also proved that the ingestion of an appropriate amount of atropin produced glycosuria four out of five times.

Mitteilungen a. d. Hamburg. Staatskrankenanstalten, II, 2.

Dementia Paralytica Appearing in Boy of 12 as Sole Manifestation of Hereditary Syphilis. NONNE—The etiology of the case reported is "pure," no alcoholism nor trauma, in which respect it is unique, also in the rapid course of the progressive simple dementia, free from the phases of depression and excitement common in adults.

Infection by Diplococcus Lanceolatus. J. WIETING—Nine cases are studied and the paths of the infection traced to the blood and lymph routes, the focus determined by some pre-existing trauma or thrombus, and the entering point assumed to be some lesion too insignificant to have been noted, in the cases called primary. In one case, a girl of 8, prompt recovery followed the evacuation of an enormous suppurative cavity occupying both small and large pelvis. In two cases of croupous pneumonia in men of 44 and 53, the knee was affected, and a third case, a child, died from pyemia produced by mixed infection with the staphylococcus aureus, which was found pure in an abscess in the hip. A fourth case of croupous pneumonia in a man of 29, three days after a fall down a few steps, was followed by suppurations in three joints, finger, toe and knee, in which the diplococcus was found pure at the autopsy. This case is an exception to the general experience that localized infection with the diplococcus alone is usually a benign affection. When combined with pyogenic microbes the diplococcus is usually soon destroyed, leaving the entire field to its partner. An interesting case is a workman of 60, under treatment for a fractured rib and slight emphysema of the lung, who developed an abscess in the epididymis in which the diplococcus was found pure with evidences of an old thrombus formation in the vessels. Complete recovery followed evacuation.

External Anthrax on Man. JUSTI—Sixteen cases are described, with five deaths, in which the results of conservative and operative treatment are compared, very much to the disadvantage of the latter, emphatically confirming C. Mueller's statement that the only effective treatment of anthrax pustule, especially on the neck, is to leave it entirely alone, and merely protect it from secondary infection. The patient must remain in bed, with exceptionally strengthening diet, and the extremities, raised in certain cases.

Wiener Klinische Wochenschrift, July 6 and 13.

Third Case of Tetanus Traumaticus Cured by Injections of Emulsified Brain Substance. A. KRUKIEWICZ—Forty grams of rabbit's brain substance were injected in all, emulsified in a 0.6 per cent. aqueous salt solution, in the region of the pectoralis major, in the course of three days, the patient, a man of 35 years of age, in violent tetanus. The effect was remarkable from the first, and complete recovery soon followed, as in the two other cases reported. All medication had proved ineffectual, and was suspended after the injections were commenced, the ninth day of the disease.

Noma Faciei. F. PASSINI—An extensive case of noma is described in which the Loeffler bacillus was found and extremely virulent, evidently an important factor in the etiology.

Case of Morbus Addisonii with Preceding Purpura Hemorrhagica. F. VOLLEBRACHT—This careful study of a case at Neusser's clinic, the metabolism also investigated, presents a peculiar clinical picture: patient first appeared with purpura hemorrhagica which had commenced with cramps in the abdomen, then pain in the region of the right kidney, albuminuria and transient hematuria; recovery; no relapses. She returned eleven months later with classic morbus Addisonii, improved with suprarenal extract for six weeks, then nausea, vomiting, lethargy, and in five days fever, convulsions and delirium, with death the seventh day, evidently caused by irritation of the brain from cerebral hyperemia with consecutive edema of the brain. Both suprarenals were almost completely destroyed, and this destructive process must have existed before there were any clinical indications of morbus Addisonii—merely the purpura.

Societies.

French Congress of Urology.—The fourth annual meeting of the French Association of Urology will be held at Paris, October 29 to 31. Secretary, M. E. Desnos, 31 rue de Rome. "Essential Hematuria" is the subject announced for discussion.

Crawford County Medical Society.—At the recent meeting of this society, held in Robinson, Ill., the following officers

were elected: President, C. E. Price; vice-president, H. F. Jones; secretary, John Weir; treasurer, C. Barlow. The next meeting will be September 14.

Wabasha County Medical Association.—At the annual meeting of this Association, held in Wabasha, Minn., July 13, the following officers were elected: President, E. H. Bayley; vice-president, J. A. Sloumb; secretary and treasurer, W. F. Wilson. The next meeting was appointed at Lake City, July 19, 1900.

Proposed Leprosy Congress.—The program of the leprosy congress which Dr. Albert S. Ashmead of New York and Dr. J. Goldschmidt of Paris are organizing, to meet in Paris in 1900, announces the subjects for discussion as follows: 1. How to deal with leprosy. 2. How to protect hitherto non-infected Continental nations in their contact with infected nations. 3. How to avoid importation by sea. 4. Formation of an international committee to carry out the measures of the Congress.

Chicago Academy of Medicine.

Regular Meeting, June 23, 1899.

ANTENATAL ASPECTS OF CHILDHOOD IN THEIR RELATION TO ADULT DISEASE AND DEFECT.

DR. C. S. BACON—The antenatal factors which influence intrauterine life may be divided into two classes: 1, the distinctly hereditary, which may also be called the terminal or conceptional, and 2, the postconceptional, or intrauterine, also often called the placentar. The germinal factors include the ovular or maternal and the spermatie or paternal. The intrauterine factors are the nutritional and the protective, including in the latter mechanical protection and temperature regulation. Both classes of factors may be normal, causing a healthy development of the individual, or they may be pathologic. The normal factors determine the form of the individual, morphogenetic, the structure, histogenetic, and also the character formation. In the pathogenetic factors we especially consider those which cause malformations, due either to defects or excesses of growth, and also infections and intoxications.

The form, structure and character of the individual are dependent on hereditary factors, including both the ovum and sperm cell. I shall not discuss the laws which determine their influence, which are, to say the least, very indefinitely known. However interesting the hypotheses are that have been advanced by Weismann and others, we all admit that heredity is the most important element. In other words, the germs contain the fundaments or *anlagen* for the form, structure and character of the individual. We can not note in detail the variations of structure at this time, but we know that these variations of structure and of character are more dependent on the foundation in the original cells than on any other cause. However, the intrauterine factors should not be entirely neglected. The nutritional factors are important in determining, for example, the size of the child. The absence of food, and particularly a deficiency in the proper elements of food, have considerably to do with the intrauterine development of the child, and very likely have some influence on its character. Then we must consider the imperfect protection of the child. There are many things which aid in determining the production of malformations. We have a very good illustration in those rare cases of extrauterine tubal pregnancy where the child goes on to term and on account of the impossibility of proper development of the child and lack of room and pressure, considerable deformity results. We have an excellent example of the effects of pressure in determining the form of the child in the results of the experiments that have been made by certain investigators. Thus by certain experiments on animals a remarkable variation was shown in form when the egg was subjected to pressure. The insufficiency in the liquor amnii is an important element in certain malformations of the child, and the character may also be influenced through variations in its nutrition. Whether the child can be influenced either in its form or character by means of any mental impressions of the mother is so extremely improbable that it is hardly necessary to call attention to it. The popular belief in the effect of

maternal impressions is simply due to the fact that formerly this belief was held by the profession. Many of the cases cited as illustrations are hardly worthy of consideration because they have not been reported with any degree of scientific accuracy.

Having spoken of the form and character of the individual as determined by both the germinal and intrauterine factors, I will now speak of the pathogenic factors, and chiefly of the infections and intoxications. That there is such a thing as germinal infection, that is, an infection taking place in the ovule or sperm cells, is, I think, quite well established. The experiments that have been made by Baumgarten and others, for example, in infecting hens' eggs with tubercle bacilli, show that not only infection can take place, but the very interesting fact that the germs can remain latent for a long period of time, and explain the seemingly strange fact that an egg can be infected and not lead to abortion. That is to say, the tubercular germs can remain in a latent condition in the growing egg, and perhaps a long time after the fetal stage. These infections have been, so far as I know, brought about experimentally on the ovule alone. The possibility of infection of the sperm cells must rest on clinical evidence, although my knowledge of the literature on this point is not very extensive. Clinical evidence as it pertains to syphilis seems so convincing that we must admit that the sperm cells can carry the syphilitic infection to the egg without causing any infection of the mother.

As to infection during intrauterine pregnancy, our present state of investigation shows that it is not as common as was formerly thought. It was formerly a common idea that infection through the placenta was an extremely frequent occurrence. According to more exact observation in later times, germinal infection plays a much more important part than was formerly believed and placental infection is much less common. That there is such a thing as placental infection, for example, in the case of smallpox or of syphilis, is undoubtedly true. I shall not go over the large amount of work that has been done quite recently on this subject, but it seems to me the conclusions of Duering represent the best knowledge of the present time, viz.: 1. That in case of a healthy placenta infection does not occur. The healthy placenta is a perfect filter to keep the germ from the fetus. 2. Microbes may cause, in the placenta, hemorrhages, emboli, various destructive processes which destroy its filtering power, so that infection may occur later.

One other extremely interesting question is that of immunity or immunization, and the general question of intoxication or immunization of the child *in utero*. I am not speaking here of hereditary immunization or that due to germinal factors. It is necessary to premise that by immunity I allude particularly to what Ehrlich calls passive immunity. Ehrlich distinguishes between active and passive immunity, one being a condition in which the tissues are insusceptible to the germs; it is more or less a permanent condition. On the contrary, passive immunity means a condition in which there is present antitoxin or some substance which enables the system to withstand the action of the germs, but it is more or less temporary. That there may be placental immunization, as well as a placental intoxication, seems fully established. The placenta, as has been known ever since the investigations of Gusserow, and even before him, permits the passage of various substances in solution into the fetus, and these antitoxins or immunizing bodies are probably solid substances which pass through the placenta.

CHILDHOOD IN RELATION TO ADULT DISEASE AND DEFECT, which was considered from various standpoints, was the subject for discussion.

NUTRITIONAL ASPECTS.

DR. FRANK X. WALLS spoke on this topic. He said: In considering the nutritional aspects I shall confine my remarks largely to that part of nutrition which comes under the head of food assimilation. This is a phase of child study which deserves most serious consideration, because not infrequently problems of great importance come up that are very difficult for us to interpret. During the first years of life the child is in a plastic, impressionable state, and so far as we can do, we ought to guard the child against any external im-

pressions which may mar it, as these impressions, when repeated, tend to become more or less permanent and may warp the physical and intellectual growth of the child. Of all factors that make up the environment of the child, food is the most important, and the question of food is one which we as physicians can influence more than any other factor in environment.

During pregnancy it is our duty to see to it in the interests of both mother and child that the mother is properly fed. Dr. Kiernan has reminded me that a few years ago a certain fruit diet was recommended for mothers during pregnancy, which might render their labors easy, that is, decrease the pain. He tells me that the evidence as to ease of labor was conflicting, but the testimony as to the condition of the child was not. The children were nearly always weak, pale, anemic, and soon subjects of arthrepsia. When a child is born it is very fortunate if it can obtain its nourishment from its mother.

We shall not consider the rules or instructions that should be given to the mother during nursing, but pass over them because of lack of time and consider briefly the condition of artificial feeding which presents problems of greater importance. Formerly physicians did not consider the subject of a suitable diet for infants as much as they should, but more recently in this country, through the efforts and scientific study of Jacobi, Holt, Rotch and others, we are becoming more active in this phase of child study. The child, we should remember, must receive an amount of food sufficient in quality and quantity not only to nourish it and to take the place of waste matter, but a surplus must be assimilated, so that it may have something on which to grow. We are all familiar with instances of immature children who perhaps with great care have been fostered and nurtured to the degree of considerable strength; and on the other hand, with children who have been born strong and robust, but who, under adverse conditions, soon became stunted and dwarfed in both mind and body.

Cheadle, in his excellent book on infant feeding, has summarized the conditions that the food for infants should conform to: 1. The food must contain the different elements in the proportions as they are present in human milk. 2. It must contain an antiscorbutic element. 3. The quantity of food in twenty-four hours must equal about one to three pints of human milk. 4. It must not be entirely vegetable; it must be made up in great proportion of animal material. 5. It must, in form, be suited to the physiologic conditions of digestion in infancy, and lastly, it must be free from all taint of decomposition.

Fresh cow's milk adapts itself to these requirements. Cow's milk we are to look on as a food for infants, not as a simple food, but as a complex food, that is made up of proteids, carbohydrates, fats, mineral matter and water in varying proportions. In administering such food to a child we should modify it according to the requirements of Cheadle, so that it will conform to the digestive functions of the child. In order to do this we must familiarize ourselves with the symptoms of excess or deficiency in each and every one of these ingredients of cow's milk. Having mastered this, we then can intelligently prescribe a milk for the child.

The diseases that may result from faulty food may be perhaps classified under three general heads: 1. We may have those diseases brought about by the direct irritation of the gastro-intestinal tract—the dyspepsias, gastro-enteritis, enterocolitis, etc. 2. We may have a group of diseases which are dependent on the absorption of toxic materials either introduced with milk or produced by the fermentation of milk in the gastro-intestinal tract. Lastly, we have the disturbances of nutrition which are brought about sometimes by an insufficient quantity of food, but more often perhaps by a want of some one ingredient of food rather than a lack in the total quantity of the food taken, a deficiency in the fats, proteids, or antiscorbutic elements, or whatever it may be. These diseases are classed under the head of anemias, atrophies, rickets, scurvy, etc.

This subject of food or nutrition in childhood, particularly in infancy, is one of the most important subjects that could be presented to us as physicians, and one that requires considerable study, much observation and experience, as well as

tact in its administration, and I think in proportion as we master this subject and carry the principles out in private practice, in like manner will we find the children improve under our care, and become strong and hearty—*mens sana in corpore sano*.

DR. WILLIAM L. BAUM.—The child, as Havelock Ellis has shown, prophesies a promise of advance rarely realized in maturity by either sex. Arrested development of this promise of the child type will result in masculinism and femininism. In the first, female organs and functions occur, but with greater or less male predominance. In femininism the reverse obtains. Femininism, with which alone I propose to deal, may be evident in gynecomastia, or in cryptorchidism, or sloping shoulders. The nervous system may be so distorted that at puberty the sexual instincts may be female in type. These may be expressed more in extreme modesty in type. These intense liking for female rather than male occupations. Often the sex side is quiescent until awakened at puberty. Sexual education at this time, rather than any inborn tendency, may give the sex direction. Male pseudohermaphrodites—brought up as females—often display unusually womanly qualities, are married, live happily, and die ere their real sex is discovered. While, as just pointed out, the mental state of the pseudohermaphrodite may be that of the sex to which it is assigned, still to this there are more exceptions than adherence. Neugebauer (*Contrablt. f. Gyn.*, May 6, 1899), among 653 cases found 50 marriages between members of the same sex, 46 marriages between two men, and 3 between 2 women. This occurs more frequently among males, because the pseudohermaphrodites are much more frequent than the female. In the statistics collected there were 437 males, 125 females, and 11 individuals whose sex could not be determined. The results of these marriages were invariably unfortunate, leading to divorce, suicides, unhappy family relations, and even murder. Neugebauer is of the opinion that these occurrences are more frequent than statistics show, but are kept quiet for fear of unpleasant publicity. It is not an uncommon occurrence for marriages to be interrupted at the last moment because of the discovery of the hom-sexuality of the engaged couple. He impresses on the physician the necessity of careful study of pseudohermaphroditism, since a single word from him can avert these unhappy events. A careful examination in a majority of cases will reveal a hypospadiasis penisclerotia with a rudimentary vagina.

Neugebauer, however, ignores the sexopsychic training, which is as important as the malformation. Sensual experiments by tribadic relations with females might develop the male mental state in seemingly feminine male pseudohermaphrodites. As these would be likely to occur during puberty (15 to 25), the mind would then be peculiarly plastic to their influence. The sexual appetite has its origin in all probability in a desire for satisfying protoplasmic hunger. Its differentiation is late, hence the production of abnormalities in it result from training as much as in an inborn tendency. The influence of the sex perversions, inclusive of perversions proper, inversions and perversities on sociology, is much greater than would be assumed from the prurient prudery with which the subject is discussed. As has been already shown and is well remarked by Havelock Ellis (*Psychology of Sex*), there are two phases of current thought ancient sexual inversion. One attempts to enlarge the field of the acquired—represented by Binet, who, however, recognizes predisposition; Shrenk, Notzinz and others. The other seeks to enlarge the sphere of the congenital—represented by Krafft-Ebing, Moll and others—and it usually happens that there is truth in both these views, albeit those who represent the acquired frequency deny any congenital element, and ascribe everything to early association or suggestion. The logical way of regarding sexual appetite is as an inborn impulse developing about the time of puberty. At this period suggestion and association, as already stated, may come to play a part in defining the object of the emotion. There is great indefiniteness in the aim of the sexual impulse at this time; frequently signs of sexual emotion directed toward the same sex occur, but the normal passion has usually vague and undifferentiated sexual character at puberty. The channel of sexual emotion is not thereby turned into an utterly abnormal path. The seed of suggestion is sown in various

soils. In the many it dies out, in the few it flourishes. The cause can only be a difference in the soil.

Meynert and Naehle deny congenital or even sexual instinct at all. They deny instinct for food.

Kiernan suggested, in 1884-88, that sexual inversion was puberty—a variation perhaps due to imperfect sexual differentiation or reversion of type. Masturbation may be a cause of this training, the masturbation resulting from purely physical and often unconscious causes. Stone or uric crystals in the bladder often cause an irritation at the head of the penis; pulling at this to relieve pain leads to the habit. Too tight prepuces with resultant retained secretion have the same effect; so as do ascariads and scybala in the rectum. In dealing with masturbation the physical aspects should be first sought for the others later. The type of voluptuous tendency is often directed by the circumstances of the first intense voluptuousness. These often cause anomalies in voluptuous imagery, as regards sex. School strain is a factor in this direction, which should receive more attention than it does. As Talbot (*Degen-cracy: Its Signs, Causes and Effects*) remarks, noticeable effects of the nutritive disturbances produced by school strain are local irritations about the sexual organs. Neurotic persons are liable to nerve storms which express themselves in emotional displays or restlessness, or nagging tendencies. These often coincide with the uric acid tendency to express itself in "storms" like other periodic phenomena of the nervous system. In consequence "sexual storms" result in neuropaths, whether the neuropathy be inherited or acquired. Local genital organ irritation leads to scratching. From this are produced "masturbation" storms, which the subject loathes, but can not control. These occur, as already stated, from the direct effects of constipation, and from the worms and other parasites which constipation fosters in the bowel. Teachers, by compelling children to retain urine through fear of masturbation, often lead to what they intend to prevent. At the outset masturbation and sexual explosions are often a mere physical expression of school strain, destitute of moral significance. They are removable by removing the school strain and its consequences. If strengthened by protracted existence they intensify degeneracy due to school strain.

One important element of possible danger is already pointed out—training in the sexual sphere. To avoid and at the same time to enlighten is the problem presented. In dealing with this position, the great requirement—balance, not repression—must be kept in mind. Masturbation is very frequently an expression not of mental or moral deficiency, but, as already stated, of purely local—first in many cases—physical conditions. It can not be too strongly reiterated that irritation—from the presence of worms in the rectum or vagina, an intensely acid urine or constipation—to male foreskin, or female clitoris produces local itching, the attempt to relieve which leads to masturbation. Granting all that has been said about the deteriorating effects of masturbation, especially in degenerates, the source should first be sought here. Attention to these physical states will often prevent the development of this practice, and its resultant moral deterioration.

In dealing with the sexual appetite, it should be remembered that encouragement of healthy modesty is a duty in both sexes, and pre-eminently so in the male. Much of what is called "sexual purity" is but too often an expression of sexual perversity. While great stress has been laid on the evil effects of association between boys, too little stress has been laid on the danger of training of boys by women. The sexual history of boys demonstrates that their initiation into sexual life was often first at the instance of women older than themselves, frequently servants, but not rarely sexual "purists" or persons whose ostentatious religiosity covered a sexual perversity. In the healthy association of the sexes there is very little danger, but in such morbid association there is much; the more that the morbid generally conceals itself under religiosity and the allied phases of sexual perversion. Great stress has been laid on the dangers of coeducation, but the evidence is growing that education limited to one sex is the source of greater dangers to both boy and girl. It is a matter of common observation among genito-urinary specialists, alien-

ists and gynecologists that much of the alleged "purity" so ostentatiously displayed by female graduates of colleges limited to one sex is the offspring of sexual perversion, which, whether congenital or not, has been fostered by the environment of one sex without the modifying healthy influence of the other.

Chicago Society of Internal Medicine.

Meeting held June 29, 1899.

FOREIGN BODY IN A BRONCHUS—OPERATION AND RESULT.

D. JOSEPH M. PATTON—I must beg indulgence for presenting a clinical case which I think is interesting and worthy of study. This young man, in September, 1897, was employed in and about a restaurant in New York city. While engaged there in helping the culinary department, he was one day eating a plate of soup, and on being called suddenly to some duty he took a mouthful of this soup hurriedly and thought he noticed a piece of bone in the soup. He swallowed it hurriedly and was immediately seized with a violent attack of coughing and dyspnea, during which he expectorated a little blood. He soon recovered and went on with his work, continuing his duties about the place for several days, but more or less troubled all the time with coughing. He says that in performing his duties, if he stooped over to pick up anything, he would notice that the position he assumed would "shut off his wind," as he expressed it, and he would have a severe attack of coughing. He denies, however, that at that time or subsequently he was troubled sufficiently with coughing or with dyspnea to incapacitate him from work. He also denies that he had any illness which confined him to bed at any time after the occurrence of the accident. Some time in June, 1898, he appeared at the Chicago Policlinic, and since that time has been under the joint observation of myself and Dr. John Fisher. At the time he appeared there he was troubled with a cough and purulent expectoration, and exhibited a temperature of from 99 to 101.5 degrees. He had no night sweats. Cough was quite troublesome, not particularly paroxysmal, and the expectoration was free, with a decidedly fetid odor. He had lost a good deal of flesh, and was losing steadily at that time. On examination of the chest at that time it was noticed that the air entered the right lung less freely than the left; the right lung would expand almost, if not quite as much as the left lung, but it took a little longer to do it. It was hardly what you would call suppressed respiration. The expiration was prolonged. Just below the right mammary region there was an area of partial dullness with a few rales; in the center of this area there was a distinct stenosis in the bronchial tube. Inspiration was wavy and at times interrupted; expiration was prolonged, but not wavy. Fremitus was slightly increased; the vocal sounds were increased in pitch, but there was no bronchophony. The respiratory murmur was tubular and increased in pitch. There was some very slight inspiratory recession of the intercostal spaces below the point of stenosis. The point of stenosis was at the lower angle of the scapula which you see; this is where the inspiratory sound was distinctly interrupted.

He was under observation at the clinic from that time until February of this year. For a time he improved a little in a general way, then seemed to grow worse. Expectoration became more purulent, more fetid; fever became more hectic, and he lost flesh and appetite. An X-ray picture of the chest was taken, which plainly showed the ribs and sternum and a pleuritic effusion in the right pleural cavity, which came almost to the nipple level. We made an exploratory puncture and obtained some serum, so that we know the shadow was from the effusion. The picture did not show this area of partial dullness around the point of stenosis at all. There was nothing about the picture that would indicate any foreign body in the bronchus.

In February, Dr. Van Hook operated on the case before the students of the Northwestern University Medical School, in the mamillary line. The operation was performed in two tempos, the object of the first incision being the formation of adhesions between the pleurae. An incision in the line of the fibers of the major pectoral muscle was carried down to the fourth rib in the right mamillary line, two inches of rib were resected, and a dressing saturated with 10 per cent. solution of zinc chlorid applied.

One week afterward he opened into the lung with the actual cautery, first exploring the lung with an aspirator-needle in a number of different places without striking any foreign body, or without obtaining any secretion, fluid, or pus. He then went into the lung in three different directions with the actual cautery, to a depth of two or three inches, opening into a large bronchus. There was a little fetid matter discharged through the opening in the bronchial tube. Air passed quite freely in and out of the lung. The wound was drained with a tube, and the next day the patient was out of bed and downstairs, and wanted to go out on the street. He felt very well. The tube was removed in about one week, when discharge had ceased. After that he improved for several weeks; temperature was lower; there was less expectoration. In about ten days the wound was allowed to close. In the early part of April it was noticed that the lower lobe of the lung, posteriorly, was dull, and that there was no air getting into it, it evidently being in a state of collapse. Following this there developed marked tubular breathing of a cavernous type, and well-marked pectoriloquy just below the lower angle of the right scapula. These signs were accompanied by a temperature of hectic type, and by an increase in the amount and fetid character of the sputum. It was thought that these symptoms might be due to the development of an abscess in the posterior portion of the lower lobe of the lung, so an operation in this locality was advised. As no cavity was found, these signs of a cavernous character were probably due to a more free entrance of air into the bronchus supplying this area of lung, due, probably, to some change in the position of the obstructing body. The lower margins of the lower lobe being previously collapsed and the bronchus being patent, the effect would be the same as we frequently observe in marginal collapse of the lung from pleural effusions—i. e., signs simulating a cavity. In view of the outcome of the case we cannot regret the misinterpretation of these signs, as the admittance of air into the lower bronchial tract through the opening made at the second operation was undoubtedly the causative factor in expelling the foreign body. On April 27, the patient being then at the Policlinic Hospital, Dr. Van Hook resected in the region of the eighth rib just below the lower angle of the scapula. There were pleuritic adhesions, so he went directly into the lung with the actual cautery, and opened into a posterior bronchus, making a free opening, so that air entered and came out quite freely. The tube was inserted and the wound packed tightly; the next morning he had quite a severe coughing spell and choked very badly, and during this coughing spell he ejected, through the mouth, this piece of bone. It is a vertebra from the neck of a chicken. It measures two centimeters in its transverse diameter, and one centimeter and eight millimeters in its anteroposterior diameter. It is in a good state of preservation (exhibits specimen). He was up the next day, down in the clinic room, and felt all right. The tube was kept in for about a week, after which the opening was allowed to close. His temperature gradually declined; he improved in strength and flesh; the cough has gradually disappeared. He now has no cough or temperature and has not had any for several weeks. His appetite has improved; he is at work every day and feels practically as well as he ever did.

This case is interesting from two or three standpoints, first as to the clinical history. The clinical history of these cases differs according to the nature of the body which is taken into the bronchial tract. Small bones like beans and peas, usually create a great deal of disturbance because they may get into the smaller bronchi and induce immediate collapse, and as a rule soon bring on lobar pneumonia, and are very shortly followed by more or less extensive bronchial dilatation. Small pieces of vegetable fiber, like blades of grass or such like, small spicule of bone, etc., usually create more disturbance than larger bodies, because they produce more irritation in the bronchial tract. With some of the larger bodies, like this piece of bone, which do not occlude the bronchial tract entirely, it is remarkable how little disturbance we have afterward. This piece of bone was in the bronchus for eighteen months, and beyond the cough, expectoration, fever, and gradual emaciation, there was no disturbance. He might have had just as much disturbance from a localized tuberculosis as he did from this. That is the case with many bodies, although large, if they do not occlude the bronchial tract entirely.

I remember the case of a boy who sucked a woman's ordinary hatpin, five or six inches long, into the trachea, into the left bronchus, head first; the upper end became transfixed through the wall of the bronchial tube. It was in there several days, was taken out by tracheotomy, but while it was in there the boy apparently had no disturbance whatever. He had practically no cough, no dyspnea, and did not seem to suffer at all. The only thing that could be noticed was a slight difference in the amount of air entering the left lung.

On the other hand, the round bodies which occlude the bronchial tract entirely may result in extensive collapse and in pneumonia and create much more disturbance.

The next point is as to the course to be pursued in these cases. In this class of cases it is different from bodies which lodge in the trachea, or which are coughed up into the trachea at every paroxysm of coughing. There tracheotomy will often suffice, and these bodies can be picked out of the trachea, sometimes by forceps, by a string, or by a wire spatula, or something of the kind, and a coughing spell may bring the foreign body up within reach. In this kind of case it is a different matter. Here is a body which gets down into the bronchus and is fixed there. It does not come up, nor does it create much irritation. In this case a great deal of doubt was expressed by a number of physicians as to whether there was anything at all in the bronchus. They were skeptic about it. The danger from the presence of these foreign bodies is from pneumonia and collapse of the lung, secondary pneumonia and bronchiectasis. The latter is sure to develop, and pneumonia most probably will, so that there is no hope through letting the case alone. There is nothing to be gained by waiting. If one is sure that a body of this kind is in the bronchus, it is unnecessary to wait for symptoms, and if it can be localized I should advise going after it. The chances of the foreign body being coughed up, if there is collapse of the lung below, are very slight.

When the first operation was done on this young man we went in too high. This was probably my fault, as I advised operating at that place. We know that in operating for tubercular or abscess cavities in the lung, it is a common thing to find the cavity situated much higher than we are led to believe by the physical signs. That is the rule, and for fear of going too low in this case I think we did just the opposite. There was no collapse in the anterior margin of the lung; there was no retraction; no sclerosis, consequently the lung was not pushed up at all. We got in too high above the bone. The lung was carefully searched with an aspirator-needle, and whether anything could have been gained by needling with a fine needle, I do not know. When the operation was done behind and air allowed to enter the bronchus, the first violent attack of coughing forced the bone up into the trachea and we got it out. You might say that that is perhaps good luck, but I think it is the reason why the foreign body came out.

As to the surgical aspects of the case I have nothing to say except to remark that the surgery was well done and there was absolutely no disturbance in the lung whatever. He seemed just as well the next day as he was the day before. There was no pneumonia; the temperature did not vary; he had no pain or disturbance of any kind.

A question for the future is as to whether the sclerosis developing around this lung will interfere with the caliber of the bronchial tube and result in bronchial dilations. This is something we do not know, but that is quite possible. As a secondary result of these operations we have sacular dilatation of the bronchial tube. So far we can not see that anything of the kind is taking place. It is known that bronchial dilatation occurs very soon after such an occurrence as this, remarkably so.

DR. INGALS—Was respiration about the same in the upper part as lower down?

DR. PATTON—There was perhaps slight compensatory action of the upper lobe, but the respiration in the middle lobe of the right lung and the posterior part of the lower lobe, when he first came in, before the effusion was noticed, seemed to be a little slower, but quite good.

DR. INGALS—Supposing the foreign body had been lodged in the main bronchus, what would be your opinion of going through the chest for it?

DR. PATTON—On the right side there would practically be no danger in operating in the region of the right main bronchus;

on the left it would be more difficult. I should consider the result likely to be doubtful if a tracheotomy were done for the removal of such a body in the main bronchus. In the case I referred to, where a pin was taken out of the left bronchus by a tracheotomy, the pin was grasped nearly in the middle; the upper end was transfixed through the wall of the bronchus, and the pin was grasped about two inches from the point, and in twisting it it was broken, although the head of the pin was at least three inches farther in the bronchus. Very many expedients have been devised for getting foreign bodies out of a bronchus. Someone, for instance, has advised pouring into the trachea an ounce or two of liquid and inverting the patient immediately, being prepared to do a tracheotomy at once in case any difficulty was encountered. That is taking a good many chances. I would not care to search for a foreign body in that way. But this case illustrates the extreme difficulty of exactly localizing the point of obstruction for the purpose of operating.

DR. EDWARD F. WELLS—I would like to ask Dr. Patton whether in his experience or reading he has noted that perhaps frequently a foreign body has been expelled by coughing during the operation or shortly after, when it has not been found during the operation, or has not been found at all.

DR. PATTON—In the majority of cases the foreign body has been expelled by way of the mouth subsequent to the operation.

DR. WELLS—The reason I asked that question is because many years ago a child inhaled a piece of peanut. Pneumonia followed shortly afterward and an abscess developed. An operation was undertaken, and after an incision had been made down to the pleura, an aspirator-needle was introduced three times in different directions, and nothing whatever was found. But after the third introduction of the needle the child suddenly became choked, coughed spasmodically, and, to my recollection, expelled three-quarters or an ounce of pus with the piece of the peanut. My attention since then has been called to quite a number of cases in which the foreign body has been expelled during the operation or very shortly afterward, when efforts to find it during the operation were utterly futile, and it has afterward been expelled by coughing.

DR. PATTON—Godlee cautions us against removing the tube and allowing the opening to close too early. These foreign bodies may be expelled through the opening some little time after the operation, and he cites a case of that nature in a boy. The boy had inhaled the point of a top into the bronchus, he operated, and some time subsequent to the operation the boy expelled the foreign body through the opening that he had made. I think that is a good point because there is no objection, particularly, to keeping these openings patent for some little time after the operation, if they are dressed properly, and a small foreign body may readily make its exit in that way.

DR. WELLS—Did I understand you to say, Dr. Patton, that there is usually a good deal of difficulty in locating the foreign body?

DR. PATTON—There is a good deal of difficulty in localizing the foreign body after you get into the lung.

DR. WELLS—I hardly agree with that, from the fact that some impediment exists to breathing which can be usually definitely located. It is rather easily done. Is not that your experience?

DR. PATTON—Oh, yes. But I have reference to localizing the foreign body after you get into the lung.

DR. WELLS—How frequently an operation is undertaken for the removal of a foreign body apparently located by the physical signs, and yet nothing is found at that point, but the foreign body is afterward expelled.

DR. PATTON—That is true. Difficulty arises from localizing the foreign body after you have gotten through the pleura.

DR. INGALS—What was the objective point in the second operation?

DR. PATTON—It was a question at that time whether it was merely collapse, or whether he had aspirated some purulent material in there and had developed a cavity. The signs at the time of the operation were almost identical with those of a cavity. I refer to those peculiar physical signs we get where there is collapse of the margin or lower portion of the lung, retracting it and giving the signs which simulate those of a cavity. As there was no air going into the lung, and it was doubtful whether it was merely collapse or a cavity, I advised a second-

ary operation in this region, to see whether there was a cavity there or not and to open into the bronchial tract and let the air in. There was no cavity, but simply collapse.

DR. E. FLETCHER INGALS—I have had no experience in bronchotomy. I have had, however, considerable experience with foreign bodies in the bronchial tubes and trachea, but I have never opened the chest for the extraction of the body. I am greatly pleased that such cases may have so good an outcome. I have not hitherto thought that the position taken by Dr. Patton, viz., that it is better to operate as soon as we can localize the foreign body, is the best for the patient. I have thought that because many of these bodies are spontaneously expelled sooner or later, and from the fact that there is considerable danger attending bronchotomy, it is better to wait for a time, unless there are urgent symptoms, before doing a more radical operation than tracheotomy. In this case the operation was certainly the only thing to advise, and it would have been negligent to wait. I wish to ask the author of the paper whether in acute cases he believes it better to operate as soon as the foreign body is localized. The development of bronchitis, with a little dilatation of the tube, or irritation of the lung and possibly formation of a cavity in the lung itself, may eventually be the cause of secretions and expectoration which will enable the patient to get rid of the foreign body without any operation.

I remember reading of a case in which a bit of hickory-nutshell, which was retained in the lung for many years, was finally coughed up, and the patient made a good recovery. In that case it would undoubtedly have been much better could the foreign body have been found and removed earlier, but at that time operations could not be performed as safely as they are now.

I have on two or three occasions removed foreign bodies from a bronchus. On one occasion I removed a large kernel of corn from the very farthest end of the right bronchus. Again, in another case, I removed a sharp spicula of bone from the farthest end of the left bronchus. In still another case I removed a bit of wheat from a bronchus.

I was surprised not long since at hearing a gentleman of high standing recommend leaving such a foreign body entirely alone, hoping that the patient would have an attack of cough that would expel it. His view was that there was no very great danger from the operation, but little from delay. In the case of a foreign body of any considerable size in the trachea, operation should be advised at once, after other procedures have been tried, such as inverting the patient. There is always danger while the foreign body remains, but in a large percentage of cases they will be spontaneously expelled. Even small bodies are often difficult to remove.

I operated, two or three years ago, on a woman who had inhaled about five-eighths of an inch of a match. I thought I could localize the foreign body at a point about an inch and a half below the main right bronchus, by the pain of which she complained, but I could not tell from the respiratory murmur; yet I was satisfied there was something in the air-passages; I did a tracheotomy, but did not get the foreign body. I kept a tracheotomy-tube in the trachea for a few days, as I believe it is best to do in cases where we do not find the body we are after, and finally told the interne that he might take the tube out; the same day he removed the tube she coughed up the match.

I once operated on a child for a button in a branch of the bronchus, that had gone so far in that it could not be reached. In that case I felt confident the body was present, from the localized rales, but there was no distinct obstruction. The tube was worn for four or five weeks, but the button was not secured until about five weeks afterward, when it was coughed out. The usual recommendation is that we stitch the edges of the trachea to the integument, if the foreign body is not obtained at the time of the operation. This does not seem to me a good procedure. A better plan is to have in a large tube for a few weeks, and make repeated efforts to get rid of the foreign body.

I should think that the danger would be very considerable in a bronchotomy when operating near the root of the lung, much more so than at a distance like the operation in this case; but I have no doubt a modern surgeon would get in there.

DR. PATTON (closing the discussion).—I agree with Dr. Ingals in regard to the class of cases he has cited and outlined. As to the advisability of operating early in these cases, we must draw a distinct line between the class of cases he has cited and the

class to which this case belongs. The point is simply this: In small bodies which get into the trachea, and where we are in doubt as to how far in they may be, which are not localized by any distinct physical signs, it would be very doubtful surgery to go after them any further than do tracheotomy and adopt the course advised by Dr. Ingals. In this class of cases we have a different condition. Here we have a distinct stenosis to deal with. The fact that the stenosis is not complete and does not result in collapse of the lung supplied by the tube occluded is only more positive evidence that it is a local affair and can be reached and should be sought for. If we had a smaller body, it would probably go in a little farther and possibly result in immediate collapse and pneumonia. It would be a much more difficult thing to get at. But the fact that the collapse came on after the stenosis occurred, coupled with the fact that there was diminished respiratory capacity of that lung for a long time after the occurrence of the stenosis, and not complete obstruction, and the additional fact that there were local signs of stenosis of the tube, show conclusively that there is a localized condition that you can reach, or stand a good chance of reaching, and that the patient's prospects for complete recovery are much better by operating early and not waiting until we get a cavity or bronchial dilatation, which is sure to come, and which, when filled with secretions, will be likely to result in lobular pneumonia, probably septic, at a more or less early date, and which will result in further collapse of the lung and possibly in gangrene. And so it does not appear to me wise to wait for these conditions to develop before searching for the foreign body. That, I think, is the position assumed by Godlee, who has done much lung surgery. In the class described by Dr. Ingals, I agree with him as to the course to be pursued, and success is most often obtained by adopting the course he advises.

DR. INGALS—Supposing you saw a case in which there was obstruction by a foreign body similar to this, would it be your idea to operate within the first week, or to wait a month or two to see whether the body would be coughed out?

DR. PATTON—it is difficult to make a direct statement in reply to Dr. Ingals, for the reason that we are not usually present when these accidents occur. We have to take the statement of the patient to a great extent, and some physicians are rather backward in accepting the statements made by patients in this regard. I believe that we should take the statement with a good deal of credence, because he or she, as the case may be, is not likely to misinterpret the symptoms at the time, and he is not likely to greatly exaggerate because he is conscious of the fact that a body has gotten into his trachea. If we do accept the statements of patients and feel sure that there is a foreign body in a bronchus, and we believe it to be large enough so that it will probably not come out through the larynx, I do not see any use in waiting if we can localize it at all. On the other hand, this case came to us with the statement that the foreign body was inhaled months before. We did not at the time feel that we were warranted in operating until we saw what course the case was going to take. But as the bronchial dilatation grew worse, as the fetid expectoration became more abundant and the fever ranged higher and loss of flesh continued, we felt there was no use in waiting longer until he actually developed some serious condition. I think it all depends on how certain one may feel as to whether a foreign body is in there or not, and how much chance he can take.

DR. INGALS—If a patient were getting on comfortably you would feel more like waiting than if fever were developing?

DR. PATTON—I should; yes.

Chicago Neurological Society.

Regular Meeting, April 25, 1899.

(Continued from Page 284.)

DR. ARCHIBALD CURRIE—I would like to ask attention to a form of brain disease which is comparatively rare, and of which I have seen two cases and suspected the same condition in a third instance. The first case was a man, 50 years of age, who, at the age of 23, was digging a well, and some boys, in trying to annoy him, tossed a pebble into the well, which had reached a depth of about twenty feet, striking him in the parietal region. It simply angered him at the time, made a trivial

scalp cut, and very little was thought of it. Afterward he acted as a conductor in the railway service for many years, gradually developing more or less disturbance of sensation on the right side, and finally became hemiplegic. He would have convulsions affecting the right side at times. Frequently these convulsions commenced in the right hand, becoming generalized, in other instances only the right upper extremity was involved. At one time he was actually incapacitated by right hemiplegia, which partially subsided for a time and subsequently became complete. I saw the man some twenty years after the original injury; he was hemiparetic, and had occasional convulsions on that side. I advised an exploratory operation, and when the trephine had been used for a few moments suddenly there was a gush of hemorrhage of the most startling character I have ever witnessed. It was with the greatest difficulty that it could be checked by plugging with iodoform gauze, some of which was pressed within the skull, and not until the carotid was ligated on the same side was the hemorrhage controlled. Dr. McArthur did the operation, and it was our belief that he had opened an aneurysm within the skull. The man improved temporarily and went to Southern Ohio. Three years later he died and an examination was made by a physician, who stated that the left side of the head was empty except for the rags the doctors in Chicago had tucked into it.

Another case I saw at about the same time was a young boy who had fits which commenced in the left hand. There was a history of cephalic traumatism, the exact nature of which I can not now recall. Finally, being very urgent for an operation, it was done at the County Hospital, by Dr. T. A. Davis. He cut down through the dura, explored the brain and suddenly got a terrific hemorrhage, and yet was able, by plugging the cavity with gauze, to check the bleeding. I saw the boy two days after, when the dressing was removed, and in withdrawing the gauze there was a cavity large enough to accommodate a hen's egg, lined with dense, fibrous, glistening membrane, reminding one of a large arterial pouch. The boy recovered from the operation but I have failed in all attempts to trace the case.

A young woman, 21 years of age, came from Quincy. She gave a history pointing to brain disease. There was a hemiplegic condition, spasticity and tetanoid spasms. She gave a history of having had a decided subjective bruit synchronous with the pulse. Upon auscultation I could objectively make out a bruit corresponding to the indicated location of the disease. I suspected that there might be an aneurysm. She is still alive; I heard from her last week, and her condition remains about stationary.

Aneurysmal tumors should be detectable by the X-ray. If we can make out the arch of the aorta, the heart and other blood-channels by this means, these growths should also give a shadow.

DR. DANIEL R. BROWER—Seeing these interesting cases of Dr. Patrick recalls an experience I had about a year ago. A man, 55 years of age, was brought to my office by a physician, as a well-marked case of Jacksonian epilepsy, and with the classical symptoms of intracranial tumor. The case was operated on by Dr. Senn. He remained here for a short time under treatment by potassium iodid, with very great amelioration of all his symptoms. The paroxysms, which were several a day, had ceased, and his mental condition improved. He went home, continued the treatment for a time, stopped it, and very soon his symptoms returned with great exaggeration, and he was again brought back to the city. Dr. Senn then operated upon him. The paroxysms began in the hand; the tumor was supposed to be located in the hand center. No tumor was found by the operation. He gave a history of having some years before had considerable trouble with a suppurating ear, which had existed for a long time. Dr. Senn thought it might possibly be a mastoid abscess, but he found none at the operation. A few days afterward the man died. A post-mortem examination was made, and revealed a subcortical tumor, the size of a walnut, and an abscess in the mastoid cells. I have never seen any but temporary benefit from surgical interference in tumors of the brain.

During the past winter I have seen remarkable effects from lumbar puncture in relieving pressure symptoms in cases of cerebrospinal meningitis, and, inasmuch as the most distressing

symptoms of these tumors are due to pressure. I shall advise its use in the next case showing these symptoms.

DR. PATRICK—I have not recently followed the literature closely in regard to lumbar puncture in cases of tumor, but a couple of years ago I did keep track of it pretty thoroughly for a time, and the results from this measure, even for amelioration of the symptoms, were not particularly good. A number of cases died suddenly when puncture was made; in others the headache was enormously increased, so that patients complained bitterly of headache as soon as the fluid began to flow from the spinal canal.

DR. JAMES B. HERRICK—What Dr. Patrick has said regarding the mental condition of patients with cerebral tumors in the frontal region recalls to mind a patient whom I saw two or three years ago in whom there was a history of change in the mental condition, and later symptoms of severe headache, Jacksonian epilepsy, etc., so that there was little question about the case being one of tumor of the brain. The mental condition was, however, that of melancholia and despondency. While the patient was in the hospital he cut his throat with a razor. At autopsy the tumor was found in the frontal lobe, and by its pressure it had involved some of the motor centers, and induced Jacksonian epilepsy.

There is one form of tumor which, strictly speaking, might not be called tumor of the brain, that presents a great deal of difficulty in diagnosis, and that is the multiple tumor as it involves the meninges. A close resemblance to tuberculous meningitis may exist in these cases. One case of unusual interest I recall, seen about a year ago in the Presbyterian Hospital. Dr. Lyman asked me to give his clinic, and the interne in going through the hospital with me to look for material, said to me, "there is a good case of tuberculous meningitis in the children's ward." I looked the patient over, and thought it would be a beautiful case for clinical demonstration. I showed the case to the class as one of tuberculous meningitis. It was a child with a somewhat vague and indefinite history. There had been complaint of considerable headache and of irritability for several days, then two or three convulsions. The history was very indefinite as regards temperature. The child had gradually become comatose, and at the time I examined the patient there was complete coma. This was interrupted occasionally by the typical cephalic cry; the neck was rigid; the head drawn back; there was some paralysis of the ocular muscles; there was distinct optic neuritis, and most pronounced emaciation. The patient died a little later. An autopsy showed a walnut-sized sarcoma of the frontal lobe, with diffuse sarcomatosis of the pia mater of the brain and cord, the nodules varying from those of minute size up to those the size of a hazelnut. This rather rare case has been reported by Dr. Weaver in the *Journal of Experimental Medicine*.

In looking over the history again in the light of the post-mortem, I think there are two facts which should have drawn at least suspicion toward the existence of such a condition rather than that of tuberculous meningitis, namely, the long continuance of the disease, which extended over fully ten or twelve weeks, and the fact that there was but slight elevation of temperature.

DR. KUH—Was the fever intermittent?

DR. HERRICK—Yes, but the elevation of temperature was very slight, seldom up to 100.

DR. SANGER BROWN—I think we often lose sight of the fact that in cases of brain tumor many of the severest symptoms are actually neurosthenic, and not, as is too frequently believed, focal. I refer particularly to the headaches. These are generally, in my opinion, practically identical with those found in many cases of severe neurosthenia; that is, the patient will wake up from 3 to 5 a.m., after having gone to bed feeling fairly comfortable, with a most insufferable and profound headache, so prostrating that he often has to sit down and rest several times while getting dressed. He is often able, notwithstanding this, to take a fair breakfast, and after this gradually he is relieved, so that often not later than 10 a.m. he is fairly comfortable again, and this may not be repeated, with anything like the same severity at least, more than several times in a week. It may be accompanied with nausea and vomiting in both cases, and I favor the hypothesis that this is caused by the depressing effect of the growth upon the vital portions,

rather than by irritation of the meninges, or indeed by the irritation of any of the cerebral tissues.

I wish to draw attention also, by way of criticism, to the doctrine that pressure or irritation of a growth in the brain is the cause of optic neuritis, by stating that it quite frequently, or perhaps more properly, quite occasionally, happens that in cases of severe anemia, optic neuritis is found associated with the headache and symptoms of nervous prostration, which I have already referred to. I make these statements simply as suggestive criticisms upon the theories rather currently held.

Dr. RICHARD DEWEY—I wish to speak briefly of the symptoms in cases of brain tumor. It would seem that it is very rare to find any typical form of mental disturbance in these cases, most of them presenting symptoms the result of pressure or irritation of the locality that is affected, with a great deal of dullness, semi-stupor, apathy, and at times a good deal of emotional disturbance as the result of the irritation and pain. But in rare cases, something almost corresponding to maniacal attacks seems to make its appearance. The mental symptoms of cerebral tumors have received comparatively little systematic attention. These are certainly worthy of more attention than they generally receive. The surgeon or family practitioner scarcely ever gives desirable attention to these matters, and the family themselves are not likely to notice them. It is surprising how very great degrees of mental aberration may exist, both in cases of tumor and in other brain diseases, without intimate friends and acquaintances realizing them. There are certain forms of mental disease that may appear in almost typical form in cases of brain tumor. Two of them have been mentioned here this evening—neurasthenia and hysteria. Sometimes neurasthenia and hysteria are considered to be the sole causes of the disturbance. Another form of brain trouble which may be confounded with tumor, and is accompanied by symptoms of a more or less typical character, is paresis. Many, very many, of these cases have been reported as cases of paresis where subsequently brain tumor has been found to exist.

MULTIPLE SCLEROSIS.

Dr. M. L. GOODING—Our patient is a young man 23 years of age, of Russian parentage, the eldest of five children. He was born at term and was perfectly well up to the age of 6 years, at which time he had scarlet fever, but as far as we can ascertain this was followed by no renal, glandular, anginous, articular or aural sequelae. His parents, as well as three brothers and one sister, are living and well and free from any nervous or mental disease. No history or evidence of syphilis or alcoholism can be elicited.

When 7 years of age, he was lost during a blizzard and almost succumbed to the exposure to which he was subjected. Shortly afterward he began to exhibit the first symptoms of his present malady. He began to have some difficulty in walking, and seemed to become easily fatigued on exertion. He also began to fall behind in his school work, although previously maintaining a good standing. He further began to have occasional spells of headache and dizziness. At the age of 13 he had an apoplectic onset involving the entire right side. When 15 years of age he had ptosis of the right lid, lasting six months.

The unsteadiness in gait now became more marked, the limbs, as well as the trunk and head, being thrown into violent oscillations on the slightest voluntary effort. His speech also became defective. He has had no bladder, sensory or visceral disturbances. The lad appears well nourished and of fair size for his age. The skull, scalp, ears, teeth, gums and tongue present no abnormality.

As we observe him closely, we note the expressionless face, and as we engage him in conversation the incapacity for continuous mental effort is strikingly shown. There is slight obliteration of the nasolabial fold and drooping of the angle of the mouth on the right side.

Several years ago, while being shown before the class at the College of Physicians and Surgeons, peculiar grimaces, involuntary and uncontrollable, were remarked, but the condition seems now to be absent. As we listen to his speech we notice that the words are uttered slowly and in a monotone. This bradyphasia is associated with tremorlessness of the lips. As he attempts to walk, the stiffness and inco-ordination of his legs

prevent the performance of this act without the assistance of a cane. A pronounced swaying is present when standing with closed eyes.

Inco-ordination and a rough jerky tremor of the upper extremities are apparent, as we ask him to bring the tips of his fingers together, but on his coat or carry a glass of water to his lips. This is more marked on the left side. The knee-jerks are excessively exaggerated and ankle-clonus is present.

We can find no sensory disturbance. As we examine his eyes we detect a nystagmus—lateral, vertical and rotary. The right eye deviates somewhat from its proper axis, and is slightly turned inward. The pupils are normal. The fundus shows a secondary atrophy, with a peculiar discoloration of the disc.

From this array of symptoms we are enabled to make a very positive diagnosis of multiple sclerosis. On account of the gait, ataxia, tremor, nystagmus and speech defect, this disease may be confounded with the several hereditary ataxias. Friederich's ataxia can be excluded by the presence of knee-jerk with clonus and optic atrophy, and the absence of sclerosis and club-feet. The Romberg phenomenon, transitory oculomotor palsy, absence of family history, and early onset differentiate the picture from a hereditary cerebellar ataxia.

Syphilis of the brain and cord can be ruled out by the absence of history and signs of the disease, and the therapeutic test.

Brain tumor of the posterior fossa is sometimes accompanied by this form of gait, ataxia and nystagmus, but the more rapid progress of this condition, the greater degree of headache and vertigo and the positive symptoms of multiple sclerosis present no difficulty in eliminating tumor. As already indicated, the treatment by potassium iodid and mercury were futile. His nutrition has been maintained through appropriate regulation of diet, exercise and hygiene. For the relief of his tremor and agitation he has received the static breeze, together with a combination of

Meeting Held in Topeka, Kan., July 10, 1899.

INFANT FEEDING.

Dr. J. M. PEERS presented a paper on "Feeding of Infants in Relation to Diarrhea." He spoke especially of the proper preparation and use of milk, showing the difference between cow's and human milk, and how to make the former suitable for infants' use.

Dr. H. B. HOGENDOORN emphasized the importance of artificial feeding.

Dr. I. BARNES recommended artificial food prepared with cream 2 parts, milk 3, lime-water 1 and water 10 parts.

Dr. R. McVEY spoke of food, heat and bacteria in causing infantile troubles, and the relation they sustain to each other. If indigestion is the result of bacteria, food and heat aid the development. He pointed out the dependence of the food and bacteria. It is a question whether the food or bacteria causes the indigestion, or whether the indigestion causes the bacteria.

Dr. O. DAVIS spoke of preparing the food by leaving the milk in a cool place until the cream rises, then drawing off two-thirds of the bottom with a siphon, and adding water and sugar.

Dr. S. G. STEWART—The mother complains as soon as the child begins to eructate; then try artificial foods. Cow's milk comes first. Sterilize it, then neutralize it with lime-water. We need to teach the laity that artificial foods are a poor substitute for milk, and should never be used when milk can be obtained.

It is generally a year after the introduction of a sick animal that the disease breaks out in a stable. Nothing is more common than, in an infected stable, to see a healthy cow become tubercular, some time after having occupied the place left vacant by the death of a tubercular cow. (Strauss: Tuberculose et son bacille.)

Sketch of Century's Progress in Medicine and Surgery.*

DR. J. WARD COUSINS, M.D., F.R.C.S., opened his address with a general review of the conditions of medical science at the beginning of the century, the birth of the modern school of medicine, the discovery of vaccination and its results, the progress in sanitary science and preventive medicine, the lessons of the cholera epidemic of 1848 and the Crimean War, and paid a tribute to the labors of Florence Nightingale in hospital reform, and to

ERNEST HART,

who was a devoted pioneer in preventive medicine, and labored with enthusiasm in the great questions of epidemic cholera, water-borne disease, vaccination, and many other topics. He rendered invaluable help to the children of the land, and made plain the necessity for reform in the Poor-law infirmaries of the United Kingdom. He threw all his energy into his editorial labors, and speedily raised the *British Medical Journal* into the commanding position it now occupies. His name and work will forever be intimately associated with the history and growth of our great and world-wide organization.

PATHOLOGY.

The early part of the century will ever be recognized as the birthtime of modern pathology—the period when the huge chasm between dead morbid anatomy and living pathology began to be bridged over. The teachings of John Hunter had long exploded the old humoral theories of disease. The leading minds in those days no longer considered that disease depended on an excess of bile, or blood, or phlegm, and the other fluids of the body, and that it could be cured by getting rid of these faulty elements. The principles formulated by Hunter were maintained by succeeding writers in the same field for many years. His pathology was a long way in advance of his predecessors, and he was the first to recognize that all the processes of the organism belonged to biologic science. He saw that disease was only a deviation from health, and that both conditions were regulated by the same vital laws. He regarded the blood as possessed of life, like the solid parts of the body, and its plastic materials as the elements of all growth and structural repair, and taught that exudations composed of homogeneous and transparent fluids containing within them no visible form sweated through the walls of the blood-vessels, and then became changed into living tissue by a process of vital crystallization.

About the year 1830 great improvement took place in the manufacture of the achromatic compound microscope, and this gave a great impetus both to physiology and pathology, and the value of microscopic examination began to be generally appreciated. Moreover, the Council of the Royal College of Surgeons of that day was so impressed with the utility and importance of the facts revealed by the minute dissection and examination of elementary structures that in 1841 they determined to establish a professorship of histology, and to form a collection of preparations both of the healthy and morbid tissues of plants and animals which should elucidate the value of microscopic investigation.

We can now look back on the time when the progress of physiology was everywhere recognized as the true basis of all pathologic science. In 1838 Schleiden made his brilliant discoveries in vegetable tissues, and soon after Schwann investigated the cellular structure of animal bodies. He followed Hunter in believing that vital centers of new growth were spontaneously developed in semi-solid exudations, and that constructive elements could actually be formed within amorphous substances. But, although the progress of the century has been the outcome of the labors of many able workers, still I venture to think we can justly give the first place to Rudolph Virchow. We are indebted to him for exhibiting histology as the real instrument for unfolding the deep

mysteries of disease. He practically gave the medical world a new pathology founded on laborious observation and experiment. Every kind of organic structure and every new formation, he announced, could be traced to a vital source. There never has been and there never will be such an erratic phenomenon as spontaneous generation in either physiology or pathology. He recognized that every plastic exudation, which had been called amorphous material, had wrapped up within it living cells, and that these had come from living structures, and thus every new formation must be the offspring of some living tissue in which its living germs arose.

To-day we are able to appreciate the fact that the evolution of our new pathology has progressed side by side with the evolution of biology, and that, in its broadest sense, pathology is an outgrowth of biology. The work of the last fifty years may be rightly defined as the great unraveling of the deep relations between the healthy phenomena of life and the variations which are outside the normal cycle of these vital phenomena. Through many years biology and pathology have been mutual helps in their onward and remarkable evolution, and we may rest assured that in the coming century their healthy reaction on each other will still go on. Pathology will still advance, and the new discoveries of biology will serve as starting points of new pathologic truths; at the same time, the ordeal of biologic criticism will be accepted as the test of every new pathologic development.

BACTERIOLOGY.

Recent investigations in bacteriology have proved a great stimulus to the study of the relations between the diseases of mankind and those of the lower animals, and this relationship will form an important part of future researches. It is only a few years ago that the real nature of that dreadful scourge of the human race, tuberculosis, was discovered, and its intimate association with the same disorder in domestic animals clearly brought to light. Laennec was the first observer who described tuberculous nodules, and traced their development from milky tubercles. In 1865 the inoculation of animals with caseous material was found to produce tiny masses in their bodies which were in all respects similar to the disease in man. Some physicians were bold enough to assert that the phenomena suggested the probability of contagion, but the notion only excited the ridicule of the profession at that period. Tuberculous disease was generally regarded as a hereditary disorder transmissible in various degrees of intensity. At the same time external influences were looked on as powerful factors which could kindle the smoldering flame into activity. From the very dawn of modern pathology tuberculous disease received profound investigation, and the researches only corroborated the time-honored theory. The microscope failed to detect in the diseased parts any specific elements, and in vain cells and granules, and cells of giant form were searched for some characteristic quality. Tubercle was examined by the best observers in the civilized world; thousands of clever eyes had gazed at it with intense devotion, and with a remarkable unanimity they pronounced the opinion that it was so indefinite in structure it could be recognized as much by negative as positive qualities.

In 1882 the whole pathology underwent a great revolution by the demonstration of the life history of the tubercle bacillus. The disease, occurring in any tissue or organ, is now universally regarded as a specific disorder, the bacillus the absolute proof of its invasion, and the cause of the morbid changes. The long-accepted causes are now dislodged from their position, and are now rightly grouped as morbid tendencies. The inheritance of constitutional peculiarities, the liability to chronic inflammations, and the susceptibility to external influences, are now regarded as conditions which help the microbe to establish itself within the body. Still, these factors are not less potent because the specific characters of tuberculosis have been revealed.

* Abstract of President's address at the Sixty-seventh Annual Meeting of the British Medical Association, from advance sheets of the *British Medical Journal*.

This pathologic transformation still has around it many unsettled problems. It is, however, a fact of history that Koch, by his own researches, brought to light from the microscopic elements of tubercle a living atom which no human eye had before seen. I believe that one may anticipate that this great discovery will be of priceless benefit to mankind.

Bacteriology investigation has already unfolded many of the problems connected with diphtheria. The researches began in Germany in 1882, the chief experiments were by Drs. Behring and Kitasato, and they were soon followed by Dr. Roux, of the Pasteur Institute in Paris. We now know that many animals are liable to its attacks. It is communicable to the horse, rabbit, guinea-pig, and fowl, and some species seem to suffer from a chronic form of the disease. Horses when attacked develop similar symptoms to those which follow inoculation of diphtherial toxin.

The deadly bubonic plague which was epidemic throughout Europe during the Middle Ages, has unfortunately proved a dreadful scourge in India and the East during the last three years. Many earnest workers have made the disease the subject of an elaborate inquiry. In 1894 a specific bacillus was discovered in the blood of a patient suffering from epidemic plague. There is much reason to believe that domestic animals and rats are responsible for spreading the infection, and squirrels and cats have been known to die of the disease. It has recently been stated by a French observer that fleas are dangerous disseminators of the disease. As the result of a series of experiments, he affirms that fleas taken from rats suffering from plague can communicate the disease to healthy rats, which in their turn become centers of infection.

Professor Ogsten in 1881 detected micro-organisms in acute abscesses, and this important discovery has been followed by many elaborate inquiries which have proved the direct connection between suppuration and pathogenic organisms. It is certain that the staphylococcus, the streptococcus, and the bacillus coli communis, and other species also, may be the exciting cause of septic conditions in man and the lower animals. Around septicæmia to-day there are many unsolved problems. Are the micro-organisms the direct cause of the disease, or is it produced by the chemical substances which they elaborate? All animals appear to be liable to blood poisoning. Dr. Hewlett says that poultry, pigeons, pheasants, and sparrows are susceptible to a disease, which Pasteur proved to be excited by a bacillus identical with the bacillus of rabbit septicæmia. Even the mouse has its specific septic disturbance, and the organisms which are present in its blood appear to be identical with those discovered in the septic disorders of swine.

MALARIA.

Investigators have recently been endeavoring to unravel the secrets of malaria poisoning. The disease has been traced by Surgeon-Major Ross and Dr. Manson to a parasite which has the power of assuming a latent condition within the human body. It actually lives in the interior of the red corpuscles of the blood. Dr. Manson thinks that it is removed from the blood by some suctorial insect, and that this insect is a species of mosquito. The parasite is propagated outside the human body. The insects are capable of infecting their larvae, and man is in turn infected by drinking the water contaminated by the mosquito, or by inhaling the dust of the dry mud of the pools in which mosquitoes have perished.

I refer to these facts only to show the great impulse bacteriology has given to the study of the intimate connection between the diseases of mankind and the diseases of animals. It is certain that the latter are far more often the agents by which diseases are distributed than we are at present able to detect. The same disorder in different animals produces very different manifestations, and the symptoms may be so variable that the recognition of a common specific cause is almost impossible.

What may we expect from this young science in the future? We are only touching the fringe of its possible revelations. Much that has been done will have to be done over again, and much that has been written will have to be rewritten. How many questions have yet to be solved? Will the further evolution of bacteriology solve the great problem concerning immunity? The striking differences in the susceptibility to disease in individuals are still unfathomed. Some seem to possess a natural insusceptibility to infectious disorders while others are susceptible on the smallest exposure. I do not believe that any individual can inherit or acquire a resisting power for all forms of disease: some races appear to acquire immunity, and native populations in some parts of the world exhibit very little susceptibility to yellow fever and malaria. Race immunity is generally explained by natural selection and protection by inheritance. During the long periods susceptible persons were weeded out, and those that remain are capable of transmitting their insusceptibility. But we learn from experience the resisting power to infectious diseases is very variable, and that there is no such thing in the world as absolute immunity. On the other hand, bacteriology offers us the comforting doctrine of phagocytosis. The cells of the blood are ever ready to engulf and destroy living bacteria, and to cast them out as unwelcome guests. The leucocytes may be compared to a great army of invisible warriors. They send out their scouts, and as soon as an enemy is in sight myriads appear at the very seat of infection and are drawn up to open the attack on the intruding bacterial forces; all ends well when the battle of the cells terminates in the destruction of the enemy, but unfortunately sometimes the leucocytes are beaten back and the bacteria are victorious; then they can multiply without hindrance, and general infection is the result of the defeat.

SURGICAL ANESTHESIA.

Of the history of the discovery of surgical anesthesia he spoke at length:

In the noontime of this Victorian era surgical anesthesia was the brilliant gift to the civilized world by our brethren and kinsmen across the great Atlantic, and at the last annual meeting but one of this, the greatest of the centuries, we desire to record our admiration of the courage and genius of William Morton and the wisdom and surgical skill of Charles Collins Warren, and again to crown their memories with enduring fame as great benefactors of the human race.

It is an interesting fact that the original anesthetic agents still hold the confidence of the medical world. There are many differences of opinion on their essential virtues and a wide spread hope that soon safer remedies may be discovered. Sir James Simpson entertained this hope until the end of his career, and Dr. Snow, who did so much during his life to perfect anesthesia administration, believed that better agents would be found. It is my opinion that surgical anesthesia can never be wholly stripped of risk, and that to-day the risk is greatly reduced by our modern safeguards and improved methods of administration. It is certain that we have not reached finality in the matter of surgical anesthesia, but that by experience and the skillful adjustment of the dose we are entitled to regard the inhalation of our present agents as practically safe.

During the preanesthetic age, operations were confined to cases in which surgical interference was absolutely necessary, and both patient and surgeon had to be brave and determined—one to suffer pain, and the other to perform delicate manipulations with rapidity and dexterity. The introduction of surgical anesthesia exercised at once a great influence on the practice of surgery, and the number of operations increased in all directions. Within six months the surgical work of the London hospitals was actually doubled, and in every department the domain of surgery rapidly extended.

Unfortunately, the surgical world was quite unprepared for

the sudden outburst of enthusiasm which followed the great discovery. At this period surgical instruments were few in number, and very different from what they are to-day. The microscope was only just adopted as an instrument of pathologic research, and many ingenious aids to diagnosis now universal were not then in existence. The hospitals were for the most part wretched receptacles for the sick. They were constructed regardless of all sanitary precautions, and without any means for securing adequate light and fresh air for the safe treatment of urgent surgical cases and acute diseases. The nursing system, too, was rotten to the core. Nursing then meant nothing more than the attendance of a parcel of ignorant women who possessed no qualification for their high and self-sacrificing duties, and who had never received a moment's training. It is a fact that in those days thousands of lives were extinguished at the shrine of ignorance and superstition, and thousands more for the want of sobriety and cleanliness. Under such conditions it is not surprising that suppuration followed almost every wound, and that septic processes were started by every operation.

The high mortality which occurred both in the institutions of this country and the Continent excited great anxiety, and roused the profession to earnest investigation. The great increase in the work of the hospitals soon revealed their insanitary condition, and many structural defects. Again and again gangrene, pyemia, and erysipelas ran through the wards of these old buildings, and the medical officers saw clearly that these outbreaks were infective disorders, and were carried from one patient to another.

We have now reached the dawn of another important epoch in the medical history of the century. The terrible ravages of sepsis, which appeared to have gone almost beyond control, helped to bring about better ward ventilation, and improved sanitary arrangements in many of the old buildings. The evil of overcrowding was checked, and increased cubic space provided for patients. Many reforms soon followed in the administrative and nursing departments, as well as an improved technic in operative surgery. Some treated their cases with water dressing or irrigation; some, having discarded greasy compounds, closed all their wounds with friar's balsam; and others, after bringing together the cut integuments with strapping, used dry wool and pressure. There can be no doubt that greater cleanliness and new methods of treatment were introduced at this period with success, and these advances helped to prepare the surgical world for the coming of the great crisis when the doctrines of Lister shook the foundation and revolutionized the practice of surgery. Lord Lister demonstrated to the world the part that living organisms play in the production of septic diseases, and then exhibited the simple means by which their growth and development could be prevented. He proved that wounds could be made to heal by first intention, that the process of suppuration could be controlled, and that precautions easy of application would stop the development of septic disorders.

RECENT ADVANCES IN SURGERY.

Notwithstanding the great progress of medicine during recent years, the results have been less manifest than the brilliant advances of modern surgery. There is no organ nor region of the body which has not been investigated by the surgeon; year by year the science has gained wider application, and reached a higher state of perfection by new methods of diagnosis and improvements in surgical technic. Only three and a half years ago the remarkable discovery of Professor Roentgen was communicated to the scientific world, and it has already proved of great value in surgical practice. It has revolutionized the old methods of military surgery, and rendered easy the location of metallic substances impacted in the body. It has given a fresh impulse to the study of diseases and deformities of the skeleton, and is an invaluable guide to the treatment of injuries and diseases of the epiphyses and joints. We can anticipate with confidence that the treatment of this large group of disorders will steadily improve.

The time is coming when there will be a considerable reduction in the number of adults suffering from hernial troubles,

and this important result will be due to the latest improvements in radical operations. There will be a great reduction in the number of persons afflicted with loss of sight, the issue of the modern treatment of infantile ophthalmia and the corneal diseases of children, and also the early correction of errors of refraction.

HANS WILHELM MEYER.

During the last twenty-five years great advances have been made in aural surgery, and the number of deaf persons in this and other countries has been greatly lowered. The celebrated Danish physician, Dr. Hans Wilhelm Meyer, was the first to put his finger into the little space between the nose and the throat for the purpose of removing "pharyngeal vegetations." It took him some years to convince the profession that these outgrowths were a common cause not only of loss of hearing and obstructed nasal respiration, but also of defective articulation and impaired mental and bodily development. It is no exaggeration to assert that the number of young persons who have been saved from life-long deafness by the removal of these obstructing glands amounts already to hundreds of thousands, and that hundreds of thousands more will be delivered from this terrible affliction in future times. Dr. Meyer lived just long enough to know that the medical world recognize the great value of his discovery, and to-night we desire to honor his memory and to record our admiration of his splendid labors.

SEPTICEMIA.

The experimental investigation of the causation of human septic disease is still far from complete. Up to the present time the virus of septicemia has not been isolated, although the bodies of infected animals must contain a very powerful poison. The filtrates of streptococcus cultures have exhibited very little toxic action, and there is no very satisfactory evidence of their value in the complex disorders included in the term "blood poisoning." The prevention of inoculation through a wounded surface is now possible, but when the disorder is once fully established we are practically powerless to overcome the wide-spread disturbance. I have no doubt that some of the surgical victories of the future will be won by bacteriologic science. At the present time we have no cure for sepsis when it has entered the body; still we have much reason to hope that a remedy will be found, and that the destruction of sepsis-producing organisms within the blood and tissues may be at length accomplished.

CANCER.

The treatment of cancer and its manifold complications is another great field for inquiry in coming years. For some time a growing impression has prevailed that the disease has been steadily on the increase. Cancer causes about 6 or 7 per cent. of the total deaths of both sexes over 45 years, but these figures are probably rather under than over the real number. No doubt during the next few years the question of increase will be settled. Recently some investigations have been published suggesting that the disease is due to a parasite, and Mr. Plummer states that he has discovered parasitic bodies in 1130 cases out of 1278. Local irritation is certainly a great factor in the development of cancer, and this may possibly be the channel for the entrance of the parasite. Other observers have suggested that the disorder is liable to recur in particular places, and if this statement is corroborated by further investigation, it will certainly form a presumption in favor of cancer being an infective disease. A curative serum for carcinoma has not yet been discovered. Up to the present time surgical treatment yields the best results, and the earlier it is adopted the better. We look forward to the development of new methods of diagnosis, so that the surgeon may be able to recognize the seat and character of the disease in the incipient stage. The pathology and treatment of cancer still bristle with difficulties. We are anxiously waiting for more light and we are ready to receive it from whatever quarter it may fall upon us. It is at least some satisfaction to know that many of the best pathologists and surgeons are diligently laboring in all parts of the world to unfold the mysteries which still surround this terrible disease.

The address concludes with remarks on the future needs and progress of preventive medicine, the latter of which is to be fought in the dwellings of the working classes and the education of the public in needs of sanitary cleanliness.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

Those now members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 5, 1899.

PRESENCE OF TYPHOID BACILLI IN URINE OF
TYPHOID FEVER PATIENTS.

Attention has already been directed in this journal¹ to current studies on the presence of typhoid bacilli in the urine in typhoid fever. It has been shown that the bacilli may persist in the urine during and long after convalescence, and that the danger of infection from this source demands serious consideration. It is probably true that up to the present time this source of infection has been completely overlooked, and that the systematic disinfection of the urine in typhoid fever has never been carried out. The observations bearing on this phase of typhoid fever appear to be rapidly multiplying.

In the *Johns Hopkins Hospital Bulletin* for June, Gwyn summarizes the results obtained by the previous observers, as follows: In perhaps from 20 to 30 per cent. of all cases of typhoid fever, typhoid bacilli may be present in the urine at some time or other. When present, they are usually in pure culture, often numerous enough to render the urine turbid and to be recognizable on cover-slip examination. They generally make their appearance in the second and third week of the illness, and may persist for months and even years, in all probability multiplying in the bladder, the urine being apparently a suitable medium for their growth.

Often there may be symptoms of cystitis and also of renal changes, but the urine containing bacilli generally presents only the characteristics of febrile urine, and the presence of bacilli is of no prognostic significance, their disappearance or persistence without inducing local changes being the rule.

These conclusions differ somewhat from the opinion of Schichhold², who examined the urine in seventeen cases of severe typhoid with reference to the presence of typhoid bacilli. His conclusions are that the typhoid bacilli may be eliminated in the urine, but only when there are well-established lesions in the kidney substance, either due to typhoid bacilli or to complicating conditions. Typhoid bacilli appear in the urine shortly after the development of the renal lesions and without any reference to the appearance of rose spots, hence earlier when the renal changes develop abnormally early. Typhoid bacilli may be demonstrable in the urine during convalescence. The bacilli eliminated during the active disease appear to be strongly virulent, as shown especially by their behavior in the agglutination test.

Konjajeff also held that the typhoid bacteria indicated the presence of lymphoid nodules in the kidney, and Borges regards the renal changes as necessary to allow bacteria to pass through.

The work of Fütterer, showing the almost immediate appearance in the gall-bladder and the urine of organisms injected into the portal and jugular veins, taken in conjunction with the observation that many urines containing bacilli show no evidences of renal changes, may be regarded as indicating that typhoid bacilli in the urine owe their presence therein to a process of simple secretion from the blood. (Gwyn.)

The occurrence of several cases of cystitis in typhoid fever patients in the Johns Hopkins Hospital led to renewed attention to the urine. A number of cases were selected for examination for the presence of typhoid bacilli in the urine, hence these cases can not be used as data from which to figure percentages. In a series of seven unselected cases, positive results were obtained in three, i. e., in 42 per cent. In one case cystitis developed three months after an attack of typhoid fever, and typhoid bacilli were found present in abundance in the fresh urine. In one of the cases the number of bacilli present was estimated at five hundred million per cubic centimeter, so that a daily amount of 1000 c.c. of urine would contain five hundred thousand million organisms. In one of the cases studied and described by Petruschky, he estimated that 170,000,000 bacilli were present in 1 c.c. of the urine. These numbers indicate sufficiently well the grave danger of infection of water by such urines.

In most of the cases studied by Gwyn there was pyuria; albumin was twice present in large amount, usually only in traces. In the albuminous urines there were usually also found a few hyaline and granular casts; in one case the urine was otherwise perfectly normal. One case is remarkable because it presented a chronic cystitis of four years' duration, developing shortly after an attack of typhoid fever; pure cultures of typhoid bacilli were obtained from the urine in this case.

Newmann's observation that cloudy, freshly-drawn, acid urine in typhoid fever should be regarded as sus-

¹ See Journal, March 18 and June 17, 1899.

² Deutsche Arch. f. Klin. Med., 1899, Bd. Lxiv, p. 505.

precious is confirmed by Gwyn's observations. In such cases the bacilli were detected in fresh specimens in all but one case. Since typhoid bacilli are present so frequently, and in such abundance in the urine, Gwyn very correctly emphasizes that all typhoid urine should be disinfected before being thrown out. Great care should also be exercised in handling and in the routine examination of urine in typhoid fever. Centrifugation of urine is usually possible, and in the absence of cultures, this should be carried out, and the detection by this means of bacilli in fresh urines in typhoid fever should suggest the proper antibacteriuric treatment and proper disinfection of the urine.

It will be recalled, as pointed out in the *JOURNAL*,³ that Richardson has shown that irrigation of the bladder with bichlorid of mercury solution and the internal administration of urotropin, a compound of ammonia and formaldehyde, appear to be safe methods of removing the bacilli. In his series of cases 30 to 60 grains of urotropin quickly removed all the bacilli.

OPEN-AIR TREATMENT OF PHTHISIS.

The sanitarium treatment for tuberculosis is becoming familiar to the profession, but is usually associated in one's mind with specially favoring conditions of climate, altitude, etc. The experience of one or two establishments in this country, that near Boston, for example, has to some extent corrected these impressions, but they still exist and further evidence that with ordinary climatic surroundings the open-air treatment can still be carried on, is of interest. The July number of the *London (Eng.) Practitioner* is chiefly devoted to this subject, the five original papers it contains being reports of the success of this method under what we would not call specially favoring natural conditions. Dr. R. W. Philip, who works in what the editor of the *Practitioner* calls "the most villainous climate in the kingdom," that of Edinburgh, gives a tabulated statement of the number of hours each of his patients spent in the open air during a particularly inclement period of the year, February, March and April. During the first two months there were only six days when there were over seven hours of sunshine, and less than a quarter of the time when there were only five, yet the patients were able to spend an average of at least five or six hours daily in the open air, or lie in bed at a wide open window, as was done in one or two instances. The results are certainly remarkable: improvement apparent within a week, increased appetite and better digestion, phenomenal gain in weight, disappearance of cough, lessened expectoration, cessation of night sweats, improved circulation, reduction of body temperature, are all reported. The testimony of Drs. Calwell (Belfast), Burton Fanning and Jane Walker (Norfolk), and Rowland Thurnam, all bear witness to the same facts of improvement, the latter giving a tabulated statement that makes consumption appear almost as a universally curable disorder, in every

case of which a hopeful prognosis may be given. In only one of his twenty-four cases is there no improvement, in one the gain was in weight only, all the rest were actually or relatively cured or improved greatly.

We are not accustomed to think of the climate of the British Islands as a specially bracing one, or as particularly adapted to the treatment of tuberculosis, though its comparative mildness is an advantage. As regards dryness and sunshine, it is certainly far below this country in the scale. Our rather inclement winters in the northern states might seem unfavorable to outdoor treatment at that season of the year, but the experience of the Adirondack and Catskill sanatoria shows that they are not an insuperable objection even where the winters as a rule are unusually severe. In any case we have within our borders almost every possible climate, but these British experiences are encouraging as showing that even comparatively unfavorable surroundings are no sufficient bar to the care and cure of consumptives. In no part of our country can it be said that open-air treatment is climatically beyond the reach of the poor, provided the proper and perfectly practicable local sanatoria are established. While Colorado, California and other mountain and seaside resorts have their special advantages, they are by no means a *sine qua non* if cures can be brought about as in Thurnam's cases, by three or four months' open-air treatment in a reasonably healthy country district conveniently near the great centers of population, which are the breeding-grounds of phthisis. It is one of the most hopeful signs of the present interest in the subject that it is bringing out facts like these.

PSEUDORELIGION AND QUACKERY.

As we near the end of the nineteenth century, we congratulate ourselves on the remarkable advances that have been made in the various branches of the medical sciences and arts. We read of these advances in medical journals, in the metropolitan newspapers and in the magazines. Diseases and various afflictions which a quarter of a century ago were called incurable are now amenable to treatment. Not only this, but what is still more desirable and satisfactory is that the better understanding of the cause—the etiology—of many diseases has made these absolutely preventable. In one particular branch of medicine is the duplex advantage of today over the past specially noticeable. The pangs of childbirth have been removed or lessened by the discovery of anesthetics, but what is of still more importance, the terrible death-rate has been eliminated. The complications and diseases heretofore incident to maternity have been brought within the category of not only the easily curable, but what is still better, the easily preventable diseases. "Childbed fever," the dread of the physician and the nightmare of terrors to the expectant mother, is now recognized as a "blood-poisoning," a preventable disease, and curable if taken before the system is saturated. These remarks are made to show one side of a picture; let us see the other.

Here in Chicago, a city which has excellent medical colleges with well-qualified teachers, a city which contains as scientific, as well educated, as conscientious, and as noble a body of medical men as any city on earth; a city which proudly refers to its schools, colleges, and universities; a city of free libraries in which are contained the best of the literature of the world; a city of art and culture—here in the great and enlightened metropolis of the central states of the “most enlightened nation on earth,” was enacted during the past week, what would have been a disgrace to the most barbarous times. For three days a poor woman, deluded into beliefs that one would suppose to be excusable only in the superstitious natives of central Africa, suffered the pangs of childbirth, and at the end, torn and exhausted, was allowed to lie with wounds unrepaired, and slowly absorb the poison, to which she finally succumbed. She was treated by a woman, a follower of Dowie, a member of his “Zion.” No physician was called in to help the poor woman, none of the aids which medical science has always ready were allowed to be used. Insetad, this “healer” prayed and prayed, and, after the agony of childbirth was over, the mother lacerated through neglect, was allowed to lie with her bodily needs uncared for, while, we presume, the “healer” prayed, prayed and prayed—for money.

It is not pleasant to think that we are living among those who can calmly allow people to die in this way. We dislike also to remember that the intelligent legislature of the great State of Illinois legalized such crimes during its session last winter. And we wish we did not know that such murders are being permitted in practically every state in this enlightened country of ours. For while this particular class of cases appeals to the sentiments of the populace more than others, and as it is known to be preventable, still this murder by neglect is going on all the time. Whether it be “Christian Science” or Dowieism, or any other form of pseudoreligious quackery, it is a disgrace to the community that permits it under the plea of religious liberty to trifle with human life or human suffering. Religion, however misguided, if sincere and honest is respectable, and tolerable while it keeps in its own proper sphere, but these mercenary and homicidal deluders are criminal and should be dealt with as such. Pure religion and undefiled is worthy of all respect.

DIAGNOSIS OF SMALLPOX.

The timeliness of this seemingly trite topic is suggested by the recent prevalence of the disease, with frequent mistakes in diagnosis, and also by the collection of the observations of physicians on the present epidemic. Only a few meager reports have appeared, but they contain much that is of very great general importance. Conlett has given us the best summary that has yet appeared. The mistakes that have occurred in the diagnosis of smallpox during the last two years have been due in part to the unfamiliarity of a large part of the profes-

sion with the lesions of the disease, but in greater part to a change in the type of the disease itself, consequent on the wide practice of vaccination. Most recent cases indeed are varioloid, and very few are typical smallpox as described in the books. Despite this, the modified form is every whit as dangerous to the public health, for at any time confluent and hemorrhagic cases may obtain their contagion from a very mild case. Mistakes have been made easy by the fact that so many cases have been sporadic and the physician had not the help of the known presence of infection to aid in the diagnosis. Vast numbers of cases have been called chickenpox, and from them, lacking isolation, extensive epidemics have arisen. In cases as now seen there may be but few of the characteristic lesions, and they may mature early, frequently in ten to fourteen days. Also there may be no destruction of the true skin as in the well-developed pox. But it will always be possible with thorough search to find a few of the typical indurated pustules that are simulated by practically no other condition. So in a suspected case, careful scrutiny of the whole body-surface is demanded. It is characteristic that these indurated bodies will not on pricking completely discharge their contents, and that, when by repeated pricks they are nearly discharged, they will be found to retain a firm base, raised somewhat above the level of the surrounding skin. Along with an eruption some of whose components will exhibit these characters, there will be the abdominal pain and vomiting, the sudden onset, the chills, the headache and backache, the fever and delirium, the sweating and subsidence of fever on the appearance of the eruption, the furred tongue and fetid breath, and the early erythema or petechial eruption about the abdomen, buttocks and thighs. At times the history and a possible source of contagion will lend assistance. As the chief confusion has been in mistaking smallpox for varicella, the physician should remember that many keen observers of long and wide experience have never seen a case of chickenpox in the adult. It might be a safe rule in some respects, to call every case in an adult smallpox that one feels tempted to diagnose as varicella. Then in varicella the lesions are superficial and never indurated. They can readily be emptied by a single prick, each one lasts but a day or two, and they leave an excoriated skin-surface beneath, instead of a deeply attached crust. When there arises a question as between smallpox and scarlet fever, it is easy to remember that in the former the premonitory signs are more severe, that in the latter the erythema appears first on the chest and neck, and not on the abdomen and thighs as in smallpox. Measles has the early nasal and bronchial catarrh, with profuse lachrymation and injection of the conjunctivæ, and not the lumbar pain and other characters of smallpox. The eruption of measles is not raised or hard, and the temperature does not fall at the appearance of the eruption as in smallpox. Those who will bear these few points in mind will find their course, always beset with difficulty, not quite so doubtful. Be-

cause it is a dangerous disease, and because of late years there have appeared among us, both by lack of vaccination and by lapse of time since vaccination, many susceptible persons, it is highly important to recognize the disease at the earliest possible moment.

VENTRICULAR BAND SPEECH IN HYSTERIC APHONIA.

In this issue (p. 345) we publish an abstract of the article by Dr. Middlemass Hunt, in the English *Jour. of Laryng. Rhin. and Otol.*, where he describes a case in which speech was made possible by hypertrophy of the ventricular bands in a case of hysteric paralysis of the vocal cords. The case is of interest, as he says, in the development of the temporary ventricular band speech which seemed to be Nature's effort to meet even hysteric paralysis. The text-books appear to have pretty generally overlooked the subject from this point of view.

INTERNATIONAL CONFERENCE ON SYPHILIS AND VENEREAL DISEASES.

This conference, which, as previously noted in the *JOURNAL*, is to be held in Brussels, September 4 to 8, will discuss the possibility of ridding society of syphilis and venereal disease. Next to consumption come these diseases in their direful effects on humanity, and as they are certainly preventable, it would seem about time that international action be taken in the premises. While radical and harsh measures may be necessary for a generation or two, there are certainly no insurmountable obstacles to prevent their total elimination. Invited to the Conference are not only physicians, but lawyers and all public functionaries who are interested in the question. We hope and expect to see good results from the Conference.

QUACKERY WINS A POINT IN IOWA.

A local judge in Knoxville, Iowa, has declared the provisions of the state code in reference to the licensing of physicians to be unconstitutional, thus throwing over the state to the irregulars and quacks. The decision was given in granting a writ of habeas corpus to a notorious "Indian" doctor who had been arrested for the illegal practice of medicine. The grounds of his decision are not stated in the newspaper dispatch, and one cannot therefore form any judgment as to their validity, but the judge apparently made up his mind without taking any undue length of time, as the argument was made on Wednesday and the case decided Friday. One is naturally inclined to suspect a sympathy with quacks in some judicial and executive decisions, and we shall watch for further details of the case. It is understood that appeal to the supreme court will be taken promptly, and it is to be hoped that that body will see things differently than does this local judge. In the meantime it will probably be claimed that the state is "wide open" for all sorts of unlicensed practitioners and the beauties of judge-made law be admired *ad lib.*; but it is not, for happily, one county judge does not make decisions for the whole state.

YELLOW FEVER.

The country was startled at the beginning of the week by the announcement that many cases of yellow fever

existed at the National Soldiers' Home, near Hampton, Va., midway between Newport News and Old Point Comfort. Just how the disease got there is hard to understand. One report traces the cause to an old soldier recently from Santiago, who entered the home in the early part of July; several patients were ill and one died before the disease was recognized. As we write, the cases are all confined to that locality, and as rigorous precautions are being taken no spread of the disease is liable to occur. While it is not an agreeable contemplation, still the fact remains that with all the precautions taken, the dread disease has found a foothold in our country; and that too at a place where it was least to be expected; also, we might add, where it can do but little harm, for while the virulence of the disease seems to be severe, it is so far north that no serious spread, in the ordinary course of events, is likely to take place. At least it is much better that it should be as far north as it is, and especially at a place away from the highways of commerce, than at New Orleans, Charleston or other southern seaport towns.

MEDICAL LEGISLATION.

No less than 241 bills relating directly or indirectly to the medical profession and to questions of public health are enumerated in full as to their titles, in the *Post-Graduate*, as having been presented to the New York Legislature during its last session. Of these, forty-one became laws. Probably a proportional number were introduced in the other state legislatures and many—some good, others bad—have passed. In some cases executive vetoes have saved the people from bad laws, and we regret to have to believe that in a few others they have not been interposed in behalf of the public welfare, or have been exercised to its detriment. In these days of general public interest in medical and sanitary matters, and of dissemination of the little knowledge that is a dangerous thing, it is of the highest importance that the medical profession should keep watch on the measures thus introduced. The session of a legislature is considered by many business men as a time of special peril; it should be a matter of concern to us also as guardians of the public health. If every legislature could have among its committees one on state medicine, largely made up of physicians, to which all bills directly or indirectly involving medical questions could be committed, it would be a rational step in advance and save us from a vast amount of useless and harmful legislation. If as a profession we could combine and insure, as is certainly possible with our united influence, the election of a few intelligent and upright physicians—not mere seekers after public places—to each legislature it would be a boon to our country and to ourselves.

THE BRITISH MEDICAL ASSOCIATION.

The report of the Council to the British Medical Association shows that the number of members of the Association last year was 17,746; during the year 1128 new members were elected, 183 died, and 506 resigned, leaving a net gain of 439, or a total of 18,185. This membership covers the Colonial branches and is not limited to Great Britain. The revenue for the year ending Dec. 31, 1898, amounted to £42,924; the expendi-

ture including £500 written off for depreciation of plant, £549 for losses on subscription, amounted to a total of £38,188, leaving a surplus of £4736. The accumulated surplus, which is mostly invested in real estate, now amounts to £69,721. Of the *British Medical Journal* the report says:

The high position of the *Journal* among the medical periodicals of the world has been strengthened and extended, while its circulation has shown a satisfactory increase. It is read not only in every part of the United Kingdom, but in every colony and dependency, while it is recognized abroad as a chief exponent of medical opinion in this country.

The prosperity of the medical profession rests primarily on the ability of its members to keep themselves acquainted with the rapid progress of the science and art of medicine, and one of the chief services which the *Journal* renders to members is the publication of original papers, special articles, and an epitome of foreign medical literature, which together reflect the best opinions and the most recent observations in medicine and the ancillary sciences selected with special reference to their bearing on practice. Tropical diseases, which are of interest not only to those members who practice in India and in tropical and subtropical countries, but also, in these days of rapid travel and extending empire, to a large proportion of those who practice in the United Kingdom, which is the center of the world's traffic, have recently demanded increased attention. By the prominence given to these subjects the *Journal* has contributed in no small degree to bring about the establishment of schools of tropical medicine in England, an example which has been followed in Germany and will probably soon be followed in France.

FAMILY FORM OF CYSTINURIA.

The appearance of cystin in the urine has been attributed to disturbances in metabolism comparable with those that give rise to diabetes and gout. In support of this view, the appearance of the conditions in families and its hereditary transmission are cited as evidence. It has, however, been suggested that the condition arises in consequence of the activity of micro-organisms, as in some cases cadaverin and putrescin have been found in the urine in conjunction with cystin. Some recent observations by Cohn¹ rather lend support to the former than the latter view. This observer reports the case of a girl, 7½ years old, who had been operated on several years previous for tuberculosis of the right knee-joint. For a year increased frequency of micturition had been noticed, and pain in the region of the bladder was complained of. These symptoms had increased in severity within three months, and the mother had observed that the urine appeared turbid and emitted a disagreeable odor. Exploration with a sound disclosed the presence of a calculus in the bladder, which rectal examination indicated to be the size of a walnut. Suprapubic cystotomy was performed, and a friable and rough stone found and extracted. On chemical examination the calculus was found to consist of cystin, and subsequent examination of the urine from the patient showed that it also contained cystin. Investigation with regard to the presence of putrescin and cadaverin yielded entirely negative results. Further inquiry elicited the fact that

of eleven other members of the family, of whom nine could be examined, cystinuria was found to exist in six, but in none other than that reported could a calculus be detected.

PATHOGENIC SARCINA.

Loewenberg,¹ in a case of ozena, isolated a pathogenic sarcina. The nasal mucus in this case was composed exclusively of polynuclear leucocytes, and an enormous number of packets of sarcinae. The cultures gave rise to pure growths of sarcinae. The treatment instituted led to complete and definite healing at the same time as the organisms disappeared and the fetor faded away. Of the usual solid media the sarcinae form a shining moist coat, sometimes whitish, at other times slightly yellowish; isolated colonies resemble small drops of rich milk. Gelatin is not liquefied; the older colonies on this medium are rather yellowish. On the ordinary potato media it grows very luxuriously and forms moist white growths. In liquid media it forms an abundant sediment, while the fluid remains clear. In the cover-slip preparations from the nasal mucus of the patient it appeared in the form of characteristic cubical packages, but in the successive generations on artificial media it soon loses this mode of grouping, finally assuming the form of groups and masses and short chains of cocci; as is well known the ordinary yellow and red sarcinae act in the same way. In the liquid media, however, the sarcina in question rearranges itself in the characteristic grouping. Loewenberg finds that this sarcina does not correspond to any of the three principal varieties established by Stubenrath, namely the sarcina alba, variabilis, and canescens. The new sarcina distinguishes itself from the others especially by the fact that it is pathogenic. Stubenrath, in his study of the genus sarcina, concluded that no sarcina had been described as pathogenic to either man or animals. Injected in the dose of 2 c.c. of a suspension in sterilized bouillon, into the peritoneal cavity of rabbits and guinea-pigs, Loewenberg's sarcina produced death in twenty-four hours; there was an intense peritonitis. White rats, injected under the skin, died from septicemia in twenty-four hours, cultures from the blood giving rise to pure growths. Loewenberg is inclined to attribute the ozena to the action of this sarcina. The nasal secretion from the nose from which it was isolated was alkaline instead of neutral, as is the case ordinarily. Not having observed the patient when he was well, it cannot be said whether this alkalinity was the result of the presence of the sarcina or not. The fetor undoubtedly depended on the presence of the sarcina, as shown by the fact that when the sarcina disappeared the fetor subsided. The cultures of the sarcina, however, did not possess any appreciable odor.

MEDICAL BIBLIOGRAPHY.

The discontinuance of the publication of the *Index Medicus* is undoubtedly a medical misfortune. How serious a misfortune it may be time will tell, but we already have our comforters. In the *Semaine Medicale* of June 28, we find a lengthy editorial review of the medical bibliography at the end of the nineteenth century.

¹ Berlin Klin. Woeh., June 5, 1890, p. 503.

¹ Annales de l'Institut Pasteur, 1899.

ry, in which, after noticing the discontinuance of the *Index Medicus* and referring to the *Centralblatts* and year-books that in a way make up for its absence, it goes on to point out its own work in the line of international bibliography. It says, "actually after the disappearance of the *Index Medicus* from the field, the *International Bibliographical Bulletin of the Semaine Medicale* is the only general bibliographic review, all the other lists of new publications embracing only a special branch of medical science in a single country and language, even when qualified by the term international. Recently some periodic international bibliographies have appeared abroad, but these are monthly or quarterly publications, and as they are in their beginnings one cannot say that they will long survive. Considered as a retrospective bibliography with its general index constantly appearing, the bibliographic *Bulletin of the Semaine Medicale* will have a greater practical value than all the other bibliographies of the same period, including the *Index Medicus*, and even the 'Index Catalogue,' in that it gives a complete list of the works of each author under his name, whether published separately as books or monographs or in journals, while the subjects are noted with the greatest precision and detail in their alphabetic order." Each thinks his own the best, and we confess to being unconvinced of the superiority of the *Semaine Medicale's* bibliography. It is true that the "Index Catalogue," which we have still with us, is not absolutely complete, and that it publishes under the authors' names only the separate reprints or works that may be in the surgeon-general's library, but its subject catalogue is by far the fullest of anything that has yet been sent out. This may be readily seen by a comparison with the bibliography of acromegaly, given as a sample of the French journal, and that in the new series of the "Index Catalogue." The bibliography of gastrectomy has not been reached in the new series of the "Index Catalogue," but the incompleteness of that of the *Semaine Medicale* is shown by the lack of mention of a number of important papers and methods such as those of Kader and of Senn. In fact, its bibliography is very incomplete in some directions; in examining, for example, several issues taken at random, we find very little mention of English and American literature, especially the latter, which we cannot honestly admit, altogether aside from national prejudices, is so undeserving of notice, as would thus appear. The *Semaine Medicale* does not appear to be conscious of these omissions and we, therefore, take this opportunity to call its attention to their occurrence. As a bibliography of the more important articles by French authors, the list will probably take first rank. German authorities are also not neglected. For thoroughness and completeness, however, it falls far short of equaling either the *Index Medicus* or the "Index Catalogue." The continuance of the latter still keeps our country well ahead of all others in this matter of medical bibliography.

PROFESSOR BACCELLI is winning almost as much renown as from his scientific achievements, by the excavations in the Roman Forum which are being carried on under his inspiration and direction as Minister of Public Instruction.

Medical News.

PROF. F. MUELLER of Marburg has received a call to Basle, as Immerman's successor.

DEDICATION of the Houston Memorial Hospital, Coatesville, Pa., took place July 13.

DR. F. W. PARHAM, New Orleans, has been elected a member of the American Surgical Society.

DR. NORVAL H. PIERCE, Chicago, sailed from New York, July 26, to attend the International Congress of Otologists, in London.

MICHAEL FOSTER of London will deliver the next course of Lane Medical Lectures at Cooper Medical College, San Francisco, in 1900.

ERNEST LAPLACE, Philadelphia, has gone to England, to demonstrate by invitation a new instrument before the British Medical Association.

JULY 25 the attention of the medical authorities was called to the occurrence of eight cases of typhoid fever among the new recruits for the army at Camp Meade, Pa.

THE NEW buildings of the College of Physicians and Surgeons, Baltimore, are rapidly nearing completion and will be ready for occupation by the beginning of the session.

PROF. KARL EWALD, editor of the *Berliner Klinische Wochenschrift*, recently celebrated the twenty-fifth anniversary of his connection with the university as privat docent.

THE CENTENNIAL of the birth of Vincenz Priesnitz is to be celebrated at Dresden in August by an international exposition of appliances for hygiene and the care of the sick.

SINCE THE treatment of tetanus by injection of carbolic acid has been mentioned by the press, it has been learned that in Philadelphia at least two cases have been so treated, but as yet definite results can not be reported.

THE FIRST examinations under the new practice act of Illinois were held in Chicago Aug. 1 to 4. Thirty-four appeared for examination; five physicians, fifteen midwives and fourteen osteopaths.

PROFESSOR CERVELLO of Palermo now has a model sanatorium, constructed for him by a wealthy Italian, with accommodations for 150 patients, to test on a large scale his "igazolo" formic aldehyd treatment, described in the *JOURNAL*, June 24, p. 1438.

HENRY T. LEA of Philadelphia has given an additional donation of \$8000 to the Pennsylvania Hospital for Epileptics, at Oakburne, for the erection of an industrial building. A previous donation of \$50,000 had been given this institution by Mr. Lea.

ONE of the unpleasant incidents of the recent strike of the employes of the Metropolitan Street Railway Company, New York, was an assault on a reputable physician who was performing his professional duty in dressing the wounds of an injured non-union conductor, on the street.

IT HAS always been claimed that leprosy did not exist in eastern Siberia, except among the natives, but recent advices to the *Semaine Medicale* announce that the wife of an official, a private soldier and six other persons have become affected with the disease since their arrival in the country.

AS A RESULT of the recent examination of candidates

for license to practice medicine in Pennsylvania, the State Board of Examiners has granted certificates to 375 out of a total of 435 who presented themselves. This was the largest number ever before the Board at one meeting.

REPORTS of deaths from tetanus are still coming in. While nearly all cases thus far reported are the result of injury received on or about the Fourth of July, there are a number the cause of which are aside from the annual fireworks. One such is recorded this week in Chicago, the original cause being a simple flesh wound.

DRS. S. R. OLLIPHANT, J. J. Archinard and Hermann B. Gessner are members of the faculty of the recently organized New Orleans College of Dentistry, filling respectively the chairs of chemistry, materia medica and hygiene, physiology, pathology, microscopic anatomy and bacteriology, anatomy and surgery.

DR. ALONZO GARCELON, President of the Board of Trustees of the AMERICAN MEDICAL ASSOCIATION, has been ill, and confined to his bed for the past three weeks. Dr. Garcelon is one of the oldest, and, at the same time, one of the most enthusiastic members of the ASSOCIATION, and his many friends we are sure are hoping for his early recovery.

THE QUESTION of removal of the Municipal Hospital of Philadelphia to new quarters still remains quite unsettled. Considerable inconvenience is caused by lack of room, and should an epidemic of smallpox or any disease of an infectious nature occur, it is hardly possible that all patients could be cared for in the hospital as it is at present arranged.

IN PHILADELPHIA the sum of \$465.50 has been contributed during the week ending July 21, toward defraying the expenses incurred by the Children's Week Association. The object of this association is to give an opportunity for children to enjoy a few days' recreation away from the crowded tenement districts of the city, thereby lessening the infantile mortality.

TO DR. C. ALEXANDER of Breslau has been awarded the prize of \$60 for the best work suitable for distribution in pamphlet form for the enlightenment of the public in respect to quacks, faith-healers, etc. The committee, which includes Professors Eulenburg and Gutstadt of Berlin, states that fifteen works were received in competition, all very good. Two others were awarded a smaller prize.

AN EPIDEMIC of anthrax is now prevailing to a moderate extent in Bedford Co., Pa. Up to July 25, six deaths had occurred among horses, and two men were seriously ill with the disease. State Veterinarian Leonard Pearson is making a thorough investigation. The epidemic is thought to be due to cattle contracting the disease by drinking water from a tannery in which infected hides had been used last year.

A NEW research scholarship has been founded by the British Medical Association, of the annual value of £200—\$1000—to be known as the Ernest Hart Memorial Scholarship, in memory of the late editor of the *British Medical Journal*. The appointee must devote himself to the study of some subject connected with state medicine. Dr. John W. H. Eyre has been appointed the first scholar.

THE Rebecca Smith Playhouse for Children, recently built in East Fairmount Park, Philadelphia, at a cost of many thousands of dollars, and afterward presented to the city, was opened to the public on July 24. The building is of the colonial style of architecture, with spacious verandas extending entirely around the struc-

ture. On the first floor is the superintendent's office, dispensary and kitchen, on the second floor a dormitory, playroom, sitting-room, bath-room, etc.

THE SEQUEL of the Bianchini case—the pardoning of the wife through the petitions and efforts of the husband—is as extraordinary as the case itself, in which the wife was condemned to five years' solitary confinement on clinical, with absolutely no chemical, evidence that she had been trying to poison her husband with atropin. (*JOURNAL*, xxxii, p. 900.) Bianchini is a well-known Paris artist.

MR. MARCEL BAUDOUIN entertained the French Medical Press Association after its trimestrial banquet in Paris, July 7, with an exhibition of original photographic views taken by himself during his tour of this country. They included scenes along the Northern and Union Pacific railroads, and their connections between New York and San Francisco, and in the Yellowstone National Park.

IN SEVERAL of the principal cities of Cuba there have been asylums for lepers who resorted to them voluntarily, but no strict isolation; during certain hours of the day the inmates were free to go in and out as they pleased. The sanitary authorities of Havana have now forbidden the lepers to leave the asylum and have decreed that all persons affected with the disease, rich or poor, must henceforth reside in them.

THE SEMICENTENNIAL of the Netherlands Association for the Progress of Medicine is being celebrated with a retrospective exposition which has collected many curious medical and surgical relics of former ages and shows the great progress accomplished, especially in the treatment of the insane. Among them are the wooden clappers which lepers were compelled to carry to give warning of their approach, and their peculiar black hats with white ribbons.

THE WORK of our American sanitarians in Cuba is already bearing fruit far beyond its borders. The last issue of the *Gaceta Medica de Bahia* republishes some ringing lay editorials which assert that the sanitizing of Rio Janeiro and other South American ports may possibly prove one of the most remarkable and direct results of the Spanish-American War and "North American jingoism."

ENTERED on the records of the Medical Institute of Bavaria, according to *Echo Med.*, July 16, is a resolution, voted and presented to the authorities in 1836, protesting against the introduction of railroads into the country: "the rapid movement of the train cannot fail to produce serious mental disturbances in the brain, of the nature of delirium tremens." "Persons gazing at a rapidly moving train are also liable to be similarly affected and the track should be concealed by a five-foot fence its entire length."

OSCAR F. LACKEY, the first yellow fever patient in this country to be treated with antitoxin serum, was discharged, cured, from the New York Quarantine Hospital, July 24. In commenting on the case, Dr. A. H. Doty, health officer of the port, is credited with saying that the case was well marked and of the pronounced type. With his consent the serum was used subcutaneously, the first injection of 25 c.c. being given about five hours after the patient arrived at the hospital, July 6. Three hours later he received the second injection of 25 c.c., and four hours later a final injection of 50 c.c. No other treatment was given. The case was kept under close observation day and night and every detail carefully noted.

A PHYSICIAN of Sparrow's Point, a suburb of Baltimore, is being tried on a charge made by the State Board of Health for failure to notify the authorities of the existence of a case of smallpox. As this is the first prosecution of the kind outside of that city, the result is regarded with much interest to medical circles.

THE BACTERIOLOGIC department of Baltimore, under Dr. Royal Stokes, is saving the city thousands of dollars in the way of prophylaxis of communicable diseases. Examinations are made free of charge for all physicians, and reports sent to the sender of the specimens. In connection with the work an examiner of throats has been appointed to make examinations whenever deemed expedient in the case of school children.

THE GOVERNMENT of Colombia has officially requested the presence and advice of the Swedish leprologist, A. Hansen, in its struggle against the high tide of leprosy that threatens to overwhelm the land. He has not decided yet whether to undertake the task or not. The conditions are by no means so favorable as in Norway, where the number of lepers is comparatively small and the government is pecuniarily equipped. It is very different in Colombia, with its bankrupt and unsettled government and 1 per cent. of its entire population of three and one-fourth millions already affected. The scheme for establishing a great leprosorium on the island of Coiba was found impracticable. A communication to the last *Derm. Cbl.* states that the disease has spread to a frightful extent among the wealthier white families.

A PUBLIC subscription has been opened in France for the benefit of the laboratories for research in infectious and contagious diseases. The state allows them \$25,000 a year, which is divided among the thirty-three institutions of the kind, and the committee in charge has issued a strong appeal for liberal contributions, stating that any disaster causing loss of life meets with a generous response from the public, while the fact that 657 persons die every day from preventable diseases is regarded with apathy. An instance is a recent explosion in which fifty-three lives were lost and \$60,000 was promptly contributed by the people throughout the country to relieve the suffering, while no one thought of contributing a cent in the case of an epidemic of typhoid in a neighboring town at the same time, and which caused a hundred deaths. The amount received is already \$15,000, the railroads heading the list with \$8,000.

THE EXPERTS have established in the F. Maier case at Vienna, according to *Neue Freie Presse*, July 1, that transient mania from carbon dioxide intoxication was the cause of the murder, although there is only a single case of mania from inhalation of carbon dioxide on record, and none in which such a deed of violence occurred. The accused, a trusted and reliable employé of the railroad for thirty-five years, 58 years of age and happily married, had been advised to "take a sweat" for his influenza, and when he went to bed stuffed a rag into the stove-pipe to keep the room warm as the fire was nearly extinct. Aroused several hours later by an approaching train he rushed out of doors, and the fresh air in his condition must have produced mania, as he vaguely remembers going back into the house and calling his wife and sister to come out. When they failed to respond he became furiously enraged and, seizing a razor, attacked them in a frenzy. The sister in an adjoining room managed to escape, but the wife's throat was cut. Carbon dioxide intoxication was evident in the blood of the wife.

ACCORDING to a circular letter from Dr. J. N. McCormack, secretary of the Kentucky State Board of

Health, the Board will hereafter refuse to recognize, as a basis for certificates to practice medicine, diplomas from any medical college which does not, in good faith, comply with the requirements of the Association of American Medical Colleges, the American Institute of Homeopathy and the American Eclectic Medical College Association, respectively, both as to preliminary education and four years' course of study. This means that no school that graduates three-year students will be recognized in that state hereafter. The Board provided an examination for three-year graduates of the present year, as many of the students had attended such schools in ignorance of its advanced requirements, but found this course unsatisfactory, a large percentage of the examinations indicating incomplete preliminary education as well as imperfect medical training.

REPORTS of August 2 indicate that the yellow fever situation at the National Soldiers' Home, near Hampton, Va., and commented on in our editorial pages, has improved, with, however, 4 suspicious cases on that date, while 2 cases were reported at Phoebus. The announcement of yellow fever at the Home was made on July 30, when it was said that 30 well-developed cases existed, with 7 deaths on the 29th and 3 on the 30th. The authorities at once instituted a most rigid quarantine along the coast and about the Home, where there are about 4000 old soldiers from all parts of the Union. On July 31 there was but one death and one new case. On August 1 there were 4 deaths at the Home and 2 at Phoebus, with 6 new cases at the latter place and 1 at Hampton. The disease is supposed to have been brought to the Home by an old soldier who recently visited Santiago on leave of absence.

CRIMINAL FAITH-HEALING.—A recent attempt to practice obstetrics by means of "faith healing," by a Chicago disciple of Dowie, may possibly prove to be an eliminating factor of this masquerading sect in the State of Illinois. Mrs. Flanders, a member of the Dowie Tabernacle, invoked the aid of one Mrs. Bratz, to attend her in the capacity of a midwife, and after a prolonged labor of three days a child was finally born. When several days had elapsed it was observed that the prayers that had been so effectual in the delivery of the child were of an opposite character in the case of the mother, who was steadily becoming weaker. In spite of the prayers and entreaties of the patient and her "divine" assistant, a physician was summoned July 23. When he arrived he found the patient in the final stages of puerperal fever. She was in a semi-delirious condition; temperature was 105.2, with very rapid pulse, typhoid present; the perineum was lacerated, with a fetid discharge which permeated the entire room. The patient was immediately taken to St. Luke's Hospital, where, in spite of all efforts she died July 27. The coroner's inquest will be held August 8, and the State Board of Health will probably prosecute Mrs. Bratz for practicing midwifery without a license.

Menstruation by Ear.—Lermoyez has a patient who commenced to menstruate with the clear, non-coagulating blood issuing from the right ear each month, after the usual premonitory symptoms of the period. No lesion of the ear can be discovered; the tympanum is intact. After three years the menses occurred normally through the vagina, alternating with the ear, and gradually the normal menstruation has supplanted the aurial. A slight degree of hypoesthesia of the tympanum and meatus and auditory anesthesia indicate auricular hysteria.—*Semaine Méd.*, July 13.

Therapeutics.

Therapeutics of Camphor.

Herrgott, quoted in "Sajous' Annual," states that when used as an antialtagogueit may be applied over the breasts in the form of an ointment or liniment of camphor, and the drug also should be given internally in doses of 1 or 2 grains (.065—.13 gm.) once, twice or three daily.

"In infectious diseases, the exanthemata, pleuro-pneumonia with meningal symptoms, in infections endocarditis, etc., more especially if the patient is in a condition of collapse, 15 to 45 minims (.72—2.26 gm.) of a 10 per cent. solution of camphorated oil affords prompt relief, employed subcutaneously. Even as much as 15 grains (1 gm.) of camphor daily, far from aggravating ameliorates cerebral symptoms. From 7 to 15 grains (.46 gm.) produces remarkable restorative effects."

"In influenza, pneumonia, typhoid, bronchopneumonia, etc., camphorated oil yields good results, but should be administered before the patient is too weak; it produces an increase of arterial pressure, free expectoration, and a feeling of physical well-being. If given by the mouth its taste may be disguised by essence of peppermint. It appears to be contraindicated where there is great cerebral excitement."—*Taussig*.

Camphorated oil produces the most remarkable effects in follicular angina, coryza, and acute pharyngo-laryngitis; in bronchitis it is a good expectorant; in fibrinous pneumonia it diminishes temperature and notably ameliorates the general condition. It is also serviceable in chloranemia and in phthisis during the period of softening with ulceration, night sweats, and hectic fever. In tuberculosis of the larynx the pains in the throat are notably diminished. Favorable action is likewise observed in hemoptysis.—*Alexander*.

"Camphor is to be recommended hyperdermically in heart-failure, preferably employing camphorated oil. In a case in which the patient had a number of times been absolutely pulseless and apparently lifeless, its use was followed by the most gratifying results."—*West Philadelphia Polyclinic*.

For intestinal fluxes camphor is an efficient remedy. "It is essential to use the strong solution or essence (spirit) of camphor, of which 3 minims (.18 gm.) should be given on a cube of sugar or on a crumb of bread every few minutes. After one or two doses the diarrhea ceases, the pulse becomes stronger, color returns to the face, and the patient is on the high road to recovery. The tincture is almost equally useful in the initial rigor of acute specific diseases and in severe chill."—*Murrell*.

Local Treatment of Burns.

The local treatment is to be directed toward the limitation of the resulting inflammation, the prevention of septic infection, assisting the normal elimination of the eschar, the development of granulations, and limitation of the deformity. In burns of the first degree little or no treatment may be demanded. In the more aggravated cases of this type the application of home measures, such as bicarbonate of sodium, the white of egg and sweet oil (equal parts), lead water and laudanum, and the various hot or cold means generally at the disposal of the house-wives will suffice.

Burns of the second and third degrees must be more strenuously treated. It is often a difficult problem to know which is the more soothing application to be advised and from which we may get the better result. In one case hot applications, in another cold; in some wet, and in others dry measures are to be employed. The vesicles, if numerous, should be untouched; but if only a few, they are best evacuated. The use of carbolyzed vaselin, 15 to 20 grains (1.2 gm.) to 1 ounce (31.1 gm.) watery solutions of carbolic acid, about 20 grains (1.3 gm.) to an ounce, (31.1 gm.), subnitrate of bismuth $\frac{1}{2}$ to 1 dram (1.95—3.9 gm.) to an ounce (31.1 gm.) of ointment of zinc

oxid or petrolatum, boric acid, either in watery saturated solutions or ointments of either zinc oxid or petrolatum in strengths varying from $\frac{1}{2}$ to 2 drams (1.95—7.8 gm.) to 1 ounce (31.1 gm.) bicarbonate of soda in almost full strength, in ointment or watery solutions, and starch in varying proportions will usually be found very efficacious. Turpentin, where granulations are sluggish, will give excellent results, used either in full or diluted strengths, taking care not to produce too much stimulation. H. L. Melnis states that spirits of turpentin applied to a burn of either the first, second, or third degree almost at once relieves the pain, while the burn heals. After wrapping a thin layer of absorbent cotton over the burn the cotton is saturated with common turpentin and covered with bandages. Being volatile, the turpentin evaporates, and it is therefore necessary to keep the cotton moistened with it. When there are large vesicles, they are opened on the second or third day. It is best to keep the spirit off the healthy skin if possible, to avoid the local irritation.

Surgery of this day has placed many excellent antiseptics at our disposal, and there is no better application than bichlorid of mercury in the proportion of 1 grain (.065 gm.) or more, to 1000 parts of water and kept in constant contact, the dressings being made without removing the former cloths.

Acetanilid in full strengths of powder will be found effective, care always being given not to apply it over too great an area without watching its effect.

Ichthylol in watery solutions 1 (3.9 gm.) or more drams to the ounce (31.1 gm.), or in glycerin similar strength, or even in ointment form, with zinc oxid or petrolatum, about 1 to 3 iodid derivatives, such as iodol, aristol, europen, applied iodid derivatives, such as iodol, aristol, europenod, applied preferably in ointment, 15 to 30 grains (1.2 gm.) to the ounce (31.1 gm.) of petrolatum or lard are reliable measures.—*J. Abbott Cantrell in Sajous' Annual*.

The following prescriptions containing ichthylol are recommended by Leistikow for burns of the first and second degree:

BURNS OF THE FIRST DEGREE.

B. Zinc oxid.....	20 parts
Magnes. carb.....	10 parts
Ichthylol.....	1 to 3 parts

This powder, containing ichthylol, is the most satisfactory form in extensive burns of the first degree, and should be plentifully applied, being spread evenly over the surface.

BURNS OF THE SECOND DEGREE.

In extensive burns of the second degree a soft paste like the following is preferable:

B. Carbonate of lime.....	10 parts
Zinc oxid.....	5 parts
Oil.....	10 parts
Lime water.....	10 parts
Ichthylol.....	1 to 3 parts

BURNS LIMITED TO REFRECTION OR VESICATION.

Nolda recommends the following:

B. Europen.....	1 part
Vaselin.....	
Lanolin, of each.....	10 parts

This is applied three or four times a day to burns limited to refubefaction or vesication.

EXTENSIVE BURNS.

"The following may be used in the treatment of extensive burns:

B. Aristol.....	1 part
Sterilized olive oil.....	2 parts
Vaselin.....	8 parts

Around the edges of the burns, after the ointment is spread, the aristol in powdered form is dusted. In burns of small extent the powder form only is employed. Cleanliness must be thorough whenever the dressing is changed. One of its great advantages is its freedom from poisonous effects. There is some smarting at first, but it soon passes off."—*Walton*.

Pericarditis.

J. L. Lynch advises the following mixture in pericarditis:
 B. Tinct. veratri viridis
 Tinct. opii aa. ʒi 3/90
 Sodii bicarb. ʒii 7/80
 Sacchari albi. ʒiv 15/50
 Aque q. s. ad. ʒvi 186/60
 M. Sig. Tablespoonful every two or three hours.
 Thomas Stretch Dowse says the treatment must be in a degree palliative, and symptoms must receive special consideration and treatment as they arise. The rheumatic element may apparently demand the salicylates, but they must be given with caution. A mixture of

B. Liquor ammon acetatis.	ʒi	3/90
Spts. ether nit.	ʒss.	1/95
Tinct. digitalis	m. v	30
Aque, ad.	ʒi	31/10

may be given every four hours. Should there be pain, 1 grain (.065 gm.) of the watery extract of opium may be given, with each dose of the mixture. Preordial distress is best relieved by the application of six or eight leeches. In the initial stage, with high fever and well-marked friction sounds, the writer believes in the administration of Dovers' powder gr. iiss (.16 gm.) with calomel gr. ʒ (0.08 gm.) every four hours. Preordial distress is sometimes relieved by camphor liniment and belladonna and spongio piline wrung out of hot water and sprinkled with a few drops of turpentin, which may be applied to the chest. If the dyspnea is urgent from great distension of the sac with fluid, potassium iodid may be given with bark (cinchona) in full doses, and diuretics may be tried, with saline purges. This failing, paracentesis may be performed. The fifth left intercostal space is usually selected. An incision is made through the skin one inch from the sternum, and a trocar and canula are then inserted. When pericarditis is secondary to ulcerative endocarditis or septicemia, brandy and quinin must be freely given.

PERICARDITIS WITH EFFUSION.

The following prescription is recommended by Kilgour for pericarditis with effusion:

B. Infusi digitalis.	ʒiv	124/40
Potass. acetat.	ʒii	7/80
Spts ether nit.	ʒii	7/80
Aque cassiae.	ʒiiss	46/60
M. Sig. Tablespoonful every four hours.		

Deaths and Obituaries.

ROBERT HUNTER, M.D., New York University, 1846, died suddenly on his hunting preserves in Cesarea, Ontario, July 29. He was born in Ayrshire, Scotland, seventy-six years ago, was educated in Edinburgh, and then came to New York, where he lived for twenty years.

L. A. CLARK, M.D., Rockford, Ill., died July 22, after a long illness. Dr. Clark was born in 1849, and during the early seventies served as surgeon on one of the Pacific steamers between California and China and Japan, and was at one time head of a smallpox hospital at San Francisco.

JOSEPH DONSON LOMAX, M.D., Troy, N. Y., a graduate of the College of Physicians and Surgeons, New York City, 1862, and superintendent of Marshall Infirmary, Troy, died July 22.

CHARLES J. MADDOX, M.D., Rockville, Md., died July 26 at the age of 80 years. The Doctor was a descendant of one of the earliest settlers of Maryland, and received his degree of A.B. from Georgetown University and of M.D. from the University of Maryland. His death was the result of a fall received in 1891.

J. N. Charbonnet, M.D., New Orleans, La., Tulane University of 1887, died July 23, at the age of 33 years. . . . J. N. Hall, M.D., New Philadelphia, Ill., aged 85 years, July 28. . . . Acting Ast. Surgeon John V. Hamilton died at Matanzas, Cuba,

July 26. . . . Henry Navigo, M.D., Georgetown, Pa., July 19, aged 50 years. . . . W. W. Nelson, M.D., Tabery, N. Y., July 22, aged 36 years. . . . H. V. Sooter, M.D., Ibernia, Mo., July 24. . . . John F. Wolff, M.D., Philadelphia, July 24, aged 26 years. . . . J. S. Tracy, M.D., formerly of Winona, Minn., died in Honolulu recently.

DEATHS ABROAD.

V. Mihalkovics, Budapest, noted for his works on microscopic and embryonic anatomy. . . . Professor Herpin, Tours. . . . Professor Campos da Paz. . . . T. B. M. Dack, M.D., Clemore, Ont., a graduate of the Toronto School of Medicine, aged 35.

Miscellany.

Philadelphia Mortality Statistics.—During the week ending July 29, there were 481 deaths, this being a decrease of 29 over the previous week and an increase of 16 over the corresponding week of last year. Of the total number of deaths 112 occurred in children under the age of 5 years. The principal causes of death were: apoplexy, 5; nephritis, 39; cholera infantum, 78; cancer, 13; tuberculosis, 51; heart disease, 26.

Tuberculosis Among Cattle in Canada.—The *Union Medicale du Canada* asserts that comparatively few cattle in Canada are affected with tuberculosis. Only 8.5 per cent, reacted to tuberculin, out of 10,000 animals tested at the request of the owners, in 1898. Generalized tuberculosis was found in but 24 out of 33,000 slaughtered at Montreal in 1896. The severity of the quarantine for the European and United States markets has reduced the number of tuberculous animals offered for exportation, but this means that suspicious animals are retained for domestic use. The editorial urges the necessity of the detection of affected animals and their isolation, killing all with manurary or generalized infection, and keeping the rest for breeding and slaughtering, which would soon eradicate the disease without loss to the owners.

Symptoms and Morbid Anatomy of Yellow Fever.—The presence in the United States of an epidemic of yellow fever, and the yellow fever scare which occurs from time to time, should stimulate us to learn and to keep at our fingers' ends the more prominent and early symptoms of this disease. The morbid anatomy, too, is most essential as a diagnostic aid in settling disputes in doubtful cases. The bacteriologic findings, while still in doubt, may soon be cleared up, but for the present we will have to rely more or less on the classic symptoms and the results depicted on the post-mortem table. Some weeks ago Major and Brigade-Surgeon D. T. Laine made a collective investigation of yellow fever in the Island of Cuba. Thirty-five answers were received from physicians of note practicing in Havana, and two from Matanzas, relative to this question. In reply to the question: "What do you consider the most pathognomonic symptoms of yellow fever?" seventeen were of the opinion that pathognomonic symptoms do not exist, and eighteen do not rely alone on one symptom, but on all presented in a given case. It was the opinion of the majority that: "The remission from the first period, followed by the sudden elevation of temperature of the second period, in conjunction with *albuminuria, icterus, and hemorrhages* are the most typical symptoms" (*Med. News*, lxxv, No. 1). The symptoms not classed as characteristic were black vomit, bloody evacuations, headache, rachialgia, congestion of the conjunctiva, and congestion of the face. These latter symptoms, it was believed, might also be present in other infectious fevers as well as yellow fever. It would appear, however, that with this opinion Guitéras does not entirely agree. A portion of the report is in accord with his belief relative to the diagnosis of yellow fever. In a pamphlet on yellow fever recently issued by the United States Marine-Hospital Service, Guitéras says:

"The diagnosis of individual cases of yellow fever is in my opinion very easy. There is no acute febrile disease in which there are so many signs that may be called pathognomonic. The diagnosis of the disease rests upon three such symptoms, namely: 'the facies, the albuminuria, and the want of correlation between the pulse and the temperature.' I rely mainly for my diagnosis upon the facies, which I consider extremely characteristic. However, as I consider it my duty to convince the local practitioners of the existence of the disease, I make it a rule not to announce officially the existence of yellow fever until I have been able to show the presence of albumin in the urine (Heller's contact method), which occurs on the second, third or fourth day." In an article in Keating's "Cyclopaedia of Children's Diseases," Guitéras states that this albuminuria may only persist for a few hours during the day, but careful search will nearly always detect its presence. He concedes that albuminuria may also occur in other febrile diseases than yellow fever, but in none of them so constantly nor so early when in connection with such mild manifestations of the toxemia. In all such diseases the albuminuria will be found at the end of the first week, or during the second week. He lays considerable stress on the detection of jaundice early in the onset of the disease, speaking as follows (pamphlet on yellow fever, see above): "The physician to whom I am showing the signs of the disease usually expresses surprise when I state that jaundice is present. It is, of course, best noticed in the sclerotics. The icteric hue is better seen at some distance from the patient than when the eyes are closely inspected. The jaundice of the skin is best detected by taking up a fold of the skin between the fingers, when the contrast between the yellowish, anemic skin and the surrounding congested area will become well marked. The characteristic feature of the pulse is that while the temperature may be rising, the pulse will be falling. This frequently occurs on the third or fourth day, and the pulse in the evening may be ten beats slower than in the morning. In dengue the fall in the pulse-rate corresponds to the fall in the temperature."

Regarding the morbid anatomy Wasdin makes the assertion that the yellow fever cadaver has assuredly a most characteristic appearance, as follows: "All subjects dead of this disease bear a close resemblance to each other (*Med. News*, lxxiii, No. 10). The body is usually quite rigid, more or less intensely yellow, whites of eyes yellow, hypostasis in the dependent portions of the body comes on very early, the gums are bloody and the anterior nares caked with blood." In addition Guitéras states that the features of the cadaver are somewhat bloated. In the abdominal cavity the most notable change from the normal is seen in the liver. It is at once recognized by its peculiar color, and Guitéras goes so far as to state that he has never seen it absent in an unsuspected case of yellow fever. It is thus described by the latter writer: "The organ is not enlarged. It is light in color, in which yellow predominates decidedly. The comparison to boxwood is a good one. In some cases the discoloration may appear in patches. Microscopically the evidences of fatty degeneration are present, as well as interstitial inflammation. The blood-vessels are empty. The liver cells are cloudy or decidedly fatty."

Wasdin describes the color of the liver as being from a light buff or boxwood to a dark brown. In some cases it has a nutmeg appearance. On section it has a pale yellow color and imparts to the knife a greasy stain. Both Guitéras and Wasdin lay stress on the contents and conditions of the stomach. Thus the former states that the organ is inflamed, the blood-vessels engorged with blood, and in some places extravasations may be found, and the organ may during the dark, fluid "black vomit," even though ejected containing life. Wasdin states that: "The most marked changes are found on the anterior surface and near the pylorus, the membrane here presenting a deep port wine stain from diffuse extravasation and often evi-

dence of free hemorrhage. After the lapse of several hours the mucous membrane becomes softened and many erosions are found. The vessels of the duodenum are swollen, hemorrhagic, and contain dark blood, and the whole intestinal tract shows minute extravasations. The intestines have a glazed appearance and are sticky to the touch, and the peritoneal fluid has a darkish tint." Both writers state that the kidneys present the lesion of parenchymatous nephritis. There may be extravasations on the cortex, but the capsule shows no change from the normal. Its general appearance is "paleness," but incision shows congestion of the renal veins. At the bases of the pyramids of Malpighii, pale yellow fatty areas are seen. This latter change, according to Wasdin, is quite marked. The spleen is not altered in yellow fever; any deviation from the normal indicates some concurrent complication. This latter observation is important in excluding malaria, in which the organ would be enlarged. According to Guitéras the two diseases have been found to coexist in the same patient, and have led to mistake in diagnosing yellow fever. The adrenals are normal. The contents of the thoracic cavity show no special change except that a yellow tint is prominent. Wasdin has noticed considerable congestion of the vasa vasorum at the base of the heart, forming a tracery over the serosa and on the walls of the auricles, and at times being echymotic.

London.

[From our Regular Correspondent, July 15.]

DREYFUS AND HIS PHYSICIAN.—There is one fact in the later revelations of the unspeakable Dreyfus case of which we as a profession have a right to be proud, and that is the statement of Captain Dreyfus, in his pathetically moderate description of the atrocities to which he was subjected, that he owes his life to a prison physician, whose name even he does not know, but whose emphatic protests compelled and frightened his brutal jailers to abandon their fiendish plan of treatment, which was intended to either kill or drive him insane. He it was who insisted on the removal of the leg-irons, and secured the alteration of the fence which was converting the wretched little hut into a veritable Black Hole of Calcutta. This took courage, for we must remember that the entire infamy was approved, if not actually devised by the Minister for the Colonies himself, and the doctor's name certainly ought to be learned at once and placed on the roll of honor with those of Picquart and Zola. A profession which can make a Frenchman behave like a man in the Dreyfus case has something remarkable about it.

PILLS BY THE BOTTLE.—A most singular cause of death was recorded yesterday at Bath, where a man died of perforation of the stomach, due to the presence of some twenty small bottles, tightly corked and sealed, and containing mercury. These together weighed over a pound, and had been swallowed by the deceased while in a state of dementia, under the impression that they were medicine—presumably pills of much potency.

DEATH OF THE CZAREVITCH.—A melancholy medical interest attaches to the death of the Czarevitch, previously noted in the JOURNAL, that he died of the same disease as did his father only five years before. The hereditary influence could only have been of the most indirect character, as the first symptoms of consumption appeared in both father and son within a few years of each other; indeed, the son's condition was publicly admitted first, and it seemed at one time as if he were going to succumb before his father.

BLACKMAILER RIGHTFULLY TREATED.—There is some sense in an honest man going to law in England; in America, alas, the utmost that a doctor can hope to obtain from an appearance in court against a patient is to escape with his life—and the privilege of paying his own costs. But in England he can actually get justice on the blackmailer. Dr. Davidson, of Gosherton, has just had this pleasure, and deserves the hearty thanks of our entire profession for his high-minded pluck in "carrying the war into Africa." A couple of months ago he

received the usual note from a woman who had consulted him a day or two before. "Sir—Unless you do me some recompense for insulting me the way you did at your surgery I shall inform someone else about it. It ought to be well worth £10 to you for me to say nothing about it." This has a most familiar sound, but the sequel is a delightful novelty. Dr. Davidson not only rejected her demand but promptly prosecuted her as a blackmailer, and within a month she was found guilty and sentenced to twelve months' imprisonment with hard labor, and most wonderful of all, by a jury. Fancy twelve untried American citizens, of the noble and chivalrous type that usually get on our juries, passing such a sentence as this on a woman, and a poor woman at that, for anything she might have done or threatened to do to any "doctur feller." We have known physicians in the Middle West who actually dared not hold any property in the state in which they lived, except a homestead in the name of their wife, for dread of the malpractice and other blackmail suits with which they were threatened, and which would certainly be brought, in full reliance on a sympathetic jury, if any trace of attachable property could be found.

APPENDICITIS IN CLASSIC LITERATURE.—Appendicitis has been given a place in classic literature at last. In an interesting note in the *Guy's Hospital Gazette*, Sir Samuel Wilks quotes a paragraph, written by Addison—of "Addison Disease" fame—in 1836, giving a full and surprisingly accurate account of "a deep-seated abscess in the right iliac region—which arises in a large majority of cases from disease of the appendix cæci: this is often found detached in the midst of the abscess, with perforation at its extremity." He even alludes to the "grape-seed" theory, to condemn it, on the shrewd, if slightly mistaken ground that the real cause of the disease is the presence of oval fecal concretions, containing "much limy matter." Dr. Wilks also calls attention to a curious passage, referring to the oecum, in "Tristram Shandy." It occurs in the famous conversation on all sort of improper anatomic matters between Dr. Slop and Tristram's father, the night of his birth. "Tell me, Doctor, where is the blind gut?" said my father. "It lies between the ilion and the colon," replied Dr. Slop. "Is it the same in woman as in man?" "The very same," said Slop. "That's more than I know," quoth my father." The question and curiously skeptical rejoinder of Shandy, Sr., is oddly significant, in view of the far greater frequency of "typhlitis" in men than in women, and as Sterne himself was a practicing physician, one is almost tempted to suspect that some knowledge of this clinical fact had been gained by him, or was current in the profession, even at that early date.

COMPARATIVE RARITY OF APPENDICITIS IN ENGLAND.—Now that appendicitis has been given a respectable antiquity, perhaps the English practitioner will begin to recognize it officially. The difference between the frequency of appendicitis in England and in America is something astonishing. We have talked with intelligent English physicians in large practice, and they have assured us that they do not see three cases a year, and with consulting surgeons who operate almost as infrequently. We can hardly believe that all this discrepancy is due to the greater frequency of the disease on this side of the Atlantic, although a decided difference is proved to exist by the rarity with which appendicular mischief is found in the routine autopsies at the great hospitals. Our English brethren, with characteristic frankness and self-deprecation, explain it by the statement that appendicitis is the rage in America, and we diagnose it to please our patients. Others, even more benighted, ascribe it to the fact that we eat "such a beastly lot of fruit," a weak and reprehensible habit fit only for children and "furriners." The truth probably lies between us, too great an enthusiasm to be fully abreast of the pathologic procession, on our part, and too strong a tendency to keep a safe distance behind it, on theirs. Possibly the mixture of nationalities, and changed environment, in our new country, may make our

attaching appendicular "remnant" even more variable and unstable.

COMMENDABLE COURTESY.—The invitation of Clark University to Ramon y Cajal, to deliver a series of lectures on the structure of the brain, at its centenary celebration, is widely commented on in England as a gratifying proof of the absolute internationalism of science, and as a most graceful and commendable act of courtesy to a whilom foe.

ROYAL COLLEGE OF SURGEONS.—The annual meeting of the Royal College of Surgeons revealed that the Council had no intention of granting any rights whatever to Members. A new charter was asked for, simply adding the power to create Honorary Fellows, and the president plaintively begged the meeting not to cloud the glory of the coming centenary by raising "discordant issues." But as this was simply a graceful dodge to cajole the Members into remaining unrepresented until the next centenary, the meeting naturally objected, and a motion to return the proposed charter to the Council, with a statement that the powers asked for were inadequate, was carried by a large majority.

KEROSENE AND MOSQUITOES.—It is of interest in connection with the approaching expedition to Sierra Leone, to test the possibility of exterminating mosquitoes, to know that a test has just been made of the kerosene method. The water-tank of an Italian villa was found swarming with culex larvæ estimated at 400 or 500 to the bucketful. Ten drops of kerosene added to the bucketful killed them all in twenty minutes, and a few teaspoonfuls sufficed for the whole tank of 300 cubic feet capacity. At this proportion quite large ponds or even marshes may be coated at a very slight expense.

SEATS FOR SHOPWOMEN.—The much-needed seats-for-shop-women-bill has just passed the House of Lords by a large majority, this giving Lord Salisbury a well-deserved snub for his captious and unintelligent resistance to the measure. He again attacked it, but to no effect.

Queries and Minor Notes.

DOSAGE OF CURARE.

ANTIGO, WIS., July 26, 1899.

To the Editor:—The enclosed was taken from the JOURNAL, and as I have a case of epilepsy I would like to try curare, but it seems to me the dose altogether too large. Is the prescription correct? Kindly let me know through next week's JOURNAL, and oblige.

Yours respectfully, M. J. D.

ANSWER.—The clipping enclosed is taken from the JOURNAL, Jan. 7, 1899, p. 29, and is an abstract from the *Jour. de Med. de Paris*, Dec. 11, 1898. The dose as given is unquestionably too large. The dose of curare is from 1-20 to 1/2 grain (0.005-0.03 gm.), while that of the alkaloid curarin is as small as 1-200 or 1-100 grain (0.0005-0.0006 gm.), hypodermically.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including July 27, 1899:

- F. M. Barney, acting asst.-surgeon, leave of absence granted.
- Henry H. Bradley, acting asst.-surgeon, to temporary duty in the camp hospital at Camp Meade, Pa.; later orders require him to proceed to San Francisco, Cal., for duty in the department of California.
- Robert Burns, acting asst.-surgeon, from Plymouth, N. H., to Fort Ethan Allen, Vt., to accompany the 3d Cavalry to Manila.
- John R. Clark, acting asst.-surgeon, from Fort Wadsworth, N. Y., to San Francisco, Cal., for duty in the department of California.
- A. P. D. Cleary, acting asst.-surgeon, from Fort Screven, Tybee Island, Ga., to Atlanta, Ga., as attendant surgeon and examiner of recruits.
- Charles F. Craig, acting asst.-surgeon, orders directing him to proceed from the Josiah Simpson Hospital, Fort Monroe, Va., to San Francisco, Cal., are revoked and he will proceed to Havana, Cuba, for duty at Camp Columbia, Cuba.
- Gerry S. Driver, acting asst.-surgeon, from Porto Rico to Fort Myer, Va., to accompany the 3d Cav. to Manila, P. I.
- Douglas F. Duval, lieutenant and asst.-surgeon, U. S. A., from West Point, N. Y., to San Francisco, Cal., for duty in the Department of California.
- Charles B. Ewing, captain and asst.-surgeon, U. S. A., from Fort Brady, Mich., to San Francisco, Cal., to report for duty with the 3d Cav.; these orders so amended as to direct him to join the said regiment at Seattle, Wash., on or before August 10.
- Hyman Finkelstone, acting asst.-surgeon, from New York City to Fort Ethan Allen, Vt., to accompany the 3d Cav. to Manila, P. I.

John N. Goltra, acting asst.-surgeon, from Fort Niagara, N. Y., to Fort Brady, Mich.

John C. Greenwalt, lieutenant and asst.-surgeon 33d Inf. Vols., from Chambersburg, Pa., to Fort Sam Houston, Texas.

William R. Hall, major and surgeon, U. S. A., from duty as attending surgeon, Washington, D. C., to New York City, August 15, 1899, for duty in the Department of the East; on the completion of this duty he will sail as a passenger on the hospital ship *Missouri* for duty in the Philippine Islands.

Charles L. Heilmann, major and surgeon, U. S. A., assigned as chief surgeon, Department of Texas.

John R. Hicks, acting asst.-surgeon, from Fort Crook, Neb., to Fort Scriven, Tybee Island, Ga.

William Reelin Kirk, acting asst.-surgeon, leave of absence granted. William F. Lippitt, jr., captain and asst.-surgeon of the general hospital at Washington Barracks, D. C.

Theodore J. Lyster, acting asst.-surgeon, from Ann Arbor, Mich., to Havana, Cuba, for duty in the Division of Cuba.

J. G. Marro, acting asst.-surgeon from Brainard, Neb., to San Francisco, Cal., for duty in the Department of California.

Louis M. Maus, major and surgeon, U. S. A., temporarily a member of a retiring board convened at Governor's Island, N. Y.

Willson Murray, acting asst.-surgeon, from Platte City, Mo., to Fort Myers, Va., to accompany the 3d Cav. to Manila.

George J. Newgarden, captain and asst.-surgeon, U. S. A., sick leave extended.

Jonathan D. Poindexter, captain and asst.-surgeon, U. S. A., relieved from further duty and station at Columbus Barracks, Ohio.

Ogden Rafferty, major and surgeon 27th Inf. Vols., relieved from further duty and station at Camp Meade, Pa.

Henry D. Snyder, captain and asst.-surgeon, U. S. A., member of a board of survey on subsistence stores at Savannah, Ga.

James B. Stuard, acting asst.-surgeon, from Burlington, N. C., to San Francisco, Cal., for duty in the Department of California.

Thomas C. Stunkard, acting asst.-surgeon, from Terre Haute, Ind., to San Francisco, Cal., for duty in the Department of California.

Frank L. R. Tetauere, acting asst.-surgeon, from Buffalo, N. Y., to San Francisco, Cal., for duty in the Department of California.

William H. Tukey, acting asst.-surgeon, from Malden, Mass., to San Francisco, Cal., for duty in the Department of California.

Wilfrid Turnbull, major and surgeon, Vols., leave of absence extended.

Charles Wilcox, captain and asst.-surgeon, U. S. A., leave of absence extended.

Charles E. Woodruff, captain and asst.-surgeon, U. S. A., from Benicia Barracks, Cal., to Manila, by the first available transport.

Movements of Navy Medical Officers.—Changes in the medical staff of the U. S. Navy for the week ending July 29, 1899:

Surgeon L. W. Atlee, detached from the *Bennington* and ordered home via *Solace*.

P. A. Surgeon G. Rothganger, detached from the *Marlette* and ordered home and to wait orders.

P. A. Surgeon M. K. Johnson, detached from the naval hospital, New York and ordered to the *Marlette*.

Asst.-Surgeon W. M. Wheeler, when discharged from further treatment at hospital, Yokohama, Japan, ordered home in the United States and to wait orders.

Asst.-Surgeon T. M. Lippitt, detached from the *Solace* and ordered to the *Baltimore*.

Asst.-Surgeon R. W. Plummer, ordered to the naval hospital, New York.

Surgeon J. W. Ross, retired, granted leave for one year abroad.

Asst.-Surgeon H. A. Dunn, detached from the *Panther* and ordered to the Washington Navy Yard.

P. A. Surgeon L. L. Von Wedekind, detached from the hospital, Cavite, P. I., and ordered to Mare Island, Cal.

Marine-Hospital Changes.—Official List of Changes of Station, and Duties of Commissioned and Non-Commissioned Officers of the U. S. Marine-Hospital Service, for the seven days ended July 27, 1899.

Surgeon F. W. Mead, to proceed to New York City and assume temporary charge of the purveying Depot.

P. A. Surgeon H. D. Geddings, relieved temporarily from duty on the commission for the scientific investigation of yellow fever, and assigned to temporary duty in the Hygienic Laboratory. To proceed to Boston, Mass., for special temporary duty.

P. A. Surgeon J. C. Berry, detailed for duty in the office of the U. S. Consul, Hongkong, China.

P. A. Surgeon C. H. Gardner, to assume temporary charge of the Port Townsend Quarantine.

P. A. Surgeon E. K. Sprague, granted leave of absence for 27 days from August 7, 1899.

P. A. Surgeon H. W. Wickes, granted leave of absence for 30 days from August 6, 1899.

Asst.-Surgeon S. R. Tabb, upon being relieved from duty at Baltimore, Md., to proceed to Savannah, Ga., and assume command of the service.

Asst.-Surgeon M. H. Foster, upon being relieved from duty at Savannah, Ga., to proceed to the Port Townsend Quarantine station, and report to the commanding officer for duty.

Asst.-Surgeon L. L. Lumsden, to proceed to Port Townsend, Wash., and assume temporary charge of the service.

Asst.-Surgeon W. C. Billins, relieved from duty at the Immigration Depot and directed to report to the commanding officer at New York City for duty and assignment to quarters.

Asst.-Surgeon Carroll Fox, to report to commanding officer, Baltimore, Md., for duty and assignment to quarters.

Asst.-Surgeon T. B. McClinton, to report to commanding officer, Cape Charles Quarantine, for duty and assignment to quarters.

Asst.-Surgeon D. H. Currie, to report to commanding officer at Louisville, Ky., for duty and assignment to quarters.

Asst.-Surgeon Joseph Goldberger, to report to Surgeon L. L. Williams, Immigration Depot, New York City, for duty.

Asst.-Surgeon Wm. A. Korn, to report to commanding officer, Chicago, Ill., for duty and assignment to quarters.

Asst.-Surgeon J. M. Holt, to report to commanding officer, St. Louis, Mo., for duty and assignment to quarters.

Asst.-Surgeon E. E. Trotter, to report to Surgeon L. L. Williams, Immigration Depot, New York City, for duty.

Asst.-Surgeon C. W. Vogel, to report to commanding officer, Boston, Mass., for temporary duty and assignment to quarters.

Acting Asst.-Surgeon Jay Tuttle, granted leave of absence for 7 days.

PROMOTIONS.

Hospital Steward Henry Gahn to be hospital steward and chemist. Hospital Steward W. L. Stearns to be hospital steward and assistant chemist.

APPOINTMENTS.

Carroll Fox of Pennsylvania, commissioned as assistant-surgeon. Thomas B. McClinton of New York, commissioned as assistant-surgeon.

Donald H. Currie of Missouri, commissioned as assistant-surgeon. John Goldberger of Pennsylvania, commissioned as assistant-surgeon.

William A. Korn of New Jersey, commissioned as assistant-surgeon. John M. Holt of New York, commissioned as assistant-surgeon.

Frederick E. Trotter of New York, commissioned as assistant-surgeon. Charles W. Vogel of Maryland, commissioned as assistant-surgeon.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended July 29, 1899:

SMALLPOX—UNITED STATES.

Florida: Jacksonville, July 8 to 22, 5 cases.

Kentucky: Louisville, July 13 to 20, 10 cases.

Louisiana: New Orleans, July 15 to 22, 1 case.

New York: New York, July 15 to 22, 3 cases.

Ohio: Cincinnati, July 22, 5 cases, 1 death; Cleveland, July 15 to 22, 2 cases; Dayton, July 15 to 22, 2.

Pennsylvania: Pittsburg, July 15 to 22, 1 case.

Virginia: Portsmouth, July 15 to 22, 1 case.

Washington: Spokane, July 18 to 22, 5 cases.

SMALLPOX—FOREIGN.

Belgium: Antwerp, July 1 to 8, 3 cases, 1 death.

Brazil: Sao Paulo, June 27, epidemic.

China: Hongkong, May 27 to June 3, 5 cases, 1 death.

Cuba: Santiago, July 1 to 8, 1 case.

Greece: Athens, July 1 to 8, 15 cases, 5 deaths.

India: Bombay, June 20 to 27, 14 deaths.

Mexico: Mexico, June 9 to 16, 10 cases, 5 deaths.

Russia: Moscow, June 17 to July 1, 27 cases, 11 deaths; Warsaw, June 24 to July 1, 3 deaths.

Straits Settlements: Singapore, June 10 to 17, 1 death.

Uruguay: Montevideo, May 27 to June 3, 1 case.

YELLOW FEVER.

Brazil: Rio de Janeiro, June 9 to 16, 3 deaths.

Columbia: Panama, June 8 to 15, 10 cases, 4 deaths.

Cuba: Havana, July 6 to 13, 2 deaths; Manzanillo, June 27, 1 case in barracks; Santiago, June 27 to July 1, 08 cases, 13 deaths.

Mexico: Cordoba, June 27 to July 1, 17 cases, 9 deaths; Tampico, July 1 to 7, 1 case, 1 death; Vera Cruz, July 13 to 20, 17 deaths.

CHOLEERA.

India: Calcutta, June 10 to 17, 6 deaths.

Japan: Asaka and Hiogo, June 10 to 17, 1 case, 1 death.

PLAGUE.

China: Hongkong, May 27 to June 3, 92 cases, 97 deaths.

Egypt: Alexandria, July 6, one or two new cases daily.

India: Bombay, June 20 to 27, 50 deaths; Calcutta, June 10 to 18, 9 deaths.

Straits Settlements: Penang, June 10 to 17, 11 cases, 8 deaths; Singapore, June 10 to 17, 1 death.

CHANGE OF ADDRESS.

Brown, G. H., from Davis Junction to 298 Maxwell St., Chicago.

Bryan, C. M., from 2642 Wentworth to 3030 Washab Avenue, Chicago.

Brucker, C. G., from Canon City, Colo. to 1575 Yates St., Denver, Colo.

Clark, C. M., from Pittsfield, Mass. to 317 E. 86th St., New York City.

Clareh, C. G., from Marysville to Van Wert, Ohio.

Dannaker C. A., from 159 Grand to 393 E. 12th St., Kansas City, Mo.

Dorian, J. S., from Buffalo to 6 C. St., Niagara Falls, N. Y.

Gillespie, W. J., from Philadelphia to Ambler, Pa.

Hegele, H. W., from 201 Lincoln to 153 Robey St., Chicago.

Hamilton, G. W., from St. Mary and Elizabeth Hospt. to 615 W. Broadway, Louisville, Ky.

Jefferson, E. L., from Hayden to Steamboat Springs, Colo.

Lester, E. S., from Dominion to Kadesb, Va.

Miller, W. G., from New Castle, Pa., to Angel Island, San Francisco, Cal.

McBride, M. A., from Watt to Battle, Texas.

Price, E. M., from Rushville to Astoria, Ill.

Quillin, N., from Linton to Carp, Ind.

Raymond, J. H., from Brooklyn, N. Y., to Box 1285, Pittsfield, Mass.

Sherill, E. A., from Cookes Point to Hix, Texas.

Scott, A. C., from 825 Willson Ave. to Central Ave., Cor. Van Buren St., Cleveland, Ohio.

Van Duzen, A. C., from 3010 Prairie Ave. to the Renfost, 52d and Cottage Grove Ave., Chicago.

Watkins, G. A., from Lead Hill to Carrollton, Ark.

Wallace, A. M., from 927 North Kansas Ave. to 724 Kansas Ave., Topeka Kansas.

Original Articles.

TUBERCULOSIS OF FASCIA.*

BY JAMES E. MOORE, M.D.
MINNEAPOLIS, MINN.

Very few writers mention connective tissue as a primary seat of tuberculosis. Senn, in his "Principles of Surgery," gives the only article of importance upon this subject that I have been able to find, and that is a very brief one. We are learning, however, that the fasciae of various parts of the body are not infrequently the primary seat of disease. Every surgeon is familiar with tuberculosis of fascia secondary to gland, bone and joint disease, but in these cases the communicating sinuses can be found and the relation between the disease of the fascia and the gland, bone or joint easily established. I have the history of quite a number of cases in which there was no disease of gland, bone or joint and in which there was extensive disease of the fascia. There are two varieties. In the first variety the disease is confined to the surface of the fascia and is practically the same as a tuberculosis of the tissue secondary to a joint tuberculosis. There may be a very small area affected, or it may be quite extensive. There is a layer of tubercular granulation tissue which can be readily scraped off, leaving the protection wall of inflammatory deposit which nature always throws around a tubercular abscess. It is found most frequently in the fascia lata, in the fascia covering the popliteal space and in the deeper fascia of the thigh and leg. In the second variety the disease is not limited to the surface of the fascia, but dips down through it, attacking deeper layers of the fascia and muscular tissue. It is found most frequently in the chest-walls and in the deeper layers of the thigh.

The symptoms of fascial tuberculosis are a slowly developing swelling accompanied by little or no pain, and a local rise of temperature which can be detected by a sensitive hand. The general temperature rarely rises above 99 F. There is no change in color until the disease approaches the surface, when the skin will become red at first and later purple in spots. These purple spots finally give way and sinuses are formed. After the sinuses are formed a secondary pyogenic infection takes place, and the patient begins to suffer pain. There is a marked difference in the effect upon the general health in different cases. In some, the health may be little affected for a long time, or until sinuses form and the mixed infection takes place, after which there is liable to be a rapid decline in health. In others, mixed infection will occur before sinuses form, and the patient will have a high temperature and other symptoms of a phlegmon.

The diagnosis is to be made largely by exclusion. At times it will be impossible to make a positive diagnosis without an exploratory incision. An experienced sur-

geon will usually be able to detect a joint tuberculosis, but he may not be able to differentiate a fascial tuberculosis from one beginning in some other tissue. The evidences of a joint tuberculosis are usually easily detected, but a bone tuberculosis independent of a joint lesion may be very obscure indeed. While we should always remember that fascial tuberculosis may be primary we should not forget that in the vast majority of cases it is secondary. I have seen one case in which the patient came to the surgeon for relief from a tuberculosis of the fascia just below the crest of the ilium, which was found to be connected through a sinus thirty inches long with a primary disease of the tibia. Most careful search should always be made for foci in neighboring lymphatic glands, bones and joints before accepting a diagnosis of fascial tuberculosis.

When the patient first comes to the surgeon with open sinuses the tubercular nature of the disease is readily established by their characteristic appearance. When he comes with a mixed infection and without a sinus the surgeon will surely make a diagnosis of phlegmon as in my case (No. 6), unless he is very careful to get a full case history. Cases in which phlegmon is said to have been followed by a tubercular infection were probably originally tubercular, the pyogenic infection being secondary.

The prognosis varies with the variety, the location, and the extent of the disease. Under proper treatment that variety which is confined to the superficial fascia will usually disappear promptly, but in the other variety in which the disease dips down into the deeper parts, the prognosis is grave. When situated in the deeper layers of the thigh the prognosis is very grave indeed.

The treatment consists of thoroughly removing every trace of disease with knife, curette and scissors. In the milder variety a free incision should be made and the diseased tissue scraped away, exercising extreme care that every nook and corner is reached. The cavity should then be wiped dry or irrigated with sterile water and closed without drainage. When pyogenic infection is present, with or without sinuses, gauze drainage should be employed. Rubber drainage-tubes should be avoided in tuberculosis, because their track is almost certain to become tubercular.

In the severe or perforating variety it is necessary to be more thorough, and at times heroic, in the treatment, for half-way operating is worse than useless. Even after the most painstaking and careful operation there is a very great tendency for this variety to relapse. When relapse does occur, another operation should be performed as soon as the disease is recognized, because the tendency is to grow progressively worse, and the danger of a general tubercular infection is imminent. It has been my good fortune to save some of these patients by repeated operations. When this disease is located in the chest-wall the patient usually comes to the surgeon with sinuses, mixed infection and a diagnosis of disease of

*Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

the ribs. I have learned from very trying experience that the treatment of these cases must be decidedly heroic, not because of a special tendency to lung involvement, as might be inferred from the location, but because the disease often dips down between the ribs, and unless very thorough work is done it will not all be removed. Each individual sinus must be laid open from end to end, regardless of the number or size of scars to be left. It will not do to follow the sinus along under or between the pectoral muscle until it dips down between the ribs and then curette the remaining portion, but it must be laid open for inspection to the uttermost part. The rule is that after dipping down between the ribs a sinus will extend for a considerable distance between the ribs, and unless it is followed by the eye, it will not be found, and the operation will be a failure. Sometimes an abscess cavity will be found so situated that it is necessary to remove a section of the rib in order to properly clean and drain it. I have found the actual cautery very efficient when thoroughly applied after scraping. Comparatively little closing up can be done after these operations. The wounds must be firmly packed with iodoform gauze so that they are cone-shaped with the apex at the bottom. They must be watched and overhauled whenever tubercular granulations appear. Most of my relapses in these cases have occurred when the after-treatment had been carried out by the family physician, but I am bound to admit that some have recurred while under my own care.

When this disease occurs in the extremities the treatment must be carried out along the lines just suggested. It may be necessary at times to remove diseased layers of fascia and whole muscles, and when persistent relapses occur and the patient's health is failing, amputation may become our only resource.

When situated in the deeper layers of the thigh this disease is apt to become very extensive and is particularly difficult to treat successfully, and when the upper third of the thigh is involved, we are deprived of amputation as a last resource. Early and oft-repeated operations offer our only hope in these cases. An added danger in this location is that the disease may become very extensive before a diagnosis can be made, on account of its distance from the surface.

The following are brief histories of cases selected to illustrate the different phases of the disease as well as the trials, difficulties and varying success in its treatment:

CASE 1.—J. F. J., aged 48 years, a deputy-sheriff, came from Madison, Minn., in May, 1895, to see me on account of an enlargement of the thigh. The whole thigh seemed swollen and at its lower end the swelling came to an abrupt ending around the upper margin of the patella so that that bone seemed to be at the bottom of a deep depression. The swelling had been coming on slowly for nearly two years. There had been but little pain or disturbance of general health until toward the last, when his strength began to fail somewhat and he had some pain from pressure. It was quite symmetrical and gave an indistinct sense of fluctuation. There was local heat but little tenderness; temperature 99. The neighboring joints were healthy and the patient could walk with the aid of a cane.

Diagnosis.—Cold abscess probably due to tuberculosis of some portion of the shaft of femur.

I made an incision nearly the whole length of the thigh, evacuating a large quantity of the characteristic contents of the so-called tubercular abscess. No sinus leading to the bone could be found after scraping away

the lining of the abscess cavity, and a diagnosis of tuberculosis of the fascia lata was made. The cavity was thoroughly irrigated with a 1 to 2000 corrosive sublimate solution, and, with the exception of a small opening at the lower end, through which passed a small strip of iodoform gauze, the wound was closed with a continuous silk suture. There was quite free drainage at first, but it soon ceased, and on the fifth day the drain was removed, after which the patient made a speedy recovery, returning to his home on June 14, just two weeks after the operation. He has been in excellent health ever since and has had no return of his local trouble.

This case is a typical example of the simple variety of tuberculosis of fascia.

CASE 2.—On Feb. 13, 1893, I was called by Dr. Rogers to operate upon Mrs. S., who had been suffering from what was supposed to be tuberculosis of the ribs. There were sinuses over the front of the chest, below the right breast and at the outer margin of the right scapula. All the sinuses in front were laid open, curetted and packed. The right breast was turned up in a flap, the sinuses dissected out, the breast replaced and the wound partially closed. Extensive dissection was necessary to expose the whole of the disease in the back, but we were fortunate in reaching all of it, for the patient made an exceptionally speedy recovery.

I fully expected to find disease of the ribs in this case but none was found, the whole trouble being confined to the fascia.

CASE 3.—H. N., aged 24 years, came under my care on May 28, 1897, with a number of sinuses over the anterior thoracic wall, which were due to tuberculosis of the fascia. He had been operated upon once before, but without success. I laid all the sinuses open down to a point where some of them dipped down through the fascia and seemed to end in blind pockets. These pockets were curetted and packed. Prompt recovery occurred, so that he returned to his home in the country in three weeks with the wounds so nearly healed that I thought they would heal under a few dressings by the family physician. He returned on July 9 with the sinuses almost as bad as before. At this, my second operation, the deep sinuses were followed down through the fascia into the spaces between the ribs and thoroughly curetted and cauterized with the Paquelin cautery. He returned to his home August 4, with the wounds completely healed, and has suffered no relapse since.

This is a typical case of the perforating variety, and illustrates the practical point made in the paper that success can only be gained by laying every sinus open for inspection throughout its whole length.

CASE 4.—F. F., aged 48 years, a Mexican coffee-planter, came to me in January, 1896, suffering from a hydrops articulari of the right knee. The disease, although chronic, was quite mild in character and yielded promptly to treatment, which consisted of tapping, followed by irrigation with a bichlorid solution and rest in a plaster cast. Twenty months later, in September, 1897, he returned with a beginning tuberculosis of the fascia of the lower third of the left thigh. There were two sinuses and the disease seemed to be superficial. The part was laid open, freely scraped, and packed with gauze.

On Jan. 16, 1898, at St. Barnabas Hospital, I operated a second time removing all the diseased tissue I could find. On January 29 I realized that the last operation was a failure, and determined to operate again and to be as radical as possible. There were at

this time several sinuses and a mixed infection, and the patient was rapidly failing. I made an incision from just above the knee-joint to the tip of the greater trochanter. At the lower third of the thigh a strip of integument two inches wide and eight inches long, which was perforated by the sinus, was removed. A large portion of the fascia lata was removed, because it was diseased beyond all hope of recovery. The disease was found dipping down into the vastus externus muscle to such an extent that it was necessary to remove the whole of that muscle. It should be noted that this disease was in the left thigh, while his hyprois articulari had been on the right side. The left knee was healthy, but its synovial membrane was being attacked from the outside, and in my efforts to remove all the diseased tissue, I opened into the upper pouch of the knee. A piece of synovial membrane two inches long and one inch wide was removed, and the opening into the joint immediately closed with a running catgut suture, and although the patient was suffering from a mixed infection at the time of the operation, no joint symptoms followed. This enormous wound was closed, and, with the exception of a small spot at the lower end, where there was a small slough of the integument, it healed by first intention. The slough soon separated, and the wound granulated over without a return of tuberculosis. The patient left the hospital in less than three weeks, and very soon afterward returned to his Mexican home. Before he left he walked into my office with a cane, and the function of the limb was remarkably good, considering the amount of tissue removed. In May, 1899, I received a report that his leg is giving him no trouble, but that his general health is failing and that he has a cough.

CASE 5.—John M., a blacksmith, 24 years of age, came under my care in April, 1897, for an extensive tuberculosis of the fascia of the left leg and popliteal space and a cold abscess between the ribs on the right side. An extensive dissection of the popliteal space was made and every visible trace of diseased tissue removed. The abscess in the side was opened, scraped, and packed.

One month after the first operation it was evident that the disease was returning, and a second scraping was done. Although the wounds did not heal rapidly, the patient improved rapidly in general health for a time. On July 3, he began to suffer from an acute synovitis of the left knee, which was non-suppurative and recovered in about two weeks. At this time the leg and popliteal space were healthy, but there was beginning disease on the outer side of the lower third of the thigh of the same limb, which was opened and scraped. Shortly after this his limb seemed to be perfectly well, and although his side was not entirely healed, it looked healthy, and his general health was excellent. He then went to his home in the country, where he remained until April, 1898, when he returned with extensive disease of the outer side of the thigh at the site of the old disease and with his side much worse. He re-entered St. Barnabas Hospital, where I removed every trace of disease from the thigh and removed a section of one rib in order to thoroughly clean out the abscess in his side. At this time I could find no trace of bone or joint disease. The portion of rib removed was perfectly healthy. Soon after this he returned to his home in good general health, but with open sinuses in the thigh and side. I did not see him from June, 1898, until the spring of 1899, when he returned to the city with a relapse of the disease in the lower third of the thigh and in the side. The site of the original disease in the leg and popliteal space remained healthy.

At this time I advised amputation of the thigh above the disease and a very heroic operation upon the side. He entered St. Mary's Hospital, where he was under the care of my colleague, Dr. Dunn, who amputated the leg and cleaned out the side. May 26, 1899, Dr. Dunn reports to me that the thigh is entirely healed and seems to be well; that his general health is good, but that his side is still unhealed. The specimen was taken to the University laboratory, where it was thoroughly examined, and, in addition to the extensive fascia tuberculosis, a beginning tuberculosis of the knee-joint was found. The joint disease was clearly secondary to the disease of the fascia.

CASE 6.—On Dec. 24, 1897, I was called to see Wm. E., aged 20 years, who had come in from the country with an acute inflammation of the right leg. He gave a history of a traumatism, and I made a diagnosis of a phlegmon. The history given excluded osteomyelitis. He entered St. Barnabas Hospital, where I operated upon him on Christmas day. A large abscess was opened and drained in the usual manner, after which his high temperature disappeared and he improved very rapidly. He left the hospital in a few days feeling quite well, but with an open wound. Shortly after this his wound showed unmistakable evidences of tuberculosis. Upon careful inquiry I learned that one year before I saw him he had had trouble with this leg, which had kept him from work for some time, but which had recovered without an abscess forming. His leg had never been well after this, but had not kept him from work until a few days before I saw him. He re-entered the hospital, and I opened up the leg freely and found quite an extensive tuberculosis of the fascia, but no disease of bone. The diseased tissue was removed, and the wound packed with iodoform gauze. In three months the wound healed and he has had no trouble since. This was evidently a case of tuberculosis of the fascia which had been progressing slowly when a pyogenic infection occurred without the presence of a sinus. By exercising a little more care in securing the history I might have avoided an error in diagnosis.

KNEE-JOINT TUBERCULOSIS.

RESECTION FOR ITS CURE, WITH A PLEA FOR EARLIER OPERATION.*

BY A. F. JONAS, M.D.

Professor of Surgery in the Omaha Medical College; Surgeon to the Omaha (M. E.) Hospital and the Douglas County Hospital; Chief Surgeon of the Union Pacific Railroad.

OMAHA, NEB.

When we consider the anatomical changes as we find them in knee-joint tuberculosis, we at once must concede that there can be no one uniform method of treatment that will insure a favorable outcome in all cases.

We need only to recall the large and small primary bone-centers, not always occupying the same relations to the articular surfaces, progressing now slowly and again rapidly, usually forming small abscesses and at other times large ones; of the occurrence of mixed infection; of invasion of the periarticular structures, to show us that our management must be adapted to and changed from case to case. Especially is this true when we consider metastatic infections, systemic complications and resulting deformities. We would certainly be censurable if we adopted a uniform method for all cases, such as antituberculous remedies, either local or

* Presented to the Section on Surgery and Anatomy, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

general; arthrotoomy or arthrectomy, resection or possible amputation. It is true we are often perplexed as to the method best adapted to the case, because it is difficult, as a rule, to make a specific anatomical diagnosis, without opening the joint. Consequently, as practical surgeons, we classify our cases from a clinical standpoint, into mild or recent and severe or chronic.

No man can, in a given case, state positively whether the primary depot is located in the bone or in the synovial membrane, and since rest, immobilization, avoidance of irritation, and removal of superincumbent weight are the indications for the management of joint tuberculosis, whenever found, we employ these so-called conservative methods in recent and mild cases. And not until we find mechanical, local and general medicamentary means of no avail do we pass on to the more radical operative measures. The advent of antiseptics with its operative furor, was the cause of frequent and early invasion of the knee-joint with suspected tuberculosis. The findings and results did not always justify the intervention; the function of the knee-joint was not restored as had been hoped, and now we have receded to a middle ground. The great praise bestowed on intra-articular injections of iodoform emulsion and other medicaments is possibly partly responsible for our present stand. We have also learned that the natural tendency for bone tuberculosis, under favorable conditions, is to recover. It is surprising how many cases do eventually recover with fairly useful joints that receive no other treatment than immobilization and the removal of the superincumbent weight.

To draw an exact line between the cases to be managed mechanically and those to be subjected to operation is not so simple, or to always decide when the time has come when purely mechanical means have accomplished what is possible and radical surgery is indicated is not easy. Reliable rules can not be laid down. Each case must be considered by itself, and general principles must be our guide.

In the presentation of this subject here I have nothing new to offer, but I rather desire to emphasize some things in connection with this question, and at the same time record my own experiences and impressions, and possibly contribute something toward the indications for resection of the knee-joint when affected by tuberculosis.

The cases of knee-joint tuberculosis coming under my care during the past ten years are 55 in number. The methods of treatment employed in these cases may be divided under the following heads:

1. Mechanical: Immobilization, with plaster-of-paris, starch bandage, and braces.
2. Intra-articular injections of iodoform emulsion, followed by compression.
3. Puncture with canula, copious irrigation with 2 per cent. carbolic, or 1000 sublimate solution, withdrawal of fluid, compression.
4. Free incision, irrigation, filling the joint with iodoform, closure by suture without drainage, immobilization.
5. Para-articular operations, opening of abscesses, excavation of bone centers.
6. Arthrectomy.
7. Resection.
8. Amputation.

Tuberculin was not employed.

Of the entire number treated, 15 passed from observation before the final outcome could be noted. The remaining 40 were kept under control until the local process had come to an end. Of this number 7 came to resection of the joint surfaces and two to amputation. This leaves 31 cases that recovered without severe operative measures, and yielded partly to medicamentary and partly to mechanical means, associated in a number of

instances with joint puncture for evacuation of joint contents followed by injection or irrigation, simple incision, compression, iguipuncture, and local applications of various kinds.

It is my purpose to limit this dissertation to the consideration of the indications for, and the method of, resection employed and a brief reference to amputation, together with a short history of the cases so managed. Case 1 will be described in detail to illustrate the method of operation; the subsequent cases will be alluded to more briefly. It is my purpose to report the other cases at another time and place.

CASE 1.—Mrs. A. O., aged 62 years, housewife, mother of several grown children, in her youth had suffered from pain, stiffness and swelling of the right knee, extending over a period of nearly two years. She recovered with a limited degree of motion. Since then she had enjoyed good health until a year previous to her admission, when her knee began to swell. It became sensitive and painful and she was unable to bear her weight on it.

When admitted to the hospital we found her appearing much older than her actual age, illy nourished and very pale. She was unable to bear her weight on her right leg.

On examination we found the knee swollen, of a glassy, almost pearly white appearance, painful on pressure, externally and internally. The joint was semiflexed; there was no fluctuation; thigh and calf were atrophied. There was no fever nor acceleration of pulse. On palpation a doughy, elastic sensation was imparted to the finger; no pitting. This condition was easily recognized to be tuberculosis. She having undergone much treatment without benefit, a resection was recommended and agreed to by the patient.

After the usual antiseptic preparation of the knee, and the application of an Esmarch rubber bandage to the middle portion of the thigh, an incision reaching the bone was made, beginning over the posterior border of the internal condyle, extending outward, transversely over the middle portion of the patella, thence to a point midway over the lower margin of the external condyle. The patella was divided transversely with a saw. On flexing the calf on the thigh by forcing the heel backward against the buttocks the entire articular surface was exposed. The joint cartilages were almost entirely destroyed, and had been replaced by a dense irregular growth of fibrous tissue, in the meshes of which was a mass of fungoid structures. A large half-dollar-sized bone cavity existed on the tibial articulation, another somewhat larger on the femoral side. The synovia had been replaced by a soft, pale, translucent, friable structure. The upper patellar fragment with its quadriceps tendon was pulled upward with a retractor, and the lower portion attached to the patellar tendon pulled downward; all restraining soft parts were clipped with a pair of scissors. A section one-third inch thick was removed from the tibia and femur, care being taken to make the plane of the sawed surfaces at a right angle with the long axis of the bones. All suspected soft structures, including the upper recess of the capsule, were cut away with a heavy pair of curved scissors. After a copious irrigation, the leg was extended and the vivified bone ends adjusted. The joint capsule was closed with catgut. The patellar fragments were adjusted and held together with a strong catgut, placed in the soft part at the outer and inner margin of the bone. The patellar periosteum was united by a running catgut suture. The integument was sutured with interrupted silk stitches. An antiseptic hygroscopic dressing

was applied and fastened with a roller, and the Esmarch tourniquet then removed. The extremity was placed on a Volkmann posterior tin split, the foot being kept elevated twenty-four hours. At the end of a week the dressing and sutures were removed. A small iodoform gauze pad was placed over the line of union, and the leg and thigh were placed in plaster of paris, which was worn for six weeks. The patient was allowed to sit up as soon as the plaster cast was hard. Weight was borne on the extremity during the seventh week. Bony union became firm, the final result being all that could be desired.

CASE 2.—Miss D. A., aged 20 years, had always enjoyed good health until the age of 16 years, when she fell and bruised her right knee, which became swollen and had remained so. She had intervals of apparent improvement followed by relapses, always leaving the periarticular tissues more swollen than before. During the last eight months the pain has been continuous. The swelling presented a doughy feeling to the touch; fluctuation could be made out beneath and to each side of the patella. The overlying skin was pale. She had undergone almost continuous treatment, but in spite of immobilization, protection, removal of superincumbent weight, intra-articular injections of iodoform emulsion and ignipuncture, she became continually worse. Operative intervention was recommended and agreed to.

Under chloroform anesthesia and a through transverse incision the joint surfaces were exposed. The articular cartilage of both tibia and femur was perforated in many places; it was detached along the outer portion of the tibial articulation. The synovia was thickened, soft and translucent. The joint cavity contained a fluid in which caseous material was suspected.

A section of bone including the articular surfaces was removed from the tibia and femur, and all suspicious soft parts clipped away. The leg was extended, the wound closed, dressed, and at once placed in a plaster-of-paris cast, which was removed in six weeks. Wound healed *per primam*. Another cast was applied, and the patient allowed to walk on it, aided by crutches. Recovery was complete.

CASE 3.—Mrs. C. E., aged 40 years, married, housewife, has always been well except for a stiffness of the right knee, which she has had since childhood, and which began after an injury, followed by swelling. She had had several attacks of pain, lasting from two weeks to six months, her present pain dating back one year. The condition of the knee was found to be semiflexion, swelling without discoloration, pain on pressure, inability to bear weight. There was indistinct fluctuation and much atrophy of calf and thigh. Immediate operation was recommended.

A transverse incision exposed a totally destroyed joint. The cartilage had almost entirely disappeared and was replaced by a thick fibrous mass, containing in it several hazel-nut-sized abscesses. The ends of the tibia and femur were removed, and suspicious soft parts clipped away. Bone ends were adjusted and the wound closed. The limb was dressed and put in a plaster-of-paris cast, reaching from metatarsophalangeal joints to the groin. The cast was removed in six weeks, and union was found to be complete. She was able to walk in eight weeks, and has remained well since.

CASE 4.—Miss J., aged 28 years, says she has suffered from a swelled, painful and stiff knee nearly twelve years. She has been treated with braces, plaster casts and local applications, and as a result has experienced freedom from pain at various times, so that she could

attend to her household duties for periods varying from five months to nearly two years. The writer has seen her at various times during the past four years and always recommended operative procedure until the present time.

Under chloroform anesthesia the articular surfaces were exposed by a transverse incision. The cartilage was found to be entirely destroyed and partly replaced by fibrous structures and granulation tissue, and the joint cavity was filled with a moderate amount of creamy odorless fluid. The joint surfaces were excised, and the affected soft structures removed. One bone cavity in the tibia extended below the line of section; it was scooped out with a Volkmann sharp spoon. After irrigation, the leg was extended, dressed and placed on a Volkmann posterior tin splint. After one week the extremity was placed in a plaster-of-paris cast for six weeks. On removal of the cast, bony union was not firm. A moulded leather splint, reaching from a point midway over the thigh to the middle part of the calf was applied, with advice that the patient bear weight on the leg. Union gradually became firm.

CASE 5.—Wm. B., aged 35 years, single, a farmer, says he injured his knee about ten years ago, resulting in swelling and pain, which never entirely left him. He has suffered many exacerbations, entirely incapacitating him for labor for varying periods.

At present his knee is swollen. All normal lines are obliterated, large bluish veins passing over the surface. There is a doughy sensation on palpation. The knee is sensitive on pressure. A fistula exists on the outer side of the upper end of the tibia, discharging on pressure a creamy odorless fluid. Demuded bone can be felt with a probe. There is no mobility of the joint. The condition was recognized to be tuberculosis. He suffered from general debility.

Under chloroform anesthesia the joint was opened by a transverse incision. Both articular surfaces were destroyed and replaced by a mass of more or less dense connective tissue, which was filled with a creamy fluid. On the tibial surface existed a cavity nearly one-half inch deep and in circumference as large as a twenty-five-cent piece. The patella was not involved. Two bone sections, one-third inch in thickness, one of the tibial and the other from the femoral end, were removed. It was found that the cavity in the tibia was not entirely included in the bone section, so the remainder was scooped away with a Volkmann spoon, the suspicious soft parts being clipped away. The wound was closed and dressed in the usual way, on a Volkmann splint one week, in plaster of paris six weeks. Union seemed complete. The patient went home on crutches. He returned in one year, with several fistulae about the knee. The left wrist and dorsum of the hand was swollen and fluctuated. Both lungs were involved. The wrist was incised and drained, which gave relief from pain. Nothing was done with the knee. He was sent home, where he died six months later.

CASE 6.—Mrs. K., aged 28 years, housewife, has one healthy child 3 years of age. She has always enjoyed fair health, except for painful swelling of the left knee, which began some eight years ago. The pain has never been acute, but has been more or less constant, with occasional exacerbations and remissions, but never entirely ceasing. There is much sensitiveness when the weight of the body is borne upon it. The swelling, which is devoid of redness, has very slowly but gradually increased; impairment of articular mobility has been progressive. She can not recall ever having had fever.

On admission we find a rather pale blonde of medium height, fairly well nourished, walking by the aid of a crutch. We find an enlargement of the left knee; no discoloration of the skin. The swelling is of a doughy consistency and sensitive on pressure; no fluctuation can be made out. This swelling extends upward into the upper recess of the synovial sac and downward as low as the insertion of the patellar tendon. The joint mobility is extremely limited and very painful. The patella seems to ride on a doughy springy substance. There are no fistulae. She has not menstruated for nearly three months. Pregnancy is suspected. Otherwise she enjoys good health. We conclude that we have to deal with a tubercular arthritis.

She has been under almost constant treatment since the beginning of her affection. The methods of treatment have been of every variety, including prolonged extension and fixation, counterirritation, etc. We concluded to employ intra-articular injections of iodoform and the internal administration of creosote. This method was faithfully carried out for nearly three months, with no improvement, but rather a change for the worse. Resection was then determined upon, which was accordingly done on January 7, through a transverse incision. We found the entire joint cartilage replaced by a vascular structure composed chiefly of granulation and connective fibrous tissue, a network of capillary blood-vessels, a condition spoken of by Hunter as pannus and a hyperplastic synovitis. Many miliary nodules could be seen. In several portions were noticed perforations filled with caseous substance, leading into the subchondral, cancellated bone structure, which were deepest on the tibial articular surface—the probable origin. The crucial ligament was softened and easily broken down; the synovial sac, which was greatly thickened, was lined with, and largely composed of, a greyish, fragile, fungus structure.

The articular surfaces, after separation of the softened crucial ligament, to the thickness of one-third of an inch were removed with a saw. It was found that the osseous defect of the tibia was not entirely included in the excised bone. The remaining bone cavity, the probable primary depot, was thoroughly cleaned with a sharp spoon. The entire synovial sac, together with all suspicious tissue was removed with a strong pair of scissors. After a copious 1 to 1000 sublimate irrigation, the exposed bone ends were adjusted, the wound was closed in the usual way. An antiseptic hygroscopic dressing was securely applied. The whole was placed and fastened on a Völkann tin splint, sufficiently long to reach the gluteal fold.

The progress was absolutely afebrile. The first dressing was removed in three weeks, when all sutures were taken out and the leg enveloped in a plaster-of-paris dressing, which remained for nearly two months, and, on its removal, bony union was complete. The patient has been entirely free from pain since and has given birth to a healthy child, passing through a perfectly normal puerperium.

Portions of the excised synovial sac, which microscopically presented a pale, anemic, soft, nodular, fragile appearance, exhibited microscopically clusters of miliary tubercles, in section of which were easily recognized small round, epithelial and giant cells, containing tubercle bacilli. The contents of the cavity in the tibial head was made the object of the most careful study, and it was not difficult to find tubercles with the characteristic microbes located on and in the walls of the cavity. Neither tubercles nor bacilli could be found

in the caseous mass itself, which was the result of retrograde changes, due to a local anemia and the products of tubercle bacilli, the mass consisting of a coagulation necrosis and caseation, usually containing no formed elements.

CASE 7.—E. D., aged 25 years, a clerk, single, has suffered from a swollen and painful knee for seven years. He has been under orthopedic treatment nearly the entire period, and has had periods of freedom from pain for varying periods during this time. Joint immobility has existed from the commencement. We find a swelling involving the entire joint, with fluctuation in its inner aspect. The condition is one of typical tuberculous. Exploratory incision was recommended, to be followed by resection or amputation if necessary.

Under chloroform anesthesia an incision beginning at the outer margin of the patella, extending backward almost to the hamstring, freely admits the index finger, which reveals a panarthritis, with complete destruction of the articular cartilage. A typical resection is made, the final outcome of which is painless. He has a useful but stiff extremity.

Excision of the knee-joint is no longer an experiment. This operation has found a permanent place in surgical procedure, and while the method of procedure and detail may still be a matter of discussion, the object to be attained is a settled one.

Surgeons still take issue as to the time when operation is indicated, but all agree that when a reasonable amount of mechanical and local treatment has not stayed the progress of the disease nor improved the condition, operative intervention must be resorted to. All agree that a stiff extremity is preferable to the best artificial limb, and amputation becomes necessary only when the pathologic factors have either transcended certain bounds, or secondary infection threatens, or when employed as a life-saving measure.

Early recognition and early treatment in the critical stage of joint tuberculosis can not be too greatly emphasized. Rheumatism, sprain and growing pains too often mislead to a false security. The awakening to the true state of affairs occurs only when the mischief has become irreparable. Every painful knee-joint must be regarded with serious consideration. It is better to err in the direction of ultimately finding a painful knee-joint a simple traumatism, than to mistake a tuberculous knee for a sprain or contusion.

When shall we resect the knee-joint for chronic inflammatory disease? Here we differ, sometimes widely, owing it seems, largely as the bulk of our cases come to us in private or hospital practice. Those who see their cases early and appreciate their true nature, will see a large percentage of them recover by non-operative means. While the hospital surgeon has to deal chiefly with the chronic, badly managed and neglected cases, he naturally finds the bulk of his subjects suited only to radical operative intervention.

When considering our cases we note that they were all late resections. I am convinced they were unnecessarily late. Had radical procedures been adopted earlier, we could in all cases have saved much suffering and much time, which is so valuable to the class of individuals who comprise the larger number of these cases. At least one life, Case 5, might have been saved. Does an individual gain anything who recovers with an ankylosed joint after two or more years' mechanical treatment? Would it not be advisable in all cases where we are convinced that the ultimate outcome will be ankylosis, to open the joint early, excise all diseased structures,

and save from one to two years of pain, at the same time restoring the individual to usefulness? The outcome of chronic knee tuberculosis is a fixed joint and more or less deformity. Resection produces a stiff joint minus the distress, incapacity, loss of time, possible metastatic infection and deformity, and in some cases prevents loss of life. I believe it to be correct practice to resort to early exploratory incision, provided improvement has not commenced in three, or at most four, months. Explore the joint with the finger, and in certain cases expose the articular surfaces to ocular inspection, as we have done repeatedly in traumatic infected cases. If the joint cavity is free from tubercular infection no harm can be done. If the primary focus can be found it can easily be removed. If the joint surfaces are destroyed, time is gained by their early removal.

Our plan has been, if after two or three months of mechanical management no improvement has been noted, or if after even a month, no progress has been made, to explore the joint by puncture or incision. If the exploring finger found limited lesions, irrigation was done, if small bone lesions could be detected, curette. If the articular surface was involved, enlarge the incision and excise. If the cases were old and had undergone more or less treatment, resection was recommended.

The seven cases of resection in our series do not comprise the entire number in whom this operation was indicated. In a number of those that passed from observation, radical means were insisted on, but were refused by patients and friends. It will be noted that our resections were all in adults.

As we pass to the consideration of the method of operative procedure in our cases, the one which served us seemed the simplest possible. The transverse incision of Volkmann was employed in all. Without entering into the relative merits of the incisions employed by Fenwick, Olliver, Heuter and others, there certainly is none that more quickly, simply and completely exposes the entire joint surfaces than the transverse. The facility with which the affected bone and soft structures can be removed can hardly be improved on. The excision of the diseased tissues was always carried out with extreme care, cutting well into healthy structure. The bone section was always made parallel with the articular surfaces. The V-shaped section of Phelps and mortises by others were never attempted. There never was difficulty of maintaining the sawed ends of the bones in apposition. The method of closing the joint capsule and uniting the patella as described in our first case was adhered to in all. Bone pegs, nails or wires to hold the bone in apposition were never used, experience having proved that they are not only unnecessary, but useless and sometimes harmful. They prolong the operation. They are fastened in cancellous structure which can not hold firmly if strain should be put on them, and in most cases must be removed by secondary operation.

Bilateral tubular drainage was used in several cases, but as we gained more confidence in our aseptic procedure, it was omitted. When much oozing after more than ordinarily extensive operation was anticipated, the extremity was placed for a week on a Volkmann posterior splint, and then in a plaster-of-paris cast reaching from the metacarpophalangeal joint to the groin. I am convinced that in the majority of instances the plaster cast can be applied immediately.

Two of our cases underwent amputation because the tubercular process had invaded the shaft of the long bones, and we were not at all sure that the tubercular process could be entirely removed.

Antituberculous medicaments were not given internally after these radical operations. Abundant food, good air and sunshine will restore these individuals to vigor in less time than any pharmaceutical preparation of which I have knowledge.

DISCUSSION ON PAPERS BY DRs. MOORE AND JONAS.

DR. DR. FOREST WILLARD, Philadelphia.—Dr. Moore has certainly indicated the proper method of procedure in cases of tuberculosis of fascia, where we are satisfied that the bone is not diseased, or where, upon laying open the sinus, there is no implication of bone. The free laying open of the sinus, no matter if it is twelve inches in length, and the excision of all tubercular tissue is the only form of removal that is likely to give us quick and positive results. We know of no caustic that is to be compared with the knife and scissors; they only are the proper tissue destroyers in tuberculosis. With the thorough excision of all diseased tissue at the time of operation, and immediate closure, we can hope for excellent results. In regard to knee-joint tuberculosis, it is difficult to lay down any positive rules for operation, but I think that the most certain indication that we have, or the rule we must apply most frequently, is in regard to the age of the patient. The method of procedure that should be carried out in young children—that is, whether we shall adopt radical or conservative measures—will depend upon a variety of conditions. By conservatism I do not mean the conservatism of doing nothing or little; I include in conservatism everything even to amputation. As a rule excision in children should be practiced early; remove the tubercle foci, hard and soft, and you will give the individual not only a good limb but one of considerable length; that is the important point. So often when children's knees are excised, we have shortening of three, four, or five inches, giving a useless limb; but if we can do two or three operations of excision, avoiding the epiphyseal lines, get rid of all the tubercle foci, we have benefited him exceedingly. Excision I do not like in children: excision is far better. With adults, excision and amputation come in most largely; excision is ordinarily preferable, but the line must be drawn between children and adults.

In regard to injections of iodiform I desire to go on record most absolutely and positively as among those who have from experience become dissatisfied with its use. It may be that I am less cleanly than others and yet I yield to no man in my belief in the practice of absolute cleanliness, but I must say that my experience in injections of iodiform is that it is worse than worthless, and that it often increases suppuration. Yet I believe that I have been absolutely cleanly in these injections.

In regard to extreme conservatism, I do not believe in it; I believe that we should be conservative in every case, but that necessary operation is often conservatism.

In knee tuberculosis, early diagnosis is of the utmost importance: the time to treat knee tuberculosis is the first two weeks. Let us get rid of the false idea that rheumatism is common knee-joint disease in the hip in children. Let us consider and treat these cases as tubercular ones, and not go on for one or six months with the death-dealing plan of saying that it is "only rheumatism." I believe that tuberculosis can be arrested, if taken early.

DR. H. M. SHERMAN, San Francisco.—Dr. Moore's paper illustrates what has been experienced by all of us, that we should open a tubercular abscess and find that it is not connected with a bone, but in the soft tissues. Some of us have at times treated a joint for tuberculosis where the lesion was tuberculosis in the muscles near the joint. The question is one which is annoying, for one is liable to keep a child on an apparatus for a considerable period of time which would be unnecessary. I have done this sometimes and have seen it done by others. The differentiation between a soft-tissue tuberculosis and one originating in the bone is an exceedingly difficult matter when the abscess is close to the joint. I do not know of any way of definitely doing this short of the use of the X-ray. So far as I understand that at present, a great deal will depend upon the way the showings of the X-ray are interpreted. If, in a given case, the abscess is found to be not connected with the bone, it would be proper and wise to follow out the plan of Dr. Moore. If it is connected with the bone, then that is a complication of the bone lesion and must be considered to be one of the symptoms. From its title, that it would take up the diagnosis of the focus from its title, that it would take up the diagnosis of the focus of tuberculosis at the knee-joint before it had gotten on to infection of the joint itself. In that lies the best chance and practice for treatment of knee-joint tuberculosis—the early

recognition of the location of foci and their removal before the joint is attacked. Dr. Jonas is right in saying that we frequently do not know whether the lesion is primarily in the synovial membrane or bone, but as it is in the bone in the vast preponderance of cases, we must assume that it is there until the contrary is proved. One's guide is one's knowledge of where the foci are usually found in the bone, and the testimony of the X-rays to definitely locate them will help one in saving the joint. These cases, locally do not need a drug. Iodoform is, so far as my experience goes, an inert drug. One question as to the management of focal tuberculosis is how the growth of the limb be affected afterward. All of the cases that I have operated on have had certain injury done to the epiphyseal cartilage and following that there has been partial inhibition of the growth of the limb; however, the joint was an active, useful joint, and the limb was perfectly useful, with the help of a little wedge underneath the sole. One more thing regarding excisions. I do not think it wise to begin an excision of the knee unless the surgeon has full permission to amputate it, in the course of the operation, it proved necessary to do so.

Dr. J. E. MOORE, Minneapolis, Minn.—I have nothing further to say for my own paper. In discussing Dr. Jonas' paper, in answer to his question: Would it not be well to operate on these cases early? I would say, "yes," with the same reservation that Dr. Willard put—provided the patient is old enough. Excision of the knee-joint in children is scarcely justifiable under any condition. If the child were my own, and there was a useless limb after erosion or mechanical treatment, I think I would prefer to have it amputated, because these joints always become deformed in later years and are an imbrance, not as good as a good artificial limb. If the patient is over 18 to 20—yes, excise early, where your conservative measures are failures—when the patient is growing worse rather than better. I want to go on record as to the uselessness of iodoform in the local treatment of tuberculosis. I have some results in other directions, but not in tuberculosis. There was a time when I used the Esmarch. Since I have ceased using it I have less oozing of blood. I have for the last three or four years employed the method first suggested by Ferguson—making a slight ridge transversely in the femur and a corresponding gutter transversely in the tibia. Thus, I am sure that my toes will not rotate too far out or in. You can do this without shortening the limb to any degree. Just one word about conservatism: I wish to insist that conservatism does not consist in simply refusing to use the knife. The best conservative agent I know is the knife, in good, skilled, judicious hands.

Dr. A. F. JONAS, Omaha, Neb.—One is always very much at a disadvantage when reading a paper in the abstract.

The great difficulty in this subject is early diagnosis. They come on with a sprain or with rheumatism for years before the patient gets into the hands of the surgeon.

By conservatism I mean anything that conserves the function of the joint for the individual—whether it is necessary for that purpose to use a knife, sharp spoon or any other instrument; that is conservatism. To let a thing alone is criminal. To do something for the purpose of restoring the function I believe is conservatism. For that reason I have recommended that we shall make early operations. If we find after mechanical treatment that we have made no advance in treatment, make an incision in the edge of the patella, exposing the healthy joint. If you find nothing, close it up again and you have done no harm; if you have proceeded in an aseptic manner you have restored the joint to the best possible condition. I wish to place myself on record with the other two speakers—that I have never obtained one good result from iodoform emulsion. I have not made anybody worse, but I do not recall a case made better by it. I have had better results with carbolic or sublimate solution.

THE LONGITUDINAL SILVER-WIRE SUTURE.

"EN ETAGE" IN THE CLOSURE OF WOUNDS.*

BY M. L. HARRIS, M.D.

PROFESSOR OF SURGERY, CHICAGO POLICLINIC,
CHICAGO.

Excluding the viscera, etc., the most important incisions to consider: 1, accurate coaptation of like structures; 2, the suture material; 3, the method of applying the suture. All surgeons agree as to the end to be accomplished, differences existing only as to the means.

*Presented to the Section on Surgery and Anatomy, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1909.

Excluding the viscera, etc., the most important incision with which we have to deal is that of anterior median celiotomy, and while our remarks are pertinent to incisions generally, they find special application in the closure of this one.

That like structures should be coaptated in order to restore as nearly as possible the normal relation of the parts is so universally recognized that no argument is necessary to support the statement. The coaptated parts should be in intimate contact throughout in order that union may take place with the production of the least possible amount of cicatricial tissue, as the lesser the amount of new connective tissue formed between the divided edges, the more intimate and firmer the union.

The selection of the suture material can not rest simply upon individual preference, but merit must decide. The points which specially enter into competition are: 1, ease and certainty of sterilization; 2, imbibition capacity or extent to which fluids are permitted or favored to pass along the suture. Other points which may be raised for or against the various suture materials are of minor importance in comparison with the two just mentioned. Only the more commonly used materials will be considered—catgut, silk, silkworm gut and wire—as these four represent each a distinct class.

Concerning the first point, sterilization, there can be no question as to the certainty of being able to sterilize all these materials except, perhaps, the first. Wire is certainly the easiest to sterilize, with silkworm gut next. Both these materials simply requiring boiling a few minutes in water, and may be easily prepared with the instruments each time as needed. Silk, to be absolutely reliable, requires fractional boiling, hence, must be prepared beforehand and preserved ready for use. With catgut the question is not so simple. While I think catgut can certainly be sterilized by any one of several methods, still the methods are time-consuming, and considerable experience is necessary with some of them in order to insure perfect results.

The second point, imbibition capacity or the passage of fluids through or along the suture, is of very great importance, for to this property is due most of the secondary infections, stitch-hole abscesses, etc. It is well known that it is practically impossible to render the skin and its glandular appendages germ free. Lauenstein states that even after repeated or, better still, several daily disinfections by the most approved methods, the skin was found germ free only 33 times in 58 cases. A suture, then, which passes through a germ-containing skin, by imbibition or capillary attraction, may permit germs to pass with the fluids from the superficial to the deeper portions of the suture tract, where, the tissues being less immune than the surface epithelium, the germs develop and local infections take place.

The facility with which the different suture materials here considered permit or favor this infection of the deeper tissue has been very thoroughly studied by Troller². Briefly, Troller proceeded in the following manner: Operation wounds, produced under the strictest technic, were sutured in the usual manner with the different materials here under consideration. Control experiments showed the suture materials were sterile when used. After forty-eight hours the sutures were removed and divided into two portions, the extracutaneous and the subcutaneous portions, or that part which lay on the skin was separated from that part which was buried in the tissue. These separate parts were then ex-

¹ Arch. f. Klin., B. III, H. 1.

² Beitr. zur Klin. Chir., B. xxii, H. 44.

amined bacteriologically, with the following results: The subcutaneous loop was found germ free in 82.4 per cent. of the wire, in 60 per cent. of the silkworm, in 30 per cent. of the silk, and in 25 per cent. of the catgut sutures. The extracutaneous loop was found germ free in 53 per cent. of the wire, in 7 per cent. of the silk, and only in 4 per cent. of the catgut sutures.

The germs found on the subcutaneous loops were always of the same kinds and varieties found on the skin and the extracutaneous loops, showing conclusively that the germs had gained the deeper parts of the tract by being transmitted along the suture material by imbibition or capillary attraction. When judged by the two points mentioned above, namely, facility of sterilization and imbibition capacity, the materials stand in point of excellence in the following order: wire, silkworm gut, silk, catgut.

It will thus be seen that wire, either aluminum, bronze or silver, heads the list of suture materials. The next point for consideration is the method of application.

It is not the intention to discuss the various methods of suturing commonly employed, but to direct your attention to the technic and the advantages offered by the longitudinal silver-wire suture. It is called the longitudinal suture because it parallels the wound. The idea of a longitudinal suture is not new, as it dates back to Chassaignac, who in 1852 employed a silk suture, extending lengthwise, and lying beneath the surface, which he called "suture celluluse" or *sous-cutanee*. The subcutaneous continuous catgut suture has long been used by many, and Daurand, in 1896, in a thesis, again elaborated the many advantages of the "suture intradermique." The use of silver wire for the subcutaneous suture had its origin in Johns Hopkins Hospital.

I have extended the use of the longitudinal suture so as to include, not only the cutaneous edges but the deep layers as well, making a longitudinal suture "en etage." The suture will be described in connection with an anterior median celiotomy. Three layers are employed: peritoneal; fascial or sheath of rectus; subcuticular.

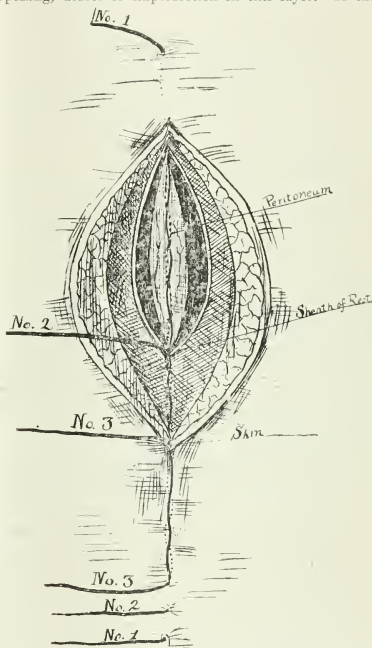

For the peritoneal layer, silver wire No. 24 to 22 is threaded directly to a smooth, round, non-cutting, curved needle. The needle is made to enter the skin in the midline, one to three centimeters from the angle of the incision, and penetrate obliquely all the tissues down to the peritoneum, where it should appear at the angle of the peritoneal incision. The obliquity of the transfixion prevents too sharp an angle in the suture at the peritoneum.

The peritoneum is now taken up with the needle, parallel with and quite near to its edge, first on one side and then on the other, constantly in an advancing manner until the entire length of the incision has been traversed. The grasp of the needle should not be more than a centimeter in length, and the point of entrance of one grasp should be but very slightly in advance of the point of exit of the last grasp. The suture is then brought obliquely to the surface about the same distance from the cutaneous angle at its point of entrance. The second suture, wire No. 22 to 20, enters in the midline, but a little nearer the angle of the incision. It penetrates as far as the sheath of the rectus muscle, where the edges of this fascia are taken up longitudinally in exactly the same manner as has just been described for the peritoneum.

No sutures are applied to the recti muscles. At no point in the midline do the recti muscles lie in contact with each other, hence, in closing a median incision it is unnecessary to suture together the recti muscles

with the expectation of obtaining union between them. The dense, thick, conjoined fascia of the linea alba in the upper part of the abdomen of the firm anterior layer of the muscle sheath below Douglas' fold is the all-important layer to be sutured. This is the layer in which the most perfect apposition, edge to edge, should be secured.

Ventral hernia never occurs with this layer covering the sac, but the sac invariably protrudes through an opening, defect or imperfection in this layer. If this

Showing the three layers of wire sutures in partially closed medial incision. Suture No. 1, peritoneal suture; No. 2, suture of fascia; No. 3, subcuticular suture.

layer be perfectly restored, if the edges be accurately coaptated and the union secured throughout between them, with the production of the least possible amount of cicatricial tissue, ventral hernia will never occur, regardless of the relations of the recti muscles.

The great trouble with all transverse or transfixion sutures is that the edges of this layer are not accurately coaptated, but gaping takes place between the stitches, thus materially interfering with perfect, close, definitive union. If the finger be passed along the line after the usual transverse suture, the tip may frequently be felt to engage in the small defects caused by the gaping between the stitches and at such places the occurrence of a ventral hernia may often be predicted with reasonable certainty. By the use of the longitudinal silver-wire suture, as here described, the edges of this fascia are

accurately coapted throughout in the most perfect manner, and the finger passed along the line of incision meets with a firmness and solidity of union not found in any other method of suturing.

The third suture is the usual subcutaneous or subcuticular suture. The wire enters and leaves at the angles of the incision running along in the corium, in and out, in the same manner as has been described for the other two. It does not appear on the skin at any point except where it enters and leaves. After the wires are introduced, they are drawn back and forth until they are perfectly straight and move easily through the tissues. The wound may now be dressed in any manner one chooses. The method I use, and think the neatest and best, is to seal the line of union with silver foil after Halstead. Place on this a compress of a few layers of plain sterile gauze over which are folded the ends of the wires, which should be left long. On these is placed another similar compress followed by the usual dressing of plain sterile gauze and cotton.

The wires are usually allowed to remain from ten days to two weeks. To remove the wires, they should be drawn back and forth gently until loosened in the tissue then one at a time cut close to the skin and withdrawn. They are easily removed, with scarcely any pain. Care should be taken not to break the wires by pulling suddenly before loosening them.

While the suture has been described in connection with the closure of median celiotomy incisions, it finds many other valuable applications. In closing the muscle-splitting incision in interval operations for appendicitis, one wire parallels the fibers of the internal oblique and transversalis, entering and leaving the skin some distance from the cutaneous incision, and crossing it almost at right angles. Another wire parallels the fibers of the external oblique, and a third forms the subcuticular suture.

In the radical operation for hernia after the general plan of Bassini, I think it a most valuable suture. The first wire unites the conjoined tendon with the inner edge of Poupart's ligament, closing firmly this layer, leaving but sufficient opening at the internal ring to permit the safe exit of the cord. The cord is then laid on this layer and a second wire paralleling the external oblique securely closes this layer with the exception of a small external ring. The usual subcuticular wire completes the operation.

I can not speak too highly of the longitudinal silver-wire suture "*en etage*" in the radical operation for hernia, as the results have been so very gratifying. There are no absorbable sutures to soften or non-absorbable sutures to come out at some future time. Other uses of this method of suturing will readily suggest themselves.

In addition to the reasons already given for selecting silver wire as the suture material, it possesses another distinct advantage over all other materials when applied longitudinally, in its rigidity. When the wire is drawn straight the edges of the wound are kept in perfect coaptation, the rigidity of the wire preventing the slightest gaping or bulging. The application of lead plates, shot, buttons, rolls of gauze, etc., to the wire to keep it tense are entirely unnecessary.

The technic of application of the suture is very simple; the following points, however, are of sufficient importance to merit mention: Keep the wire perfectly smooth, and free from kinks; do not draw the wire all the way through at each stitch, but have only sufficient lead to permit the use of the needle; draw the suture straight, and see that it can be moved easily through the tissues.

It is not advisable to have a single suture through firm, deep tissues longer than 15 cm., owing to the possibility of breaking it when attempting to withdraw it. A suture may be brought to the surface at any point and another one begun without in the least weakening the line or modifying the principle.

The advantages of the longitudinal silver-wire suture may be briefly summarized as follows:

The material can always be sterilized with ease and certainty.

It is non-hygroscopic, consequently does not convey infection to the deeper tissues thus producing stitch-hole abscesses, etc.

The edges of the wound throughout its various layers are more perfectly coapted than by any other method of suturing.

The accurate coaptation leads to an intimate union with the production of the least possible amount of new-formed connective tissue, and hence the greatest possible strength of union.

The very narrow linear cicatrix is a great improvement in a cosmetic sense, as there is an absence of the numerous lateral stitch-holes, the scars of which are often more disfiguring than that of the cut itself.

The suture will withstand any desirable amount of traction without yielding.

It can be easily and quickly applied.

DISCUSSION.

DR. J. P. LORD, Omaha, Neb.—I am greatly impressed with the value of this method, as exemplified in this paper. Following the work of those who early introduced the use of the buried silver-wire suture, I had some experience in the use of silver wire, and came to the conclusion which has been arrived at by those who worked with it, and that is that it is of no value as a permanent support. I discarded the deep silver-wire suture. I have used wire, wormgut and catgut for my superficial skin wound closures. I have used all of them; and I have buried them, to suit my fancy in individual cases. I, too, have recognized the relative merits of the different materials, and have acknowledged the superiority of wire; yet with the thorough methods of preparation which we have for silkworm gut, I have confined myself mostly to the silkworm gut for subcutaneous sutures. With this experience—which has been considerable, having closed most of my hernia incisions, most of my face-wound incisions with subcutaneous stitches—I have had opportunity to judge of the value of the subcutaneous method. Now, as the doctor has demonstrated the utility of the temporary silver-wire suture in the deep structures as well as in the skin-wound sutures, I am particularly impressed with the value of his method, so much so, that I am going to investigate its value. I believe that this is founded on scientific data given you in the percentages of the risk in the use of these different materials, and following out his technic, as given us, I believe much is to be gained in the use of this method.

DR. J. B. EGGLESON, Seattle, Wash.—Is the silver wire as easily removed as the silkworm gut?

DR. W. J. MEANS, Columbus, Ohio—I have been very much interested in the method of closing incised wounds by subcutaneous removable sutures, as outlined by the author in this paper. I have been using the same method in part for several years. It has been my experience that silkworm gut is much easier placed than silver wire, but harder to remove. I have had the wire break in removing it in a few cases. The suture is much harder to remove from the integument than from the fascia or peritoneum.

During the past two years I have been using galvanized, annealed steel wire. It was suggested by Dr. Baldwin of Columbus, and I believe, he has been using it almost exclusively. This wire is much stronger than silver wire, fully as pliable, and is tolerated by the tissues just as kindly. I have never had a suture of this material break in removing it. It is much cheaper than silver wire. I suggest a trial of this wire to those who use the subcutaneous method of closing incisions. It can be had at any good hardware store.

DR. M. L. HARRIS, Chicago—The silver wire is as easily removed as silkworm gut. The influence of silver on wounds has been found to be beneficial. The silver wire probably stands at the head of wire materials in the percentage of non-

infection of the deep parts. This is the particular advantage of still adhering to silver wire: There is less infection of the deep tissues following the use of silver than of any other wire, except perhaps aluminum bronze, which has also been found to have a beneficial effect when in contact with living tissues. These wires are superior to any of the iron wires which have been used.

FEMORAL ARTERY AND VEIN.

THEIR DESTRUCTION WITHOUT LOSS OF LEG.*

BY B. MERRILL RICKETTS, Ph.B., M.D.
CINCINNATI, OHIO.

The experiments of Niebergall upon the circulatory system have shown that the upper and lower extremities have many times been needlessly sacrificed. It was shown by him that the resistance of the valves of the veins could be overcome by moderate arterial pressure, thus making it unnecessary to ligate the artery in cases of venous occlusion. Branne taught that the presence of these valves precluded the possibility of collateral circulation, and that ligation of the vein alone would render gangrene inevitable.

The modern methods of dealing with blood-vessels have proved beyond peradventure that many teachings concerning them are fallacious, but, like the progress in all other departments of science, many erratic steps must be taken before the goal is reached.

While the anastomosis of arteries and veins has been accomplished, it has not been as satisfactory as hoped for. It has been shown that the lumen of an ass's abdominal aorta may be sufficiently restored by end-to-end anastomosis to permit of constant and sufficient circulation. This demonstration was the basis upon which all subsequent work in this direction has been done.

So far as the work with the blood-vessels of the human body is concerned, nothing has been presented which is at all satisfactory. The experiments of both end-to-end and lateral anastomosis in the smaller animals and the actual work with the human blood-vessels have shown that complete occlusion sooner or later takes place, thus showing that the results are no better than the immediate occlusion by ligatures. It is safe to say that sepsis has been more responsible for gangrene—especially in the moist form—than simple occlusion.

The older operators of this country found gangrene resulting from ligation of the subclavian artery—outer third—in from 8 to 12 per cent; external iliac artery 12 to 20 per cent; femoral artery 10 to 15 per cent. The mortality of ligation of the femoral artery is shown by the following reports:

	Operations.	Deaths.
Norris' tables	204	50
Crisp's tables	122	15
Grey's Hospital, 1862 to 1876	24	4
Syme	23	0
Pennsylvania Hospital, 1868 to 1876	11	2
G. H. Potter	5	0
McNamara	8	1
Gross	2	1
Total	399	*70
*23 per cent.		

Ligation in these cases was, no doubt, for various causes; and it is fair to presume that the leg was preserved in all in which death did not occur. The cause of death in four of Norris' fifty deaths is not stated. Twenty-three died from gangrene, eight from hemorrhage, five from phlebitis, one from sloughing of the sac, three from tetanus, and the rest from "fever, hectic, pyemia, etc."

These compilations, like many others, are very unsatisfactory. They do not show at what point upon the artery the ligature was applied, or the cause of its application. They do, however, indicate that the percentage of cases resulting in gangrene or death is far greater than with the modern method of doing the work.

Of the 299 operations reported by Norris, 7 per cent. resulted in gangrene. These percentages have been very much reduced during the days of more recent antiseptic surgery.

The obstruction of veins occurs as often, and is as serious as when it occurs in arteries. The sudden obstruction of either is likely to produce moist gangrene, while slow obliteration results in dry gangrene. Careful consideration of the collateral circulation of the thigh would doubtless disprove the statement that there is more danger of gangrene ensuing from a ligature applied between the epigastric and profunda than when it is applied either above or below them. Langenbeck's philosophy, which taught that it was necessary to ligate both in case of injury of one, has, like that of Branne, been proved erroneous. Hunter, who was the first to ligate the artery in the canal bearing his name, thought it safer to ligate the external iliac artery than any part of the femoral artery.

Billroth mentions a case of chronic occlusion of the ascending vena cava, collateral circulation having been established by the superficial veins, which could be seen enormously distended. Dr. R. J. Pumphrey of Massillon, Ohio, reports by private correspondence recovery in a case of injury during operation for strangulated hernia to both the femoral artery and vein, which necessitated complete occlusion of both by ligature; recovery was uneventful.

Dr. H. K. Adams of Maysville, Ky., reports a case of a male, 40 years of age, who received a pistol ball in the right Scarpa's triangle; the femoral artery was partially severed; large clots and distension prevented death from hemorrhage for forty-two days, when the leg was amputated below the knee, sepsis no doubt being more responsible for gangrene of the foot than mere occlusion; recovery followed with a useful knee-joint.

My own experience is limited to the following three cases:

CASE 1.—A male 38 years of age, with strangulated femoral hernia; the femoral vein was ligated below Poupart's ligament, for laceration; no unfavorable results.

CASE 2.—A male, 42 years of age, with sarcoma of the left iliac fossa; the external iliac vein was lacerated during operation; ligation without any indication of occlusion.

CASE 3.—A male 36 years of age, with sarcoma of the sheath of the sartorius muscle; new growth about three pounds in weight; incision extending from Poupart's ligament to knee; both the femoral artery and vein, together with the sartorius muscles were so entangled in the new growth that their removal was necessary; a former extirpation of the growth no doubt made their removal more difficult. Recovery was rapid and uneventful, comfort and the use of the leg being assured for eight months, at the end of which time the new growth caused him to take his bed, upon which he will soon find relief in death.

Either one of the following varieties of the femoral artery may exist, and thereby explain how the leg may be nourished when a femoral artery is ligated, especially if either one or more of them should be present with an apparently normal femoral artery.

"1. The femoral artery may divide below the origin of

*Presented to the Section on Surgery and Anatomy at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1898.

the profunda into two vessels which reunite at a variable distance above the opening in the adductor magnus, to form a single popliteal artery.

"2. A vas aberrans may leave the external iliac artery and running by the inner side of the common femoral artery, may join the superficial femoral about the apex of Scarpa's triangle.

"3. The main artery of the limb may be found wholly at the back of the thigh, and be derived from a greatly distended sciatic artery.

"4. The profunda may arise from the inner or from the posterior side of the main vessel, and may take origin more than one inch or less than two inches below Poupert's ligament.

"5. The circumflex arteries may arise in whole or in part from the femoral; this especially applies to the internal circumflex.

"6. The femoral may give off the deep epigastric, the circumflex iliac, or the great saphenous artery. The last named vessel arises above or below the origin of the profunda, and passing along Hunter's canal, becomes superficial at the inner side of the knee, and follows the internal saphenous vein to the ankle." (Treves.)

CONCLUSIONS.

1. Amputation of the leg is not always necessary when the lumen of the femoral artery or vein or both, is suddenly or slowly occluded by injury or otherwise.

2. It is better to ligate the femoral artery or vein, or both, and give the patient the benefit of a doubt than to amputate immediately.

3. It is impossible to determine the circulation of the thigh or any given part of the human body without a complete dissection, which can only be done post-mortem.

4. Ligating the femoral artery or vein, or both, in the various pathologic conditions of the thigh, seems less likely to result in death or gangrene than when the ligature is applied in case of accidents in a normal thigh.

5. It can not be determined what role, if any, any one of the six varieties of the femoral artery has played in any case in which the femoral artery or vein, or both, have been ligated, as no record of dissection seems to have been made.

6. While end-to-end anastomosis may be accomplished, complete occlusion sooner or later takes place.

7. Suturing and the application of ligatures to arteries and veins which have been lacerated have no advantage over complete immediate occlusion by ligature.

8. Gangrene is possibly due to septic infection and not merely to the occlusion of the femoral artery or vein, or both, unless the vessels for collateral circulation are absent.

9. The preservation of the leg does not seem to depend upon the ligating of the femoral artery or vein, or both, at any particular point.

DISCUSSION.

DR. THOS. H. MANLEY, New York City—This paper of Dr. Ricketts is peculiarly rich in suggestion and raises so many points for discussion, that to cover them all would be impossible, within the range of time permitted. Those of us who have made an experimental study of the circulation must come to the conclusion that all the phenomena of the circulation are not altogether understood by the physiologist. As an illustration of that, in the course of my own experiments I ligated the aorta, the iliac and the brachial arteries of a frog, but found that the circulation went on quite the same as when the heart was unhampered. I found, therefore, that the circulation was to a certain extent quite independent of the heart's action. The point raised by Dr. Ricketts is a very important one, and I have been able to verify it several times in cases of moist gangrene: the primary trouble beginning in the veins. It is probable that in almost all these cases where

the senile changes set in the primary lesion is in the veins of the periphery of different areas of the trunk. We have also found lately that what has been submitted by Bennett, in the operation for varicose leg, is another rebuttal of the theory, showing that the simplest way to treat a varicose vessel is to strip the saphenous vein, choke off the circulation, divide it, and destroy the vein, thereby diverting the blood from the periphery to the center, although the distal distended veins remain.

TUBERCULOSIS OF PHARYNX.*

WITH PRELIMINARY REPORT OF TUBERCULOUS INFECTION OF TONSILS AND LYMPHOID TISSUE OF NASO-PHARYNX.

BY CLEMENT F. THEISEN, M.D.

Instructor in Diseases of the Nose and Throat, Albany Medical College; Attending Laryngologist and Rhinologist to St. Peter's and the Child's Hospitals.

ALBANY, N. Y.

It is a strange fact that although pulmonary tuberculosis carries off more of the human race than any other disease, its local manifestations in the upper respiratory tract occur with comparative infrequency. The larynx is much more often affected than the pharynx. In 1226 cases of tuberculosis, Heinze found the larynx involved in 276 or 30.6 per cent. Mackenzie, in 100 cases in the second and third stages, found changes in the larynx in 71. Tuberculosis of the pharynx must be regarded as an extremely rare condition. Lennox Browne¹² states that acute tuberculous sore throat occurs in about 1 per cent. of all cases of tuberculosis of the upper air-passages. This percentage, according to the consensus of opinion, is if anything too large. Willigk, in 1307 autopsies, found only 1 case of pharyngeal tuberculosis. Bosworth¹⁸, who thinks that tuberculosis of the fauces is an evidence of acute miliary tuberculosis, has only seen 5 cases. Levy²⁰ has reported 162 cases of tuberculosis of the pharynx and larynx. In 17 of these, the pharynx only was diseased. It is rather difficult to explain if the statement made by Wright¹⁷ and Schmidt²⁶, that the tubercle bacillus may penetrate the perfectly intact epithelium, is correct, why tuberculosis of the pharynx is so rare, as bacilli are frequently found in the nasal cavities and throats of healthy people. Strauss⁵ examined the dust and mucus from the nasal cavities of 29 persons, all in the best health, with no indications of tuberculosis. Bouillon cultures were made and the fluid injected into 29 guinea-pigs. Injections were made into the peritoneum: Seven died of septicemia or purulent peritonitis, 13 remained healthy and 9 got tuberculous processes, which plainly started in the peritoneal cavity.

In children pharyngeal tuberculosis is even a much rarer condition. Schifferowitch³, in a thorough search of the literature, has been able to find only 87 cases reported up to 1887, and only 1 case in a child—6 years old. Other cases of faucial tuberculosis in children have been reported by Siegert²⁹ and Geel. In one of Siegert's cases, that of a boy aged 11, there were present superficial ulcers of both tonsils, mucous membrane of soft palate, uvula and a portion of the posterior wall of the pharynx. There was also tuberculosis of the lungs. In the second case, a girl of 4½ years, the ulceration involved the right side of the soft palate, the right palatine arch and the left faucial pillar. The lungs were not involved in this case. In Geel's case, a child 7 years old, there were tuberculous ulcers of the soft palate, uvula, base of tongue and epiglottis; there was also pulmonary

*Presented to the Section on Laryngology and Otology, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1890.

tuberculosis. Frobelius² has recorded 18,569 autopsies of infants in the first four months of life, in 416 of whom tuberculosis was the cause of death; the pharynx was not affected in a single case.

Pharyngeal tuberculosis is as a rule secondary to the lung involvement, or may be coincident with it and is usually a symptom of acute general tuberculosis. In many cases the sputum causes the infection, but in the large majority it is undoubtedly conveyed by the blood and lymph channels. The ulcers probably result from the breaking through of tubercles toward the surface of the mucous membrane, and the breaking down of many small tubercles forms the larger ulcers. The rapid extension of the ulceration is without doubt favored by the presence in the throat, at the same time with the tubercle bacilli, of pus-producing bacteria. Fraenkel⁴ has demonstrated the frequent presence of the staphylococcus pyogenes aureus and the streptococcus pyogenes in throat tuberculosis.

Pharyngeal tuberculosis may be also secondary to tuberculous caries of the cervical vertebræ. According to Osler¹³, tubercular adenitis of the cervical glands and tuberculosis of the pharynx in children, may follow tubercular processes of the axillary glands or carious cervical vertebræ.

Primary cases, although exceedingly rare, have been reported. Rosenberg⁴², in 22,000 throat diseases, has reported 22 cases of pharyngeal tuberculosis, 3 of which were primary. Out of 7 cases observed by Delavan⁴³, one had its primary seat on the velum. Pluder²³ has seen a case in a male of 16 years. There was extensive ulceration of the posterior wall of the pharynx extending into the posterior nares, and of the surface of the right tonsil and uvula. There was no evidence of pulmonary tuberculosis. Another case has been reported by Crossfield⁷; in this case there was primary pharyngeal as well as laryngeal tuberculosis. One case has been reported by Chappell²¹; Rethi²⁵ has reported a case starting from the posterior pharyngeal wall. A case of extensive ulceration of the entire palate and larynx with little lung involvement has been described by Zaruko⁹. Mention must again be made of Siebert's second case.

Other cases of pharyngeal tuberculosis have been reported by Heindl²⁶, Griffin¹⁵, Bowlby⁸ and Parker²². In Parker's case there was ulceration of the right tonsil, nasopharynx and soft palate, which developed after the removal of enlarged tonsils and adenoids. Smith²⁵ has seen 5 cases of tuberculous ulceration of the soft palate and adjoining soft tissues. Catti⁶ has described a pharyngolaryngeal type of acute miliary tuberculosis. In children it may be mistaken for diphtheria; it runs a very acute and rapid course.

Only two cases of pharyngeal tuberculosis have come under the writer's observation:

CASE 1.—Henry R., aged 21, native of U. S. The ulceration, when the case was first seen, involved a large portion of the posterior wall of the pharynx, uvula and tonsils, and extended into the nasopharynx. There was extensive lung involvement. The larynx was almost free from ulceration. The disease ran a rapid course, terminating fatally within six weeks after the patient came under my observation. Iodid of potash had been tried without effect.

CASE 2.—E. L., a young woman 22 years old, native of U. S. In this case the pharyngeal ulceration was very slight and started on the posterior wall. There was present a superficial ulcer half as large as a ten-cent-piece, on the posterior wall directly back of the uvula. There

was also a small ulcer in the larynx in the interarytenoid space. There was dulness at the right apex, with bronchial breathing. The pulmonary and laryngeal tuberculosis was first present in this case so that the development of the disease in the pharynx could be watched from the beginning. There was first some slight redness of the mucous membrane with several small grayish nodules; these, in the course of another week or so, broke down, forming the ulcer which had all the characteristic appearances. After continued applications alternately of lactic acid and orthoform in olive-oil, the pharyngeal ulcer got entirely well. The patient is now in Denver, where she is doing very well indeed.

A bacteriologic diagnosis was made in both cases.

The ulceration in the pharynx and particularly of the tongue sometimes extends quite deeply into the muscles of these parts. This has been demonstrated by Beale¹⁶.

If the cases above mentioned, which represent a considerable number of those reported during the past five years, are considered, it seems evident that tuberculosis of the pharynx is after all not so very rare. I quite agree with Shurley, however, that pure tuberculous conditions of the pharynx unassociated with other affections, are very rare. In fact, Shurley has made the statement, that he has not seen cases of tuberculosis of the pharynx except in mixed infection. While the diagnosis can usually be made by the appearance of the ulcers and the bacteriologic examination, in cases of mixed infection, it is at times very difficult. This is so in the cases of mixed tuberculous and syphilitic infection. It has been shown too by Naegeli²⁷, that localized tuberculosis may take on a carcinomatous character, the tuberculosis usually being the older process. On the other hand, tubercle bacilli may enter a carcinomatous ulcer. Loeb found in 111 cases of carcinoma, that in 31 it was combined with tuberculosis. Warthin²⁸ has reported a combination of sarcoma and tuberculosis occurring in a wart of the skin, has twice seen tuberculosis and carcinoma combined in the mammary gland, and in one case this combination occurred in the axillary glands.

Except in these combined cases, the differential diagnosis between pharyngeal tuberculosis and beginning carcinoma should not present any particular difficulties. The only other forms which, according to Mikulicz²⁸, may have diagnostic difficulties, are the severe ulcerations occurring in cases of advanced phthisis, and the very rare solitary tubercular ulcer usually situated only on the posterior pharyngeal wall. Another form of tuberculosis of the pharynx or nasopharynx, which is extremely difficult to diagnose clinically, is the tuberculous tumor. Hajek⁴⁴ has reported such a case which was at the time the first one on record. Then the type of acute miliary tuberculosis in children may present difficulties in diagnosis. A positive diagnosis of pharyngeal tuberculosis ought not to be made without a bacteriologic examination, and without first trying potassium iodid. It is really surprising how many ulcerative throat conditions, even with positive evidence of pulmonary tuberculosis, and which clinically present all the appearances of tuberculosis, get well when potassium iodid is administered. I have had a number of such cases.

Since the publication of Dieulafoy's experiments, in which he called attention to tuberculous infection of the tonsils and the lymphoid tissue of the nasopharynx, much greater interest has been taken in the subject. Dieulafoy¹⁸ inoculated portions of extirpated tonsils into 61 guinea-pigs, 8 of which became tuberculous. Guinea-

pigs were also inoculated with adenoid tissue from 35 cases, and 7 developed tuberculous processes. He distinguishes three stages: 1. Latent tuberculosis, in which the bacillus causes a multiplication of phagocytes and enlargement of the tonsils; this process, by development of fibrous tissue in the tonsils, may not extend, but often does. 2. The submaxillary and cervical lymphatic glands are invaded, and from there they may be extension through the lymphatics, until the thoracic duct or right lymphatic duct is reached, whence the bacillus is carried to the right side of the heart. 3. From the heart the process may finally reach the lung.

Wright²⁴ has questioned the accuracy of Dieulafoy's experiments. His investigations, made in the same way, were entirely negative. Guinea-pigs were inoculated with tonsillar and adenoid tissue from 12 unselected cases, which had before been histologically and bacteriologically examined. The experiments of W. H. Park and those of Botey were also negative. Lermoyez and Macaigne²⁵ have reported a case of primary tuberculosis of the tonsils of a young girl. There was no tuberculosis of the lungs; microscopic examination of the extirpated tonsils showed separate and confluent necrotic tubercles with giant cells and some bacilli. Tusseau¹⁹ has reported 3 cases of tuberculosis of the tonsils. Lermoyez, in 32 cases of adenoids found tuberculosis in 2. Brindell, in 64 cases, found tuberculosis 8 times in the adenoid tissue that was removed. Gottstein¹⁰, in 33 cases, found it 4 times. Fischer and Pluder¹⁹, in 32 cases, found tuberculosis 5 times; twenty-eight of these cases were children and 4 adolescents and adults; only 10 of the children were scrofulous; not one of them had general tuberculosis. The diagnosis was made histologically. Latent tubercles were found in the mucous membrane of the adenoids. A few bacilli were present in the diseased part, never in the epithelium nor healthy lymph follicles. Distinct caseation was found in half of the cases. Walsham²² examined the tonsils of 34 tuberculous subjects, on all of whom autopsies were held. During life, with two exceptions, there had been no symptoms of tuberculosis of the tonsils. In 20 cases, the tonsils were found to be tuberculous. Broca, on the other hand, examined the extirpated adenoid tissue from 100 cases, without finding evidence of tuberculosis in a single case. For some time, tonsils and adenoids removed in operations in private and hospital practice have been carefully examined histologically and bacteriologically, at the Bender Laboratory, by Dr. George Blumer. Of these, 23 were cases of adenoids and 12 of enlarged tonsils. These 35 specimens were all from unselected cases, children between the ages of 4 and 15 years. In each case a careful physical examination was made of the patient, particularly for evidences of pulmonary tuberculosis. None of the 23 adenoid cases had any tuberculosis that could be detected, and 11 of the tonsil cases were also free from general tuberculosis. In nearly all of these cases, however, the cervical lymphatic glands were markedly enlarged, and a number of the children had had operations for suppurating glands in the neck. On histologic examination, none of the hypertrophied lymphoid tissue removed from the nasopharynx was found to be tuberculous, but of the 12 tonsils, two were found to be tuberculous. In one case, the tuberculosis of the tonsil was probably primary. The tonsil of the one case (Specimen 51 of the report) was from a girl 6 years old, a patient in the Child's Hospital, who had had an operation for tubercular arthritis of the knee. In the second case (Specimen 52), a girl 5 years old, there

was absolutely no evidence, on careful physical examination, of tuberculosis anywhere else, so that the tuberculosis of the tonsil must be considered the primary condition.

Following is the report of the examination of the tonsils, at the Bender Hygienic Laboratory, Albany, N. Y., May 22, 1899.

Specimen 51.—The tonsillar substance is, for the most part, perfectly normal in appearance. At one or two points, however, there are areas of cells which contract very sharply with the tonsillar substance, on account of the lighter stain which they take. These areas consist of sharply circumscribed cellular nodules made up mostly of oval or irregular cells of an epithelioid type; and of small round lymphoid cells. There are also present, in some of them, large multinucleated cells, in some of which the nuclei have a peripheral arrangement. The centers of some of the nodules are entirely necrotic, taking a pink stain, containing a good many nuclear fragments, and into these necrotic areas a good many typical polymorphonuclear leucocytes have wandered. A few tubercle bacilli were found after appropriate staining.

Specimen 52.—The greater portion of the tonsil is normal, but at a number of places there can be seen, in the tonsillar substance, sharply circumscribed cellular nodules, made up, for the most part, of cells of an epithelioid type, but also containing small round lymphoid cells, and typical giant cells of the Langhan's type. The majority of these nodules are very small and show no signs of degeneration, but in one or two of the larger ones, beginning central necrosis can be made out. In this specimen also a few tubercle bacilli were found after appropriate staining.

GEORGE BLUMER, Pathologist.

Not enough consideration has been given to the fact that the tonsils are of considerable etiologic importance, as perhaps often the primary seat of infection in general tuberculosis. As mentioned before, Dieulafoy has shown how the tuberculosis may extend from the tonsils to the lungs.

Winckler¹⁴ found that in scrofulous eye affections, 50 per cent. had diseases of the nose or nasopharynx. He examines all eye cases for adenoids. If it is granted that scrofulous lesions are due to the development of the bacillus tuberculosis, the importance of diseased tonsils as a cause of scrofula is readily seen. It is a question whether hypertrophied tonsils and adenoids are not frequent causes of scrofula. As Baginski¹⁶ has said, "subjects of the lymphatic constitution are only selected cases of the most outspoken form of scrofula."

The bacteria cause an increased hyperplasia of the lymphoid tissue of the nasopharynx and tonsils, and from there the scrofulous process extends by way of the lymph-channels to the glands of the neck, and to the ears and eyes. Certainly children of this lymphatic type are extremely subject to infection. This is frequently shown by their enlarged glands, and the involvement of the lymphatic structures all over the body. We have all seen how wonderfully these children improve when their diseased tonsils and the lymphoid tissue of the nasopharynx are promptly removed, provided there are no tuberculous processes in other parts of the body. If not removed early enough, they are a constant menace to the general health. I do not think there is any doubt, even though our own examinations of adenoids were negative, that if all extirpated tonsils and adenoids were subjected to a very careful histologic and bacteriologic examination, tuberculous conditions would be frequently found. That other general infections, as well, have their origin in the tonsils, has been pointed out by Jessen¹⁴. He has reported four cases to prove this: a case of severe general infection following disease of the tonsils, and a second case of fatal pyemia, the result of tonsillar abscess. The third case was one of pneumonia with pericarditis, pleuritis and nephritis, following

a streptococcus angina. In the fourth case there was a fatal double pneumonia with its origin in the tonsils. The author states that without a bacteriologic examination it would be natural to attribute some of these cases to influenza. He also believes that these cases are not rare; that many of the septicemias, and the streptococcus and staphylococcus pneumonias, gain entrance into the system through the tonsils. Richardiere and Hanot have reported fatal cases of lymphangitis, pleurisy and sepsis, following non-phlegmonous inflammation of the tonsils. Hodenpyl has claimed that bacteria could not enter the tonsils unless there was a "loosened" epithelium. This, however, is always the condition of the epithelium in the crypts of the tonsils. Whether the scarlatinal angina is not the point of entrance for the scarlet fever is still an open question. Abrahams, Trousseau and others, have reported cases of rheumatism following inflammation of the tonsils.

In conclusion I would express my thanks to Dr. Blumer for his valuable aid.

DISCUSSION.

DR. ROBERT LEVY, Denver, Colo.—I regret that I was not here to hear all of the Doctor's paper, for it is one of exceeding

interest to those of us living in the section of country I do, and seeing as we do, a great many cases of tuberculosis and not a few cases of tuberculosis of the pharynx. A few years ago I reported seventeen cases of laryngo-pharyngeal tuberculosis and since then I have records of a number of additional cases. While potassium iodid often will clear up ulceration in the pharynx, those ulcerations in my experience have not been very suggestive of tuberculosis of the pharynx, neither in their own clinical appearance nor in the clinical appearance of the patient. In tuberculosis of the pharynx the general condition is usually quite distinctly tubercular. In laryngeal tuberculosis the diagnosis often is more difficult. I will not say there are not exceptions, but in a general way those cases which have cleared up under potassium iodid have given a history sufficiently suggestive to lead us up to the administration of potassium iodid with considerable certainty. As to the source and the mode of infection, in my hospital experience I was struck with the presence of acute pharyngitis in cases which afterward developed pharyngeal tuberculosis. In reading the works of a number of men as to the mode of infection I was particularly struck with the fact that frequently the infection is local and is the result of a destruction of the epithelial covering, whereby an opening is made for the entrance of the specific poison. I will not say that many cases do not occur through lymphatic infection, but I do believe that a local inflammation may exist which will assist in admitting the infection. As a rule tuberculosis of the pharynx occurs in advanced cases of pulmonary tuberculosis, and rarely is it found that tuberculosis of the pharynx occurs early in the disease.

DR. EMIL MAYER, New York City.—The Chair would ask the reader of the paper to state, if he can, the final outcome of the case where he found tubercle bacilli where the disease had not been suspected. And also, I failed to notice whether he had anything at all about the diagnosis clinically between tuberculosis of the pharynx and lupus.

DR. E. FLETCHER INGALLS, Chicago—I was interested especially in the views expressed in this paper as to the mode of infection of the pharynx. If the infection results from the sputum, we ought to have tuberculosis of the pharynx more frequently than we do in tuberculosis of the lungs, therefore it seems that the infection must usually be through the blood-vessels rather than from the surface of the pharyngeal mucous membrane. A form of sore throat, known as scrofulosis, that causes large and comparatively deep ulcers, sometimes occurs, in which we do not know the exact etiology. It has been thought that these cases are generally the result of an inherited mixed infection of tuberculosis and syphilis. At any rate the ulcer is likely to occur in individuals whose parents have had one or both of these diseases. These cases occur in comparatively young children; they do not present the appearance that we commonly see in tuberculosis of the pharynx, nor that of the deep ulcer of syphilis. As a rule, these ulcers have beveled edges and they are about midway in depth between the tubercular and deep syphilitic ulcers. In such cases it is difficult to determine whether there is a tubercular process or not for we are not likely to discover the tubercle bacilli, and I think they have been sufficiently studied. I have seen a few of these cases and have found that they generally yield to the treatment that I commonly employ in tertiary syphilitic ulcerations of the pharynx. This consists of the tincture of iodine in full strength, carefully applied until the surface has a dry brown glazed appearance. These applications are made daily for about ten days and they less frequently, usually for about two weeks until the ulcer is healed. At the same time the patient is given moderate doses of iodids, and nux vomica or other tonics as indicated.

DR. C. F. THEISEN, Albany, N. Y.—In reply to Dr. Mayer's query, I would say that in the cases I have seen in private practice, I was only able to make out these two positive cases of tuberculosis of the pharynx. In all the ulcerative cases the bacteriologic examination is made. In most such cases the streptococcus is found and I have no doubt it is the streptococcus that causes the rapid ulceration and destruction. But in all the other cases (except the two I reported), iodid of potassium cleared up the pharyngeal ulceration. Dr. Mayer asked about the child in which the condition was only found on histologic examination. The examination showed the necrotic tubercles with giant cells and tubercle bacilli, a typical microscopic picture of tuberculosis. It was impossible to tell whether the other case was primary or not. I did not go into the diagnosis of tuberculosis in detail, because I had to handle the subject in a short space of time. I think there is no doubt the diagnosis is easy between tuberculosis and lupus. The bacteriologic examination in these cases does not always clear up the case.

ACCESSORY THYROID TUMORS AT BASE OF TONGUE.*

REPORT OF CASES.

BY JACOB E. SCHADLE, M.D.

Clinical Professor of Diseases of the Nose and Throat, University of Minnesota, Minneapolis.
ST. PAUL, MINN.

Accessory thyroid tumors appearing at the root of the tongue are a rare affection. For this reason, if for no other, I desire to bring the subject before the members of the Section for discussion. Several cases coming under my observation I will report, while at the same time I shall take the opportunity to refer to others, which have already been reported. It will be interesting to note the various methods employed for the removal of these tumors.

The first case coming under my notice was that of a Mrs. J., who consulted me May 12, 1896, in reference to a growth at the base of her tongue, which she discovered six months earlier. The condition seemed to cause her more mental annoyance than physical discomfort. She was 25 years of age, and married. Her weight was 133 pounds, and height 5 ft. 6 inches. Though presenting the appearance of a good physique, she was anemic, mus-

Accessory thyroid tumor of tongue. Schadle-McBurney case.

cular tissues soft and flabby. Evidences of malnutrition and nervous exhaustion were marked. She complained of insomnia and gastric derangement. A heavily-coated tongue, loss of appetite, constipation and distressing flatulency of the bowels were pronounced symptoms. During her unmarried life she had enjoyed excellent health. Menstruation commenced normally, and no irregularity in the epochs occurred. In two years and nine months she was pregnant three times, having given birth to two children at full term and "miscarried" once, suffering much discomfort during pregnancy. Her family history was good.

On examination of the patient's throat, the growth was found to be about the size of an English walnut (Fig. 1). It was plainly visible upon forcible protrusion of the tongue, and was covered with mucous mem-

brane which showed an intense superficial vascularity. The color was a deep, purplish-red. At times it seemed to quite fill the fauces, especially when in a state of acute hyperemia, crowding up the uvula and coming in close contact with the pillars and arch of the soft palate. After the birth of her last child menstruation appeared earlier than usual under such circumstances, but was irregular as to time and continuance of the epoch.

During the time of the apparently suppressed menstrual function, the lingual tumor would swell and become very vascular, a most peculiar phenomenon. On palpation it was found hard and immovable. Externally, underneath the lower jaw the same condition existed. No pain was present, and respiration and deglutition were not interfered with. Impairment of speech was noticeable, the voice being thick and non-resonant. On laryngoscopic examination, the larynx was visible and the epiglottis seemed normal, except, perhaps, being interfered with in its movements produced by the presence of the tumor.

Being in doubt as to the nature of the tumor, and judging from its physical appearances that severe hemorrhage was sure to follow radical removal, I determined on first testing its vascularity by the introduction of an exploratory needle into the growth, which procedure was followed by considerable bleeding. After this experience I concluded the removal of a piece for microscopic purpose was not justifiable, thus preventing me from arriving at a proper diagnosis. Comparing the tumor as to appearance and vascular behavior, with what seemed to me similar growths sometimes seen in the nose and nasopharynx. I made up my mind that this was a fibroma. Feeling that removal by the use of the snare, either hot or cold, would involve considerable danger as to hemorrhage, I accordingly suggested that a conservative line be adopted and await results. With this end in view I began the use of electrolysis. The tumor, under this method of treatment, was reduced to about one-third of its original size in a period of two months, from May 11 to July 15. On the latter date the withdrawal of the needle was followed by a copious bleeding, which was brought under control by applications of Monsel's solution.

The use of electrolysis was now continued. After another week a hemorrhage, more violent than either of the others, occurred, and left the patient in a weak and anemic state. I now advised consultation, and Dr. McBurney of New York was seen. But before visiting him Drs. Ingals and Lincoln also saw the patient, the former in a measure confirming my opinion, while the latter had no opinion to offer.*

Dr. McBurney's letter under date of Oct. 25, 1896, in answer to my note of introduction, reads as follows:

"Mrs. J., whom you kindly referred to me, has called on me twice, and I have carefully examined her. Her tumor is a rare one, and I have only twice before seen its counterpart. I regard it as a myxoma, or adenomyxoma. Its true seat is in the substance of the tongue, the portion that can be seen on the dorsum being only about one-third of the whole mass. There is only one method by which it can be safely and entirely removed, and this one I have no hesitation in recommending, a straight incision should be made in the median line, beginning a little below the symphysis menti and extending to the hyoid bone—as this incision is deepened and the edges separated, the surface of the tumor nearest the skin can be easily uncovered and the whole tumor dissected out. The muscular fibers of the tongue are pushed

*Presented to the Section on Laryngology and Otology, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

*Since this paper was read Dr. Lincoln informs me that he viewed the growth as a tumor of the fibroid type.

to either side and the tumor enucleated with little or no injury to the tongue. This operation is safe and certain, and no danger from hemorrhage will arise. Every vessel would be tied as soon as cut."

The operation was performed by Dr. McBurney in accordance with the above description. Considerable loss of blood attended the removal of the tumor, which rendered the operation tedious and difficult. The patient made a good recovery, and has been well ever since.

The growth was microscopically examined by one of the pathologists connected with the Vanderbilt Clinic, who reported it to be a gland of the thyroid—ductless—type.

Dr. J. L. Rothrock of St. Paul also made a microscopic examination of a section of the growth which I gave him, and the following is his report:

"Microscopic examination of the section submitted to me shows it to consist histologically of structure identical with the thyroid gland. From the location from which this tumor is removed there is no doubt that you are dealing with an accessory thyroid gland."

I wish also to report the case of a young woman, aged 23 years, patient of Dr. A. C. Heath, who came under my observation during the past year. A growth appeared in her throat at least ten years ago, as the patient thought. Inspection of the pharynx revealed a tumor slightly larger than a hen's egg situated on the base of the tongue just anterior to the epiglottis. This tumor was smooth, dense, of a dusky-red color, with a characteristic resilient feel and appeared perfectly homogeneous. It filled the mouth so that it was impossible to get a view of the larynx or even the epiglottis. Her voice had entirely lost its resonance; it was dead and muffled. She had some difficulty in swallowing, and a shallow, resistant cough. This case was watched for four weeks, and surgical procedure advised. Unfortunately, however, she would not submit to an operation, thus preventing the verification of the diagnosis. But from its various characteristics the growth seemed very similar to the above case, and would justify the diagnosis of accessory thyroid situated at the base of the tongue.

On searching for literature on the subject of thyroid tumors at the base of the tongue, I found that Dr. J. Collins Warren of Boston reported a case¹. The following is a synopsis of his report, the patient being sent to him by Dr. F. I. Knight:

On examination of the throat a tumor presented at the base of the tongue about the size of a hen's egg. The laryngoscope showed that it was not connected with the epiglottis. It seemed to be covered with normal mucous membrane, and a tortuous vessel of considerable size could be seen running over the anterior surface. The patient was a woman over 52 years of age, who had always enjoyed good health, is at present strong and stout, mother of three healthy children, but her parents both died of consumption. She first noticed a lump in her throat about twenty-two years ago. Since that time it has been slowly but steadily increasing in size. The catamenia ceased about five years ago, but no special change in the tumor occurred. The removal was accomplished May 4, 1892. After etherization, a ligature was passed through the tip of the tongue, and two additional ones through the dorsum of the tongue on either side of the tumor in the region of the papillæ circumvallatæ. Traction brought the whole tongue forward, so that the tumor presented between the incisor teeth, then an incision was made on the median line of the tumor, which was enucleated. It

appeared to be situated just beneath the mucous membrane, and it did not involve the substance of the tongue. Three vessels required ligature. The patient made an uninterrupted recovery, and two weeks later returned to her home. Three months after the operation there was no sign of return of the tumor. Microscopically (Dr. Whitney), the structure was that of a ductless gland with colloid degeneration, and in all its essential histological details corresponded to the thyroid. In the *British Medical Journal*, Dec. 1, 1894, appears the following report of a case admitted to the Golden Square Throat Hospital:

A. D., a girl 17 years of age, complained of a lump at the back of the tongue. It was giving no trouble, and had only been discovered two months previously, when her singing master examined her throat and noticed the lump there. Her speech was somewhat thick. She was an undersized but well-nourished girl. Situated at the base of the tongue, close to the position of the foramen cecum, was a tumor about the size of a small walnut. The larger half of it was to the right side. It felt semi-elastic, and was immovable on the deep tissues of the tongue. It pressed backward on the epiglottis, and when the tongue was pulled out it almost touched the base of the uvula and the soft palate. The thyroid was normal. Under chloroform, Dr. Bond cut the mucous membrane round about it with a pair of curved scissors. The tumor was fixed with a pair of tenaculum forceps and removed with the aid of a raspatory and a Mackenzie's polyus snare. Bleeding was profuse, but was controlled by pressure on the base with a finger around which a piece of lint steeped in turpentin was wrapped, while the girl was turned almost on her face to allow the blood to run out of her mouth. There was no recurrence of hemorrhage, and the patient made an uninterrupted recovery, the wound being healed in ten days. Microscopic examinations showed the tumor to present the ordinary appearances of thyroid gland structure.

In the Transactions of the Clinical Society (Vol. xxiii, 1890), Butlin reports eight cases. The history of two of these cases is thus briefly stated:

The first occurred in a female 32 years of age, and was thought to be about the size of a hen's egg. Tracheotomy was performed, and the tumor was removed through the mouth by an incision on the median line and scooping out the soft mass. There was a recurrence, but the tumor remained much smaller in size. The second case was also a female, 23 years of age. The tumor, which had existed two years, and was smaller than the former, was removed by the galvanocautery loop.

The question arises: Why should thyroid tumors make their appearance at the base of the tongue? The occurrence doubtless is due to a congenital defect or a lack of closure of the thyroglossal duct as development goes on. On this point Sutton, in an abridged form, makes the following remarks:

Tumors which structurally resemble the thyroid gland are not infrequently met with in this region. They originate in connection with the lingual duct, a structure of embryonic significance. In the embryo a diverticulum takes place from the anterior wall of the pharynx, forming what is known as the thyroglossal duct, and about this the thyroid gland is developed. This duct opens at the base of the tongue at a spot represented in the adult by the foramen cecum, and, passing downward, bifurcates to form the isthmus of the thyroid, the branches uniting with the embryonic gland structure to form the lateral lobes. As development goes on the hyoid bone is formed, and in its growth divides the duct

¹ American Jour. Med. Sci., October, 1892.

into an upper (lingual) and a lower (thyroid) portion. Both of these are obliterated, as a rule, when development is complete; but sometimes, in the newly-born child, a fine probe or bristle can be passed for a short distance along the lingual part from the foramen cecum, between the geniohyoglossi muscles to the body of the hyoid bone, where it is continuous with a fibrous cord passing in front of it over the thyroid membrane, and down toward the thyroid isthmus. Occasionally either of the two portions persists—closed at both ends—and gives rise to a dermoid cyst. It is in connection with this lingual portion of the thyroglossal duct that a tumor such as above noted is developed.

DISCUSSION.

DR. EMIL MAYER, New York City—The Chair would like to report briefly a case that came under his observation some time ago, in which he was quite confident that there was a thyroid tumor at the base of the tongue. At the base of the tongue there was a large tumor pointing toward the epiglottis, so that the individual had suffocative attacks and for some time did not dare to go to bed. When I saw the patient I found him to be a stout man, and only with the greatest difficulty was I able to get a view of the larynx and the posterior portion of his tongue. The growth was fully an inch long at that time. I felt confident we would have some trouble, because of the suffocative attacks, but I advised the attending physician to give the patient potassium iodid in large doses. Some weeks afterward the patient returned, claiming that he was in much better condition. The growth was evidently a specific tumor of the base of the tongue, which is a very rare condition. Later I saw his physician, who had treated him some years ago for syphilitic iritis. Although he has no specific history he has two of the most pronounced tertiary syphilitic lesions.

DR. C. R. HOLMES, Cincinnati, Ohio—I have at present a case under observation, which I mention more for information than for any other reason. The patient is a young married woman, the mother of several children, who came to me about three months ago with a tumor about as large as a hen's egg attached almost throughout to the base of the tongue and extending up almost to the apex of the left tonsil. In fact, it was impossible to say where the left tonsil began and the tumor ended. The tumor was of a dark purple color, smooth and soft to touch. It was impossible to make a rhinoscopic examination, for there was only a small passage on the right side, and yet the tumor was so elastic that the patient had no trouble eating or drinking. The tumor caused only a charge in the sound of the voice. I called in Dr. Thorne, who also gave as his opinion that it was an angiosarcoma. On attempting aspiration, the moment the needle was passed, there was a spurt of blood that squirted through the open mouth and stained my operating gown. I determined on the use of the cautery. A surgeon was called, and he thought it best to ligate both common carotids and go in and cut the tumor out. But as I was not yet willing to place the patient in that condition, I used the galvanocautery. There is now only a small mass left at the base of the tongue. A microscopist reported sarcoma, but I have had cases that did not turn out to be what the microscopist reported. However, in this case the evidence seemed to point in that direction. In connection with the paper by Dr. Schade, it is of much interest to me now, because he speaks of one tumor that was about that color and resilient and vascular, and I would like to know whether he thinks from his experience that a tumor such as I have described would be likely to be a sarcoma or one of the tumors such as he has reported. I communicated with a doctor in Philadelphia who used electricity very much, and he advised using an anesthetic and a current of 400 milliampères, and having oxygen and everything ready, because the approximation of the phrenic nerve might stop the respiration and action of the heart. I have not tried that except under cocaine, and I found the patient could take only a much weaker current.

DR. J. SCHADE, St. Paul, Minn., in closing—I will only say that from his description I believe the case reported by Dr. Holmes was similar in character to the one I related.

CRIMINAL MORPHOMANIA.*

BY T. D. CROTHERS, M.D.

Superintendent of Walnut Lodge Hospital; Editor
Journal of Inebriety.
HARTFORD, CONN.

The physiologic action of opium and its alkaloids, with symptomatologies, is becoming more familiar with the increasing frequency of cases and studies of many persons. As in other fields of research, there are vast stretches of unknown lands awaiting discovery, and many new facts in the etiology, progress and treatment to be seen and described. My purpose is to point out a new phase in the symptomatology, and describe a condition which has been noticed, but not defined or studied before. I shall use the term "palsy of the higher psychic centers" to describe in part this condition. The former personality of the person is lost, and he acts from a different point of view; his conduct and thoughts vary widely from former conditions, and he seems to have new purposes and changing motives, foreign to any previous life. These strange inconsistencies of conduct and thought come into legal notice, in the question of responsibility in crime. The apparent cunning, honesty and reasoning are so unusual and foreign to all theories of mental failures that the expert is unable to detect any defined insanity, and yet, he can not doubt that some condition of brain disturbance is present.

One case was that of a woman who, after using morphin, went about the house secreting things of value and locking doors and windows, putting away matches, fearing robbers and fire. This was a clear, defined period of several hours, during which she appeared almost rational, and talked clearly of other matters, as well as the danger from these sources. Then she relapsed into her former indifference.

A still more prominent case was that of a noted banker retired from business, who became a morphin taker, following the constant use of spirits. He never appeared to be other than sane and clear on all matters. Occasionally he was stupid at night, at home, but always appeared well in public. Finally, he was detected setting fire to a building. He was found to have been the author of numerous fires in the villages about. He would go to a town and rise in the middle of the night, start a fire in some old building, return to his bed, and so secretly as to disarm all suspicion. He was caught in the act and stoutly denied it, explaining his presence in the most plausible way. The result of investigation showed that after using four or five grains of morphin, he would become very secretive and go about in a stealthy manner, but never at a loss to explain his conduct, or appear other than natural to others. He would show unusual cunning and frankness if found in some suspicious place, and yet without doubt set fire to old buildings, such as barns and outhouses with every opportunity. A number of experts could not find signs of insanity, and yet when the morphin was withdrawn there were many symptoms of dementia and mental instability. The morphin roused up another personality, giving clearness and power to his brain and breaking up all sense of right and wrong. When under these pyromaniacal impulses he acted with unusual cunning and judgment, and seemed to reason that it was clearly his duty to do so. When away from the morphia he had a confused notion of his conduct, and was filled with

*Presented to the Section on Neurology and Medical Jurisprudence, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

remorse at the changed conditions of his life. When under the influence of morphia a new personality of expansive character, came on. He seemed to have a desire to destroy and burn down old unsightly buildings.

A patient under my care for excesses in spirits, suddenly became a speculator, buying stocks on a margin. Fortunately his resources were limited, but the mania continued in lottery tickets and bucket-shop ventures. This was foreign to his past conduct and character, and was unexplainable until his secret morphia addiction was discovered. He left, and two years after began a career of cunning, sharp, dishonest speculations, and was arrested. On trial the resumption of the morphia addiction was shown, but the mental power and skill displayed indicated such unusual ability that he was convicted. I saw him in jail later, when the morphia had been taken away, and the evident unsoundness of his mind could not be mistaken.

A third case came under my notice as an expert. A graduate and prizeman of a college, who married wealth and spent two years traveling, suddenly left his home and began a career as a confidence man and forger. He traveled around under assumed names, passed bogus notes, raised checks, and when caught gave such clear explanations as to disarm all suspicion. Finally he was arrested and held for trial. As long as he could procure morphia he was calm, clear, adroit and possessed of unusual brain power, but after his sentence and removal to prison he became a partial dement and was very feeble mentally. In this case the morphia developed a new personality. He acted and talked as if he believed most firmly the honesty of his acts, and never doubted his ability to deceive and falsify, acting as if he was thoroughly in earnest. When confronted with his deception he did not recognize it, but showed the greatest skill to justify and explain it, never displaying any visible consciousness of the dual life, but always appearing honest and frank to an extreme degree. He passed a forged note, went out on a back street, changed his dress, put on false whiskers and came back on the street, walking about with extreme coolness. He went into a store, bought some morphia, and then purchased a pair of shoes, giving a forged note as before. A detective who had followed him closely, arrested him, and after a short examination before the chief of police he was discharged. His earnest, frank manner convinced them that he was not the man. The next week, in a neighboring city, he did the same thing, was arrested and discharged as innocent. Finally, a detective followed him, and found that he was constantly changing his dress, and assuming different disguises, buying clothes and other things which were finally pawned, giving checks, some good, others bad, and making deposits at banks and drawing them out. During this time he bought morphia freely, but never seemed other than calm and sane. He was finally arrested, and after serving a short sentence disappeared. While using morphia he appeared very frank and honest in his manner and conduct, especially in public and in conversation with others. He carried cards and bill-heads of different well-known firms far away and represented different members of these firms or traveling men connected with them. He always carried an overcoat and means for suddenly changing his appearance. While under the influence of morphia he appeared to be possessed of unusual clearness and cunning, with a most contagious frankness and honesty. There seemed to be no consciousness of the duplicity in his talk or conduct. When the morphia was taken away

the very opposite appeared. He was remorseful and depressed, timid and shrinking, displaying his motives and thoughts in a most marked way.

Another case reported to me was of equal interest. A series of very remarkable swindling operations had been carried on the Hudson River and Long Island Sound night boats. The detectives were unable to fasten the crime on any one, until finally, a young man of refined, delicate appearance, was arrested for passing a forged check. It was ascertained that he was the probable author of all the swindling for the past two years. He was a morphinist and had an income from an annuity. He spent his time traveling around, appearing to be a clergyman, an actor and a business man, and talked freely with every one, inquiring very minutely into the personal history of persons and offices. He would secure advances on brass watches, bogus diamonds, and pass worthless checks and railroad tickets; solicit loans and give in security worthless bonds and stocks, buy goods, giving bogus checks and receiving money in return, show bank deposit books of large sums, and leave them as security. He would make the acquaintance of some rich man, and after swindling him, disappear with some frivolous excuse. He changed his appearance frequently, wearing spectacles, false whiskers and wigs, appearing as a large fleshy man, then wearing half military suits, and so on. His wardrobe was composed of a great variety of theatrical suits, and he claimed to be an actor. In jail he was identified by many persons as assuming different disguises and defrauding them in various ways. As long as he could procure morphia, he was genial, self-reliant, open, honest, and very frank. He never appeared to be deceitful, and always acted and talked as if he believed everything he said and did. The most careful questioning and efforts to have him explain his conduct left a strong impression of his honesty, although it did not explain his life and conduct. The detectives called him an honest rogue while using morphia. His manner on the witness stand was so frank and clear that the mystery of his conduct deepened and the jury was half inclined to think that some mistake had been made. He was sent to prison and the morphia removed, and all his manner changed. His frank, honest, clear thought and talk disappeared and the fawning, lying hypocrite appeared with all the criminal instincts. He is still in prison, and is regarded with much suspicion by the keepers.

While these may be considered extreme cases, they are types of an unknown state, following the use of morphia. I find from inquiry that morphia criminals are regarded as the most dangerous by police authorities. They have full control of their nerves at times and can act a double part so clearly as to disarm suspicion. Such cases are bold, defiant, and adroit, and possess a rare power of deception entirely foreign to other criminals. This is sustained in the ordinary medical treatment of such cases. The cunning deception and the unconscious reasoning and concealment of their plans and motives, seemed to point to some local palsies of certain brain functions. Where a patient is suffering from withdrawal symptoms, and suddenly becomes cheerful, and quiet, and is loud in his protests against the suspicion of having used any morphia, some condition of psychic palsy exists. Innumerable instances of the most cunning intrigue and seductive falsehoods are common in such cases. They act and talk with the certainty of truthfulness, and seem unconscious of the deceptions they practice.

One such case was detected by examination of the urine, finding morphin reaction. For a long time it

was impossible to detect where and how the drug had been procured. The woman's earnest, emphatic denials were clearly impossible to a normal mind, and showed some obscure palsy of the higher centers. Yet during this period she went about in her usual way. She was a most earnest, praying Christian, whose high ideals of truth and honesty were beyond question or suspicion. This case aroused some bitterness among her friends. Her husband and family could not believe that it was deception, and when the morphia reaction was shown, thought it a fraud. She finally went to a secluded place in the country and after a time the morphia reaction symptoms appeared. Then all her former self-possession and boldness disappeared. She became very penitent and was a different person in every way. The mystery of this deception was called by the clergyman, "A possession of the Devil." It was a trance state, literally, in which reasoning and consciousness of her relation to others was suspended. Her mind was concentrated on procuring morphia and concealing it from others. This dominated every other consideration and was probably a sacred duty to be carried out above every other thing.

In the history of the two swindlers, the morphia roused a mania for deception and double life. The gain which they procured was of minor consideration, but the greatest pleasure was in taking advantage of the credulity of others. In one case the confusion and mystery which followed the deception seemed to be the most enjoyable part. They would stand around and talk about the act and show sympathy with the sufferers. In another case after changing his dress, and appearance, the morphinist would appear and show great interest about the act. I can not find from inquiry any cases where capital crime was committed in this morphia state. Thefts, swindling, and general falsehoods, with concealment of motives and conduct, seem to be the most common.

I have met with two cases where a will mania followed. Both the persons, men of some property, made from seven to eight wills a year for several years. These were concealed, and on the death of one this was brought to light. The other recovered and ordered them all destroyed.

The cunning, skill and ability shown in the deception must apparently be based on the dominance of the idea as true and real. No shadow of the real condition or the danger of exposure was apparent. Each case acted only as persons do who are fully possessed with the honesty and reality of their notions. A noted physician under my care displayed extraordinary deception to conceal his real condition and was fully unconscious of his acts or the consequences. Even when he was convicted of his deception, he seemed roused to greater efforts for concealment. No reasoning or counsel could displace the mania for deception. On other matters he was in no wise disturbed mentally—reasoning and acting with excellent sense and judgment. He could discern motives and deceptions in others, but was unable to realize his own condition. When morphia was removed this changed, and he realized and acted differently.

In another case, a man of noted honesty and strong character denied all use of morphia and when a quantity was found on him he persisted in explaining it in the most adroit way. He seemed actually to believe his own statements and could not be convinced otherwise. The foolish deceptions of alcoholists are quite different. They display a consciousness of their real condition and the concealment they are practicing. All morphinists do not exhibit these special phases, like alcoholists. They

are weak and childish in deception and show by their conduct a consciousness of their real condition and the efforts to cover it up. But these cases differ in thought and act, appearing to be thoroughly impressed with the idea of the correctness of the act and unconsciousness of the deception and danger of exposure, at the same time using wise precautions to make the act appear real. Two of these cases seemed to realize the danger of exposure in the unusual precaution to make their conduct appear honest. With this was a perfect self-possession and command of themselves. It was noticed that they took morphia frequently in small doses. When the amount taken was followed by the symptoms of narcotism they disappeared, and remained in bed until the effects wore away. This state has been noted in long intervals in other, less prominent cases. A physician displayed great harshness to his patients and family at times, then he would recognize it and be very penitent for his conduct. On one occasion he drove his wife away from the house, and two hours later went after her, showing great tenderness. This was not a so-called mania seen in alcoholics, but a calm, reasoning, morbid impulse, carried out deliberately and with every appearance of sanity.

In a case in which I was called in consultation, a delusion of sudden death appeared at stated intervals. The patient demanded most unusual preparations for a death-bed scene. Clergymen were called, and a large family gathered to witness his exit. Finally a slight interval of sleep would bring a change and a desire to live again. This was not a hysterical and emotional state, but a calm, reasoning, hopeful interval of several hours. He gave no signs of mental disturbance nor seemed unreasonable in his thoughts or conduct. He was known as a moderate user of morphia, and was never seen stupefied by its results. He was under treatment for its removal by the family physician, and was secretly using it when these trance periods arrived. He had only a faint recollection of these events after, and attempted foolish explanations, showing he did not realize his condition.

In another case, after using a certain amount of morphia, a quiet, unassuming dentist became a strong religionist. He would march with the Salvation Army and make eloquent prayers and exhortations. This would last for several days, then he would relapse to his former quiet life. In this religious period no signs of mental failure or weakness appear. He seems every way clear, sensible, and earnest, and explains his change of conduct in the most plausible way. These cases illustrate the mental state which I wish to make prominent, and which I believe occurs more frequently among neurotics of the higher classes—persons with culture, and more than usual mental development. They are called by detectives "dangerous first-class criminals," where detection only follows the limitation or withdrawal of morphia. The confinement of such a person for a few days, with removal of all opportunity for procuring drugs, reveals their real condition. This condition resembles reasoning mania, only the usual signs of mental defects are wanting. There is mental calmness and self-possession, and the brain operations seem clear and rational. The strange acts and conduct are explained with a conscious honesty that is convincing. It would seem that a new personality is involved, and that new ideas or motives take full possession of the mind, and all other conditions and surroundings are ignored. Yet, with this appears the unusual cunning to make the act a success.

In a recent murder trial, a morphinist who had evidently been associated with the crime in some indirect way displayed masterly ability in the explanation of his

conduct. He shed tears and created a strong feeling that he was the victim of deception by others. After the trial, the facts of his complicity came out, but he continued indifferent. He, no doubt, actually believed his own statements, and used cunning measures to make them appear true. A man under observation has on several occasions sent startling telephone news which was false. He has defended his acts with unusual plausibility and his associates believe him. He is an editor of ability, and a user of morphia. The same apparent notion of enjoyment in the emotion produced by such news was possible. He talked of this false news, and seemed as startled as others at the time. He is under medical care, although working at home daily.

There are no theories to explain this condition other than some obscure palsy of certain brain-centers, which breaks up the consciousness of right and wrong, or suspends reasoning on the nature and consequences of acts. It may be a state of local poisoning which centers in some psychic function, giving prominence to some idea and defending and explaining it with all the force of a normal brain. The usual efforts to explain and defend acts committed when under the influence of alcohol and opium are so obscure as to carry their own refutation. The morphinist in this state, as long as he can secure a sufficient amount of the drug, makes few mistakes and shows no weakness in making his position and conduct clear and sensible. There may be many inconsistencies and acts not common to the average man, but he has no difficulty in explaining them to his apparent satisfaction.

The clinical fact that I wish to make prominent is that in certain conditions of morphia addiction a new personality appears—some psychic trance state, in which great mental clearness, self-possession and cunning, with unusual frankness and candor, are the prominent symptoms.

Criminal acts and purposeless deceptions are common. Forgery, swindling and manias for certain acts, and adroit concealment of them have appeared so far. In the court cases no study has been made; the only recognition is that they are most dangerous criminals because of their superior capacity to lie, steal and cheat, because they appear to be honest and have no conception of the nature of their acts. In the medical cases no one has studied this symptom of deception. It is even doubted by some persons whose experience should have taught them differently. It is a distinct pathologic condition, which may be understood, and is the most significant of the brain defects and degeneration. It is only a step from childish falsifying to criminal acts, and on to more serious symptoms.

Morphin may be said to cultivate the crime instinct; at all events, it prepares the way to certain criminal acts, which often have some previous predisposition. The perversion and damage to the higher centers which govern the ethical relations of life are always associated with morphinists. The criminal side of these cases is the psychic wreckage of the criminal relations of the higher operations of the brain. The criminal who is a morphia taker is such a wreck. No exhibition of mental power and acuteness in such cases is evidence of sanity.

Again I wish to emphasize the need of exact study of these cases, of the delusions, of the manias, of the strange symptoms of strength, cunning and weakness, and indicate the possibility of medical means for relief. The criminal side of morphia cases is practically a sealed book, awaiting psychologic research and study, and promising a new field of the most practical facts.

RATIONAL TREATMENT OF CHRONIC MORPHINISM.*

BY AUSTIN J. PRESSEY, M.D.
CLEVELAND, OHIO.

I submit for your consideration a method for the treatment of chronic morphinism which has been, in my hands, very satisfactory, both to myself and patients. The principal advantage to be derived from this method of slow reduction is the lessened amount of discomfort to the patient. Usually there is no pain or diarrhea, no vomiting, no profuse perspiration, no extreme nervousness, and never anything like a state of collapse; in fact, there are none of the severe symptoms, such as described by those who have written on the subject of chronic morphinism.

It is a most barbarous thing to suddenly withdraw the morphia, as in the method described by Levenstein, and now called the Levenstein method. A patient with knowledge of the symptoms which follow the sudden withdrawal of morphia who would then have the fortitude to place himself under that form of treatment, certainly must have the courage to face any event that one is liable to meet with in this life. The modifications, as described and practiced by others who have withdrawn the morphia more gradually, but yet have minimized the dose in advance of restoration of the nervous system, seem almost equally severe.

Erlenmeyer says that the sum of the suffering from the gradual reduction more than equals the suffering of the sudden withdrawal. While, perhaps, this is true with a fixed rule for reducing the quantity of morphia so much for each twenty-four hours, or if the reduction is conducted on any plan that reduces the dose before the patient is prepared for the reduction, it is not true if the reduction of the amount of morphia is made only as the condition of the patient is so improved that his necessity for the drug is lessened to the extent of the reduction made.

I always endeavor, and in 90 per cent. of the cases I am successful in so far restoring the nervous system to its normal condition in advance of withdrawing the morphia that the amount withdrawn is not discovered by the patient. I never withdrew the last fraction of a grain until the quantity used is so small that the patient is unable to tell the day he took his last dose. It is easily understood that the nervous system is in a most unfavorable condition for recuperation while the patient is suffering for want of morphia. He can neither eat nor sleep. He can not rest easy in any place or position. The effect of any drug that may be given him as a substitute, or to quiet him while withdrawing the morphia, is equally as bad and may be worse than that of morphia itself.

Nearly every patient, when he presents himself for treatment, is taking more morphia than he requires to make him comfortable. Some take two, three, or four times as much as needed. This surplus can at once be withdrawn and the patient feel and be the better for it. When the largest amount has been withdrawn that can be and still leave the patient quite comfortable, then the reduction must cease until the system has had time to adjust itself to this new condition of things. With this lessened amount of morphia the secretions become more active. The appetite improves; sleep, while not so profound, is yet more refreshing; in fact, every function of the body approximates a more normal con-

*Presented to the Section on Neurology and Medical Jurisprudence, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

dition, except it be the heart. The heart, which has for perhaps many years been constantly stimulated by the use of morphin, now becomes weak and fast or irregular. However, this symptom will soon pass away under the influence of small doses of strychnin or hydrastin. In a few days the system will have so far accommodated itself to the lessened amount that another very small reduction can be made. This and all future reductions should be so small that the patient is unable to tell when they are made.

The first point that I wish to emphasize—the real key to success—is to keep the patient on just as small a quantity as is compatible with comparative comfort, and yet not to get his dose so small that he will be in misery before the next regular hour for morphin. A patient should feel almost perfectly comfortable, so far as morphin is concerned, for three or four hours after getting his dose. I give the morphin four times a day, at 7 a. m., 12 m., 5 p. m. and 9 p. m. I divide the time in this particular manner for the sake of giving the morphin just previous to meals and bedtime. Patients will eat and sleep much better thereby. It is useless to ask a patient to take nourishment when he is needing morphin, and no one thing is more essential to an easy and rapid recovery than a good appetite. There are no drugs that can compare with plenty of good food and sleep to restore the nervous system, and the patient can neither partake of the one nor secure the other when too much of his accustomed amount of morphin has been withheld.

Erlenmeyer condemns the gradual reduction severely. However, it is evident from his description of the symptoms that, while the reduction extends over three, four or more weeks, the reductions have been made in advance of recuperation. He says that during reduction patients cannot recuperate, and convalescence is very tedious. This certainly has not been my experience. I have recently discharged two patients, one of whom was taking eight to ten grains of morphin a day when he came to me, and weighed one hundred and twenty-seven pounds. He was under treatment two and one-half months. On the day he took his last dose of morphin he weighed one hundred and forty-nine pounds. He remained with me two weeks after the morphin was entirely discontinued and at the end of that time weighed one hundred and fifty-four pounds—a total gain of twenty-seven pounds, and he never felt better in his life. The other was a man 51 years of age, who had taken morphin for fifteen years, and for a number of years had taken as much as twenty-five or thirty grains per day. There was only one night during his treatment that he did not sleep well. He ate well after the first week's treatment. He was with me four months and had increased in weight twenty-four pounds.

These are exceptional cases, but the majority will improve more or less in weight during the stage of withdrawal, and four out of five patients say that they feel better during the treatment than while taking morphin *ad libitum*.

Perhaps there is no way in which I can better illustrate the method than by giving a condensed report of a case. Mr. T. B., aged 26 years, married, general health fairly good, bowels badly constipated and appetite poor, had used opiates six years. The first three years he smoked opium; the last three he had used morphin, and was using from twenty to thirty grains per day hypodermically when he came to me for treatment. I ordered

B. Strychnin	gr. $\frac{1}{4}$	016
Hydrastin, hydrochlor.	gr. vi	39
Sparteïn sulph.	gr. iii	195
Atropin sulph.	gr. $\frac{1}{6}$	01
Aqua	ʒ i	31 10
M. Sig. Twenty minims hypodermically four times a day at the same time morphin was given.		

I also prepared a solution of morphin containing thirty-two grains to the ounce, or one grain in fifteen minims, of this solution I gave him thirty minims, or two grains four times a day. Finding that he was very comfortable on this amount, I quite rapidly reduced the quantity of morphin until, twelve days after commencing treatment, he was taking fifteen drops at a time, or one grain four times a day. Seventeen days later he was taking ten drops or two-thirds of a grain. Up to this time I had reduced the amount of the solution given, one drop at a time whenever a reduction was made, but to reduce one drop now would mean one-tenth of the whole, and he would feel quite perceptibly the loss of that proportion, so I prepared another solution of one-half the quantity of morphin—one grain to thirty minims—and gave him nineteen minims, nearly twice the quantity of the solution. I then very gradually reduced this quantity one minim at a time, and only as that could be done without his knowledge, for no progress can be made while he is suffering for the want of morphin. March 1 he was taking four minims, when the morphin solution was again reduced to one grain to sixty minims, and of this seven minims given at a time. Again the quantity was reduced as before until March 14 when he was taking three minims at a time. A solution was then made containing one grain to 120 of water, and five minims given. The quantity was then reduced to three minims on March 17, when a solution containing one grain to two hundred and forty of water was made and five minims given; and reduced to three minims on March 20. At this time a solution of one grain to the ounce was made, and on March 25 he was taking four minims or 1/120 grain. This was the last day that he took any morphin, three months from the day that he came for treatment. His improvement in flesh and appearance was constant while being treated. He was uncomfortable only a few times during the entire period; at such times I always gave him enough extra morphin to relieve him.

This I consider an important factor. The physician must have the confidence of his patient. Unless the patient can feel sure that he can get morphin when he asks for it, he is sure to imagine that he is badly in need of it much of the time, when otherwise he will feel fairly comfortable until the regular hour for taking it. Many times a patient imagines that he requires morphin when a syringe of water will do as well. One has to study each case and be constantly on guard that he does not give morphin when water would do as well. Some patients are continually asking for extra hypodermics, and water will satisfy perfectly.

One who treats morphin has no time for other practice. He must devote his entire time to his patients. I never leave my patients with a nurse for a few hours that some or all of them do not require more morphin than they would if I were with them. On the other hand, be as careful as possible not to make mistakes and give water when morphin is required. The patient gets nervous, becomes irritable, does not eat and loses sleep unless the error is rectified in time. There is no disease with which I am acquainted that requires the constant study and watchfulness that morphinism does. Patients can seldom be treated successfully at their homes; gen-

eral hospitals or sanitariums, for obvious reasons, are not good places to treat this class of patients. The most suitable place to care for them is in institutions devoted exclusively to that class of work, where physicians and attendants can constantly have an eye on each patient in the institution. So far as medicine is concerned, no fixed formulæ can be given, every case is a law unto itself and must be treated according to its particular condition and requirements. The one thing that is to be done in every case is to build the patient up physically, improve the general health just as much as possible. Give general tonics, heart tonics, nerve tonics, according to indications. Keep all the secretions in a condition as nearly normal as possible, and look well after the condition of the stomach. When the quantity of morphin has been reduced to a very small amount, or, in some cases after it has been entirely discontinued, the patient will have a better appetite than digestion. A little care should then be exercised that easily digested food is used.

Baths and massage are beneficial in many cases. Often a hot bath at bedtime will secure a good night's sleep. In others dry heat will be more successful. The more exercise one takes, the more morphin he will require, therefore, where it is desirable to get rid of the morphin as soon as possible, the patient should take little or no exercise. In the treatment of about two hundred cases upon the above plan, my experience has been that in direct proportion to the success that I have had in recuperation previous to the reduction of morphin, has been the lessened amount of discomfort to the patient, and in the cases, only, that have shown little tendency to recuperation in spite of all efforts has there been sufficient discomfort to be worth mentioning.

PERSISTENT PYORRHEA.*

SOME POINTS ON ITS ETIOLOGY, PATHOLOGY AND TREATMENT.

BY GEO. T. CARPENTER, M.D., D.D.S.

CHICAGO.

It is not my intention to give a new name to the so-called pyorrhæa alveolaris, but to call attention to that class of so-called incurable cases of pyorrhæa in which, after all efforts at treatment on the part of both practitioner and patient, pus continues to ooze from the pocket. I do not wish to be understood as including in this class the teeth that are ready for the forceps, having lost two-thirds or more of their natural support, but teeth that in the judgment of the operator should be saved, yet do not yield to his attempts to eradicate the disease.

The one word that covers more than any other in the handling of pyorrhæa is thoroughness; thoroughness in diagnosis, thoroughness in mechanical and surgical procedures, and thoroughness in all subsequent treatment. It is very generally known and accepted by most practitioners that the extraction of any tooth affected by pyorrhæa will in time result in a permanent cure of the disease. It has also been repeatedly demonstrated that, in the majority of cases where pyorrhætic teeth have been extracted and thoroughly cleansed of deposits, and the roots trimmed, removing all roughened parts, also pulp removed and canals filled and then replauted, such teeth grow firm, and pus and pockets are not present. There must be some good reason for this changed condition,

and I am convinced that this change is brought about by removing the exciting or irritating cause. I do not wish to be understood as not believing in constitutional predispositions to pyorrhæa. I do believe that cachexia, in some cases, will render pyorrhæa incurable through malnutrition. But even in this class of cases we must not lose hope. Do something, and do it with thoroughness; break up the sameness of life; change the conditions. Tonics and alteratives are valuable, especially rest, sunshine and fresh air; also constitutional treatment for syphilitic or other taints may prove very beneficial. But the exciting causes are by far the most common and will be the principal theme of this paper.

There are three points in the irritating or exciting causes of persistent pyorrhæa to which I wish to call attention: 1. The failure to reach, recognize and remove deposits. 2. Infection, indefinitely continued from septic pulp. 3. Decalcification or molecular change in cementum and dentine.

The causes of failure in removing deposits are twofold: 1, a failure to locate the deposits; and 2, a failure to reach the deposit with any set of instruments now on the market. In pyorrhæa cases, that have received previous treatment, and where pus is still found present, we should make a careful differential diagnosis between deposits, pulp infection, and roughened spiculi. To aid in this work I use a 5 to 10 per cent. aqueous solution of cocain on cotton, pack it firmly into the pocket and allow it to remain for fifteen or twenty minutes, then protect the parts with a napkin, dry the surroundings and carefully remove the cotton, holding the mouth mirror in position so as to see all parts of the pocket the instant the cotton is removed. In cases where a better view is required pack with antiseptic gauze, and allow it to remain two or three days. If deposits are seen remove them if you can.

To insure success in removing deposits I use a pyorrhæa model of thirty-two natural teeth set in rubber tubing, and arranged in upper and lower sets in an articulator with a heavy rubber band in front, which acts as lips, and all tooth surfaces and pockets must be reached through the rubber lips. By fastening this model to the head-rest of the operating-chair, an instrument can be readily fitted by using annealed stovepipe wire, one and one-half to two inches in length, in a socket-handle. Flatten the point of the wire and bend it so as to reach the required spot or surface; then bend or make an instrument of the same angle, with a spoon-shaped point, and with it remove the troublesome deposit. I have a set of twenty-four special shapes, but I find cases where it is necessary to change the angles of these instruments in order that the spoon point may rest at the proper angle against the affected surfaces. In this way any deposit in any location can be reached and removed. The instruments should be kept sharp for this work, and the pull motion should be used, as with the push motion there is danger of dislodging and forcing a scale of calculus into the tissues, where it will be difficult to find it, and if not removed it will again become attached and the disease will continue in a more aggravated form.

The rough deposits can be detected by the tactile sense, but the hard, smooth, or glazed deposits can only be detected by actual sight. A true alveolar abscess does not discharge pus through a pyorrhæa pocket. But it is not uncommon, as a result of encroachment of pyorrhæa at the apex of a root, for inflammatory action to cause the death of the pulp, which becomes infected, and in turn will reinfest the cleansed or treated pockets, and this state of affairs will continue, or be repeated, until

*Presented to the Section on Stomatology, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1898.

the pulp is extirpated and the canals antiseptically cleaned and filled.

Circumscribed abscesses may be the result of incased deposits caused by some local irritation, and swelling that forms a barrier to the free escape of pus. From experiments which I have been making on rabbits I find that after infecting a fresh wound in the gum, with pyorrhea or other pus, the parts will continue inflamed from two to four days, and then rapidly heal, but by putting a rubber band around the tooth and pressing it under the gum and allowing it to remain, and in this way establishing a pocket, and then infecting this wound with pus from pyorrhea or chronic ulcer, you will establish the disease, which will be self-sustaining.

There have been experiments made in the human mouth where the teeth have received little or no care, but where there was no pyorrhea present, with similar results as in the rabbits, but there was a tendency to outgrow the disease without treatment; but with treatment the cases yielded quickly and a cure resulted. I think that in these cases the condition of the system was such as to resist disease, and re-establish health, and also that the exciting cause was not continued long enough or to the extent where we have deposits or other causes named in this paper.

From recent examinations for a specific alveolar pyorrhea bacillus, from cultures infected by pus-germs taken from pyorrhea pockets, a competent bacteriologist¹ has thus far been unable to find bacilli that are not found in pus from other infected traumatizations of the mouth. Yes, we mean traumatism, the same as an infected condition from a sliver in the flesh, and that is the condition that we have in pyorrhea alveolaris, with the same results becoming chronic from long standing, as fistula, ulcers, etc., in other parts. The condition of the apex of the roots of some teeth will remind one of a condition known as absorption, and is generally acknowledged as such. But can tissue be absorbed and still remain as debris in the pocket? Such is the condition found in pyorrhea pockets, which can be easily proved by taking the contents of a pocket, dissolving it in hydrochloric acid, then adding three times its bulk of water; filter, boil, and when cold add a solution of ammonia, which will precipitate the phosphate of calcium². The same result is attained by rinsing a freshly extracted roughened pyorrhea root in cold water, then with a stiff brush and water brush the roughened parts and put the resulting product into a test-tube; add hydrochloric acid and water, if necessary; filter and boil, and to this add a solution of ammonia, and the lime salts are precipitated. The decalcified cementum and dentine, through their roughened surface, spiculi and debris, act as irritants to the already inflamed tissues which are in the depth of the pocket, and as a result pus will continue to flow. Many teeth affected with pyorrhea may have a pocket only on one side of the root, leaving the three remaining sides healthy. Other teeth may have only one root affected, and the other root, or roots, as the case may be, are in good condition. To illustrate, I will cite some persistent cases from practice:

CASE 1.—Mr. G., about 30 years of age, was employed indoors at very confining work. The color of the skin and mucous membrane would suggest anemia. Lacerations or injuries to soft parts are slow to heal. He had very serious trouble after the removal of an impacted

third molar. In 1898 I made an examination of his mouth and found the right upper central and left lower central affected, having deep anterior pyorrhea pockets, with a profuse flow of pus. I gave both cases thorough surgical treatment, which consisted in the removal of all deposits and the curetting of pockets and margins of the process. I then filled the pockets with iatrol which had been moistened with equal parts of oil of cassia and carbonate of creosote, and painted the gums with tincture of iodine, repeating the iodine treatment about twice a week³. He derived little, if any, benefit from this treatment. I then put the patient on tonic and alterative treatment, and in about three months the pus in the pocket of the upper central disappeared, and the pocket closed. About this time I drilled into the lingual surface of the lower central and found the absence of the pulp. I used thorough antiseptic treatment of the canal and filled the same with chloral percha and guttapercha points. Treatment was continued from once to twice a week for two months longer, but pus still persisted. In June I examined the apex of the root and found it denuded and roughened. I amputated the lower fourth of the root and rounded the stump, and the soft parts healed kindly under antiseptic treatment, and no pus has been present at any time since the operation. The gums are not yet entirely restored, but the tooth is doing good service.

CASE 2.—Mr. H., about 50 years of age, has given his teeth considerable care, and, I think caused pyorrhea from the injudicious use of a wooden toothpick. He had several teeth affected by, and treated for, pyorrhea during the last ten years, and in all but two cases a cure had been effected. In June, 1898, he was referred to me by a brother practitioner, and on examination I found the upper right second bicuspid, and first and second upper right molars, also the interproximal space between right lower second bicuspid, and first lower molar, also lower central on same side, diseased. He had an old chronic pocket on the anterior root of the left lower first molar. This tooth and the first upper molar on the opposite side had been treated by a good dentist and given up as hopeless about eight years previous, and the patient was instructed to use a syringe with an antiseptic to keep the pockets clean, as the best that could be done for them. I gave the usual surgical treatment, as in the former case for the four other teeth, which yielded readily and where a cure was affected. At my solicitation the gentleman allowed me to experiment with the two chronic cases. On examination I found the pulps dead in both teeth; they were removed and the canals filled. I then gave them both a most thorough surgical treatment, which resulted in the almost entire cessation of pus for a short time, but the old condition was resumed. I re-examined the pockets for the cause, and continued antiseptic and stimulating treatment until September, when I considered the cases hopeless and decided to amputate the roots. In the upper molar I removed the anterior buccal root. The soft parts closed up and yielded readily to treatment and we have not had the appearance of pus up to the present time. After becoming satisfied with the result obtained in the upper molar, I amputated the anterior root of the lower molar, with similar results. The teeth are now doing good work with an absence of pus. The roots were found roughened, with slight nodules of cementum around the apices, showing Nature's attempt to recalcify and thus produce a cure.

¹ The author of this experiment will give a full report of his work on pyorrhea bacilli as soon as he completes his course of experiments.

² Atfield's General Medical and Pharmaceutical Chemistry—Calcium Reaction.

³ Talbot: Pyorrhea Alveolaris. International Dental Journal, April, 1896.

Many other cases could be reported to show the success following the thorough removal of the cause for persistence of pus in pyorrhea, which to my mind proves the local character of the disease, and shows that malnutrition plays but a small part when the actual irritation is removed.

THERAPEUTICS OF INFLAMMATION.*

BY WARREN B. HILL, M.D.

Professor of Materia Medica and Therapeutics, Milwaukee Medical College; Professor of Therapeutics, Dental Department, MILWAUKEE, WIS.

This subject would indicate a paper of wide scope and the consideration of a matter which has often been thoroughly aired and discussed. I do not wish, however, to weary you with any generalities, but rather to take up some forms and conditions of inflammation which will interest you as dentists, as well as practitioners of medicine. As was suggested here last year, there is a common ground upon which dentists and doctors may meet, and the therapeutics of inflammatory conditions about the mouth, though a place oftentimes studiously avoided by both professions, should be cultivated in common by both.

I do not wish to enter into a controversy as to the definition of inflammation, but will merely state that my remarks have to do more particularly with the pathologic condition characterized by an exaggeration of physiologic function in which engorgement and pain are the two characteristic symptoms. The rational treatment for all inflammatory processes is to remove the cause, if possible. This usually takes us into the field of surgery, as nearly all the inflammatory processes are of bacterial origin, but there is still left for the therapist an opportunity of relieving the pathologic conditions present when the other alternative is not to be accomplished, or during the time when a diagnosis is being made.

Heat and cold are the two remedies most extensively used for the relief of congestion and pain and there has been considerable discussion as to which is the more efficacious for this purpose. When the up-to-date surgeon appears before a learned body of his professional brethren he advocates the use of cold only, as that impedes the propagation of the germs which he assumes cause the trouble. In his private practice, however, he allows the use of hot applications and poultices, because it relieves the pain, and nobody will find out how antiquated his practices are in comparison with his precepts. On the other hand, the empiricist adheres strictly in precept and practice to the use of hot applications, because experience has taught him that they alleviate the two prominent symptoms present—engorgement and pain. For my part, however, it appears that each has a proper place in the therapeutics in inflammation without violating the laws of reason or repudiating clinical experience.

In the first stage in inflammation, when there is dilatation of the afferent blood-vessels and an increase in the rapidity of the flow of blood, cold applied to the part will contract the vessels and prevent the subsequent engorgement, and in this manner pain may be avoided. On the other hand, when the engorgement is already present and blood stasis has supervened, then the application of heat will dilate the afferent vessels, relieve the engorgement and alleviate the pain. This same principle

applied to internal medication will also be useful in the relief of these symptoms.

The immediate indications in the treatment of these conditions are for the relief of pain. In true inflammatory processes pain is caused by the engorgement of the blood-vessels and the impingement of the nerve filaments by the consequent exudate. The rational method, therefore, of relieving it is to reduce the arterial tension. This may be done by dilating the peripheral vessels, either by the use of diaphoretics, cardiac depressants, or counterirritants. Arterial tension is also reduced by the use of hydragogue cathartics, and congestions about the head are particularly benefited by the use of cholagogues. On the other hand, opiates, by checking alimentary secretion and increasing the blood-supply to the head, not only fail to be useful, but are contraindicated, except when given in the form of Dover's powder, which acts as a powerful diaphoretic, and relieves the congestion. In painful affections of an asthenic type, such as in neuralgias caused by faulty nutrition of the nerve-centers, they act promptly and well. In treating inflammations about the mouth I think the following hints will be of service: 1, a powerful purge, such as calomel in 10-grain doses, should be given, followed by a saline cathartic; 2, a coal-tar analgesic acting upon the skin, such as antipyrin in from 5 to 10 grain doses, or, in people of rheumatic tendencies, salol and phenacetin in 5-grain doses, each, or acetanilid and salicylate of soda in similar doses. If, on account of the condition of the patient, these heart-depressing coal-tar derivatives may not be deemed advisable, Dover's powder in 5 to 10 grain doses may be substituted. This treatment is not calculated in any way to remove the cause of the malady, but rather to mitigate the pathologic conditions presenting during the interval between the time of diagnosis and the completion of the surgical procedure. In inflammation, especially in the bony cavities about the mouth, such as pulpitis, this treatment will be found to be particularly valuable, as a considerable time often elapses before an accurate diagnosis can be made. The rationale of this treatment is apparent, as the lowering of the arterial tension by cathartics and diaphoretics not only prevents any further exudate and consequent pain, but also promotes absorption, while the coal-tar derivatives have specific analgesic properties. Illustrative of this point I wish to relate a case:

Mr. X., aged 45 years, laborer, was attacked with severe headache. A physician was consulted, who pronounced it neuralgic in its nature. The patient was told to consult a dentist, who extracted one or two teeth in the neighborhood of the most painful portion of the jaw from which the pain seemed to start. This afforded no relief. The dentist was asked to remove the one remaining tooth, which he refused to do, because it was perfectly sound. He was referred back to the doctor, who was convinced that his diagnosis was wrong and proceeded to treat the case symptomatically, as he had no basis for a diagnosis. Morphine was given in $\frac{1}{6}$ -grain doses, which was increased until the patient received $\frac{1}{3}$ grain in every three hours, the result being that the pain increased to such an extent that he could not lie down at all. At the same time, on account of the soporific action of the morphine, he could not stay awake long enough to stand up. When in this pitiable condition I was called to see him. I made a diagnosis of a circumscribed inflammation within a bony cavity and too much morphine; and prescribed 10 grains of calomel and 10 grains of jalap to be taken in one dose, followed in four hours by one ounce of Epsom salts. The relief

*Presented to the Section on Stomatology, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1898.

as remarkable, and to my mind-strengthened the diagnosis. Dr. G. V. I. Brown was called in consultation, and a careful examination was made. Percussion elicited the fact that an inflammatory process was going on in the pulp of this apparently sound tooth. Dr. Brown removed the cause, and an immediate recovery followed. The conclusions that I wish to draw from this case are:

1. Patients should not be sent from doctor to dentist and back again when a consultation is possible.
2. We should not take such a radical view of surgical procedure as the only method of curing inflammatory processes as to prevent our using all possible means for the relief of the patients during the time when a diagnosis is being made and the surgical treatment instituted.
3. We should not resort to the promiscuous use of opiates or any other analgesic as a temporary measure when the pathologic conditions may be treated rationally.
4. Having made our patients comfortable we should make plenty of time to make an absolute and accurate diagnosis, thereby saving the patient the annoyance of undergoing unnecessary and painful operations and possibly preserving for him his teeth or other necessary organs.

MEDICAL JOURNALISM.*

ITS END AND AIMS.

BY JOHN DUNCAN EMMET, M.D.

Assistant Surgeon to the Woman's Hospital in the State of New York; Assist. Gynecologist St. Vincent's Hospital New York; Consulting Gynecologist to St. Joseph's Hospital, Yonkers, N.Y., and to St. Mary's Hospital, Passaic, N.J.; Fellow of the American Gynecological, the N.Y. Obstetrical, the Woman's Hospital and Celtic Medical Societies; Charter Member of the Periodical International Congress for Gynecology and Obstetrics; Editor and Proprietor of the American Gynecological and Obstetrical Journal.

NEW YORK CITY.

Let me preface my paper with an expression of my deep appreciation of the honor which your President has conferred upon me by asking me to address you. But the personal element in his invitation, however flattering, was entirely overshadowed by the fact that the invitation itself was an evidence that the principles whose adoption by the profession I was perhaps the first to urge, in an insistent and chronic fashion, were to receive the recognition of a public hearing before the representative body of American medical journalists. For your President suggested that I write upon part of the general subject to which my editorials have been devoted.

My paper is not a long one because, not devoted to a scientific subject, it gives no scope for the usual padding of domestic and foreign quotations and references; it is, moreover, upon a theme of such paramount and urgent importance that any save the directest treatment would be inappropriate and nugatory. I have chosen for this dissertation "The End and Aims of Medical Journalism," and I shall endeavor to show that this journalism, if true to itself, can adopt but one End though its Aims may be many.

In the economy of human nature there is a principle to which all of us are at all times subject. It is a necessity of intelligent existence and is called "the law of accomplishment." In every act or series of acts of every man, whether it be to pass an idle hour or the performance of some serious work, there must always be, latent or expressed, one dominant idea—a purpose, an ultimate

object, an end. So complex are we, for the accomplishment of every ultimate object or end one or more subsidiary acts are necessary and the particular purposes or objects of these secondary acts are properly defined, in their relation to the main object, as *aims*.

It is in this sense and thus defined that I would consider the end and aims of medical journalism. It is beside the question to discuss the end and aims of individual journals or the special ideas of individual editors; it is the idea of *united accomplishment*, conveyed by the term "journalism," and its special application not only to medical subjects but to the medical profession, as expressed by its adjective, which shall occupy our attention.

It is not enough to minister to the wants of the profession merely as individual men, for it means little save irony to the average practitioner that he may read of the latest advances in his science if his family be constantly at the starvation point because his profession is powerless to protect him against the rivalry of pseudo-charitable hospitals and dispensaries, legalized quacks and other malignant enemies. To enlarge upon this idea I would say that everything which makes not only for the advancement of scientific knowledge but for the better application of this knowledge in the prevention and cure of disease comes within the scope of medical journalism. But the higher the profession stands as a corporate body in the estimation of the community, the greater must be its influence for good upon the public health. The piping voices of individual physicians can not command more than the passing, casual attention of the body politic or social but the united voice of the medical profession would come as an authoritative, irresistible force. It would be the decision of the supreme court of science, against which there is no appeal.

The end of medical journalism, therefore, must be to strive for the corporate interests of the profession, to struggle to obtain its recognition as a corporate force in fact as well as in name, that thus the public well-being in all that pertains to health, of which the profession avowedly stand as the mentors and arbiters, may be best protected and advanced. Nothing less, evidently, than this idea in its broadest scope can fill the end of medical journalism.

With this end in view, what are the means to be employed in its accomplishment, what are its "indications?" Some of these are self-evident, others are not. If medical journalism is to become the constructor of an united, corporate profession, if hereafter it is to be the defender and the mouth-piece of this great body, it must first construct *itself*; it must subordinate its special, individual interests, when necessary, to the common good and must unite in earnest for the same end and with the same aims. Petty jealousies, born of the fear of competition, and distrust must be put aside. The great journals, of far-reaching influence owing to a larger capital, must not contemn and elbow out their smaller brethren who are conscientiously working, to the extent of their ability, for the same great end. On the contrary, a policy of encouragement and helpfulness is absolutely called for here. And indeed it is needed. No society was ever reformed by those, no matter how well inclined, whose existence was a daily struggle for bare maintenance; it is there we must look rather for a natural resentment against the irony of an undeserved fate. And it is well if, beset as they are by spacious temptations, they maintain the ethical code of their more fortunate fellows. What a parody upon honesty and truth, what hypocrisy, if the great and well-to-do medical journals, preaching altru-

*Read before the American Medical Editors' Association, June 7, 1899.

istic principles and high ideals for the regeneration of the profession, turn in the same breath to their smaller struggling brethren and say: "You are too poor and insignificant to be of any assistance to us" (not to the cause, mark you!); "on the contrary you impede our influence by taking from us a certain number of subscribers who, if you did not stand in our way, would come to us!" Think you that medical journalism will become powerful and united by means of such a policy? And may we expect the editors and proprietors of the smaller journals, who for years have manfully and unselfishly struggled to maintain an ethical standard and to work for the interests of the profession, to be favorably impressed by any plan for its regeneration which involves their own extinction? No, let those of us whose influence is greater win the confidence of those who have less than, recognizing the justice and earnestness of our intentions by the consistency of our actions, they may come in with us and form a strong and united journalism. Then indeed can we successfully crush the mass of unethical, money-grubbing, journalistic small fry, who have so long been a reproach, a hindrance and a pollution to the profession.

I have heard it said that there were too many small journals in this country, that many of them were too poor and insignificant to assist the cause of medical science by the presentation of useful matter; hence, by catering to a cheap and unscientific taste, they degrade the standard of journalism and retard the development of the profession. There is much truth in this complaint, but I do not believe the remedy lies in a policy, on the part of the higher class of journals, of extermination. If these small journals maintain the code of medical ethics they accomplish within their own sphere, even though their taste from a scientific and literary point of view be execrable, what the great journals edited in our great cities can not do—they appeal to and satisfy the taste of a class of honest and hard-worked practitioners to whom a finer and more expensive mental diet, under present conditions, would mean starvation.

This class of men will not subscribe, under present conditions, for the great scientific journals. They are comforted and not abashed to read of the perplexity and ignorance of physicians of their own class and opportunities; their wives enjoy the announcement that "Dr. Smith, in the adjoining county, became the proud possessor, as the journal went to press, of a fine and healthy pair of twins and that the mother is doing well." This supplements the weekly newspaper and the interspersed jokes are not too deep or original to puzzle the fired brain of the physician when he returns to a late supper from professional calls in a thirty-mile circuit. Yes, they supply a demand. Not in contemptuous aloofness or organized attack lies the remedy against this class of journals. On the contrary, it lies in the opposite policy. By encouraging the editors of these journals, whose subscriptions are more frequently paid in chickens and potatoes than in cash, to keep in touch through their exchange lists with the journals of happier fortunes, we will make them realize that they are joined in close brotherhood with those who are ready to share their greater opportunities for the advancement of a united and powerful press. Not long could such influence be resisted; insensibly would the subscriber feel the inspiration and remember the days of the medical college, when he came face to face with the great men of his profession and dreamed that Life held something more for him than hard knocks in her closed fist.

Thus would the regenerative principle leaven the pro-

fession and the idea of union and co-operation become fixed and practical. Medical journals *then* which, through a natural inaptitude or the perverseness of their editors, refused to respond to the new awakening and, not fit to lead still dragged in the wake of their subscribers, would quickly die of inanition.

We who call ourselves the representatives of medical journalism in this country must recognize the fact that we are first called to this responsibility and we can neither ignore nor shirk it. We can not work for ourselves alone nor withhold recognition and assistance in lifting others because we fear to let them stand by our side. There is room for all who in themselves are worthy.

If all medical journals would adopt the motto "When we help each other we help ourselves," would believe it and practice it, there would soon cease to be so great a disparity in the prosperity of equally ethical journals; nor would anyone be less prosperous because another became so. For example, if the medical press would unitedly demand prompt payment from its subscribers, each journal urging this justice not for itself alone but insisting upon the broader principle that *all* medical journals are equally entitled to the support of their subscribers, the great journals, who can afford to be pioneers of reform, would not only benefit themselves but give heart of grace to their less prosperous brethren who do not dare, without such initiative, to demand that which is not only their due but for the want of which their influence for good to the profession is retarded and minimized. Then would enter into the field of journalism the only form of competition which should exist there—the personal equation of editorial ability and conscientious work.

As a beginning or working basis for the union or co-operation of the medical press I believe the following to be essential factors:

1. The formal adoption by an organized and representative body of medical editors of the End or ultimate purpose which I have outlined in this paper; by unremitting dissemination through editorials to inculcate the profession with the idea of union and co-operation; an insistence upon the necessity of this action and an explanation of its urgency and of the immense power and influence which would accrue therefrom; and the financial betterment as well which must be felt throughout its ranks, especially by those who are now struggling with the grim problem of bare existence owing to the unholy competition which is engendered and necessitated by the powerless of our disintegrated profession to protect its members from outside attacks.

2. The prompt and generous response of all journals to the call, by any one journal, for editorial support on any subject which clearly tends to the unity of the profession or its betterment as a whole.

3. The encouragement of medical proprietorship of medical journals and the discouragement of all journals whose policy is not entirely under medical control. Especially does this cause apply to those journals which do not contain editorial comment. They are "dead-wood," so far as the true end of medical journalism is concerned, and must always remain a hindrance and a clog by their immobility.

4. The adoption by all of the principle that medical journals, like other journals, must be paid for *in advance*; the abolition of the credit system and the ruthless cutting off the subscription list of all subscribers who are too dishonest to pay for what they have bought and consumed. The adoption of this principle is absolutely necessary to the existence of independent journal-

ism and the absence of it has been the sole cause of the weakness and insignificant influence of the medical press hitherto and consequently of the segregation of the profession. In order to make this rule effective, so that all may benefit, and none may suffer, it will be necessary that all should enter into a specified agreement. Moreover it will be necessary to force by all legitimate means—and they are many and practicable—those journals whose financial resources are independent of their subscription-lists and who have pursued the policy of long credits for the sake of competition to change their policy and follow our lead.

These cardinal points I believe to be the stepping-stones to an united and powerful press, whose advance in material prosperity and the dissemination of knowledge, in honor and influence, no man can gauge.

When this first aim has been accomplished, when medical editors show an united front and concerted action, we may undertake the next with full surety of accomplishment. This is to awake the profession to a realization of its corporate needs, to point out to it not only the benefits which must accrue to it, individually and collectively, by union and co-operation, but to convince it that only through these means can the elements of disintegration within itself be counteracted and even the existence of its influence for good be maintained.

We can further show how necessary it is to increase and to exert this good influence, until it shall become a controlling one, upon everything which ministers and is necessary to the dissemination of medical science and its application to health and disease.

There are several trades which are entirely dependent upon the profession for their existence. They live by us and yet here, in reversal of all laws of trade, it is the supply and not the demand which governs the equation. Large profits have been made in each of these trades at the expense of the profession; yet all the benefits have gone to enrich the producers except in so far as competition, regulated not by our demands but by themselves, have worked in our favor.

First in order of these is the medical book trade. Absolutely necessary as medical literature is to the medical man, its quality and quantity are entirely outside his control. Representing as a medical book does to its author the arduous and difficult work of years and of incalculable benefit as it frequently is to the whole world, he rarely receives from his publisher more than a pittance in comparison with the compensation of the lay author. The profits from its large sale enrich the publisher, while the medical author is expected to be content with the personal advertisement and increase in practice.

Let us take next the manufacturers of medical instruments. Here the case is far worse. No matter how much time, labor and experience an instrument has cost its inventor; no matter how valuable and even necessary its use may be in a large field of work; no matter how great and profitable its sale, its author receives his compensation again in notoriety and honor, while to the manufacturer go the financial benefits. When once the model has been given to the maker of instruments, its control passes out of the surgeon's hands. It is generally materially altered, after a varying period, to suit the exigencies of trade and a so-called improvement made by an irresponsible and usually ignorant person is expected to give another boom to its sale. In this way the most valuable instruments have passed out of their author's recognition and their usefulness has been entirely destroyed. There is no protection and no redress.

In the drug trade we find a similar state of things. The interests of the physician are ignored on all sides. Many of the most valuable preparations are proprietary while, owing to the evil of "substitution," he can not even be certain that his patients will obtain the medicine which he prescribes. Patients can procure drugs of all kinds without prescription and the retail druggist does not even hesitate to usurp the physician's rights and prescribe. The daily press teems with advertisements of drugs and remedies for every form of disease, the inducement to buy which is that thereby a physician's diagnosis and prescription are rendered unnecessary. Thus the profession can protect neither itself nor others.

In the necessary process of regeneration the profession will realize the importance and the justice of taking under its own control and regulation the output of all trades which are dependent upon it. It will thereby secure a more equitable division of the emoluments, great abuses will be remedied and the benefit conferred upon itself and on the general public will be incalculable.

Until very recent years, the end of medical journalism in this country was that of all commercial enterprises—money-making. It was entirely in the hands of the publishers of medical books. The means they employed for the accomplishment of their end were undoubtedly of benefit, if only a partial one, to the profession, in that they supplied medical literature which the profession could not or would not supply for itself, but the greater interests of the profession, its dignity, its immense potential influence, its opportunities for greater prosperity and power were never touched upon—as how could they be?—and the profession has slumbered on or quarreled and fought, taking its pap contentedly from whatever careless hand would give it.

But to-day, when medical journalism is coming rapidly into the hands of medical men, its end and aims have changed. We will no longer feed the profession upon pap with a medium of soothing syrup; we will say: *Stand up and feel your limbs; they are massive and strong. Here is a man's food; feed yourself.*

For we are not hirelings; and the interests of the profession are our own interests.

RECENT BACTERIOLOGIC RESEARCH.*

ITS EFFECTS ON MODERN SURGERY.

BY JAMES J. CLAUSEN, M.D.,

Instructor in Pathology and Bacteriology, Kansas City Medical College;
Pathologist to the Kansas City, Fort Scott and
Memphis R. R. Hospital.
KANSAS CITY, MO.

The prevention of infection and the securing of ideal aseptic healing of wounds inflicted by the surgeon's knife being almost entirely a question of mechanics, many physical difficulties have become familiar to us. We have learned to mistrust the efficiency of antiseptics and have become aware of their toxic and devitalizing effects upon wound surfaces. Fortunately, bacteriologic experimentation has been revolutionized, and led to more reliable results, owing to the recognition of the very different behavior of bacteria in test-tubes and in wounds. With the inauguration of aseptic principles by Neuber, Bergmann, Schimmelbusch¹ and a host of others over ten years ago, the perfection of simplicity seemed within reach. And yet, while in our days, phlegmonous inflammation, erysipelas, tetanus and malignant edema following operations are almost unheard of, we not infrequently see a

* Read before the Missouri State Medical Association, at Sedalia, May 17, 1899.

stitch-abscess, an escaping ligature or a local suppuration interfere with the ultimate cure for which the operation was undertaken.

Of the four sources of infection, only one has been satisfactorily eliminated by boiling or steam sterilization. I refer to instruments, ligatures, sponges, dressing material, etc. The remaining three sources—the air, the surgeon's hands and the skin of the patient—are still with us. To prevent infection from the air, it is well to have the operating-room well ventilated, and then thoroughly closed a short time before the operation, and every one entering the room should wear a sterilized gown. The shoes take a not inconsiderable amount of dust into the room, which dust is liable to be deposited upon the wound; to avoid this, some advise the use of rubber overshoes, moistened with bichlorid solution, on operator, assistants and spectators.

A much more fruitful source of infection than dry dust is the bacteria thrown into the wound enclosed in minute droplets of moisture from the mouths of the operator and assistants. Tyndall's² experiments seem to show that air, quietly expired from the lungs, is practically free from microbes. Flügge³, however, has proved that numerous and often virulent microbes exist in the air expired during the acts of speaking, coughing, sneezing, etc. This virulence is due to their existence in a moist state, ready for immediate reproduction, while those in dry dust require a period of incubation. Silence while operating is the best preventive against this accident, but when one considers the prevalence of "catarrh," it may perhaps be wise to wear a mask consisting of two layers of fine mull, as devised by Hübener⁴, and also a protection for the beard and hair. Nutrient plates exposed for ten minutes to air expired from a man talking without a mask have given 100 to 600 colonies, while with a mask the colonies varied from 0-1 or 2, or exceptionally 10-20.

Recently, Gottstein⁵, in Mikulicz's clinic, has shown that it is impossible to render the hands bacteriologically sterile by any present known method. He found that hands apparently sterile, immediately after disinfection, were often not sterile soon afterward, and never sterile at the end of an operation. Pyogenic organisms were often found among the colonies. These experiments led to a technic in which no brush was used twice without re-sterilization, and each individual had his own supply of alcohol, lysol or bichlorid. The finger tips were dipped in strong Tr. iodine, and during the course of the operation, the hands were frequently antiseptized. Finally, in the same clinic, the superior asepticity of sterilized thread operating-gloves, changed frequently during the work, was demonstrated beyond a doubt by means of a large series of culture-tests, but whether they should come into general use in aseptic work, remains to be determined, as they are a hindrance to delicate manipulations. At present, many of the world's best surgeons are making use of them.

In view of ascertaining to what extent the last source of infection—the patient's skin—can be overcome, Lowenstein⁶ in over 100 cases placed small pieces of disinfected skin into culture-media at the time of operation. He obtained absence of growth in 40 per cent. Lockwood⁷ and Samter⁸, similarly, but at times dividing in smaller particles, found absence in 30 per cent. Gottstein⁹, in a much larger series, by scraping the excised piece, using three sterile knives, and planting separately, superficial, middle and deep layers, found absence of growth in only 20 per cent. The deeper layers most frequently contained microbes, consequently disinfection is seldom if ever ob-

tained. Not only the deeper layers of epidermis, but hair-follicles, sebaceous glands and even the lymph-spaces of the true skin often harbor microbes. Formalin wet dressings changed every six hours for twenty-four or forty-eight hours previous to operations seem to have given the best results. Fortunately, the ordinary skin bacteria are not of a very pathogenic nature, the staphylococcus albus, the cause of stitch-abscess, being most frequently met with.

Hægler¹⁰, of Socin's clinic, found that sutures and ligatures from stitch-abscesses often gave negative results from culture, but that if microscopic sections of the knots or threads were made and stained by Gram's method, bacteria were always demonstrable inside the fabric.

To avoid stitch-abscesses and escaping ligatures, it is advisable to impregnate the ligature and suture material with some antiseptic—bichlorid, iodoform, silver—in order to inhibit the growth of any bacteria which may gain access to and find shelter within the thread, and thus escape the bactericidal action of the primary wound secretion. The necessity of returning to antiseptics in this particular is shown by another observation of Hægler. Silk ligatures, sterilized by boiling, when pulled through the fingers of disinfected hands almost always become infected, and give positive results on culture, while if, in addition, the ligature has been impregnated with bichlorid, all growth is inhibited.

While the larger absorbing surface presented by the peritoneum is capable of looking after microbes—which are introduced during all so-called aseptic operations in the abdomen—and thus our gynecologic brethren may be able to discard antiseptics more or less safely, I am firmly convinced that it is dangerous to discard them in general surgery.

A CASE OF MIDDLE EAR DISEASE.

SIMULATING MENIERE'S DISEASE.*

BY WILLIAM LINCOLN BALLENGER, M.D.

Lecturer on Laryngology and Rhinology, College of Physicians and Surgeons.

CHICAGO.

This case has excited some interest inasmuch as it has been diagnosed and treated by several physicians for very varying diseases. The same complex of symptoms has led the physicians to widely different conclusions. A few have diagnosed some form of stomach trouble, and one, Meniere's disease. My conclusions will be given after reviewing the history and symptoms of the case.

J. A. B., aged 41 years, a business man, was referred to me for examination, by Dr. W. H. Weaver, who has him on treatment for his ear disease. It is by the consent of Dr. Weaver and the patient that I report the case. He complains of recurring attacks of dizziness, nausea, vomiting and tinnitus. The tinnitus is likened to the roar of a distant moving locomotive. When the right ear is stopped the subjective noises cease. Stop-

*Read before the Chicago Laryngological and Climatological Society, May 20, 1896.

ping the left ear has no effect on the subjective noises. There is slight pain in the occipital region, occasionally. The attacks of dizziness, nausea, etc., are preceded by a full feeling in the head for about fifteen minutes. In walking there is a tendency to walk off into the gutter, or against the side of the adjacent building.

The first attack came on about four years ago and lasted for thirty days. During the height of the attack there is usually nausea and vomiting; after two to four weeks the symptoms subside and dizziness remains as the chief sign. The attacks are usually about one year apart and seem to depend somewhat on the season. The onset of winter seems to precipitate one. The last attack came on in November, 1898, and lasted until April 4, 1899, when it was suddenly relieved by Politzerization at the hands of Dr. Weaver. The ears have been inflated about three times a week since then.

In the physical examination of the drumhead in the left ear the drumhead was markedly retracted, lusterless and thickened along the manubrium, in the right slightly retracted, lusterless, and also thickened along the manubrium. Tuning-forks ranging from 26 to 2048 vibrations per second were heard with both ears, but more faintly in the left. The Weber test gave plus in the right or better ear. The Rinné experiment gave right ear $=+5''$; left ear $=$ no bone conduction. The Politzer accoumeter was heard but a few inches from either ear. The Galton whistle was heard to about 40,000 vibrations per second in each ear.

The above group of symptoms seems somewhat contradictory at first thought, but when these are studied carefully they are found to be characteristic of a certain type of middle ear instead of labyrinthine disease, or of stomach disorder. The presence of increased bone conduction on the right side, and the absence of bone conduction over the left mastoid seem to point to some form of nerve or labyrinthine deafness. When the deafness is due to middle ear disease there is usually an increase of bone conduction on that side, while if the deafness is due to nerve or labyrinthine disease there is a decrease of bone conduction on the deaf side. This gentleman is most deaf in the left ear and bone conduction is entirely lost on that side, while it is comparatively greater on the right side or side of best hearing. Thus far the signs point to nerve or labyrinthine disease. When, however, we remember that the Galton whistle was heard to the normal limit—10,000—it becomes apparent that there is need of further investigation before deciding as to the exact nature and location of the disease. If it were true nerve deafness the high tones of the Galton whistle would not be heard. I accordingly inflated the tympanic cavities through a catheter and again tried the Rinné experiment with the remarkable result as shown in the following statement: Rinné right ear, $+10''$; left ear $+10''$. In other words, bone conduction had been restored in the left ear, both ears now approaching well toward the usual normal Rinné test.

The explanation is simple: the extreme retraction of the drumhead had forcibly driven the foot-plate of the stapes into the oval window, thereby producing increased intralabyrinthine pressure which accounts for the loss of bone conduction on the left side. Real nerve deafness does not exist, but there is a functional disturbance due to a change of tension. The nausea and vomiting were also due to the increased intralabyrinthine pressure and not to real stomach disease. The case is certainly not one of Meniere's disease, as in that disorder there is sudden and complete, or almost complete, loss of hearing,

attended by nausea and vomiting, all of which are due to an effusion of blood and plastic lymph into the semi-circular canals and vestibule. The hearing is rarely if ever improved after such an effusion. In this case there was no great loss of hearing and there are abundant evidences of disease of the middle ear to account for all the phenomena in the symptom-complex herein recorded. The case may be called Meniere's symptoms, but not Meniere's disease. It is in reality a case of chronic otitis media with great retraction of the left drumhead whereby intralabyrinthine tension is increased.

Malarial Hemoglobinuria.

CINCINNATI, OHIO, July 30, 1899.

To the Editor:—I have been particularly interested in the articles on malaria, in the JOURNAL of July 29. Coming from such acute observers as Dock and Fackler, they can hardly fail to attract attention, and certainly influence if not compel belief. Of especial interest is Dr. Dock's handling of that much discussed subject, malarial hemoglobinuria, and his remarks concerning the frequency with which this complication is reported on insufficient grounds, i. e., without corroborative blood examination, leads me to report a case in which the diagnosis was repeatedly confirmed by the use of the microscope. In brief, the history is as follows: A white adult male, aged 40, with frequent attacks of chills and fever for over a year previous to passage of blood in his urine, had taken quinin irregularly during that time, but had not taken any for several weeks previous to his hematuria. Blood had appeared constantly in his urine for two weeks previous to his coming under my observation, at times, he claims, almost pure blood being passed. In addition, he complained of progressive weakness, rapid emaciation, nausea, anorexia, dizziness, shortness of breath, palpitation, slight tremor of limbs, and cough. Physical examination: temperature 100, pulse 100, respiration 30; lungs showed a few coarse and fine mucous rales at apices anteriorly and posteriorly; heart normal; spleen somewhat enlarged; no enlargement of liver. Urinalysis: color light amber, acid reaction, sp. gr. 1016; sediment reddish, amorphous and very abundant; albumin present and in considerable quantities; no sugar; no bile. Microscopic examination shows a few red corpuscles and a large number of "shadows," a few crystals of uric acid, urates, granular and epithelial casts. Examination of the blood revealed crescents and ovoids; no other form found at that time. He was put on Fowler's solution, grt. iii, three times a day, to be increased one drop per day. By the next day he had passed nineteen ounces of urine, and the red sediment and albumin were much less abundant. He was not given quinin at that time, the latter drug having but little influence over the estivo-autumnal parasite. On the second day he passed fifty-one ounces of urine with but slight red sediment. Quinin bisulphate was now started, 5 grains three times a day; the quinin did not increase the amount of blood in the urine. On the seventh day he passed seventy-three ounces of urine; flagellate bodies were seen in the blood for the first time. By the tenth day the blood had disappeared entirely from the urine, though albumin and casts still persisted, but no "shadows." At that time the quinin was increased to gr. x, t. i. d., and the Fowler's solution had increased to grt. vi, t. i. d. This treatment was kept up for forty-five days, and by that time no plasmodia had been observed for over a week. I then lost sight of him for a time, but subsequently, on dropping his treatment after a few months, he was again attacked with the passage of bloody urine. One other point of interest in the case was that after a month's treatment as above, the hemoglobin was found un-

changed, on both occasions registering 37 per cent. division of two drops; nevertheless he gained markedly in weight and in health and strength. I am somewhat inclined to the belief that the destructive action of the quinin on the red blood-corpuses neutralized in a way the good effects obtained by the administration of arsenic. Here then is an unmistakable case of malarial hemoglobinuria which was given quinin during the time of the passage of the blood, yet the blood in the urine, so far from increasing, steadily diminished. I have never seen an instance of hemoglobinuria in one of the regularly malarial intermittents, but have no doubt that if such occur, the result would be more favorable under quinin even than the case I have just reported. I do not think that even if quinin does produce hemoglobinuria in malaria, which I do not believe, that factor alone should deter us from using a drug which is almost a specific to the disease which we do know is frequently accompanied by this complication.

In regard to hypodermic injections, I wish briefly to state my experience with 7 cases of malaria all treated in this manner: all young adult males with fairly good family history; all of tertian malaria, 6 double and 1 single, in all of which the diagnosis was made by microscopic examination. In 3 all manifestations of the disease were stopped by one injection; in but 1 was no influence felt by one injection; in but 1 case was more than 6 grains given at a dose; the bisulphate was the preparation of the quinin used; all the injections but one were made deep in the gluteal region; very little pain was experienced, and that only at the time of the injection; but ten injections were used in all; no abscesses resulted from their use. In the cases in which an endeavor was made to change a quotidian or double tertian malaria into a single tertian by hypodermic injection of quinin, 1 was completely successful; 2 were partially successful; 3 were unsuccessful. Of these 3 cases 2 were completely cured by one injection, as shown by subsequent clinical history and blood examination; the remaining case was not much affected. I might say in conclusion that the injections were given at the very beginning of the chill. Very truly yours,

MARK A. BROWN, M.D.

Dr. Murphy's Letter on Optical Diagrams.

RICHMOND, IND., July 31, 1899.

To the Editor:—In the JOURNAL of July 29, there is a letter by Dr. Murphy of Kansas City as to "Misleading Statements and Illustrations in School Physiologies, Physics, and in Text-books on Diseases of the Eye," but unfortunately in this case it is Dr. Murphy who is misleading. He states that the text-books teach that parallel rays of light focus on the retina in the normal eye. This is just what they have taught, do teach, and always ought to teach.

The first three illustrations, which he states are incorrectly drawn, are just as correct as his Figures 5, 6 and 7. Possibly some slight objection may be made to them all, in that they take for their basis the old ray theory, which is entirely superseded by the wave theory.

Scheiner's experiment any one can perform by taking a visiting card through which two pinholes have been pierced, the distance between which is less than the diameter of the pupil; it will be found that if this diaphragm is held close to the eye while a bright star is being observed, and the subject is ametropic, there will appear to be two stars. If the upper right pinhole is covered with a red glass, while the subject is hyperopic, the red star will appear below; whereas, if myopic, the red star will appear to the observer as if from above. In the emmetropic there will be a fusion of the red and white stars into one.

This merely proves that Figures 1, 2, and 3 are consistent, for waves or rays from a star, that enter the pupil, are parallel. If we can suppose a case in which the upper part of the

star was flattened so that we could tell it from the lower part, then in Scheiner's experiment, no matter if the observer was myopic, emmetropic, or hyperopic, in every case the flattened part of the star would face the lower part of the retina, while to the observer it would appear erect with the flattened part at the top, as in Nature.

DAVID W. STEVENSON, M.D.

Retention of Life.

WASHINGTON, PA., July 31, 1899.

To the Editor:—Apropos of the editorial on "Retention of Life," in the JOURNAL of July 29, allow me to mention two cases which came under my observation in the past two years, while an interne in Western Pennsylvania Hospital.

The first patient, a slender youth of 19 years, slipped while attempting to board a moving train. The wheels crushed the right upper arm, right side of the pelvis, and left thigh. He reached the hospital in ten or fifteen minutes. Bleeding had stopped, but the cinder-covered bowels were protruding over the crushed right os innominatum and lateral abdominal wall. The patient was conscious and rational for fully an hour after the injury, until he died.

In October, 1897, a young tramp was found beside the Pennsylvania tracks, and brought to the hospital by ambulance. Examination showed both thighs entirely severed from the body, so closely to the pelvis that no operation could have given the needed flaps. The wounds were merely dressed; yet the patient lingered for almost a week. During this time death was expected almost hourly, yet consciousness remained till near the end.

To my mind such cases illustrate Nature's method of arresting hemorrhage from severed vessels—torsion. In this section of the country some surgeons rely almost exclusively on twisting the arteries to stop bleeding during an operation, and I have seen no untoward results, even when the popliteal and brachial arteries were twisted. The method certainly is deserving of more prominence than our works on surgery give it. Very truly yours,

THOS. WRAY GRAYSON, M.D.

[Arresting hemorrhage by torsion has been discussed in medical journals, is mentioned in most of the text-books, and is used to a great extent by many surgeons. Our correspondent is mistaken if he thinks the method is not recognized.—Ed.]

Yellow Fever.

WASHINGTON, D. C., Aug. 5, 1899.

To the Editor:—Among the outbreaks of yellow fever that have prevailed at Fortress Monroe, Va., and its vicinity let me mention one that has never been reported. In the early part of August, 1869, I had just come from quarantine duty at the mouth of the Rio Grande River, Texas, and being ordered to Fortress Monroe, found a French man-of-war quarantined in Hampton Roads because of yellow fever. Many of the crew having died, as well as the medical officers, the ship was visited daily by a surgeon from the fort, who went unrestrained about his duties after coming ashore. It was not long, however, before an unmistakable case of the fever broke out in a member of the family of one of the surgeons who had most to do with the fever patients on shipboard. We decided to keep the matter strictly secret, even from the commanding officer, and await developments. Happily the patient made a good recovery, and the disease did not spread. To this day no one but the two medical officers in attendance have ever known of its existence. To be sure, one case does not demonstrate much, but this instance shows the transmissibility of the disease, and the fact that its spread was controlled by isolation, and perhaps secrecy; for had the presence of yellow fever become known at that time among the twelve hundred people in this fort, many of them women and children, there is no telling how the panic ensuing from publicity of the fact would have ended.

1. See abstract in JOURNAL, May 20, p. 1116.
2. Ibid. p. 1117.
3. **Parotid Extract in Ovarian Disease.**—After noticing the experiences of Shober, Mallett reports and analyzes some twenty cases in which he has used parotid extract for ovarian disease, and his summary does not attempt any physiologic explanation of the action of the parotid gland, but simply states some of its effects as he has observed them. 1. It has seemed to relieve the pain of dysmenorrhœa in all cases, without regard to alleged causes and present conditions, to a greater extent than any of the numerous so-called uterine sedatives which he has been able to obtain. 2. It relieves those dull, aching pains referred to the back and ovarian regions, usually designated by those familiar, though vague and unsatisfactory terms "reflex pains, neuroses, ovarian neuralgia," etc. 3. Menstruation, when deranged, becomes more regular as to periodicity and less in amount and shorter in duration. 4. During its exhibition pelvic exudate seems to soften and become absorbed more rapidly under abdominal-pelvic massage. 5. The general health, strength, appetite, and spirits seem also to improve under its use, and those dull headaches, which constitute such a persistent and annoying symptom in these cases, are almost invariably

relieved and in some disappear entirely. 6. The only counter-indication that he has thus far met in its use has been in cases of the artificial climacteric, in which cases the flashes of heat and cold were distinctly made more frequent and severe. In concluding his paper he remarks on the decreasing birth-rate and the importance of conservative treatment of ovaries and tubes.

6. **Hour-Glass Constriction of Membranes in Labor.**—Tucker calls attention to this complication of the first stage of labor, and reports five cases which he finds due to six factors; namely: partial opening of the cervix; resistance to further opening; non-engagement of the presenting parts; separation of the choroid; toughness of the membranes, and uterine contraction. The diagnosis of this condition, if its possibility is kept in mind, ought to be made with certainty and it is of importance as enabling us to guard against too early rupture of the membranes and the unpleasant consequence of a dry labor.

8. **"Christian Science," Divine Healing and Osteopathy.**—Bullard shows up the character of these frauds very fairly, quoting from osteopaths themselves to show that they admit that their sect has no reason for existence except the financial one, the ability to extract money from their gulls.

9. **Radical Cure for Hernia.**—Wills describes and compares the various methods, viz., when the sac is not removed but used for a stop gap, or reinforcement (Koehler, Duplay, McEwen); 2, when the cord is allowed to remain in the canal, the walls being re-formed before and behind by peculiarly placed sutures (Bassini, Lucas-Championniere); and 3, entire obliterations of the canal, the cord being lifted out entirely and brought out higher up than the internal ring, through the muscular tissue, and left outside in subcutaneous tissues (Halsted, Fowler, and others). He then gives his own results. In his former series, reported two years ago, he used Halsted's method in all cases but one, and had two relapses. In the present series of fourteen cases he used Halsted's once, Fowler's transperitoneal method twice, and Bassini's method nine times. Two died; the rest have all done well. Each case was treated by the method that seemed best adapted to it. Wills believes that over-preparation of the skin about the groin, by lessening vitality, is responsible for some infection by the white skin germs whose home is in the follicles, and that interrupted s. w. g. sutures draw this down into the wound where moisture and heat favor their exciting supuration. The subcuticular suture lessens this danger. He does not especially favor the use of rubber gloves, and has had better results since he began, a year ago, to place a rubber drainage-tube in the lower angle of the wound. He admits that this looks like partial aseptic failure, but the result is what is aimed at. The method of operation is a matter of choice, but there is danger in ligating the sac neck in that it leaves a dimple on the peritoneal side, and this receives the impact of the bowels and favors a relapse. He has been in the habit of ligating the sac neck by transfexion with double suture, and with two long ends of the suture, drawing the ligated neck as far up as possible behind the abdominal wall and suturing it there, bringing out the sutures and tying outside of the aponeurosis of the external oblique muscle, fixing the dimple against sound muscular wall, thus preventing downward pressure on it and bringing a relapse. This plan has served him well. He keeps his patients in bed four to six weeks, and makes them wear a spica bandage for a month or more, but never a truss.

11. **Prevention of Conception.**—King has taken pains to collect the opinions of physicians and clergymen, Catholic and Protestant, on this subject. He finds that Catholic clergymen are almost unanimous against these practices, and physicians generally of the opinion that while they may be socially dangerous and condemnable, they are not necessarily dangerous to health, and are advisable in certain cases. He combats the Catholic view, supporting himself on physiologic and ethical grounds and by scriptural references. In conclusion he specifies the conditions on which he thinks physicians may select, and prescribes some methods of prevention, viz.: 1. When conception would prove dangerous to the mother; 2, when the child would inevitably inherit serious and incapacitating disease; 3, when the parents are obviously unable to afford the child reasonable food, raiment and care.

12. **Rational Diagnosis.**—This paper is the annual ad-

dress on medicine before the Wisconsin State Medical Society.

13. **Influenza Pneumonia.**—Holbrook, first stating that reliable statistics show that within the Lake Michigan region, out of every hundred deaths from influenza, fifty are due to complicating pneumonia, remarks that a large number of these pneumonias conform to no frank type of the disease, but present symptoms not described in the text-books or taught from college platforms. Although it has lately been somewhat the subject of writings and discussion, there is yet much to be done for the better understanding of the pneumonia that follows la grippe insidiously, with a pulse not above 90, temperature below 100, respiration of 25 to the minute, and no lancing pains, cough or expectoration, and with physical signs too obscure for diagnosis, and is yet a pneumonia that may eventually consolidate the lungs and be one of the most dangerous forms of this dreaded disease. As to the etiology, it is certainly due to the toxins, but just how is not entirely explained. The most probable theory is it causes, through the nerve-centers, a passive congestion. The bacilli of influenza and pneumonia are generally present, but as to whether the pneumococcus is essential there is a difference of opinion. After noticing the classification of grippal pneumonia of Lemoine, and stating that the symptoms are not constant with it, he reports a case which he offers as a type of atypical pneumonia of influenza. The treatment is that of other pneumonias, with special care during the convalescence. The prognosis is generally given as bad. Following a depressing disease, it is a serious form, but other things being equal, there is not so much difference between it and other pneumonias in this respect, except the greater likelihood of a slow recovery and serious complications. He calls attention in conclusion to the importance of a correct diagnosis, repeated chest examinations, and painstaking study of the case.

15. **Labor Complications.**—Dobbins' paper is to be continued, and can better be noticed when complete.

16. **Tolerance of Pregnant Uterus.**—Anderson reports a case in which he was called on to operate for vesicovaginal fistula. He found laceration of the cervix, which had extended, involving the bladder wall up to very near the angle of the right side. He operated and succeeded in pulling the uterus down far enough to pare the edges and close the bladder opening and perform trachelorrhaphy. The operation seemed to him unsatisfactory, but he introduced a drainage-tube into the uterus, irrigated the bladder with a boric acid solution, and, after a time, on examination, found that he had had perfect results. Before dismissing the woman, wishing to satisfy himself that the cervix was pervious, he had her taken to the operating room and introduced a sound into the uterus. The operation was performed Dec. 15, 1898. Menstruation had been irregular, the last having been November 25. Everything went smoothly along for some time, when he was informed that she was developing a tumor, and she was brought back to be examined. He found her seven months pregnant, so that trachelorrhaphy had been performed, drainage-tube introduced into the uterus, the uterus had been sounded, all during the early stages of pregnancy, and yet without producing abortion. All the data he can gather show that the woman was two months pregnant at the time of the operation.

18. **Diagnosis in Obstetrics.**—The previous installment of Ayers' communication was noticed in the *JOURNAL* of July 8, par. 8, p. 93. This one considers: The fetal body, movable and fixed; the highest point reached by the body in right, left, or middle of fundus; anterior lateral position, etc.

19. **Renal Tumors.**—After noticing the various forms of renal neoplasms, Weber remarks on the signs and symptoms, and says the growth and enlargement is the most constant sign; it always occupies the lumbar region except in rare cases of movable kidney. Lying between the ribs and iliac crest, it extends forward into the abdomen; the fingers can not be got behind it, and there is no resonance between the tumor and vertebra. Distinct bulging from behind is rare. The tumor usually retains the renal outline more or less. It may be somewhat nodulated, but never presents distinct notches like the spleen. The colon is invariably found in front or by the side of it, and it is very rare not to have the bowels in front of the kidney tumor. When on the right side, the cecum and

ascending colon may be displaced inward, and on the left side it may extend forward and inward, pressing the descending colon to its outer side, though it will be more frequently found on its anterior surface. The colon is practically never found in front of an enlarged spleen, and only rarely overlaps an enlarged liver. In some instances the tumor has been observed to leave its position and float forward in front of the small intestine, and may then be readily mistaken for an ovarian tumor. Renal tumors are found slightly mobile on palpation, as well as by the act of inspiration, and a deceptive sense of fluctuation is sometimes obtained. Hematuria, when nephritis or disease of the bladder and urinary tract can be excluded, is a very important symptom. It is said to occur in 50 per cent. of cases, and is more common in adults. Sometimes it is the first sign; in a few it persists throughout the case. In many cases it is intermittent, or it appears only near the close of the history. Pain, from a dull ache in the loin to severe, lancinating, colicky pain extending to the bladder, has been observed, but too much importance must not be given this symptom. The examination of urine is not generally of great value. The diagnosis is made largely by exclusion, and Weber gives the following points in regard to this: 1. By recent observations it is shown that degeneration and neoplasm of the suprarenal bodies occur more frequently than was formerly known; tumors starting in the suprarenal capsules primarily might in some instances have been diagnosed as renal tumors; when they are of considerable size it will be next to impossible to say whether the corresponding kidney be involved or not. 2. Perirenal lipomata may grow to enormous size, filling out the greater part of the abdominal cavity; dropsy, emaciation of the body and cachexia follow in the course of time. 3. Omental tumors are flattened, cake-like, and may be often palpated as a band or elongated mass passing transversely across the abdomen. 4. Mesenteric tumors, either cystic or solid, are generally round and freely movable; their prominent part is near the umbilicus; there is resonance all around them; urinary symptoms are absent. 5. Peritoneal growths, peritoneal abscess and induration, cystic and tubercular kidney may come up in the question of differential diagnosis. 6. Gumma of the kidney weighing up to one pound has been, may also be the seat of a growth. Hydatids may Israel. A case of syphilitic cirrhosis closely resembling tumor has been reported by Kelynach. 7. Hydronephrosis, pyonephrosis, nephritic and perinephritic abscess and renal calculus will be associated with renal colic and show important symptoms in the urine, such as blood and pus, which will assist us in diagnosing them. 8. Movable kidney, it is to be remembered, may also be the seat of a growth. 9. Hyatids may be deceptive when retroperitoneal; hydatid tumors of liver, projecting tongues of liver may present considerable difficulty when we try to eliminate the presence of renal tumor. An enlarged gall-bladder will be pushed upward and more prominent when the colon is inflated. A movable kidney will be pressed back into the loin under the same circumstances. 10. Splenic enlargements; no intestine in front, notched border, resonance between it and the spine. Ovarian and uterine tumors, and fecal impaction have also to be eliminated. The "phantom" tumor of the abdomen may readily simulate a number of abdominal disorders; considerable swelling of the abdomen is often noticed secondary to pelvic and other inflammatory conditions of the abdomen.

Having diagnosed a renal tumor, it is well to bear in mind that our knowledge of the biology of these growths at the present time is too limited to allow of our making a definite diagnosis as to their structure and essential nature during life. We may, however, safely make the following statements: A rapidly increasing growth of the kidney is almost always of a malignant nature. The forms usually met with in infant life are sarcomata; adenomata occasionally occur in early life, but do not often produce secondary deposits. In adult life almost any form of growth may develop; carcinomata are particularly limited to adults. The various forms of cystoma especially belong to adult life; sarcomata do occur, but much more rarely than in the young; malignant suprarenal and perirenal tumors are generally met with in adults alone. Weber reports four cases.

21. **Diseases of Children.**—In Caille's report, cases of the

following are considered: incontinence of urine; convulsions of reflex origin; acute emphysema; muscular insufficiency; eczema, and apex pneumonia.

22. **Pneumonia and Typhoid.**—Gradwohl, noticing an incorrect usage of the terms typhoid pneumonia, pneumonia typhus, etc., points out the three varieties which he thinks ought to be recognized: That form in which with croupous pneumonia there are marked typhoid symptoms without gross intestinal lesions and Vidal reaction. Here we find a true croupous pneumonia with marked toxemia and severe general symptoms, but bearing no relation to the specific attack of typhoid. This has been called by misnomer, "typhoid-pneumonia." There is also a form called by the French and Germans, "pneumo-typhus," characterized by sudden onset with symptoms of lobar pneumonia, and after the crisis we have the symptoms of typhoid fever. This is a mixed infection of pneumonia and typhoid. There is also a third variety which has been recently described by Fränkel, in which pneumonia signs appear after the appearance of typhoid symptoms. Fränkel divides this into three groups: 1. Cases of pneumonia, accompanied by typhoid symptoms, irregular fever, and diarrhea, coma, etc. In these cases, if the consolidation is central and the physical signs obscure, the diagnosis becomes very difficult. 2. In the second group he places those cases of frank lobar pneumonia which arise in the course of typhoid fever. They are extremely rare; he has seen but six in over 500 cases of typhoid fever. 3. Those cases where, in the course of typhoid fever, a pneumonia caused by the Eberth bacillus is set up. Fränkel says that pleuropneumonia often develops in the fifth week of typhoid, and that aspiration will evacuate a purulent exudate containing the bacillus typhosis in pure culture, and autopsy later will reveal the interstitial pneumonia. Gradwohl reports in full a clinical history, post-mortem and bacteriologic findings of a case of this third category of Fränkel. He closes his paper with remarks on differential diagnosis of the bacillus coli and typhus bacillus, with special mention of Hiss's culture-method for their distinction.

24. **Silver Salts in Ophthalmology.**—After noting the testimonies of various authorities in regard to protargol, Renaud gives his own experience. He finds it decidedly beneficial in catarrhal conjunctivitis, but slow in action in the gonorrhoeal form, though reliable and satisfactory in every respect. He has not found it satisfactory in trachoma. It worked well in chronic conjunctivitis and corneal ulcers.

25. **The Tuberculin Test.**—Otis' article first notices the fact that the test has been objected to, that in certain cases the reaction is not reliable, and suggests that above a certain dose, maximum to the individual, what at least stimulates a general reaction may occur in a healthy individual from temporary poisoning by the tuberculin. His observations are extended over 111 cases, and his results up to the last year were published in the *Medical News* of July 9, 1898. He adds them to the figures for this year. Out of 56 cases of unselected cervical adenitis there were 23 reactions, 6 slight reactions and 2 doubtful. Throwing out the slight and doubtful, we have 58.9 per cent., including them, 73.2, or an average of 65 per cent., indicating the proportion that were tuberculous. He compares these with the results of others and thinks it probable they are correct. In eight cases of syphilis and one doubtful one, there were 4 reactions. There does not seem to be any doubt that a certain portion of such cases will react. In 6 cases of more or less advanced pulmonary tuberculosis, bacilli and sputum, three gave no general reaction after 10 or 12 mg., and one none after 5 mg. It would appear, therefore, that the pulmonary tuberculosis when more or less advanced will not give a general reaction from 5, 10 or 12 mg. of tuberculin, and he calls attention to the fact that in advanced cases the reaction may be slight, while the reverse is true in any case. He summarizes his conclusions as follows: 1. The tuberculin test indicates early tuberculosis by a general reaction in the majority of cases, before it can be detected by other methods, the X-ray excepted. 2. The dose to accomplish this is from 5 to 10 mg. of Koch's original tuberculin. 3. No injurious results occur from the use of tuberculin in these doses. 4. Proved tuberculosis in a more or less advanced stage may fail to give a general reaction with doses of from 10 to 12 mg. 5. Syphilis gives a reaction in an undetermined proportion of

cases. 6. A non-tuberculous person may give a general reaction with a dose above the maximum used in the test. 7. The reaction may be delayed from six to twenty-four hours. As rules to be observed in making the test: 1. Always use the same tuberculin and of a standard strength. 2. Use aseptic precautions in giving the injection. 3. Make the injections deep into the muscles. 4. Keep a two, three or four hourly chart of the temperature if possible, beginning twenty-four hours before the injection. 5. Allow several days to elapse before repeating the test. 6. In early cases depend on the general reaction; in later cases, if the general reaction is wanting carefully look for the local.

26 and 27. **Diagnosis of Early Phtthisis.**—Barbour asks, "Can the early stages of pulmonary tuberculosis be diagnosed with reasonable certainty without diagnostic injection of tuberculin?" and he answers, "With reasonable certainty, yes." The earliest physical signs in the respiratory murmurs being percussion notes, pleuritic friction sounds, and sometimes moist or dry rales, in very limited areas, may often be detected before bacilli can be found. One can also be helped by the family and personal history and clinical symptoms. The clinical history of phtthisis is variable, as much so in the early as in the late stages. A slight cough of insidious onset continued over two or three months, hemoptysis, and pleuritic pains are quite suggestive. Slight rise of temperature, failure of digestion, etc., are all of value as aiding the expert to diagnose early tuberculosis. He cautions, however, those not practiced, against using tuberculin as a diagnostic aid, as it has dangers that can be avoided only by the expert and cautious. Denny's article covers much the same ground, noticing, however, in addition the signs of the pulse and the X-ray revelations.

28. **Joint Tuberculosis.**—Young's paper considers the two symptoms most positive in joint tuberculosis to be spasms and atrophy, and he gives a contrasted statement of the principal signs of non-tubercular chronic synovitis; tubercular, chronic, articular arthritis; and specific syphilitic arthritis. Beyond those already mentioned, the points he gives for tubercular disease are the lack of fluctuation, and the non-thickening of the capsule, the acute pains on motion, and the night cries.

29. **Watery Extract of Tubercular Bacilli in Phtthisis.**—Sutherland reports his own case and his treatment, by Dr. von Ruck, with the watery extract of tubercle bacilli, and reports twelve cases of his own practice. He has had, in the past year, five cases of unmistakable tuberculosis in which there has been an apparent recovery. He cautions physicians and patients, about trusting too exclusively to climate, which he thinks has, perhaps, less value than is commonly supposed.

30. **Local Treatment of Lung Diseases.**—Lyle advocates the use of local treatment of the lungs, and describes the method as used by him. The remedies are introduced in a state of minute subdivision by inhalation. The objections to this method, he thinks, have been more theoretic than practical, and are not borne out in practice.

39. **Cancer of Stomach.**—This address by Dr. Bernays, we believe before the Oregon State Medical Society, takes up the now familiar subject of cancer and its cure. He is in favor of operative treatment whenever possible, and his opinions are summed up in the following conclusions: "Knowing that cancer is incurable if totally extirpated, and knowing that it is fatal if not totally removed, I have arrived at the following method of dealing with patients who seek aid from me when they are afflicted by a cancer. 1. When the case is clearly curable, and the danger is slight, then I feel it my duty to urge the operation, and insist on an immediate performance of the same, and represent the prospects of a cure as highly favorable. 2. When there is considerable involvement of the lymphatics I do not strongly urge the operation, but tell the patient that the chance of a cure, though small, still exists, and in fact feel it a duty to make the attempt at a radical extirpation. 3. When the danger of an operation is very great, but where I still think the removal of all involved tissues can be completed, I mean by that where the operation is anatomically thinkable, I present the grave dangers of an immediate death on the operating-table, and though holding out but little hope of a cure and only probable pro-

longation of life, I still give enough encouragement to inspire the patient with some expectations of being benefited. As 2 rule, I find that these patients will decide to have the operation done. 4. Finally, in anatomically impossible cases I do not think it is justifiable to refuse to operate in some fashion if, after knowing the truth as to the hopelessness of the condition, a patient demands that an operation be done. In these cases the psychical effect of even an imperfect partial removal of the offensive cancer sometimes is very beneficial, and puts off for months the inevitable morphia syringe, which we are compelled to use during the last weeks." The latter part of Bernays's paper treats of cancer of the stomach, in which he reviews the experiences of others before stating his own. Out of 21 resections he has had only 2 deaths immediately following the operation. All of the others were benefited, and one lives from whom he removed a pyloric cancer as large as a child's head, seven years ago; thirteen died within a year, from return of the cancer, and seven lived from one and a half to four years; two of these are still in good health. He concludes by saying that should a few cases be radically cured, and twice as many killed by the operation, they would have derived more benefit than if none had been operated on. Those who are killed by the operation are saved from a most horrible slow death.

41. **Tobacco.**—Marable's presidential address is especially on smoking, and goes at considerable length into the literature of the subject. He believes that tobacco in any form is very bad for the growing boy, and especially the practice of cigarette smoking.

42.—See JOURNAL, June 17, par. 74, p. 1382.

43. **Bright's Disease Caused by Pregnancy.**—Ezell reports a case of acute dropsy with urine loaded with albumin. The woman was 21 years old, and three months pregnant. After numerous tappings she was somewhat relieved by the use of elaterium, the only drug which seemed to be effective, but after confinement this also proved inefficient. The patient died about eight or nine weeks after confinement, in convulsions. His diagnosis was acute Bright's disease, superinduced by pregnancy; he asks as to its correctness.

44. **Comatose Malaria.**—Norris describes comatose malaria, which is the most common form of pernicious malaria in temperate climates. The coma may develop suddenly, as in the apoplectic form, or the patient may fall asleep and deepen into profound unconsciousness. The coma, if not fatal, may last twenty-four hours and the temperature falls, the skin becomes moist and consciousness returns. The diagnosis is as a rule easy, but it may be confused with apoplexy, insolation and uremic coma. The microscopic examination of the blood and discovery of the parasite is the surest method. He is inclined to agree with Thayer that exposure to the sun may tend to determine the cerebral accumulation of the parasites. The treatment is with the specific quinin, and he gives it in 15-grain doses, hypodermically, in the form of the bimuriate of quinin and urea, and repeats the dose in four or five hours. If the pulse flags, he gives strychnin and digitalis, also hypodermically keeps the bowels well open, and watches the action of the bladder, catheterizing if necessary. He reports three cases.

45. **Foreign Bodies in Lungs.**—By compilation of recorded cases it is shown that the mortality attending the entrance of foreign bodies into the lungs through the air passages is about 34 per cent. when they enter by direct penetration—as bullets, etc.—other conditions being equal, there is less apt to be serious disturbance than when a bronchial tube is blocked. When a foreign body has entered the bronchiole through the trachea, in about 57 per cent. of cases it has been spontaneously expelled with favorable results. There seems to have been no special predisposition toward phtthisis following the lodgment of foreign bodies in the lung, any more than after other chronic irritations of the organ. The chance of bodies becoming encapsulated when entering the lung through the air-passages is slight, but when they result from direct penetration, Wood has experimentally proven that encapsulation may take place, but the formation of a fibrous envelope would be very slow owing to the scantiness of fibrous tissue, and such fibrous tissue is always poor in its blood-supply, and is to be considered a *locus minoris resistentiae*. From his experiments he corroborates

the theory that infarction in the lung will not take place without there be predisposing disease of the lung or circulation.

46. **Sterilization of Living Tissue.**—Bleyer advances the theory that ozone is generated in the blood, and then almost immediately transformed into H_2O_2 , which would coagulate the albuminous matters, and partly with the oxyhemoglobin, probably forming a compound which he calls *peroxyhemoglobin*. He has been able to appreciably increase the amount of ozone in the blood by passing weak currents of galvanic electricity through the body. It is probable that as the current passes through the blood, it decomposes the chlorids, which are normal constituents, forming hypochlorites or some highly oxidized compounds of chlorin. He considers these theories strengthened by the results of his treatment of tuberculosis by electric stimulation during the past few years; no report of cases is given.

47. **The Patient's Secret.**—According to the law of New Jersey, there can be no hindrance to the extraction of any testimony from a physician: the judge deciding that the testimony is pertinent, the physician is then compelled to respond, it may be to the extent of disclosing all of his patient's confidences. In half our states and territories are statutes exempting the physician from giving testimony of personal matters revealed to him by the patient in his professional capacity. Lack of uniformity marks the laws of the various states, but the majority exclude such testimony in the civil courts alone, while in New York and some other states the law applies to criminal courts also. The lesson Strock draws, after discussing the subject at length, is that a physician called to give testimony in a case that may disclose by probing a professional secret, should first ascertain the patient's wishes in the matter, and if testifying in a state where the law provides for his protection in case he refuses to answer on the ground of "privileged communication," should cautiously answer all direct questions, for fear that he make it possible for a disclosure of this secret on subsequent cross-examination. In giving testimony of such a nature as is calculated to injure the patient's character, a clear understanding is first to be had with the patient, and in case of his demise, the immediate family should always be consulted and their permission obtained. And it is urged that medical societies in such states as do not provide legal protection to the physician guarding his patient's secret, should combine and take action necessary to secure proper modification of the laws relative to this subject.

48. **Fractures of Extremities.**—Some interesting variations from existing statistics are noted; 349 of these fractures were of the upper extremities, while but 151 occurred in the lower. Fractures of one or more metacarpals were found in a proportionally large number of cases (51), due both to direct and indirect violence; in the difficulty frequently attending the late examination of these fractures the value of the radiograph was enhanced. Attention is directed to possible fallacy in reading the radiograph in supposed epiphyseal fractures, the normal epiphyseal line being frequently mistaken for a fracture. Exception is taken to the accepted rule that fractures of the shaft of the long bones are apt to be more oblique than transverse; the radiograph shows the contrary to be true. A large number of drawings in outline are reproduced from the original negative.

49. **Primary Sarcoma of Nose.**—The cases reported by Thomas are 5 in number, 3 in males, and 2 in females; the ages ranged from 27 to 59 years. Early symptoms were nasal obstruction and hemorrhage. One was found to be an adenocarcinoma, 2 were of the spindle-celled variety, one had the structure of a myxosarcoma, while the other was made up of small round cells. Degeneration of nasal polypi are cited as an important etiologic factor in the various forms of nasal sarcoma. The site of origin is more commonly the cartilaginous septum.

51. **Hemoglobin in High Altitudes.**—Averaging his observations in 69 cases recorded by Bergtold within three weeks after their arrival at Denver (5200 feet), he finds the blood's sp. gravity to be 1.059, which is exactly the average of sea-level individuals; after a residence of three weeks or more in Colorado, he finds the specific gravity to be 1.064, and allowing 5 per cent. for each degree above 1.059, the hemoglobin

normal at Denver altitude is to be considered 125 per cent.

53. **Thyroid in Cerebral Neoplasms.**—Evidence of the presence of a cerebral neoplasm was based on the symptoms of constant, increasing headache, gradual impairment of vision, indistinct outline of optical discs, with beginning atrophy. On the supposition that he had a glioma to treat, Loving administered the extract of thyroid for a period of five months, with the result of relieving all symptoms. The ophthalmoscopic examination demonstrated a marked improvement in the condition. The patient subsequently used his eyes at very exacting work, without recurrence of symptoms.

54. **Modern Veterinary Practice.**—Keynolds describes the methods of education in veterinary medicine, the social position of the veterinarian, which he thinks depends entirely on himself, the rewards of practice, and its importance in the field of public medicine.

56. **Ventrosuspension of Uterus.**—After discussing the indications and operations for retroposition of the uterus, Eggers closes his paper with the following conclusions: 1. There are three operations for retroposition which need to be taken into account, viz., Alexander's operation, or extra-peritoneal shortening of the round ligaments, Wylie's operation, or intraperitoneal shortening of the round ligament, and ventrosuspension, according to Dr. Kelly's method. 2. In cases of retroposition without adhesion, where the uterus can be lifted up, but where no relief is obtained by medical treatment or by pessary, Alexander's operation is to be performed. 3. In cases of retroposition with adhesions, where laparotomy has to be performed to loosen the adhesions, ventrosuspension ought to be preferred if both ovaries are extirpated. If one or both ovaries are left, the choice will be between ventrosuspension and Wylie's operation, with a possible preference for Wylie's, as it is impossible, even with Kelly's method, to be perfectly sure that the adhesions will be yielding enough to permit normal pregnancy and labor, while no such objection can be made against Wylie's operation. Still, the choice here might be individual with the different operators. If there are numerous very strong adhesions, leaving the posterior surface of the uterus very raw, hysterectomy would be indicated if the appendages have to be removed to avoid the danger of adhesions forming between the bowels and the denuded surface of the uterus. 4. In cases of complete prolapse, ventrosuspension is indicated.

60. **Tubercular Osteomyelitis.**—The object of McLean's article is to urge the importance of early diagnosis in tuberculous bone disease. After remarking on the pathology, methods of attack, and noticing that tubercular infection especially affects the epiphyses, because of the minuteness of the vessels in these parts, and the constant cellular change, he states that it seems natural that the bacilli should prefer the vertebrae and the head of the femur where several such unions are going on at the same time. We would not expect a primary focus in the femur after the twenty-first year, for the changes are complete at that time, while we might expect such in the vertebrae up to the twenty-fifth year. The nearer the center of circulation the focus is located, the more rapid will be its growth. The general condition of the patient does not always indicate bone tuberculosis. There may be no impairment of the general health and pain; the first symptom may be referred to some distant point, as in hip-joint disease it is frequently located in the knee. Tenderness is not marked until the bone begins to soften. If an area of tenderness can be detected around the epiphyseal line and no pain on movement of the adjacent circulation, disease of the bone may be suspected and both extremities should be carefully examined. Swelling does not occur until the compact layer is perforated and the periosteum bulges. Redness does not appear until the disease extends toward the surface. Atrophy of the limb is an important symptom and appears early. In disease of the vertebrae before puberty, it is usually confined to the bodies of the vertebrae and the first symptom detected is frequently the attitude and the effort to avoid vertebral motion. Little or no pain can be detected by pressure on the arches, but sudden jars elicit it. In young adult life, when the arches are affected pain can be elicited by pressure. The only difference in the symptoms of a primary bone and primary synovial affection is tenderness over the epiphyseal margin. The ther-

monometer is frequently a great aid, as any tubercular affection has its evening rise of temperature, though it may be very slight. In all cases the family history should be inquired into, and a careful search be made for lesions elsewhere in the body. The exploratory or aspirating-needle may be used, the bone having become softened and easily perforated, this being also a diagnostic point. Ignipuncture has been recommended, and is performed with a heated needle point of a Paquelin cautery, and has a therapeutic as well as a diagnostic value. Treatment is constitutional, mechanical and operative, the latter when the bones of the extremities are affected. To obtain benefit from constitutional and mechanical treatment an early diagnosis is of greatest importance. It is easier to prevent spinal curvature and deformity than to cure it, and a plaster-of-paris splint or braces properly applied, with good hygienic measures and surroundings and the use of constitutional remedies, will terminate many cases favorably.

61. **Modern Medical Text Books.**—Mapes criticizes the multiplication of modern text-books, many of which he thinks are useless and altogether superfluous, and merely compilations without any thing new. The illustration he gives is that of a modern author on surgery, who has had the audacity to introduce a chapter on hydrophobia which Mapes says is not entitled to be classified in the category of surgical diseases, or even as a disease at all, the arguments of nearly every medical and surgical authority notwithstanding. The bulk of his paper is taken up with extracts on this disease.

62. **Nuclein in Tuberculosis.**—Wellington reports four cases of tuberculosis treated with nuclein, two of which seem to be greatly improved and one completely cured, though in neither case was there any examination for bacteria after apparent recovery.

63. **Gruel in the Feeding of Infants.**—This paper gives the results of certain experiments made by Chapin as to the effect of diluting cow's milk with decoctions of cereals. The experiments were made *in vitro* and upon a healthy dog with a previously prepared gastric fistula. The result showed that the additions improved the digestive quality of the milk not only in attenuating the casein but by also increasing the nutritive value of the food. The proper addition of gruels to milk will not infrequently prevent wasting in bottle-fed babies who are losing flesh. The large proportion of lactose, a carbohydrate, in human milk shows the desirability of this food principle in the growing infant. Apart from the experiments, the clinical test is the real one as regards the value of this product. Chapman maintains that the common opinion that infants should not be given starch in any form is incorrect except as regards excess. The youngest infant can tolerate and digest a small amount. The paper goes into details as to preparation of infant's food.

64. **Angioneurotic Edema.**—The purpose of Onuf's paper is to show from the seven cases which he reports, the close relation of angioneurotic edema to urticaria, certain forms of erythema and other disorders which may be considered as due to disturbances in that part of the nervous system presiding over the vegetative functions in the organism. He analyzes these cases in detail as to their etiology, finding that neuropathic and psychopathic taint is the most prominent predisposing cause, while psychic influences are the most prominent exciting cause. The symptoms are reviewed in detail and the diagnosis between these disorders and mechanical local edema, hydropic edema, hysterical and blue edema, myxedema, insect bites and erythema nodosum. The treatment seems to be chiefly in a general tonic nature, and a tranquillizing action on the nervous system. More attention will have to be paid to the questions of rheumatic and lithemic diatheses. He thinks the cases reported demonstrate convincingly the affinity of this disorder with urticaria and fugitive neurotic edema. There is also a great resemblance to the so-called enteritis tubulosa or membranacea, except that here secretory innervation appears to be mainly disturbed, while in angioneurotic edema the alteration chiefly affects vascular innervation. If we consider further the tendency to coexistence with angioneurotic edema of nervous angina pectoris, anomalies of menstruation, or other disturbances, whether of vascular or of visceromotor or of a secretory innervation, either in the same

individual or in his family, the following conclusion suggests itself:

Certain individuals are especially predisposed to disease of that division of the nervous system which presides over the vegetative functions of the organism. This special predisposition may be only individual or it may be hereditary. In either case it may extend over several vegetative functions or over one in particular. Thus one patient may show predisposition to disorders of vascular innervation only; in another patient, if he suffers from asthma for instance, visceromotor innervation may be exclusively disturbed; or several vegetative functions of the nervous system, such as vascular, cardiac, and secretory innervation, may be involved in the same patient. In some cases finally the predisposition mentioned might produce the symptom complex known as Basedow's disease.

The author mentions in conclusion that what he has called visceroneurotic taint, the predisposition to disorders of the vegetative functions of the nervous system, is frequently associated with a general neuropathic or psychopathic taint.

65. **Reflex Cough.**—Richards discusses the cough due to nervous reflex from various sources pointing out the anatomy of the nerve supply of the larynx and giving the diagnostic points between nervous and respiratory cough. These are chiefly as follows: Sudden appearance; rhythmical character; free intervals when no signs of cough are present; expectoration absent or slight in amount; no fever or marked constitutional disturbance; may continue for years or stop at any time, or eventuate in other symptoms; may come at regular intervals; stops when person's attention is fully occupied; is most marked when the patient is under observation; if stopped for a time begins with an explosion; is usually absent at night, always if purely nervous; absence of physical signs in respiratory tract; cough apparently a useless one, does not accomplish anything; patient complains of usual symptoms of catarrhal cough in the respiratory tract; its tone is various, sometimes hacking, bellowing, shrill, croupy, metallic, at other times hoarse from insufficient cord tension. This latter is an imperfect cough, and according to Professor Gardner is somewhat distinctive of thoracic tumors or aneurysm pressing upon the recurrent laryngeal nerve. Its chief features are hoarseness and imperfect explosion; it is a noisy, not infrequently harsh, brassy cough. The diagnosis is often difficult. He then enumerates points from which reflex cough may be excited; the central nervous system, as in glottic spasms which commonly issue from the cortical centers, uterine and visceral coughs, ear and nasal cough, and those due to direct pressure on laryngeal structures. Cases illustrating these are reported. The therapeutics of these cases depends on diagnosis. This once accurately made, the treatment is readily adaptable to the individual.

66. **Traumatic Neurosis with Pharyngeal Hemorrhage.**

—Von Adlung reports a case of a woman who was jerked from a moving train, suffering severe mental and physical shock and had an immediate uterine hemorrhage. Has since that time had various symptoms of a hysterical traumatic neurosis and pharyngeal hemorrhages, occurring at first two or three times a week, and latterly only about once a fortnight. The previous history was not neuropathic. He speculates on the cause of these hemorrhages, and notices the observations of Laurent of similar cases. He suggests that there may be some molecular change in the nerve centers accounting for the dilated condition of the blood vessels at the base of the tongue and their occasional rupture.

67. **Soldiers and Venereal Diseases.**—Hammond remarks on the statements of the prominent anti-imperialist, Atkinson, and shows his errors as regards the American soldiers and the conditions in the Philippines.

68. **The New Industrial Position of Woman.**—Dr. Finley claims that the enlargement of the duties and life pursuits of women will tend to greater physical vigor and mental health and the perfection of the race.

69. **Typhoid Fever in Southern Camps.**—Chmelieck describes the conditions observed by him in the camps at Tampa during the late war with special reference to typhoid as it there occurred. He attributes the spread of the disease largely to the ignorance and recklessness on the part of the volunteers and their officers. In his experience there was about 78 per cent. of typhoid fever to 22 per cent. of all other disorders. He

describes the symptoms and treatment, and concludes as follows:

1. The camp should be frequently changed.
2. The division hospital is here to stay, as only in this hospital can female nurses be employed, and
3. The proper person as attendant is the female nurse.
4. All soldiers should be educated in plain sanitary hygiene.
5. The sooner the patient takes to bed the fewer complications are likely to follow. The hemorrhagic and perforation complications develop in patients who walk until they fall, and who use indigestible food during the first stages of typhoid.
6. Milk is not suitable for every case; many of the patent foods on the market, especially "predigested" foods, must replace it in many cases.
7. Sugar used during convalescence will cause relapse quicker than solid food.
8. Every case requires special study.
9. The severest case, with hemorrhages and other complications may get well, while the lightest case, apparently doing well, may prove fatal. Never give up a case as hopeless.
10. All the patients in the southern camps showed a remarkably low pulse-rate, even with high temperature, for which I can not offer any explanation.

73. Ocular and Orbital Symptoms of Lesions of the Frontal Sinus.—The recognition of lesions of the frontal sinus, their course and their treatment are discussed by Sattler, who claims that the acute disorders are quickly diagnosed but the chronic lesions are much less easily recognized. The orbital symptoms are, first, localized tenderness without redness or swelling, generally unilateral, this giving away later to transitory, painful swelling of the periosteum and bone with frequently redness and swelling of the overlying soft parts. These symptoms come and go for days and weeks, and headache may become general. At the same time there is a characteristic symptom, the change of contour of the inner, upper and sometimes even of the inferior margin of the orbit, giving rise to a change of physiognomy, pointing to an existing sinus lesion. With this there may be no serious nasal trouble. If the grade of inflammation is not high a chronic empyema may undergo absorption or thickening and terminate in a contraction of the cavity, or, in other words, hyperostosis. It may also occur that a spontaneous evacuation of the contents occurs into the nose, or the temporal angle of the sinus may give way, but this more frequently occurs at the lateral or orbital wall at points near the inner canthus of the eye. The most frequent outlet of the dissecting trail is under and at the outer or temporal border of the tear-sac. They may, however, take still other courses. With hyperostosis occurring as above stated, severe neuralgic seizures may follow as a remote result. The ocular symptoms are first noticed in the lids. A serous infiltration of the loose cellular tissues of the orbital roof depending on exacerbations of the sinus lesions may interfere with the action of the levator muscles of the upper lid and the superior rectus. Drooping of the lids and slight restriction of motion upward is often observed. Proptosis due to the same cause and lateral downward displacement of the globe may also be present even thus early. To these symptoms are added an edema of the inner third of the upper lid with dusky discolorations looking so much like the inflammatory edema of chalazion that it may lead to error. On the conjunctiva, especially the retrolateral and ocular divisions, engorgement of the veins and chemosis are frequently observed, due to venous obstruction. In some cases the upper fornix is everted. Proptosis is variable, and not conspicuous even in pronounced cases. Exophthalmos is only conspicuous in exceptional cases, in which perforation takes place behind the orbital margin and the dissecting trails push backward toward the apex of the orbit. He reports a case and remarks that the surgical methods which enable us to explore the frontal sinus from without are so satisfactory that few surgeons attempt it from the intranasal opening. He uses the external method exclusively with chisel and mallet.

74. Hip Disease.—McKenzie concludes his paper as follows: 1. Hip disease is a local manifestation of a constitutional disease. 2. Early operative treatment is seldom justifiable. 3. When softening can be determined the surgeon should operate and obey indications, observing all care not to needlessly injure

the mechanical integrity of the joint. 4. In the subsequent management of the wound asepticism and antisepticism must be carefully observed. 5. From the earliest moment efficient protection for the joint should be secured and constantly maintained by a well-fitting mechanical appliance. 6. A proper splint should fulfill two indications, i. e., secure rest for the affected joint and prevent deformity. No effort should be made to employ the splint as a crutch; ordinary crutches should be used. In the adjustment of the splint the knee should be slightly flexed. 7. Constitutional treatment is indicated as in other tubercular affections. Great emphasis should be laid on obtaining the freest exposure to direct sunshine and fresh air. Free use of iodoforn is a valuable adjunct. 8. After excision a perfect recovery never follows because the mechanical integrity of the joint is not preserved. 9. Following mechanical and constitutional treatment complete restoration of function is sometimes obtained. 10. Even when breaking down of tissue occurs which necessitates incision, there is sometimes a perfect restoration and frequently a highly useful return of the joint function.

75. Vaginal Celiotomy in Pelvic Diseases.—Glass advocates the vaginal route in a large proportion of cases. He summarizes its advantages and disadvantages as follows: 1. A preliminary or exploratory vaginal section is always warrantable. 2. Drainage when necessary is more free and natural. 3. There is less danger of extending infection. 4. The limited peritoneal field exposed and handled reduces to a minimum pain, shock and intestinal paralysis, frequent sequelæ of suprapubic abdominal section. 5. Post-operative nausea is lessened and movements of the patient are less constrained, contributing much to her comfort and general welfare. 6. Vaginal section may frequently be performed when the condition of the patient, especially in abscess cases, would interdict any other procedure. 7. The danger of hernia through the scar is practically nil. 8. Recovery is quicker. 9. The mortality, as calculated from all reported cases, is materially lessened.

The contraindications for the vaginal operation are: 1. An unusually small or septic vagina. 2. Such fixation of the uterus that it can not be drawn down, or such enlargement of the organ that operations on the adnexa, when desired, can not be carried out. 3. Evidences of tubercular degeneration or appendicular disease. 4. Carcinoma with involvement of the uterine ligaments or iliac glands. 5. Cases of pelvic hematocèle with active non-circumscribed hemorrhage.

76. Treatment of Incipient Laryngeal Cancer.—The importance of early surgical treatment of laryngeal cancer is emphasized by Scheppegrell, though he notices the non-operative methods as applicable only to cases where operation is contraindicated. Among these are the use of the animal toxins, arsenious acid, an apparent cure by which has been reported by Costinin; and pyoktanin. He discusses the operations, thyrotomy and total extirpation. In tracheotomy with thyrotomy he prefers the operation in two tempos with an interval of a week between them, unless an immediate complete operation is urgently required. As regards total laryngectomy he thinks that when malignant disease has advanced to such an extent as to require it, the prognosis is very bad.

77. The Acute Diarrheas of Infancy.—In this lengthy article Morse describes the principal varieties of infantile intestinal troubles, which he divides, first into simple or nervous diarrheas, quickly relieved by removal of the cause. If it is due from fright and fatigue, this is readily done, and if climatic, change of air is necessary. If due to indigestion, purgation followed by, in rare cases, washing out the stomach and bowels may be necessary. In this form alone, opium in the form of paregoric, a few drops in a dose, and astringents are advisable. In infective diarrheas, which he divides into fermental, floecolitis, and cholera infantum, the removal of the cause also is required. Prevention and hygienic measures are, of course, important. Opium and astringents are counterindicated. In the fermental diarrhea, which includes most cases, removal of the cause by purgation by castor-oil or calomel, occasionally washing out of the stomach and bowels with salt and boric acid solutions, temporary withholding of food for about twenty-four hours, and subsequently employing only carefully selected milk, of low percentages, in frequent doses, and use of bismuth in form of subgallate, and subnitrate is ad-

vised. In ileocolitis flushing of the bowels with the same solution as is used in the stomach, large quantities being employed until perfectly clear, followed by injection of bismuth and chalk mixture and mucilage are very useful, with other treatment on the same lines as in fermental diarrhea.

Cholera infantum is rare. The name is to be applied to all cases with extreme cholericiform symptoms. The indications are to remove the toxins from the stomach and bowels; supply fluid to the tissue by subcutaneous injections of normal salt solution, a pint daily; reduction of temperature by cold sponging, etc.; restoration of surface circulation, and keeping the patient alive until the disease is cured. Stimulants are advisable, atropin, in doses of 1/500 to 1/800 of a grain. Hypodermically is the most useful. Morphin may be given when diarrhea and vomiting are extreme or nervous manifestations very marked, in doses of not over 1/100 of a grain.

78. **Hygienics of the Skin.**—The principal points of Judd's paper, aside from his advice of the use of warm bath daily, followed immediately by cold sprinkling and full bath once every seven days with the same sequence is the importance of using linen instead of woolen underwear. He thinks that the general popular notion in regard to the value of woolen underwear is a delusion.

79. **Hernia Following Operations for Appendicitis.**—The summary of Harrington's paper is as follows:

Hernia and bulging occur frequently after operation for appendicitis, and result from the separation of muscles and other tissues in the scar. They are very common when drainage has been used.

The muscular and tendinous fibers should not be transversely cut in any appendix operation unless it is unavoidable.

As little drainage material as safety will permit should be used. When drainage is necessary the wound should be closed as far as possible with sutures, and the drainage removed as early as safety will permit. If the wound can be closed immediately the tissues should be restored to their normal position by suturing each layer.

Stout belts and trusses are of little value, and may even do harm.

The abdominal muscles from the earliest period possible after operation should be developed by appropriate exercises.

If hernia or marked bulging appears, operation for cure is safe and satisfactory.

81. **Otitis Media and Earache in Pneumonia.**—In this paper Meltzer has pointed out the relationship that frequently exists between lobar pneumonia in children and earache. The cases he observed were similar in that at the onset of the disease earache was a prominent symptom, but disappeared in the course of twenty-four hours, or else continuing in a mild degree—to disappear entirely either before the crisis set in or with it. In none of his cases did the pain outlast the disease, neither did the earache terminate in a suppurative otitis. Earache was usually on the same side with the pneumonia; hearing apparently was unaffected. The age of the children upon whom the observations were made ranged from 18 months to 8 years, the initial pain being more intense the younger the child.

In further discussion of his observations that in all the cases of lobar pneumonia complicated by otitis media not one has resulted in a discharge from the ear setting in during the course of the disease, the writer inclines to show a certain antagonism, in children at least, between pneumonia and otitis media suppurativa, "possibly because the pneumonia, by its hyperleucocytosis, acts as a derivative on the otitis."

83. **Menstruation and Pregnancy in Nursing Women.**—In this paper Brickner discusses the influence of lactation upon menstruation and pregnancy, and a number of interesting deductions may be drawn from his review of nearly 4000 cases under observation at the dispensary of the Mount Sinai Hospital. These statistics show 442 of the patients were nursing women, of these 191 had menstruated, a percentage of 43.3. Of these 20 per cent. had menstruated at regular intervals after the catamenia first returned, although the type of the flow sometimes differed from that existent prior to the pregnancy just ended. In explanation of this deviation from the normal, he considers it due in a large proportion of these cases to an unusually strong "menstrual habit." Heredity also plays an im-

portant role—four of the above cases were women whose mothers, and in one case a grandmother, had had a similar experience. Of the 191 women who had menstruated during lactation 26, or 14 per cent., were found to be pregnant, conception occurring most frequently in the fifth and ninth months of lactation. In the consideration of the influence of the milk of a menstruating woman upon the child at breast, occasionally the child is unaffected, again the larger proportion of women menstruate but a few times, or but once during lactation, the single catamenia is apt to be very profuse and then perhaps not again appear during lactation, hence the wisdom of not at once determining upon the removal of the child from breast unless the mother becomes worn and anemic.

The conclusions are different when the mother of a nursing child becomes pregnant. Ordinarily lactation should cease. In exceptional cases, if the mother is strong and healthy and capable of doing justice to both child and fetus, the child may continue nursing for a few weeks.

84. **Report of Case of Typhoid Fever.**—The case reported by Saleeby is one of typhoid, the perforation occurring early in the course of the disease, probably about the thirteenth day, coming on insidiously, with no marked reduction of temperature, pain being the most constant and pronounced symptom, the first vomiting occurring after eighteen hours. An operation was resorted to after this and the perforation located in the ileum, the intestine was brought into the abdominal incision and anchored by suture. Twisted iodoform gauze was used as a drain and placed deeply into the pouch of Douglas. Other similar drains were placed into each iliac fossa. Recovery from the surgical affection was rapid, little or no discharge resulting. A relapse in the typhoid condition occurred, with a moderate febrile run. Normal temperature was attained on the forty-second day.

86. **Chicago Drainage Canal.**—Starkloff gives his objections to the Chicago drainage canal, his arguments being mainly on *a priori* theoretical considerations.

87. **Gunshot Wounds of the Intestines.**—Spears reports a case of gunshot wound of the intestines producing thirteen perforations, all in the jejunum except two or three, treated successfully with the exception of a fecal fistula, which lasted for several months after the injury was received.

88. **Accidental Uterine Hemorrhage.**—By accidental uterine hemorrhage, Richard understands placental hemorrhage due to detachment other than in placenta previa. He reports two cases.

FOREIGN.

British Medical Journal, July 22.

Rest and Exercise in Open-Air Treatment of Phthisis. ARTHUR RANSOME.—The chief theme of this article is the value of rest in the treatment of phthisis, the claim that it produces gain in weight, better oxygenation of the blood, more continuous warmth of the body, more repose given to the bony levers overlying the injured part, and the beneficial influence of the recumbent posture on the state of fever. As regards exercise in these cases, we can attain our object by limiting the movement of the body to such a degree of exercise as will not quicken the action of the muscles of forced respiration. One source of danger is the increase of blood-pressure associated with respiration. Any exhaustion that may diminish the vital powers must be avoided. The degree of rest prescribed must depend first on the presence or absence of fever, and, again, on the digestive and assimilative powers. The amount of exercise will depend on the muscular and bodily vigor and on the amount and extent of movement allowed by the disease to the ribs in forced respiration, and especially to the bones over the injured parts of the lungs.

Treatment of Chronic Diarrhea. I. BURNEY YEO.—The writer reports a case of chronic diarrhea treated by various methods. The most interesting point, however, was the improvement under pancreatic emulsion. The cause of symptoms was obscure, but there was one that was constant, i. e., the whiteness of the motions, and this suggests the use of the remedy. The leaving off of this pancreatic emulsion was followed by a relapse of the diarrhea, and, at last report, the patient was still continuing to use it though apparently in first-rate health.

On Experimental Production of Hydrosalpinx and Hydrometra in Animals and Its Relation to Hydrosalpinx in the Human Subject. C. J. BOBO.—From his experimental investigations Bond finds that in the lower animals and in the human subject, as far as the Fallopian tube is concerned, the mucous membrane lining the canal of the oviduct has a certain secretion of a peculiar and definite character, and that this is absent during pregnancy. Human hydrosalpinx is not a final condition in infective inflammation of the tube; it is merely a mechanical distension by normal secretion in a tube the two openings of which have been closed by inflammation.

Loss of Knee-Jerk and Peripheral Neuritis in Diabetes Mellitus. KARL GRUBE.—Grube's paper is based on the study of the facts already known, and 11 personal cases. He concludes that we have three manifestations of the nervous disturbances caused by the increase of sugar in the blood: 1, cramps or an acute irritation of the nerves, probably not accompanied by any material change in the nerves; 2, neuritis or acute inflammation of the nerves, and 3, a slow degeneration or nutritive change in the nerves which seems to have a preference for the crural nerve, and is then accompanied by loss of the knee-jerks, but which may also occur in other nerves, as, for instance, in the optic. It then leads to a gradual diminution of vision with central scotoma. The impotence which is so frequently a symptom in male diabetic subjects is also probably caused by nutritive changes in the corresponding nervous apparatus. He has frequently found it to be associated with loss of the knee-jerks.

Case of Traumatic Epilepsy Following a Compound Fracture of the Skull Sustained Eleven Years Previously. PHILIP JAMES.—The author reports a case of a man suffering from epilepsy dating back within a year, but attributed to an injury received ten or eleven years previously. There was, besides the fits, marked peripheral contraction of the visual fields. The cicatrix in the scalp of the former injury measured about four and a half inches in length on the right side of the vertex extending from near the median line outward and backward. It was considerably depressed anteriorly and posteriorly. Near its middle it was divided by a bridge of apparently unfractured bone. Posteriorly pulsation of the brain could be seen and anteriorly pulsations could not be detected, but just in front of the bony ridge there was a special point showing tenderness on pressure with dimness of vision. The operation was performed, and a silver plate inserted to make up for the loss of bone. The patient has been greatly improved, and has had no fits for eighteen months since the operation. One of the most interesting points connected with the case, however, was that the painful spot, pressure on which was followed by pain, tremor, and loss of vision, was ascertained by surface measurements to correspond very nearly with the right angular convolution. The two charts of vision given with the paper show diminution on both sides, but most marked on the left side, opposite the lesion.

Revista Médica de S. Paulo (Brazil), June 15.

Chronic Mastitis. S. RODRIGUES.—The observation reported is a warning not to confound the lesions of chronic mastitis with carcinoma, as has probably occurred more than once under similar circumstances. The mastitis had lasted twenty years when a slight accident caused suppuration and pains. The entire symptoms and clinical picture almost imposed the assumption of carcinoma and removal of the breast, but after evacuation of the pus the tumor disappeared.

Muscular Suture Without Buried Threads. M. VIANNA.—The stitch resembles a simple "crochet" stitch, with one thread and a Reverdin needle. The thread is drawn through from one side to the other in a loop long enough to reach over the point for the second stitch on the upper side of the wound. The needle is then inserted as before and parallel, and the thread hooked and drawn through the first loop and through the tissues to form a second loop. The third loop is drawn through the second, and so on. The whole suture ravel out instantaneously when the end of the thread is pulled.

Bulletin de l'Académie de Médecine (Paris), July 11.

Milk Serum in Restorative Serotherapeutics. LEREBOULET.—After four years of tests and experiments, Gimbert and Tajasque of Cannes now announce that in milk serum we have a new product "as natural, as alive and as complete as bio-

logic chemistry is able to produce," which modifies in the most favorable manner, attenuating or curing, all diseases accompanied by debility and generally defective nutrition. It has no vaccinating or immunizing properties, and is absolutely non-toxic and harmless. Although readily absorbed by all the natural channels, the hypodermic method has been preferred as better adapted for comparative tests. It has proved a most valuable vehicle for arsenic, strychnin, mercury, etc. Gimbert has now a long list of tuberculous and other patients cured with this new serotherapy, which he is soon to publish. The serum is prepared by coagulating the milk; the curd is dried in the oven, and ground to a powder, mixed with a little calcium carbonate and put over the water-bath for a few hours with the whey, first filtered and sterilized at 120 C. When the serum is sufficiently saturated it is filtered, a little carbonic acid added to preserve it, and sterilized again after bottling. Lereboullet and Dumouthier have also been testing a somewhat similar preparation, at Gimbert's suggestion, which confirms in the most striking manner the value of this new variety of serotherapy, although there was frequently a slight reaction which, however, did not interfere with the cellular renovation induced by the injections. No reaction occurs with the Tajasque serum under ordinary conditions.

Rhinoplastics by Italian Method. P. BERGER.—"The conditions of success are to have the operation planned to its minutest details before commencing, and never deviate from the plan, no matter what turns up; also to restrict this method to persons under 40, and particularly to children, who bear without inconvenience the forced elevation of the arm. It should be continued for eight days at least; the longer the better. Berger fastens the arm in a gauntlet which reaches above the elbow, made of elastic cloth, by straps and buckles to a dog-skin hood fitting over the head, neck and shoulders. This allows a little mobility and free circulation to the arm."

Presse Médicale (Paris), July 12.

Mucoid Transformation of Glandular Cells of Intestine in Infants. A. B. MARFAN and BERNARD.—The lesion is observed in all catarrhal enteritis, but is more pronounced in acute attacks and is most intense in cholera infantum. Between the cells of the epithelium and especially between the cells of Lieberkuhn's follicles, certain rounded, refracted bodies appear, of a vitreous or hyaline aspect, resembling the balls of mucus in the goblet cells but differing from them by their greater number and by other characteristics. The writers conclude that these refracting globes are analogous to mucus, and are a modified, pathologic mucus or mucoid substance. If it is a phenomenon of defense on the part of the organism, it is frequently inadequate, as in spite of it, the microbes make their way through the intestinal epithelium and invade the tissue of the mucosa. Even in subacute cases with the alterations very pronounced, healthy glands are always found beside the transformed glands, and as almost the entire digestion and absorption of the milk in nurslings occurs in those portions of the intestine least affected, all seem to indicate that the initial and important morbid action in epithelial or catarrhal gastroenteritis is located in the contents of the intestine, rather than in its walls.

Focal Lesion of Internal Capsule. M. DIDE and G. A. WEILL.—In this observation a circumscribed focus in the internal capsule without other cerebral alteration, caused laryngeal paralysis on the opposite side, with Weber's syndrome. The symptoms and anatomic alterations indicate that the intracortical laryngeal fibers pass into the capsule near the knee, at the anterior part of the posterior arm; also that laryngeal paralysis accompanying Weber's syndrome is in relation with a lesion of the anterior portion of the peduncle of the brain. The frequency of laryngeal paralysis in crossed hemiplegia is also signalled.

Revue de Médecine, April-June.

Frequency of Secondary Septicemia in Course of Pulmonary Infection. BECO.—As a result of a clinical and bacteriologic investigation, Beco concludes that frank pneumonia is a primary infection of the lung. The pneumococcus, thriving in the respiratory passages, exerts its influence on the organism by intoxication, which suffices in a considerable number of fatal cases to bring about the fatal issue. Sometimes the micro-organism, setting out from the primary focus, multiplies

secondarily in the blood stream, and induces a fatal septicæmia. From a practical point of view the presence of the pneumococci in the blood of a pneumonic patient implies a variable prognosis, according as the microbe undergoes multiplication or not. In the latter event it is of little significance from the prognostic point of view, whereas in the former it constitutes a sign of great gravity. Lobar pneumonia may result from infection of the lung by the pneumobacillus of Friedländer.

Semaine Medicale (Paris), July 19.

Purification of Potable Waters with Peroxid of Chlorin. H. BOUGRES.—The process recently invented by Bergé of Brussels, by which peroxid of chlorin, formed by the action of sulphuric acid on potassium chlorate, is used for purification of water, has been applied in Belgium on a small scale, with perfectly satisfactory results—Ostende, Middlekerke and a boarding school at Lombartzdyke. It is also being tried at Liège, and a committee from the French Public Health Department has been investigating it to determine its practicability for general use. The report of the committee is extremely favorable in every respect, although it advises waiting for longer experience with the system before introducing it on a large scale. To prevent danger of explosions the acid is diluted and cold; an aqueous solution of the peroxid is used and a current of air forced across it carries off any gas that may form. It not only destroys pathogenic germs in the water but oxidizes the organic matters in a most remarkable manner, and generates ozone which also assists materially in the purifying effect. The disadvantages of the process are that the peroxid must be in excess in the water, which gives it a peculiar taste like Javelle water and stains it yellow. But the peroxid soon spontaneously vanishes—four hours—indicated by the disappearance of the taste and stain, or by tests with starch water and potassium iodid, and the vanishing process can be hastened by passing the water over coke, when it is at once ready for use. Another disadvantage is that the organic matters must not be too abundant in the water, or too much peroxid would be required, hence the process demands the previous filtration of much contaminated water. The expense for 3 grams of the chlorate, which produces 1 gram of the peroxid, sufficient to purify 1 cubic meter of water, is about \$0.0006. The Traube system of purification of water with chlorid of lime, which has been tried on quite a large scale with Nile water, requires the addition of sodium bisulphite to the water to remove the chlorin liberated by the process. The ozone method now on trial at Lille, endorsed by Calmette, is the only other important rival of the peroxid method of chemical purification.

Berliner Klinische Wochenschrift, June 5.

Varieties of Tabes Dorsalis. ADAMKIEWICZ.—In concluding a communication on traumatic tabes, Adamkiewicz makes the following classification: 1. The usual and most common form of tabes is that attended with primary parenchymatous degeneration of the posterior columns, with ataxia of progressive character, and grossly preserved muscular vigor. Its origin is unknown and it is incurable. 2. Traumatic tabes, which agrees with the preceding in its anatomic basis and its incurability, but is distinguished by its genesis, which is always traumatic, and by its stability, as compared with the progressive character of the former. 3. Syphilitic tabes, which originates in the vessels of the posterior columns, which are especially predisposed to syphilitic changes by reason of their peculiar arrangement. This variety occurs in two forms: a. As acute syphilitic tabes it depends on endarteritic processes, and like these is curable. b. Chronic syphilitic tabes, on the other hand, depends on interstitial changes in the posterior columns, and is thus stationary and incurable. Both forms of syphilitic tabes are characterized by motor weakness, ataxia, slight—in the acute form—or entirely wanting—in the chronic form, and absence of sensory disturbances. The knee-jerks are wanting in all forms of tabes, but in the acute syphilitic variety they may be variable.

Successful Operative Treatment of Case of Otitic Purulent Meningitis. LUCAS.—This author has reported the case of a boy, 14 years old, who at the age of 4 suffered with a discharge from the right ear, possibly as a complication of an attack of measles. The ear had thereafter suppurated with periodic intermissions. The boy had complained for a week of pain behind the right ear, and on examination the mastoid process, particularly toward its apex, was found sensitive, though not

swollen. The auditory canal was wide, and contained purulent fetid secretion in moderate amount. At its depth it was obstructed by large granulations, projecting from its roof, and almost entirely occupying its lumen. Hearing was impaired on the right, the temperature was slightly elevated, and the pulse accelerated, but the ophthalmoscope revealed no abnormality. A day later, the patient could not sleep on account of headache, and the neck began to be stiff, while the temperature rose a little more, and the frequency of the pulse increased. In view of the gravity of the symptoms, and the probability that a purulent leptomeningitis had set in, the mastoid process was trephined, and pus reached at a considerable depth, together with granulations and cholesteatoma masses. The exposed dura appeared necrotic and, on the introduction of a sound, pus escaped by its side. An incision into the cerebral substance was unattended with the escape of further pus. The exposed cavity was carefully cleaned. The stiffness of the neck continued for some time, but the wound progressed favorably. About two weeks after the operation it was noticed that the hearing of the left ear was also greatly impaired, but this subsequently returned to normal, and in a short while the wound had entirely healed. It is believed that there existed a basilar meningitis limited to the right temporal lobe. The appearance of deafness in the left ear is attributed to hyperæmia in the labyrinth resulting from transmission of irritation by continuity. Cerebral deafness of cortical origin is thought to be exceedingly rare, as each auditory nerve has bilateral representation, and the bearing function of one hemisphere, when lost, is readily taken up by the opposite hemisphere.

Centralblatt f. Chirurgie (Leipzig), July 8.

The Tobacco-Pouch Suture. F. DE QUERVAIN.—Doyen has lately been extending the application of the pucker string suture to abdominal surgery, using it on the appendix, intestine, stomach and Douglas's sac after abdominal hysterectomy, and now Quervain, after extensive tests on the cadaver, announces that it is stronger than the Lembert suture and is peculiarly adapted to the peritoneum, when the latter is movable and the opening is of moderate size. The ends can be tucked in and the thread drawn tight like an anus, or the edges can be left out and the stitches taken with longer stretches on the outside, which forms a particularly strong and effectual method of suturing organs invested externally with serosa, such as the intestines and gall-bladder. He is confident that one trial will convince all of the remarkable advantages to be gained from this suture on the peritoneum.

Centralblatt f. Innere Medizin (Leipzig), No. 27.

Therapeutic Action of Dialysate of Digitalis. H. BOSSE.—This Swiss preparation of the freshly plucked plants, made by a special dialyzing process with water and alcohol, enables the essential principles to be accurately dosed: each part by weight of the dialysate, corresponding exactly to a part by weight of the plant. No powerful reagents are used in its preparation and ten cases of severe cardiac disturbances treated with it reacted promptly and effectually, fully demonstrating that it is the equal of other preparations of digitalis, to say the least. The effect on the diuresis was most marked.

Centralblatt f. d. Grenzgebiet der Medizin u. Chirurgie, June 15.

Artificial Alimentation by Subcutaneous Injection. A. BASS.—The conclusions of this comparative study of all that has been written on the subject since Menzel and Perco in 1869, are that artificial alimentation by subcutaneous injection is both practicable and effectual, and if the precautions indispensable to all subcutaneous injections are observed, is absolutely free from danger. Albuminous substances are not adapted to this form of aliment-ation, although Blum's proteogen possibly inaugurates a new era in this respect. Certain carbohydrates, grape sugar in particular, are readily absorbed in moderate amounts and protect the albumin, but symptoms of irritation occasionally follow. Fats can be injected even in large amounts without causing the slightest symptom of irritation. They are entirely assimilated if rationally administered, and effectually protect the albumin. Subcutaneous injections of oil can even increase the weight. Alimentation by a combination of these three groups is only a question of time. The injections, especially of grape sugar and oil, are easily managed *in praxi*, using either a large hypodermic syringe or Leube's combination of needle, tube and funnel, which is simple and kept aseptic without difficulty.

Dermatologisches Centralblatt (Berlin), July.

Improved Technic of Irrigating the Urethra and Bladder According to Janet's Method. L. SPITZER.—Extremely satisfactory results from every point of view have been attained in Professor Lang's service at Vienna, with an improved irrigator consisting of a glass tube terminating in a slightly enlarged, almost spherical tip, the whole divided its entire length by a glass partition, into two spaces, each continued at the rear into a diverging branch, the whole forming a Y, each branch fitting into a rubber tube. The irrigator is not inserted into the urethra, but fits against the orifice, and is so easily managed that an intelligent patient can make his own irrigations. The fluid flows in through the upper tube and space and out at the other, the flow controlled by squeezing or kinking the rubber tube. Irritation from inserting the irrigator into the urethra is thus avoided; with care none of the fluid escapes and the hands remain clean and dry. The entire process occupies much less time than by any other method, which with the copious irrigation allowed is a most important factor in a rapid and thorough cure.

Deutsche Medicinische Wochenschrift (Berlin), July 20.

Sporadic and Epidemic Purulent Cerebrospinal Meningitis. E. STADELMANN.—The writer classifies acute meningitis as the purulent, the epidemic cerebrospinal and the tuberculous, with Quincke's new "meningitis serosa." He does not consider that epidemic cerebrospinal meningitis is due to any single micro-organism, but that two at least are concerned in its production: Fraenkel's pneumococcus and in the second rank, the meningococcus, with possibly others. He describes an observation in which the entire course of the disease was followed by inspection of the cerebrospinal fluid obtained by lumbar puncture: the pus cells were gradually destroyed and finally absorbed, the fluid regaining its clearness. The case was also peculiar in the recovery after intensely serious symptoms, and also from the fact that a hitherto undescribed bacterium was obtained pure in cultures which did not develop until eight days had elapsed after sowing; extremely motile, thick rods, staining with the usual anilin stains but not taking the Gram. In regard to the obligatory notification of epidemic meningitis he thinks the physician might restrict his declarations of cases to those in which Fraenkel's pneumococcus or Weichselbaum's meningococcus are found by lumbar puncture, and that other cases, due to other bacteria or cocci, are not contagious or malignant in the same way, and do not impose notification.

Epidemiology and Bacteriology of Cerebrospinal Meningitis. H. JAEGER.—It is Jaeger's opinion that we are probably in an epidemic period of meningococcus infection, which has of late years supplanted the Fraenkel pneumococcus in the etiology of most cases of cerebrospinal meningitis. Accepting the assumption of an epidemic period, the peculiarly resisting vitality of the meningococcus on the one hand, and its widespread dissemination, with the evidently slight disposition of human beings for the infection—manifested in the comparative smallness of the epidemics—would easily explain the epidemic and sporadic character of the cases. Careful scrutiny of those that have occurred in Germany the last few years, especially in military circles, shows that all the so-called sporadic cases radiate from a center of infection, and that a sporadic case may start a new center, even after long periods of latency of the microbe in dry dust. He also calls attention to the difficulty of differentiating the meningococcus from the staphylococcus, which has possibly been a source of error.

Deutsches Archiv f. Klinische Medizin (Leipzig), lxiii, 1 and 2.

Diazo-Reaction in Urine. CLEMENS.—Extensive chemical research on this subject is reported and clinical investigations which establish that normal urine never reacts positively, but that the diazo-reaction occurs in by far the largest majority of cases of typhus abdominalis, and its absence militates against the assumption of typhus in doubtful cases and positively excludes the possibility of febrile gastro-enteritis. The reaction is frequently positive in other febrile diseases, such as measles, scarlet fever, tuberculosis and especially miliary tuberculosis. The reaction seems to indicate that an abnormal katabolic product of the organic albumin is eliminated in the urine.

Latent Fever in Chronic Tuberculosis. MIRCOLI.—By latent fever, Mircoli designated all disturbance in the regulation of warmth that occurs without elevation of temperature above normal. He established, for instance, that the variation be-

tween the external and internal temperature of persons with tuberculosis is greater than with normal subjects, also that their body temperature reacts more to internal and external stimuli, such as physical exertion or dietetic disturbances. The sweats of tuberculosis are independent of the fever, and are caused by certain toxins of the tubercle bacillus which are without influence on the temperature.

Prager Medicinische Wochenschrift, July 6.

New Method of Draining After Operations for Empyema. G. FELKL.—A glass tube about 5 cm. long, with a circular groove at the point where the lips of the wound close over it, is inserted in one end of the perforated drainage-tube. The latter is then placed in the wound, the two ends together, forming a loop and proving a most effectual drain. The loose end of the rubber tube is drawn out and cut off as healing progresses. Three cases of fresh uncomplicated empyema thus treated healed promptly and the resection of a rib was avoided.

Nordiskt Medicinskt Arkiv (Stockholm), June 30.

Operative Treatment of Ankylosis of the Stapes. B. FLODERUS.—By an operation devised after much study and experimenting on cadavers, but without experience on man, Floderus proposes to replace a portion of the external wall which interferes with the transmission of sound into the labyrinth, by an elastic vibrating membrane which can transmit the sound perfectly into the internal ear. It promises fine acoustic functional results, freedom from relapses and comparatively little danger of infecting the middle ear, while it is practicable even in cases of extensive hyperostosis. It is especially adapted to cases of bony ankylosis of the vestibular articulation of the stapes, and although delicate and long, is evidently superior in many respects to the unsatisfactory operations on the stapes now in vogue. The middle ear is opened according to Stacke; the membrana tympani, the lateral wall of the attic, the malleus and the incus are extirpated; the labyrinth is trephined at the front edge of the fenestra ovalis, and the thin plate of bone is resected from a point 2 to 2.5 mm. from the anterior edge of the fenestra ovalis almost to the rear edge of the stapes plate, the resected surface measuring 2 mm. at the back and 1 mm. forward. The defect is covered with a Thiersch flap taken from the dorsal side of a finger over the middle phalanx, which forms the vibrating membrane.

Clinical Investigations of Frequency of Microbes in Blood. C. DE FINE LICHT.—Tests with one part blood to ten parts bouillon kept in the thermostat for a day or so, developed colonies of microbes in the case of several febrile diseases in 31 out of 72 subjects with various affections. The conclusions are that bacteria, and most frequently the staphylococcus, will be found in almost all fevers produced by pyogenic microbes, as well as by the typhoid bacillus, the pneumococcus and other similar bacteria, when the temperature has risen above 39 C. When the microbes once enter the blood they may linger in it a long while, three months in one case of phlebitis and another of appendicitis, even though the temperature may have returned to normal or below. The microbes were found in the blood without evidences of fever, in only two cases, one a patient with ileus, who died with intestine intact, and temperature under 38 C. when the staphylococcus was first noted in the blood. The other was a fatal case of diabetic coma, the staphylococcus discovered the day before death, while the comatose condition, was still incomplete.

Societies.

International Congress on Behalf of Blind.—An international congress for the amelioration of the condition of the blind is to be held in Paris, Aug. 1 to 5, 1900. For particulars address the Secretary-General, Maurice de Sizeranae, Avenue de Breteuil, 31, Paris.

Canadian Medical Association.—The thirty-second annual meeting of this Association is to be held at Toronto, August 30, 31 and September 1, during the first week of the Industrial Exposition in that city. The building of the Education Department, through the kindness of the Honorable Minister of Education for Ontario, has been placed at the Association's disposal, and on the program interprovincial registration will be

fully discussed. In addition to the scientific phases, there are entertainments, receptions, musicales, an afternoon tea at the Royal Canadian Yacht Club on the island, a smoking concert, etc.

Rocky Mountain Interstate Medical Association.

Salt Lake City, July 25-26, 1899.

Although the Rocky Mountain Interstate Medical Association was organized at Denver last year, when the profession of that region was gathered together to attend the meeting of the AMERICAN MEDICAL ASSOCIATION, this was its first meeting for the hearing of scientific papers and discussions.

MEDICOLEGAL SUPERVISION OF PROSTITUTION.

DR. SALATHIEL EWING of Salt Lake City advocated this as a sanitary measure. While this vice should be restricted as much as possible, the experience of 4000 years showed it could not be eradicated. He favored licensing, weekly inspection, strict quarantine and treatment of the diseased in hospitals. The funds obtained by licensing should be wholly expended in support of the necessary hospitals, and institutions for the reformation of prostitutes. He cited the experience of St. Louis with such supervision of prostitution, as showing its effect in markedly lessening the prevalence of venereal diseases.

DR. H. S. SCOTT, Salt Lake City, believed that all prostitutes should be compelled to reside in houses of prostitution under close police supervision, and that medical examinations should be made twice a week by specially trained examiners.

DR. L. FREEMAN, Denver, said that the most excellent systems on paper had failed to work in practice. He cited the theoretically complete plan in operation in Vienna, which had failed to suppress, or even to notably diminish venereal diseases.

TREATMENT OF CHOREA.

DR. S. D. HOPKINS, Denver, read a paper on this subject, based on nineteen cases. He had obtained the best results with antipyrin, administered by the method of Dr. J. T. Eskridge; but he would not undertake any case unless his directions would be rigidly carried out. In the mildest cases the patient is permitted to sit up a part of the day; but in severe cases absolute rest in bed is enjoined. Antipyrin is given in increasing doses, the initial dose being as many grains as years in the child's age; with an increase of one grain per day. In mild cases the antipyrin is given only in the evening. In severe cases it is at first given three times a day. He does not give antipyrin when the patient shows any fever, or when there is any disease of the heart.

As soon as the choreic movements cease, or become greatly diminished in frequency, the antipyrin is stopped. Fowler's solution and iron are continued for two or three weeks after the cure appears to be complete.

DR. HUBERT WORK, Pueblo, Colo., found the rest cure often sufficient for the cure of chorea, without any drug treatment. Rest in bed is not always essential; but the patient must be kept away from other children, and free from excitement.

DR. JUDSON DALAND, Philadelphia, called attention to the anemia which generally attends chorea, by the relief of which arsenic does good. Auto-intoxication from fecal retention is also an important element in these cases; and treatment by caesara and enemas produces very satisfactory results.

HYDATIDIFORM MOLE.

DR. SOL G. KARN, Leadville, Colo., called attention to slight additions that had of late years been made to our knowledge of the subject. He had attempted to ascertain its relative frequency, and the influences which might cause it. Letters of inquiry were sent to 400 physicians, and responses were received from 78, and these included the mention of 12 cases he reported; 3 of these cases, seen by himself. This study showed the hopelessness of obtaining accurate statistics, and threw no light on the causation of the disease.

HEMOPHILIA.

DR. A. A. KERR, Salt Lake City, reported two cases. One patient was a boy of 10 years with healthy parents. The mother's brother had died of hemorrhage after an operation, at the age of 17 years; 2 other children of the same parents were healthy, and had died of hemorrhage at the ages of 12 days

and 6 months respectively. The second case was that of a baby 10 months old. The family history was negative.

ADDRESS OF THE PRESIDENT.

DR. C. P. HUGHES dwelt on the need for the closer association of the physicians of the intermountain states, who were too far removed to regularly attend the meetings of the special societies held in the eastern states, and had to deal with many problems of peculiar interest to themselves. He favored regulation of the practice of medicine, but thought members of the profession of recognized ability and experience should be free to practice in any state, and that membership in the AMERICAN MEDICAL ASSOCIATION ought to be evidence of such fitness for practice. He touched on some questions now especially demanding the attention of the profession.

USE OF THE HEMATOKRIT.

DR. JUDSON DALAND, Philadelphia, pointed out the difficulties and extreme tediousness of making blood counts, the necessity of repeating them, and the large probability of inaccuracy. The method of estimating the volume of corpuscles with the hematokrit is not exactly comparable with the blood count. But on account of the rapidity with which it can be completed, it is of great practical value. With everything in readiness, and an assistant, the estimation can be effected in three minutes. More time is consumed in cleaning the apparatus and keeping it in order. Unless the tendency to coagulation of the blood is unusually great, it is not necessary to use any diluting fluid to prevent coagulation. Rapidity of manipulation is of the highest importance, to secure accuracy of results. He has found that 10,000 revolutions per minute for two minutes gives a satisfactory result. Treated thus, normal blood gave 50 per cent. of its volume corpuscles. This was taken as the standard, and the percentage read off from the instrument being multiplied by two gave the percentage of the normal. Thus if the corpuscles occupied thirty-hundredths of the tube, the blood contained 60 per cent. of the normal volume of the corpuscles. For comparison with blood counts 100 per cent. thus obtained might be taken as the equivalent of 5,000,000 corpuscles to the cubic millimeter.

FIBROID LUNG INDUCED BY EXPOSURE TO DUST.

DR. W. W. BETTS, Salt Lake City, has made a study of the fatal disease induced by working in the dust caused by grinding ore at De La Mar, Utah. The quartz ore here reduced forms a very fine powder; and he was informed that of a large number of men, all who had been exposed to this dust for a period of seven to nine months prior to January, 1898, were now dead. One case endured an exposure of eighteen months before becoming affected, and is still living. In contrast with this was one affected within three months and dead within ten months.

In 14 tabulated cases, the men having been 23 to 43 years of age, and all healthy when they engaged in the work, the average time they were able to work was thirteen months, and the average time of survival after leaving the mill ten months. Two autopsies were reported. In one the pericardium was greatly diseased. In both the lung was excessively firm, the air-cells largely obliterated by great increase of fibrous tissue. Chemical analysis showed silica present to the extent of 2.8 per cent. in the lung tissue and 3.8 per cent. in the bronchial glands. The only remedy of any value was prophylaxis.

DR. F. CLIFT, St. George, Utah, stated that all the men who had gone from that place to work in the De La Mar mills had come back with this disease. They were free from tuberculosis, and had previously been healthy.

DR. J. N. HALL had noticed among miners working at high altitudes, fibroid phthisis with emphysema.

DR. MAYO, surgeon of the De La Mar Company, believed that the number of deaths had been overrated. With the help of the records of the company, he had carefully investigated the matter, and found that of those who had worked there within the last four years thirty-four had died. Since their attention had been called to it the company had made extensive changes in their mills, supplying fans, hoods, ventilators, and respirators for the men, and instructing them with regard to their use. The men were not now in greater danger than when shovellers, grinders, and other workmen continuously exposed to dust. He believed that a similar mortality would be found

among the workers in other mills handling the same kind of ore. He thought the disease when once contracted was necessarily fatal. The De La Mar company desires to aid in the investigation of the subject, and will welcome any practical suggestion as to prophylaxis.

REPEATED EXTRA-UTERINE PREGNANCIES.

DR. C. R. FLEMING, Denver, read a paper on this subject, and reported two cases. The first case, after symptoms of rupture, had presented evidences of sepsis, and had been treated three weeks for typhoid fever. She recovered after the opening of a pelvic abscess. Eighteen months later, having menstruated regularly in the interval, she had a similar attack, but refused operation and slowly recovered without it. The second patient was operated on after the symptoms of tubal rupture, and a pelvic hematocoele removed. One year later symptoms again appeared, and operation showed the right tube ruptured, with a large blood clot in it. She again recovered. Both of these patients seemed to have been free from previous disease.

CARCINOMA OF UTERUS.

DR. W. W. GRANT, Denver, called attention to the increasing mortality from cancer, and its strong predilection for parts exposed to both traumatism and infection; especially the uterine cervix in women. On early diagnosis rests the only chance of cure. He advocated frequent examination of women near the menopause, with microscopic examination of suspicious lesions. In women who have borne children, all lesions of the cervix should be repaired at 40 years of age. Dangerous lacerations of the cervical canal might show little evidence of disease externally.

DR. J. B. PERKINS, Denver, urged that the danger of carcinoma could be lessened if we prevented laceration of the cervix, by giving plenty of time for its dilatation during labor.

(To be continued.)

California Academy of Medicine.

July Meeting.

THYROID EXTRACT IN MYXEDEMA.

DR. HERBERT C. MOFFITT presented a patient illustrating a case of myxedema treated with the thyroid extract. The patient, an Irishman, aged 43, gave no family history. All his relations, so far as he knew, were healthy, and had no trouble in any way similar to his own. The family was rather a long-lived one. He came to this country in 1868, and went at once into northern California, where he worked in the mines. At that time he was drinking mountain water, but noticed no trouble therefrom. In 1873 he met with an accident, dislocating his shoulder and breaking the clavicle, but so far as can be ascertained, no injury was sustained by the thyroid, and no ill effects followed. No goiter had developed either from this cause or from the water. He then worked in gas works, where he was exposed to overheating and sudden cooling. He followed this occupation for some years, and it was while employed in this kind of work that he first noticed symptoms of myxedema. This was seven years ago. He then commenced to gain in weight and become larger, especially in the regions of the knees, hands and face. He felt unwieldy, some slight coldness, and a general stiffness in movement. His walking was difficult, and his memory began to fail. Very shortly after the commencement of the symptoms, he could, with great difficulty only, remember recent events, and soon he was quite unable to remember anything save the episodes of his youth. This condition of affairs persisted for some three or four years, during which time he consulted many doctors, but without avail. He went to the country for a time, but again returned to the city, where he consulted Dr. Montgomery at the University of California clinic.

A lesion of the left side of the lower lip was noticed and diagnosed as epithelioma, for which he was sent to the City and County Hospital, where the growth was removed by Dr. McLean. At that time no thyroid extract had been administered, so that the effect on the epithelioma could not be determined in this case. After the operation he was referred to the medical wards of the Hospital for treatment for his general condition. Thyroid extract was at once administered. His condition before commencing the administration of the thyroid extract was as follows: The body was perfectly hair-

less—not only had the hairs of the head and face fallen out, but the hair on the entire surface of the body had also been affected. The memory was very bad; there was puffiness over the hands, face, knees and supraclavicular regions; the cheeks were red, as frequently seen in myxedema. The picture commenced to change at once on the administration of thyroid extract; he lost 47 pounds, the memory cleared up entirely, the hair returned on the head and all over the body, and the growth was thicker than previously. He left the Hospital absolutely well, and returned to his work. So long as he took thyroid extract he remained well, but cessation of the extract for a time brought on a return of the symptoms. At one time he took no thyroid for two months, and then returned to the Hospital, as bad as ever, with the exception that the hair had not fallen out to the same extent. At a subsequent time he went three months with no thyroid, and then returned with evidence of epitheliomatous trouble at the site of the old growth. He was placed on the thyroid extract for a while, and the appearance of the growth seemed to improve, but the change was not very rapid, so it was decided not to delay its eradication, and he was again operated on for the removal of the epithelioma. He has now been under thyroid treatment for about three weeks, after a lapse of no thyroid ingestion; he is much improved, the memory being again cleared up, some flesh having been lost, and the general condition rapidly improving.

DR. HERBERT C. MOFFITT—The story of this case is told by the man's hands and face, practically, for there is no other indication save what may be seen. The face is somewhat puffy, and the hands and wrists are in the same condition; the thickening under the eyes can be readily seen. He has had absolutely no trouble other than recounted; no hemorrhages after the operations, and no disturbances of any kind. There can be no question of the value of the thyroid extract in this case or in similar conditions. In myxedema, we may assume, thyroid is of great value, but in sporadic cretinism its value is problematic. I should like to mention a few of the other conditions in which thyroid extract has been used. It has been employed in a large number of different disorders and affections, sometimes with good, but more often with negative results. In psoriasis it has been found to be of much value, though the eruption seems to always return, whether the thyroid extract be continuously administered or not.

In some forms of insanity it also seems to be of value; it has been tried in many varieties of alienation, but seems to be useful in melancholia, principally; in epilepsy it is of no value whatever.

Another condition often mistaken for rheumatism, but in all probability, as described by Dercum, an early form of myxedema, is that in which the arms, back, belly and knees are found to be the seat of pads of fat; there is also an appearance of premature senility, together with pains and stiffness that strongly simulate rheumatism. The condition is at once relieved by the use of the thyroid extract. The extract has also been largely used in the treatment of sundry bone affections. In the case of delayed union after fracture, it may be of slight value; in rachitis it is of no value whatever. In the case of exophthalmic goiter, which is really a condition of over—rather than under—thyroidism, the ingestion of thyroid extract seems to be of no value, though a certain number of patients do improve under treatment by this agent.

In chlorosis most patients exhibit a slight enlargement of the thyroid gland, which may in some cases be marked. This enlargement seems to be glandular, and not vascular, and of the variety which we find physiologically at the times of menstruation and pregnancy. I am inclined to believe that some of the symptoms which we find in these cases of chlorosis are due to the enlarged thyroid, and that they are not all due to simple slow circulation, or enlargement of the jugular bulbs; these factors will not account for all the symptoms. Here the thyroid extract does not seem to be of value, perhaps owing to the over, rather than under, thyroidism. In chronic nephritis, thyroid extract has been strongly recommended, and is in some cases of slight benefit, though its value is problematic.

Thyroid extract has been strongly recommended in the treatment of inoperable cancer, and as an after-treatment following operation for the removal of cancer, to prevent recurrence. This usage of thyroid extract is strongly recommended in Eng-

land, where large doses are being used, with beneficial results reported. In affections of the prostate, and for myomata, it has been employed, but without result. Other forms of skin disease aside from psoriasis have been treated by means of the thyroid extract, but with less marked results than in the case of the disease mentioned, where it seems to have a truly marvelous effect. After a few days' treatment with the extract the lesions in psoriasis melt away like magic. Unfortunately they return in the course of time, whether ingestion of the extract be continued or not. It has been used for the treatment of lupus, but without effect, as also in the case of eczema, where, too, it seems to be of no benefit.

We find a certain amount of thyroid enlargement in a number of cases not classified, in which the affection of the thyroid has, in my opinion, an influence on the pathologic conditions that is not accepted at its true value. The case of chlorosis is an example, and we also note certain cases of affection of the male genital organs, where there is also a disturbance of the thyroid gland. I have recently seen several patients illustrating this condition. There is heart tremor, together with general nervousness and malnutrition, and the presence of an enlarged thyroid may be determined, varying in the extent of the enlargement. The symptoms are such as one sees in tobacco poisoning, but the cause is probably masturbation; at least, the patients generally give a history of excessive masturbation. Cessation of the evil practice, together with treatment by bromids and arsenic, and correcting the habits, generally cures the case. It is not a tobacco infection, for several of the patients in whom I have noted this condition do not smoke at all. In tobacco poisoning we also have an enlargement of the thyroid, but the condition is quite distinct from the case I have just mentioned.

In regard to the form of administration I would like to say a word. I have tried many methods and forms of preparation. The fresh gland is not reliable, for the butcher occasionally supplies some other gland. Parke, Davis & Co.'s tablets I have used, but find them often unreliable. I have used them with excellent results, for a time, but when the supply ran out and a fresh lot had to be obtained, all evidence of thyroid ingestion ceased. They vary, thus, very largely. I find the tablets made by Burroughs, Welcome & Co. very much more reliable, and use them, now, altogether. The effect from them is constant, so far as my experience has gone.

DR. JAMES F. McCONE asked Dr. Moffitt what his experience in the treatment of obesity by thyroid extract had been.

DR. MOFFITT, in reply—I have not used it much for the purpose mentioned. Epstein, who suggested the method of dealing with obesity, in his later report does not demonstrate its usefulness. I do not think it is of value, for though there may be a loss of a few pounds in weight, the weight runs up again as soon as the patient ceases to take the extract. In a number of cases, too, there have been very unpleasant complications resulting from thyroid poisoning.

DR. S. J. HUNKIN—I know of a patient who, of her own suggestion, took thyroid tablets for the purpose of reducing her weight. She weighed 220 pounds normally, and in a month could reduce herself twenty to thirty pounds by using the thyroid. After their use for a short time she would, however, be troubled with shortness of breath, and her mother would make her stop their use. She would then return to her former weight.

DR. J. F. McCONE—I have been using thyroid extract in the University clinic for the past two years, for the purpose of reducing weight, and have found that about three out of five patients respond to its influence. I remember one woman who lost sixty-five pounds in three months under this treatment. I do not know whether the fat returns, for it is impossible to observe many of these patients for any length of time. We have used it, too, for reduction previous to operations, and here it seems to be of use. I have not observed any unpleasant symptoms in these cases.

DR. S. J. HUNKIN—I have one patient who now has nephritis; I am not certain, but have every reason to believe that the nephritis was not present at the time the use of the thyroid was commenced.

DR. GEO. H. EVANS—I have made use of thyroid extract for reducing obesity in a few cases, and have found that if the diet is changed the weight is lessened; if the thyroid is ad-

ministered without any attention being paid to the diet, no alteration in the weight seems to follow. I had therefore thought that the reduction was more probably due to the diet than to the thyroids.

DR. DOUGLASS W. MONTGOMERY—I first saw this patient on June 4, 1897. My case-book gives me data as follows: He was at that time 41 years of age, and gave no family history. There was very evidently a condition of myxedema present, besides an epithelioma on the left side of the lower lip. He had very red cheeks, spade hands, yellowish skin, puffiness in the supraclavicular spaces, and no thyroid gland could be detected. He was ordered thyroid gland extract, and sent to the City and County Hospital for operative removal of the epithelioma. I again saw the man on April 15 of the present year. He then came once more to me at the University clinic, presenting the symptoms and condition given by Dr. Moffitt. I noticed two keratoses, one on each side the scar of the operation for the removal of the old epithelioma, but was not sure that it was a recurrence of the epitheliomatous growth. I sent the man once more to the hospital, and the subsequent history of events has been given you by Dr. Moffitt. Under thyroid administration the keratosis much improved; the skin softened, and the hard, scaly appearance disappeared almost entirely; whether it would eventually have disappeared, or been cured under the thyroid treatment, it is impossible to say.

The extract of the thyroid gland does undoubtedly have a very decided effect on the skin; principally on the general nutrition of the skin. In those cases where there is a hard, dry, scaly skin, with a seborrheic eczema of the scalp, and falling out of the hair, administration of thyroid gland improves the condition very much indeed. In psoriasis the disease is not cured, for, as Dr. Moffitt has said, it returns whether the administration of the gland be continued or not. I attribute the good effect in these skin diseases to the general tonic action on the skin, and not to any specific action on the disease itself. The nutrition of the skin being improved, in any skin disease, improvement will follow; I think it is just so in psoriasis. The action is one secondary to an improved nutrition of the skin.

GYNECOLOGIC ASPECTS OF PUBERTY IN ITS RELATIONS TO ADULT DISEASE.

DR. T. J. WATKINS—I will limit the few remarks I have to make to the relation of puberty to adult disease in the female, because "the mental and physical peculiarities of the two sexes differ in early life to a limited degree only." It is toward puberty when the organs of generation undergo secondary development, that their influence is exercised in the highest degree.¹⁷ By puberty will be meant the period between childhood and mature adult development. The length of this period of life varies much in individuals, principally as a result of the general health, and may extend over from two to five years. The importance of my subject is best illustrated by referring to the opinions of Emmet and Skene. They conclude, after very extensive experiences, that the majority of gynecologic diseases are the result primarily of imperfect development. Imperfect development is a prominent factor in the etiology of uterine displacements; injury of the pelvic floor at childbirth is often the entire cause of menstrual disturbances, and not infrequently the cause of sterility. With perfect development of the pelvic organs, congenital displacements of the uterus do not occur; and displacements following childbirth are not apt to result except as a sequel of pelvic inflammation.

During an experience of thirteen years in hospital, dispensary and private practice I have examined the pelvic organs of a large number of colored women who have borne children, and I have never, with possibly one or two exceptions, found in them relaxation of the pelvic outlet. Under the term relaxation of the pelvic floor are most cases of so-called important incomplete lacerations of the perineum; rectocele and cystocele.

¹⁷ Skene: Medical Gynecology.

I have, however, found some cases of complete laceration of the perineum in the colored woman not associated with relaxation. The inference to be drawn from this is that the colored woman has a well-developed perineum, and that a well-developed perineum is the best protection against important lacerations at childbirth. You will agree that a well-developed organ resists infection better than a poorly developed one, and this fact is frequently observed in the clinical history of pelvic infections. Nearly all cases of dysmenorrhea in women who have never been infected are due to imperfect development of the uterus.

To secure normal development of the reproductive organs is to secure a uniform, harmonious development of the whole body. There are, however, cases of imperfect development of the reproductive organs in women who have an apparently good physique. This can probably be accounted for by the fact that the reproductive organs get their principal development during a short space of time, and during the time when there is rapid growth of the body in general, and consequently during a stage of more or less impoverishment of the blood.

These facts emphasize the necessity of a large amount of nutritious food, of good air, sunlight, not too much work, especially mental, during the period of puberty.

All management of the child during puberty seems to occur as often or oftener in the families of the intelligent and rich as in the families of the poor and ignorant. No rules can be formulated for the care of girls during puberty; each case should be treated individually and the treatment will depend much on the rapidity of growth, the environment, the temperament, and the general health of the girl.

The statement is frequently made that the women of America are a weak, sickly lot of individuals. If we are, however, to measure health and strength by mental and physical labor accomplished, the women of America compare very favorably with those of other lands.

MATERNAL DRUG-TAKING ASPECTS IN THEIR RELATION TO ADULT DISEASE AND DEFECT.

DR. GEORGE F. BUTLER—Of the vegetable narcotics, the one most abused has undoubtedly been opium, its chief alkaloid having produced more misery and relieved more suffering than any other agent in the materia medica. It is not, however, with the therapeutic use of morphia, but with one of the results of its abuse, that I propose to deal in the present paper.

The close resemblance between morphia and certain products of nerve tissue change certainly tends to indicate that it is less foreign to blood transportation than many other remedies. It is not astonishing, therefore, to find, as Bureau and Ringer have shown, that it passes readily from the maternal circulation through the placenta into the fetal circulation. About thirty years ago this fact was clinically demonstrated by Calkins, who found that the children of mothers addicted to the use of opium died of marasmus unless nursed by the mother or given opium when fed from the bottle. His observations were later corroborated by Erlen and Meyer, F. H. Hubbard of New York, Kiernan and F. B. Earle of Chicago, Madison of Brooklyn, C. E. Hughes of St. Louis, P. C. Layne of Cincinnati, and others.

This congenital opium habit adds one more problem to obstetrics, since it involves both the treatment of the opium-using mother during pregnancy and the mother after delivery. It requires considerable delicate acumen to guide a mother and child between the Scylla resulting from opium deprivation and the Charybdis consequent on opium using. There is very little doubt that the maternal use of this drug during pregnancy produces, as Talbot of Chicago has shown, degenerate children, but it is equally certain that the evils of deprivation are fully as great.

The management of the infantile opium habit when congenital is, however, much less difficult than that of one acquired habit during infancy through the use of soothing syrups, etc. The use or misuse of soothing syrup for infants is much older than generally supposed. Crabbe, in "The Borough," sung of it a century ago.

Among other drugs which may be the source of infantile drug habit are cannabis indica and lactucarium. Both of these have been found to pass through the placenta and would therefore form a basis of a congenital drug habit in the infant.

The experiments as to cocaine are as yet indecisive. The habit, however, is much rarer with women than with men. This is particularly true of the habit as found among the Indians of South America, who had it for centuries. The other drug habits exert an influence on the fetus only through impairing general nutrition. Children of chloral-using mothers have been born checked at the senile time of the fifth month of pregnancy, and hence have borne some resemblance to the cases where syphilis has checked the development in a similar way. In a general way, the effect of maternal drug taking on the fetus may be summed up in the fact that any of the types of degeneracy can be produced by it.

BACTERIOLOGIC ASPECTS OF CHILDHOOD IN RELATION TO ADULT DISEASE.

DR. ADOLPH GEHRMANN—As to the bacteriologic and tubercular aspects of this subject, bacteriology teaches us that the young are the most easily affected; that is, natural immunity increases as the individual grows older, or, at least, to the time of maturity. It may increase later. There are two general conditions, as far as natural immunity is concerned, one that group of diseases of a bacteriologic or infectious nature in which there seems to be immunity, and the other large group against which there does not seem to be immunity of any marked importance. The condition of growth and development in the child, to bring about a perfect condition of maturity, should be one in which natural immunity is developed, as far as it is possible to do so. One of the most marked examples of diseases in which natural immunity can be developed is that in regard to tuberculosis. Of this I will speak in a moment.

In regard to the general diseases of a bacterial nature which occur in childhood, the impress of which is left upon the child in after years, the first one of these, and one of great importance to physicians and to the public at large is that of gonorrhoeal ophthalmia of the infant. We have evidences of this, as you know, in our large public institutions for the blind. I need not at this point bring out any of the various facts in relation to blindness in childhood and its results in after life, or the measures which should be employed to remedy that evil, but I simply present it as one of the obvious facts of bacterial diseases in relation to the effect on the adult due to disease in the child.

The second point is that of the relation of defects due to secondary infection in diseases which are recognized as affections of childhood—the exanthemata—and here the important point to bring out is the avoidance of a mixed or secondary infection during the diseases which are especially liable to occur in childhood, such as pus infection. A great many diseases occur in after life, which have absolutely no relation to anything that can be done in childhood to prevent them. In after years pneumonia will occur, for instance, and other infections due to bacteria which have no relation to anything which occurs during the period of child life, but the suppurative otitis media of scarlet fever may be the cause of changing the entire course of an individual's life.

In regard to tuberculosis, it has always been to my mind a well-established fact that it is a disease of early life, that is, it has its beginning in early life. We see the majority of cases of tuberculosis of bones, either of the joints, or of the spinal column developing during early periods of life. We know the defects and difficulties which result in after life from such infections in men or women who have been so infected.

(To be continued.)

American Association of Obstetricians and Gynecologists.—This association will hold its twelfth annual meeting in Indianapolis, Ind., Sept. 19-21, 1899. It is considered especially desirable that each author of a paper forward to the secretary a concise argument thereof, under three or four separate heads, to be printed in the permanent program. This will add to the interest of the discussions. One of the sessions, or as much thereof as may be necessary, will be devoted to the presentation of pathologic specimens and their histories, with discussions pertaining to the same. Twenty-nine papers are listed on the preliminary programme. Dr. Edward J. Ill, Newark, N. J., is president, and Dr. William Warren Potter, Buffalo, N. Y., secretary.

Single Copies	10 Cents

In requesting change of address, give old as well as new location.

Subscriptions may begin at any time and be sent to

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION

No. 61 Market Street, Chicago, Illinois.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Henry P. Newman, 100 Washington St., Chicago, Ill., sending him a certificate or statement that the applicant is in good standing in his own Society, signed by the President and Secretary of said Society. Attendance as a delegate at an annual meeting, of the Association is not necessary to obtain membership.

On receipt of the subscription the weekly JOURNAL of the Association will be forwarded regularly.

These new members of the Association should send their annual subscription direct to the Treasurer, Dr. Henry P. Newman.

All communications and manuscript of whatever character, intended for publication in the JOURNAL, should be addressed to the Editor, and all communications relative to the business of the JOURNAL, proof-sheets returned, or in regard to subscriptions, should be addressed to THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, 61 Market Street, Chicago.

Original communications are accepted with the understanding that they are exclusively contributed to this JOURNAL.

SATURDAY, AUGUST 12, 1899.

MOSQUITOES AND MALARIA.

For many years we have known that malarial fever and certain similar animal diseases are caused by minute parasites of the blood. Considering the number of investigations on the etiology of these diseases, it certainly seemed strange to some that no light could be thrown on the form and mode in which the parasites, especially of human malaria, existed outside of the body, and on the way in which they gained entrance into our bodies. A number of theories were advanced; it was assumed that the microphytes existed in the soil, air, or water of humid regions, multiplying freely in these elements; that they were carried by air currents and in mists and vapors, infecting persons through the air breathed or the water which they drank; and in not a few places it was thought that malaria stood in some close relation to the bite of mosquitoes and other insects.

The mosquito theory of malaria is not of recent origin by any means. It was held by ancient Roman writers whose clinical knowledge of malaria was very accurate and minute; Linné, Sir Henry Holland and others regarded the transmission of malaria by mosquitoes as quite probable; such was also and is to-day the popular belief of peasants in certain parts of Italy and Tyrol, and of barbarous tribes in malarial districts of Africa and elsewhere; and we find the same theory advanced in a scientific manner by such medical men as A. F. A. King and Nott of America, Laveran in France, Manson and England, Koch in Germany, Bignami, Grassi and others in Italy.

In his very complete and interesting review of the whole mosquito theory Nuttall¹ carefully considers the various

general facts and arguments which King, Laveran and others have brought forward in its favor. King looked on such arguments, as he could present, not so much as proof of the correctness of the theory, but rather as incentives to experiments and observations which might lead to convincing discoveries. From the voluminous observations tending in a general way to support the mosquito theory the following features may be selected for mention: The seasonal and soil relations of malaria which prevail especially in moist and warm seasons and in marshy regions—such as the deltas and courses of great rivers and also certain littorals—conditions which certainly greatly favor the development of mosquitoes and other insects; in malarial regions protection against the bite of mosquitoes also protects from malaria, as shown by the results of diverse measures employed by the inhabitants and of travelers through such regions; the decidedly favorable or anti-malarial influence of certain occupations, of cultivation of the soil and also of altitude, presumably the result of the prevention of the sting or of the total absence of the insects. Indeed, it is generally accepted by those who have especially studied the question that mosquitoes always occur where malaria prevails. Grassi, Ross and Koch expressly state that they have not seen malaria in regions free from mosquitoes. It goes without saying that mosquitoes often occur where there is no malaria—not all mosquitoes are necessarily carriers of infection.

The mosquito theory of malaria received powerful support by the demonstration, by Theobald Smith, that the hematozoon of Texas cattle fever is transmitted by the bite of the cattle tick (*Boophilus bovis*); Laveran, Koch and others emphasize that the mosquito probably plays an exactly analogous part in malaria. Based on his demonstration that the *filaria Bancrofti* passes part of its existence in the body of the mosquito, Patrick Manson in 1894 expounded the theory that the organisms of malaria also divide their existence between man and mosquito; arguing from the remarkable fact that the flagellate bodies in certain forms of malaria are not developed until the blood containing them has been outside of the body for some time. Manson drew the further conclusion in favor of his theory that the purpose of the flagellate bodies is the continuation of the life of the malarial parasite outside of the human body. Now the hematozoa can not leave the blood-vessels spontaneously, hence the necessity for the presence and the operations of a suctorial insect. Manson, and also Laveran, believed that the human infection took place by way of drinking water infected by mosquitoes which had sucked up malarial blood and died after laying their eggs in the water, or by the inhalation of dust produced by the drying up of small pools and puddles which once contained infected water; furthermore, that human patients may introduce malaria by infecting the mosquitoes.

Manson's deductions were destined to exercise a decisive influence on this investigation because they pointed out the exact way in which some of the problems should

¹ Cbl. f. Bakt., Abth., I, 1899, xxv, 161 et seq.

be attacked in the actual and crucial experiments which were undertaken with signal success by Ronald Ross, an English army surgeon in India. Shorn of all details the results of Ross' great work during the past three and a half years—1895-1899—may be summarized in the following statements: The "cultivation" of the parasites of human malaria in the bodies of two species of mosquitoes inoculated by being allowed to suck the blood of malarial patients; in the infected mosquito the parasites occurred as peculiar, pigmented cells in the walls of the stomach. Feeding mosquitoes on the blood of birds containing hematozoa (*Halteridium* and especially *Protoosoma*), he traced the formation in the walls of the stomach of large cells which fall asunder into spindle-shaped bodies—"germinal rods"—which are carried by the blood to the salivary glands, where they collect in huge numbers and whence they are discharged into the blood of healthy birds bitten by the infected mosquitoes. It requires seven days or so after the infection of a mosquito before the germinal rods or sporozoites reach the salivary glands, and birds bitten by such mosquitoes fall sick five or six days afterward.

The development of the parasites in the body of the mosquito, as described by Ross, has been confirmed by such scientists as Manson, Laveran, Metchnikoff and Nuttall, who have all examined his specimens.

No sooner were Ross' observations made public than they were confirmed by the independent studies of those indefatigable students of malaria, the Italians, especially Grassi, Bastianelli and Bignami, whose researches in this direction have carried our knowledge of human malaria still further than Ross. They have succeeded in not only infecting persons with malaria through the bite of infected mosquitoes, but they have traced the whole development in the body of the insect of the crescent of the estivo-autumnal type and partly that of the tertian parasite. We are also told that they have found young parasites in the eggs of infected mosquitoes². Malarial parasites have also been found in a large percentage (75) of mosquitoes captured in rooms and localities inhabited by malarial patients.

It will be recalled that Manson and others thought that the infection of persons with malaria occurred through drinking of water or the inhalation of dust containing parasites derived from dead, infected mosquitoes. King and others believed that the bite of the mosquito gave rise to the infection. Koch doubted the direct transmission of malaria from person to person by way of the mosquito; it did not seem likely to produce such a direct infection; if such should be assumed to be the case the disease would have to spread much more rapidly than it actually does—an argument which could now be met, if that were necessary, in the light of recent demonstrations, by the fact that there are many kinds of mosquitoes and that all do not carry malaria.

During their investigation Ross, and more especially the Italians, have learned that not all kinds or

species of mosquitoes act as hosts of the parasites. There are many species, and among them the common or domestic mosquito (Ross), which do not seem to bear any relation to any known hematozoon infection. The particular kinds of mosquito which can furnish the suitable conditions for the growth in their bodies of the organisms of human malaria belong largely to the genus *Anopheles*, of which there are many varieties. Whether other kinds of suctorial insects than mosquitoes can act as the carrier of human malaria has not yet been determined.

Different suggestions have also been made with respect to the modes in which mosquitoes might become infected. Bignami thought that possibly the insects picked up the parasites from the ground, but Dionisi, from his investigations, could find no facts in favor of this view. Mosquitoes eat each other's excrements and possibly become infected in this manner. Or the larvæ might become infected through eating the cadavers of the mothers. Evidence is accumulating, however, which tends to show that mosquitoes once infected by drawing blood, may perpetuate their infectiousness through succeeding generations by transmission of the parasites in a sort of sporing form to the eggs of the female. Grassi has observed spores in mosquito eggs (*Anopheles*) and it has been found that in Italy fertilized females may live through the winter, perhaps in this way preventing the dying out of the parasites.

In connection with this phase of the matter it is inter-résumé of the role of the ectoparasitic tick in Texas fever. In a recent paper, Theobald Smith³ gives a clear résumé of the role of the ectoparasitic tick in Texas fever, the devastating disease which recent studies have shown occurs in Finland, Roumania, Italy, Australia, South Africa and German East Africa. The permanently infected territory in our own country includes most of the Southern States. That ticks carry this disease was suspected long ago; as early as 1868 it was mentioned only to be condemned by John Gamgee. Smith and Kilbourne have shown conclusively by their experiments that the tick carries the disease. The tick is exclusively parasitic in its habits and does not pass from one host to another. The fertilized female after a certain time drops dead to the ground and deposits one to two thousand eggs. After a varying time the embryos emerge, attach themselves to the host and begin a new life cycle. Now by placing animals in a pasture infected with the embryos of ticks from Texas fever cattle the development of the fever is observed to follow. Artificially-hatched eggs of ticks from sick animals also produce the disease when the embryos are placed on healthy cattle. While the life history of the parasite in the tick has not yet been traced—the Texas parasite has not yet been found in the eggs of the tick—yet it is warranted to assume that the eggs carry the infection and that the young tick discharges the para-

² Nuttall, loc. cit.; see also "Koch and His Methods," correspondence in the Phil. Med. Jour., July 15, 1899, p. 103.

³ The Etiology of Texas Fever, with Special Reference to Recent Hypotheses Concerning the Transmission of Malaria, N. Y. Med. Jour., July 5, 1899.

sites into the host during the process of drawing blood. Smith assumes that partially immune cattle, in the blood of which the hematoozon may exist for years, under suitable states become the source of new centers of infection through the agency of the tick. Reasoning by analogy, Smith suggests that malaria may spread in a similar manner. Brought into a perhaps hitherto non-malarious district in the body of human beings suffering perchance from a chronic or mild infection, mosquitoes transmit the parasites to younger broods which again spread the infection among men. In temperate climates it is not unlikely that the parasite is protected over winter in the bodies of human individuals. Certainly the scattering of an infected brood of mosquitoes explains well what seems to happen in the newly malarious territory. Whether certain animals can harbor the malarial parasites of man is still undecided. Dionisi has found a hematoozon of the bat which resembles human varieties very much.

Reconstructing, in the light of the new facts, the developmental history of the malarial parasites, we find, as pointed out by the Italians, that human as well as animal parasites, or hematoozoa, possess intermediate hosts and alternating sexual and non-sexual generations. The intermediate host is a warm-blooded animal, including man. The definitive host is an acarus (mite) or a diptera (mosquito, etc.). In the warm-blooded animals the parasites multiply rapidly by segmentation; temporarily unproductive, sexual forms (crescents, flagellate bodies) are also formed, which copulate—probably as described in the case of certain hematoozoa of birds, by MacCallum⁴—when they reach the stomach of the definite host; a sporoblastic form results, from which sporozoites arise, accumulate in the salivary glands of the hosts, when they are deposited in warm-blooded animals during the bite of the insects—a complicated yet simple cycle analogous to that of many other organisms requiring two hosts for their development: *Tenia solium*, *Trichina spiralis*, *Filaria Bancrofti*, *Filaria reconditia*, the organisms of Texas fever and Tsetse fly disease. In the case of malarial organisms the insects are spoken of as definitive hosts because they harbor the higher stages of the development of the parasites.

The old mosquito theories of malaria are therefore to be considered as definitely verified by the results of recent experiment research. As a direct outcome of these new facts is to be noted the possibility of exterminating malaria from infected areas by preventing the development of dangerous mosquitoes, as advocated by Ross.⁵ He points out that the harmful insects in a given locality may be detected by ascertaining, according to Manson's induction method, whether the parasites of malaria will live in them or not; that the breeding grounds—small bodies of water—can be found by searching for their larvæ, which have distinguishing characteristics; if these spots

are sufficiently isolated and care is possible that the mosquitoes could be exterminated by filling up or draining the pools and plashe, or by the use of certain chemicals such as kerosene, which has been found quite efficacious in preliminary experiments. In the northern parts of the United States it is likely, as emphasized by Smith, that the prevention of stagnation of surface water would tend to hinder the springing up of the small foci of malaria noticed every now and then. It seems that war is about to be declared against the vexatious mosquitos.

BRITISH MEDICAL ASSOCIATION.

The JOURNAL has been favored, through the courtesy of the Editor of the *British Medical Journal*, with advance sheets of the general addresses and those before the sections of the British Medical Association. Some of these we hope to publish in full, or more fully abstract at an early date.

The address in medicine, by Sir Richard Douglas Powell, reviews a number of questions of practical interest, newer methods and instruments of precision in diagnosis, the superposition of infections, anomalous fevers and their diagnosis, the questions of immunity and susceptibility and serum therapeutics. As regards the prevention of tuberculosis, he especially cautions against alarming and exaggerated statements as to its contagiousness, "the evidence in regard to which except under the almost experimental conditions alluded to, is extremely slender." At the close of his address he adds a table indicating the actions of various sera.

Dr. Ogston's address in surgery is chiefly devoted to the disabilities of the medical men in the British naval and military services, and to the pointing out the needs of reform in these matters. He shows that the existing evils tend to perpetuate themselves, points out the remedies and gives as illustrations some account of the naval and military medical systems of Germany, France, and Russia. The scheme of reform and the danger of trusting to the broken reed of civil aid in time of emergency are clearly demonstrated.

Dr. Bulfin's address before the surgical section, reviewing its program, calls attention to the fact, not heretofore much appreciated in this country, of the increasing use of firearms, and of gunshot wounds in civil life, and to the question of the prevention of military venereal disease, a subject that has long been one of the greatest importance, especially in relation to the British Indian army.

The address of Dr. Charles, before the section of anatomy and physiologic, is a résumé of a large part of the physiologic advance of the past few years. As a somewhat critical summary of facts it is a valuable contribution, and concludes with congratulations on the present activity in physiologic research in Great Britain.

A practical subject well handled is that in Dr. Snell's address before the ophthalmologic sections, on "The Prevention of Eye Accidents Occurring in Trades," which he concludes are largely preventable. He would

⁴ Jour. of Exp. Med. 1899.

⁵ The Possibility of Extirpating Malaria from Certain Localities by a New Method. *British Med. Jour.*, July 1, 1899.

make the use of eye protectors compulsory for workers in iron and steel, whose employment renders them liable to be injured by iron or steel splinters, or who are exposed to danger from molten metal.

Of the two subjects of Dr. George Thin's address in the section on tropical medicine, the first has the greater interest, being, as it is, a very full and complete statement of the history and present status of the question of the insect origin of malarial infection in man. In his second theme, the respective advantages of the schools of tropical medicine, he shows the special points in which the Netley School is favored in this respect. With this showing his plea for the opening of this school to civil physicians can only be heartily endorsed by the profession, not only of Great Britain, but in their behalf by that of the whole civilized world. England, with her numerous tropical dependencies, has better opportunities to add to the world's knowledge than any other land, and it is to be hoped that these will not long be unduly restricted.

In the above only a part of the important addresses have been noticed. As already stated, it is hoped to reproduce some of them more fully hereafter. The session of the British Medical Association, always a matter of world-wide interest, can hardly this year have failed to keep up its traditional high standard of scientific papers and discussions.

CONSCIENTIOUS OBJECTIONS.

It is stated that the English law exempting those who have "conscientious objections," from compulsory vaccination, is not nearly so disastrous in its actual working, as was anticipated by its friends and its foes. The agitation of the subject has had an educational effect on the public, and especially that part that needed it most has shown a greatly increased demand for vaccination, and this without any special effort or pressure by local officials. It would seem, according to the testimony of Mr. Chaplin, head of the local government board, at the recent annual dinner of the London Press Club, that the opponents to vaccination had over-shot their mark, and that their success had been in some measure at least a boomerang to their cause. The wholesale misrepresentations in which they have indulged have had their effect in disgusting the public, to whom the facts have also been misrepresented.

HEAD OF "ST. LUKE'S HOSPITAL" GONE WRONG.

Those gentlemen who have so freely accepted positions on the consulting staff of "St. Luke's Hospital," Niles, Mich., and have adorned their office walls with its diplomas, will naturally be rejoiced to learn that its whilom head, "Dr. Granville," alias Burrows, has achieved still further distinction. We learn from the newspapers that he has made himself greatly desired in several states on account of his supervirile characteristics, and that he is now, as a much married man, enjoying public hospitality in one of the county seats of Minnesota with a prospect of sharing the hospitality of the state itself in company with other distinguished individuals whose photographs and biographies are

well known, at least to many public officials. Those who accepted the appointment from his institution and expressed their satisfaction in their letters of acceptance at the distinguished company they were in, will now have still another cause for self-congratulation. We only regret that "Dr. Granville" could not have achieved like celebrity directly from his connection with the institution over which he so fitly presided, and that his active colleagues there could not share it with him. Possibly some of them are also broad and versatile geniuses, and we may yet hear from them.

TUBERCULOSIS AND CATTLE.

In Illinois and several sections of the country a vigorous crusade is being inaugurated against tuberculous cattle as a source of possible infection. Herds are being examined and decimated and the prospects seem good for the extinction of bovine tuberculosis in the near future. One question suggests itself at once, however, that is apparently not noticed by the press reporters of these transactions; that is, what is done about the infected quarters, the sheds, milking yards, stables, etc., that have been occupied by the diseased cattle? These certainly are liable to have become infected, and it is poor policy to expose healthy animals to the danger of becoming diseased by leaving them undisinfected. Something might, perhaps, also be said as regards infection of dairies, and also of pastures, but this latter may be carrying the matter too far, as fresh air and sunlight will probably serve as efficient disinfectants there. This is a matter that has probably not been neglected by the veterinary adjuncts of the health boards, but we have seen no notice of it in the reports.

OSTEOPATHS WANT TO GIVE MEDICINE.

The osteopaths in Iowa are now proposing to demand legislation that shall recognize them as a separate school of medicine, give them their own board of examiners, prescribe penalties for the improper practice of osteopathy without due qualification, and permit them to prescribe drugs in the same manner "as shall be accepted and used by other physicians." In other words, as the *Iowa Medical Journal* puts it, they are trying to organize the same kind of "trust" for which they have been so roundly denouncing the medical profession. The most important feature of their demands is that after having made claims that their treatment precluded the necessity of giving medicine, they are now demanding the right to use it as do physicians. This lets out the whole secret; they are simply trying to legitimize diploma-mills, trying to open a short cut into the medical profession; as our Iowa contemporary very correctly says, one that requires no qualifications which ignorance can not overcome. This is a matter worthy the attention of our profession elsewhere than in Iowa; should they succeed there—which they are not likely to do, as the profession in that state seem to be awakening—or even think they can, they will try it elsewhere. This move simply emphasizes the need of medical organization in every part of the country to meet the various forms of quackery which are continually striving to defeat or abolish all laws made for the protection of the people against ignorance.

SANITATION IN PORTO RICO.

There has been constituted under the military government of Porto Rico a Superior Board of Health, consisting of a medical representative, each, of the army, navy and marine-hospital services and three civilian physicians. Their duties are defined in detail in General Order No. 102 of the Department Commander, and include not only supervision of health matters and vital statistics to an extent exceeding the functions of the average health board in this country, but also the supervision of public institutions, asylums, jails, court-rooms, theaters, etc., and the licensing and registration of physicians, pharmacists, undertakers and midwives. Its powers are broad, but apparently well defined, and with an intelligent but scientific board, such as is practically insured in this instance by its composition, health and collateral matters will be well looked after in Porto Rico. The advantages of the island as a winter resort are said to be very great, and there is nothing that will more enhance them than the general knowledge that sanitary supervision is thorough and complete. Whatever may be the permanent form of government adopted, it is hoped, for its best interests, that the efficient health measures of the provisional military control will be perpetuated.

YELLOW FEVER.

The latest reports regarding yellow fever at the Soldiers' Home, near Hampton, Va., are to the effect that the disease is completely under control, that no new cases are developing, and that the disease is practically stamped out. This satisfactory outcome might have been expected when it was appreciated that those in control knew the character of the disease, and went about the work of stopping its spread with energy. Every precaution was taken in the surrounding villages, not only in the way of quarantines but in preparing to isolate any cases that might develop; so that had it gotten beyond the confines in which it first started, the disease would still have had little chance of developing. During this outbreak, 42 cases have appeared, and 11 patients have died. Only one case has been found since the 31st ultimo, that one occurring or so diagnosed, on August 7. This patient had been sick and under treatment for some days, and the case is not considered as a new outbreak, but rather a delayed manifestation of the original infection. The soldiers in the Home have been removed to tents and the entire home fumigated and disinfected. A most radical quarantine is being enforced. The general health of the other inmates is excellent. House-to-house inspection of Hampton, Phoebus, Old Point Comfort and the small places on the road to Richmond is progressing and is about completed, but no new cases or suspects have been found. The Richmond authorities do not consider house-to-house inspection of that city necessary. Fear and anxiety are gradually subsiding, but there is no relaxation of quarantine rules.

YELLOW FEVER AS A CONTROLLABLE DISEASE.

The experience of the United States authorities in Cuba this year makes it appear that under strict control and sanitation, yellow fever is a manageable dis-

order. Under ordinary conditions and in previous years this disease was practically endemic in Cuban cities, Santiago in particular, which were regular foci of infection and constant sources of danger to our southern seaboard cities that were in direct communication with them. The conditions were held to be particularly favorable for the development of the disease which, while comparatively manageable on our own coasts, was beyond medical control there. The facts have proved that this is one of the fictions to be consigned to the limbo of exploded beliefs. While there have been outbreaks of yellow fever in several places among the unacclimated soldiers, in every case it has been promptly checked; the late epidemic at Santiago is a conspicuous example. Taking advantage apparently of the temporary absence of the medicomilitary governor, the germs came out, only to quickly disappear again on his return. In the second week in July, according to the press reports, the deaths from all causes were only sixteen, the lowest mortality known, and at the present time the little epidemic among the soldiers, appears to be under control. It may perhaps be too early for us to begin to congratulate ourselves that we have conquered the disease, but we have certainly scotched it and the facts show the high probability that in the future, if present conditions continue, still greater success will attend intelligent sanitation in those parts.

"CHRISTIAN SCIENCE" FOLLY.

The late peace congress at the Hague that has just ended its labors, has missed an important opportunity. According to "Christian Science"—a modern faith shared by judges, legislators, writers and others in highly civilized communities—while all disease and injury is simply a matter of belief on the part of the sufferer, its cause and hindrance to its cure may be due to the hatred and malice of others. Thus, as the *Buffalo Medical Journal* illustrates it, "No amount of water in the trenches, according to Christian Science could ever have given rheumatism or fever to an American soldier at Santiago. But a malicious thought on the part of his enemy would be liable to throw him into the hospital for months." We now see the real secret of the horrors of the war. Not explosive bullets, asphyxiating gases, or missiles from balloons should be alone excluded from civilized warfare, but malicious thoughts, which are far more deadly in what we non-illuminated think is a purely physical way. According to the latest revelations from "Christian Science," hatred is a direct cause of rheumatism, and therefore a sufficient concentration of this emotion might totally disable a hostile army. The Chinese method of training troops to make faces at the enemy is directly along this line of modern progress, and ought to meet the approval of every true "Christian Scientist."

ANTITOXIN IN THE TREATMENT OF DISEASE.

Whether or not, as a rule it is advisable or beneficent to try to enlighten the public on medical subjects, for the reason that it always seems to be able to misconstrue, there certainly can be no objection on this account to the publication of such a paper as that on "Antitoxin in the Prevention and the Treatment of Disease," contributed by Dr. J. J. Kinyoun of Washington, to the

current number of the *Forum*. While written for lay readers, the paper is strictly scientific and is a fair and plain statement of the subject. The author briefly explains immunity, and the methods of producing it, and outlines historically the gradual development of the method of treating certain diseases "by curative substances derived from bacteria," which had its inception in the discoveries of Pasteur. His statement of the question of the curability of diphtheria by antitoxin is most convincing, and his arguments, backed by irrefutable proofs in the way of statistics from all parts of the world, are certainly sufficient to satisfy any but the most prejudiced. Discussing the reported ill effects resulting from the use of antitoxin, he admits that more cases of paralysis are reported, but this is because more cases are cured. "Paralyses do not set in until a comparatively late stage of the disease; and the figures tend to prove that, if the fatal cases of former years had not died so soon after the attack, the percentage of paralysis would have been even larger than it now is under the antitoxin treatment." The author also discusses, but less fully, the treatment of tetanus by this method; the antivenin introduced by Calmette; Haffkine's investigations of the cholera spirillum; the inoculation against typhoid by Wright of the British Indian Medical Service, and, in fact, gives a general résumé of the whole subject. The paper is one that can be read with profit by those physicians who are yet pessimistic in their views in regard to the use of the serum in the treatment of disease.

THE EIGHTH COMMANDMENT.

One would not like to make the mistake of a prominent literary man who attributed the evils of a certain class of modern fiction to its "dallying with the sixth commandment," but we trust our Scriptural knowledge is sufficiently correct in the heading of this note. The special evil in a considerable portion of periodical medical literature is its dallying with the eighth commandment. The *Medical and Surgical Review of Reviews* (London), in its June issue brings out this fact very forcibly in referring to a single instance in which forty-one pages of matter out of a total of sixty-one were taken bodily from its columns without credit. This is an extreme case, but less wholesale offences of the kind are still too common and one need not look long before finding them. When so little is asked—only the due credit to the source—the theft seems the less respectable; it suggests a mental penuriousness and acquisitiveness that no one ought to possess. If the extract is of an original article, it loses much of its value if the first source is not given; of an editorial article or abstract of literature, it is practically plagiarism of the meanest kind. It is, moreover, taking and using what others have paid for, since editorial work, such as comments and abstracts of literature, is not obtained for nothing, but is a source of expense to the leading medical journals of the day. While it may be done inadvertently at times, at others there is evidence of deliberate carelessness in this regard, to call it nothing worse. The practice, while still too common, is, we are pleased to think, on the decrease, but such complaints as that of our contemporary remind us now and then that there is still room and need for reform.

DIAGNOSIS OF CARCINOMA OF DIGESTIVE ORGANS.

In the absence of a tumor the diagnosis of intra-abdominal malignant disease is at all times difficult, and even when a new growth can be detected by palpation and percussion the determination of its actual seat may be attended with much difficulty, or there may be doubt whether a single growth or more than one is present. Having observed in a series of cases of carcinoma of the digestive organs—stomach, intestines, liver, pancreas—repeated disparity between the clinical diagnosis and the post-mortem disclosures, Zennetz¹ points out some of the sources of error and the means of avoiding them. The absence of free hydrochloric acid from the gastric contents, and the presence of lactic acid cannot be accepted as infallible indications of the presence of carcinoma of the stomach. The secretion of hydrochloric acid by the stomach is intimately related with the blood-supply and the innervation of that organ, and especially its mucous membrane, and these in turn are related with the nutritive conditions of the body generally. Derangement in the blood-supply and in innervation gives rise to impaired function of the stomach and this in turn aggravates the primary condition. A like deficiency has been observed also with disease of other of the digestive organs. The presence of lactic acid in the gastric contents is a direct result of the absence of hydrochloric acid, and has no greater significance than this absence. Severe disease of any of the digestive organs exerts a marked influence on the functional activity of the pylorus, which becomes insufficient in consequence of impaired nutrition of its muscular fibers. Gastric catarrh and gastric dilatation are common accompaniments of carcinoma of the digestive organs, so that in consequence of paresis of the pyloric muscular tissue the contents of the duodenum are forced into the stomach with coughing, vomiting, sneezing, muscular efforts, etc. For this reason the patient often complains of a bitter taste, and the reactions of the gastric contents are altered from the presence of bile. The coffee-ground material often vomited is believed not always to consist of disintegrated blood, but sometimes of bile. Even in the presence of blood, the source of hemorrhage need not be a malignant new-growth of the stomach, as, for instance, when cirrhosis of the liver is associated with carcinoma of some other digestive organ. The presence of sarcinae may be accepted as excluding gastric carcinoma, whereas the presence of large non-motile bacilli visible in the gastric contents even without staining, is strongly indicative of that condition. The presence of sugar in the urine may in some cases be an important diagnostic symptom of carcinoma of the pancreas. The typical cachexia is sometimes wanting. Involvement of the biliary passages may give rise to jaundice, although this may occur with malignant disease of some digestive organ other than the liver. Carcinoma of the gall-bladder may, for obvious reasons, be entirely unattended with jaundice. The symptoms of carcinoma of the duodenum are much like those of similar disease of the stomach. From the foregoing considerations it will appear that while the diagnosis of carcinoma of the digestive apparatus may at times be made with certainty, its localization is often a matter only of probability, and this is the more so when the growths are multiple.

¹ Wiener Med. Woch., May 20, 1896, p. 983.

Medical News.

DR. A. C. BERNAYS of St. Louis has resigned his chair in the Marion Sims Medical College.

It is proposed in Germany to raise the age limit for criminal prosecution from the twelfth to the fourteenth year.

DR. CHARLES WIRGMAN of Philadelphia, who recently returned from a trip to England, has gone to Bermuda for several weeks.

TWO ADDITIONAL fatal cases of tetanus, probably the last of the long list of Fourth of July victims, are reported from New York City.

THE SITE for the new building of the medical department of Hamline University, Minneapolis, Minn., has been chosen directly opposite the new city hospital building.

THE RECONSTRUCTION of six of the Paris hospitals, including the Charité and the Laennec, is urgently demanded by the Prefect, and ways and means are now under consideration.

THE BRONZE statue in memory of Dr. William Pepper, Philadelphia, has been placed on its pedestal in front of the new Archeological Museum of the University of Pennsylvania, where it will remain until unveiled early in the autumn.

THE PHYSICIANS of Naples have been soliciting subscriptions for the purpose of founding a hospital for tuberculous patients. The Duchess of Ravaschiero has presented her large and handsome estate at Pozzuoli for the purpose, and the outlook is very flattering.

DR. WM. P. JENKINS, one of the commissioners of the New York Board of Health, is abroad, it is said for the purpose of inspecting crematories in the various European cities with a view to the establishment of a plant for the destruction of the refuse matter of New York City.

AN ASYLUM for the isolation of lepers has been constructed at Memel, in the extreme northeast of Prussia, and was opened last month. The lay press is extolling the energy and perseverance of the medical fraternity in arousing public opinion and the Government to the urgent necessity of the measure.

It is stated that Mrs. Mary Baker Eddy of Christian Science fame, is being sued in amounts aggregating \$500,000 by Mrs. Josephine Curtis Woodbury of Boston. Seven different suits are pending, all of which are for alleged libelous remarks made by Mrs. Eddy at the First Church of Christ, Boston, Sunday, June 4.

THE PROVINCE of Gothland, in southern Sweden, is in a panic from the spread of anthrax among the cattle, which are dying at the rate of a hundred a day, according to the *Vossische Ztg.* The people in towns are afraid to touch butter, cheese or milk brought in from the country, as several deaths have occurred from infection among persons much in contact with the animals.

It is reported that at the recent quarterly meeting of the Missouri State Board of Health, held in Kansas City, a resolution was passed, to become effective in January, 1901, requiring all medical students desiring certificates for the practice of medicine in that state to study four years at a reputable medical college, instead of three, the present requirement.

THEODORE STRO, president of the Legal and Medical Relief Society, recently mentioned in the *JOURNAL*, has appointed a number of well-known lawyers and physi-

cians to serve as a committee of proposed legislation regarding Christian Science healing in New York. It is expected that the committee will draft a bill to be presented at the next legislature, explicitly defining the legal status of this and other similar "healing."

UNDER the direction of Dr. S. R. Hartman, assistant milk inspector, Philadelphia, eighteen cows out of a herd of twenty-four, found to be tuberculous, were promptly slaughtered. An investigation of another disease affecting cattle near that city disclosed that the animals had suffered from anthrax supposed to have originated from the carcasses of animals buried on the farm several years ago, in which the cause of death had been due to anthrax.

CHANGES at the Baltimore Medical College are announced as follows: Dr. J. M. H. Rowland has been made associate professor of anatomy, Dr. E. L. Whitney associate professor of physiologic chemistry, and Dr. Charles H. Potter associate professor of pathology. Dr. T. R. Williamson has been made assistant in pathology and bacteriology, and Dr. Chas. O'Donovan appointed clinical professor of diseases of children.

ACCORDING to cable despatches, the International Congress of Obstetricians and Gynecologists began its third annual meeting, at Amsterdam, Tuesday, August 8, with a large attendance. The despatches give the following as being present from the United States: Drs. Charles A. L. Reed, Cincinnati, Ohio; L. S. McMurry, Louisville, Ky.; X. O. Werder, Pittsburg, Pa.; J. H. Carstens, Detroit, Mich.; W. E. B. Davis, Birmingham, Ala.; L. H. Dunning, Indianapolis, Ind.; and Clinton Cushing, Washington, D. C.

It is announced that at the Sykesville (Md.) Asylum for the Insane, as a result of the open door plan inaugurated by the late Dr. George H. Rohé, and which has been in successful operation for more than a year, no patient during that period has been mechanically restrained or subjected to cell confinement within the walls of the institution. By the beginning of the year it is expected that the new department for women will be ready to receive its 200 inmates, who are to be exclusively under the charge of female physicians and female attendants.

A MEDICAL club has been organized in Paris, on the same social lines as the Berlin Club, which has been in successful operation for a year or so. The new club was formed among the medical members of the Cercle National, but is now an entirely independent organization, with the quarters of the Cercle National, 5, Avenue de l'Opera, at its disposal. The fees are \$21 a year. Pozzi is president. Doléris and Marcel Baudouin were most actively engaged in its inception. Two hundred members are already inscribed.

THE CORONER'S inquest over the body of Mrs. Flanders, the victim of Divine healing or Dowieism, which was referred to in last week's *JOURNAL* (p. 365), was held in Chicago August 8. The jury brought in a verdict finding Mrs. Bratz guilty of criminal negligence and malpractice, and ordered that she be held to the grand jury for action. "Elder" DeWitt Holmes, a member of Dowie's Zion was also held. Pending the meeting of the grand jury, both were committed to jail, and after some hours were released on bail. The investigation developed the fact that both the above parties did enough to prove that they were practicing medicine, and the Illinois State Board of Health will bring suit against Mrs. Bratz for practicing without a license.

THERE IS a German society in New York formed for the purpose of ensuring a \$200 funeral to its members. One of them recently had a limb amputated and applied to the society for a fourth of his funeral money, as a fourth of him was dead. The officers conceded the justice of his claim and appropriated the money, but with the stipulation that it was to be used exclusively for funeral purposes, and consequently the limb, embalmed and borne in a child's hearse, was buried with all due pomp and circumstance.

SERIOUS intoxication resembling gastro-enteritis, according to *Presse Med.*, July 12, was produced by the mistake of a druggist who used zinc sulphate instead of sodium sulphate in compounding Glauber's salts. When the victim recovered he sued the druggist, who claimed that the wholesale drug house had sent him zinc instead of the sodium sulphate he had ordered. The wholesale clerk stated that the driver had been sent to the chemical factory for sodium sulphate and had brought back zinc. The court condemned the druggist to a month's imprisonment and the clerk and driver each to a \$20 fine.

Therapeutics.

Influence of Certain Substances Upon Diuresis.

MM. E. Barbier and H. Frenkel said at a recent French Congress, that if we may admit with M. Bouchard, that the diseased kidney imperfectly eliminates sodium salicylate and that in pathologic conditions diuresis may be impeded by this substance, the same is not true in the normal state. In a healthy man most clinicians admit that the salicylate has a diuretic effect. Certain authorities deny this statement upon clinical and experimental grounds. M. Siegert recently, for instance, claimed that the salicylate has no diuretic action, and attributes, indeed, opposite influence to this drug, warning the practitioner against its use in dissolving caffeine and advising the substitution for it of sodium benzoate. Surprised at this conclusion, the authors cited had undertaken a series of comparative experiments upon the action of caffeine associated with the salicylate and the benzoate of sodium. The experiments were performed upon dogs, by means of ureteral canulas. They had counted the number of drops flowing from the ureters, minute by minute, during two or three hours. At the same time the general pressure and the renal circulation were registered before and after the injections. Under these conditions the authors observed that caffeine associated with either benzoate or salicylate of sodium increased the urinary flow in a very high degree. There appeared to be no difference in this respect when the caffeine was associated with the salicylate or benzoate.

The general pressure, after a very slight and short fall, increased about 30 to 40 mm. of mercury for a medium dose of 1 centigram of caffeine to the kilogram of the animal's weight. It attained its maximum at the end of two minutes above the initial pressure. In reference to the kidney, they observed a constriction of the vessels, lasting, on an average, only thirty seconds. The salicylate of sodium alone caused a very slight augmentation of the general pressure, and produced a dilatation of the renal vessels. The benzoate of sodium alone raised the general pressure some millimeters and excited no sensible modification of the renal circulation. In fine, there is no reason to consider the salicylate as an agent which diminishes the diuretic power of caffeine. The authors do not venture to say that the salicylate is superior to the benzoate as a diuretic, but believe they can affirm that it is not inferior.—*Med. Bul. Med. and Surg.*

Alcohol As an Antidote for Carbolic Acid.

Occasional reports of carbolic acid poisoning, which appeared in recent issues of the current medical press remind us of the success achieved by Phelps in antidoting carbolic acid by the use of alcohol, says the *Med. Review*. He states that the hands may be washed with impunity in 95 per cent. carbolic acid by the use of alcohol. He has employed injections of pure carbolic acid in suppurating cavities and has then washed them out with alcohol. The procedure has not been accompanied by carbolic-acid intoxication. The method has been found to be very efficient in immediately sterilizing suppurating cavities, and many cases have been followed by a rapid absorption of the walls of the abscess and an obliteration of its cavity. The importance of the discovery in relation to accidents with carbolic acid can not be over-estimated. The frequency of accidental poisoning with this drug has greatly increased of late years, and the occasional accidental spillings of the contents of a bottle of strong carbolic acid over some portion of the body is by no means infrequent. The application of alcohol to these cases is said to furnish a perfect antidote. Carbolic acid, when swallowed, if followed at once by alcohol, is said to be immediately antidoted.

Resinol.

Dr. B. F. Ray says, in the *Western Medical Review*, that the following prescription duplicated perfectly the preparation called "Resinol," manufactured by the Resinol Chemical Company of Baltimore, and sold to physicians at the seemingly exorbitant price of 50 cents an ounce:

- B. Sulphur sub.
Acetanilid
Bismuth oxid
Plumbi acetat, ʒʒ. gr. xxx
Pix. liq. m. xxxvi
White petrolatum. ʒvi
Carmine to color, q. s.

M. Sig. To be applied whenever the product "Resinol" is indicated in the following conditions: as an antiseptic, anti-pruritic, and sedative, in pruritus ani, dry form of eczema in children, piles, superficial burns of small areas, etc.

The liquid tar used in resinol is the acid tar of commerce and can be replaced by the alkaline liquid tar of the B. P., which is non-irritating to delicate skins. The above prescription will do anything that "Resinol" can accomplish, and has the advantage that it can be varied to suit the needs of the case.

Effect of Quinin on Asthmatic Attacks.

Van Sveringen (*Indiana Med. Jour.*) tried many remedies for an attack of bronchial asthma lasting two weeks, but at no time succeeded in getting more than two hours' freedom from distress. Amyl nitrite gave the patient fifteen minutes' ease; chloroform but little longer, after the inhalations stopped. Belladonna seemed to have lost its effect for good entirely. Morphine did better than anything else, and gave her longer relief, but was followed by so much nausea and vomiting that she refused to have it again. Iodids had been given regularly from the first. Then for the purpose of stimulating the inhibitory reflex center, quinin and strychnin were tried. The effect was almost magical. The dose of the quinin was 7 grains, and the extract of nuxvomica was given in ¼-grain doses, and to this was added ¼ grain of the sulphate of codein. They were taken *pro re nata*. In the intervals the iodids were continued, and the patient had less asthma in the last year than in ten years previous.

ASTHMA.

The following prescriptions were recommended by Dr. Pepper for asthma, in the attack:

- B. Morphine sulphatis. gr. 1/6
Strychnine sulphatis. gr. 1/60
Hyoscine hydrobromatis. gr. 1/160
M. Sig. Administer by hypodermic injection each night.

R. Etheral tinct. of lobelia.....	ʒii
Tinct. of asafetida.....	ʒi
Tinct. of opium.....	ʒss
Potassium iodid.....	ʒiii
Syrup of tolu.....	ʒiv

M. Sig. From one to two teaspoonfuls every one or two hours for an adult, according to the severity of the case.

R. Ammonij bromidi.....	ʒvi
Ammonij chloridi.....	ʒss
Tinct. lobelie.....	ʒiii
Spiritus etheris comp.....	ʒi
Syrupi acacie ad.....	ʒiv

M. Sig. Dessertspoonful in water every hour or two during paroxysms.

The following prescriptions have been used with varying success:

R. Extract euphorbie piluliferae.....	m. iii
Nitroglycerin.....	gr. 1/200
Sodii iodidi.....	gr. ii
Potassij bromidi.....	gr. ii
Tinct. lobelie.....	m. ii

M. Ft. pil vel capsul, No. 1. Sig. From one to four three times a day.

FOR INHALATION.

R. Potassij nitratiss.....	ʒss.
Pulv. anisi fruct.....	ʒss.
Pulv. stramonii fol.....	ʒi

M. Sig. Use a thimbleful, place on plate, light with match, then inhale fumes.

SPASMODIC ASTHMA.

In spasmodic asthma the patient should not only take arsenic but should smoke arsenic cigarettes. The ordinary arsenical cigarette is made by saturating paper with a solution containing 15 grains of the arsenite of potassium in an ounce of water. The portion of the paper which comes in contact with the lips should not be impregnated, or, better still, a mouthpiece should be used.

In addition to smoking these cigarettes the patient should use this fuming inhalation at bedtime.

R. Powd. anise fruit.....	ʒi
Powd. fennel fruit.....	ʒss
Powd. sumbul root.....	ʒiii
Powd. stramonium leaves.....	ʒii
Iodid of potassium.....	ʒii
Powd. niter.....	ʒii

The ingredients should be perfectly dry and intimately mixed. A tablespoonful should be ignited and the fumes inhaled.

—William Murrell.

Hay Fever.

For this distressing disease Dr. William Murrell recommends the following for inhalation:

R. Menthol.....	gr. viii
Chloroform.....	m. v
Benzol.....	m. xx
Oil of cassia.....	m. iii
Light carb. of magnesia.....	gr. xxx
Water, ad.....	ʒi

M. Sig. A teaspoonful is poured into a pint of hot water at a temperature of 140 F. and the vapor is slowly inhaled for ten minutes.

The following prescriptions have been recommended for this disease:

R. Mentholiss.....	gr. xx
Olei amygdalæ dulcis.....	ʒiii
Acidi carbolicis.....	m. x
Cocainæ hydrochloratis.....	gr. vi
Ung. zinci oxidii.....	ʒss

M. Sig. Apply thoroughly to the nostrils on cotton attached to a toothpick.

—Frederick G. Smith.

R. Cocain.....	
Menthol āā.....	0/5
Boric acid.....	
Powdered acacia āā.....	5/0
M. Sig. Use as a snuff.	

R. Camphor.....	gr. x
Boric acid.....	ʒi
M. Sig. Use as a snuff.	

R. Olei eucalyptus.....	ʒi
Glycerini.....	ʒi
Tincture opii.....	ʒiii
Aque destil, q. s. ad.....	ʒvi

M. Use with atomizer three times daily.

Or

R. Liq. potassii arsenitis.....	
Extracti nucis vomice fluidi.....	
Ext. cinchonæ fluidi (detannated) āā.....	ʒiii
Alcoholis.....	ʒiii
Syrupi aurantii q. s. ad.....	ʒxvi

M. Sig. One to two teaspoonfuls, taken three times daily, with or after meals.

—Hall.

R. Chloralis.....	
Pulv. camphoræ āā.....	gr. xvi
Acidi carbolicis.....	gr. xx
Morphine.....	gr. xii
Acidi oleici.....	gr. vii
Olei ricini.....	ʒviii

Rub well together to make a lotion. Apply by means of a little ivory or hardwood plug to the interior of the nostril.

—Horace Dobell.

R. Camphor menthol.....	1-3
Lavolin.....	100

M. Sig. Use as a spray to check sneezing and arrest profuse watery discharge.

—S. S. Bishop.

FOR THE HYDRORRHEA ACCOMPANYING HAY-FEVER.

Miller says, "change of residence if possible, before the known date of annual recurrence, is the only positive prophylaxis or cure.

Make sure that the nasal passages are free from irritating obstruction. After a course of Carlsbad salts and spraying the nostrils with Carlsbad water, douche the mucous membrane with a strong solution of nitrate of silver, and, as an after-treatment, apply:

R. Mentholiss.....	
Resoreini āā.....	gr. xlv
Spiritus vini diluti.....	ʒiv

Specific for Menstrual Disturbances.

Professor Hirth of Munich was for two years superintendent of the European custom-house at Chung King, the metropolis of western China, Mongolia and Tibet, where his attention was called to the tang kui root, which has been used for many centuries in China as a remedy for menstrual disturbances. He and others have been testing it, and he is strongly inclined to believe that it is the long-sought specific for amenorrhæa without abortifacient properties. He describes it and its action in the *Munich Med. Woch.*, No. 23.

Rational Administration of Cod-Liver Oil.

An article in *Echo Med.*, July 2, states that cod-liver oil as usually administered is worse than useless. It should never be taken except after meals and, if possible, fully an hour should elapse to allow time for the stomach to secrete undisturbed. Two spoonfuls should be taken twice a day, increasing by two a month to a maximum of eight in January, and then decreasing in the same manner. The spoon used should be a tea, dessert or tablespoon, according to age and the case. The oil has no therapeutic effect, he adds, but is merely for superalimentation.

Diphtheria.

The Italians report (*Semina Med.*, July 19) that severe cases of diphtheria can be effectually treated by the administration of the diphtheria serum by intravenous injections. Gagnoni has recently saved, by this means, three children in a very advanced stage with croup and symptoms of suffocation.

Book Notices.

The Throat and Nose, and Their Diseases. With 550 illustrations in colors, mostly designed and executed by the author, J. LENNOX BROWNE, F.R.C.S.E. Senior Surgeon to the Central London Nose, Throat and Ear Hospital, etc. With special assistance as follows: Anatomy, Mayo Collier, M.S., F.R.C.S.; Nervous Diseases, James Cagney, M.D., and Histopathology, Wyatt Wingrave, M.R.C.S. Fifth Edition. Revised and rewritten. London: Bailliere, Tundell & Cox. 1899.

The fifth edition of this well-known treatise, according to the author's preface, has been so largely rewritten and changed, even from the fourth edition, that it is practically a new work. The anatomy and physiology have been brought up to date, and a new feature, that of normal histology, has been added. The morbid anatomy, gross and microscopic, has correspondingly required revision and illustration, and a new chapter on bacteriology as applied to the nose and throat has been written. These have necessitated complete revision and extension of other subjects, and the general result is an entirely different book in many respects. The illustrations have also been increased to correspond with the other changes.

Dr. Browne's former views as to the antitoxin treatment of diphtheria are well known. His discussion of the subject here is brief, too much so in our opinion, and is in striking contrast with his lengthy though skeptical treatment of the subject in the recently issued supplemental volume of "Keating's Cyclopaedia." The impression left here is that his views are perhaps in a transition state as to the importance of the method.

Besides the cuts in the text, a set of fifteen plates illustrates the more important conditions. The general make-up of the work is very fine, and there is a tolerably full index.

Urinary Analysis and Diagnosis. By Microscopic and Chemical Examinations. By LOUIS HEITZMANN, M.D. With 108 original illustrations. New York: William Wood & Co. 1899.

This volume, while giving the principal chemical methods of urinary examinations, is especially strong in the microscopic tests, the illustrations being particularly good and abundant. The third section on microscopic diagnosis is also a valuable feature and one that will be appreciated. Here also the figures are especially numerous and illustrate the text. It is in these microscopic sections of the work that its value is greatest, and this was the intention of the author, as stated by him in his preface. It will be a useful work for the student and practitioner.

A Text-Book on Practical Obstetrics. By EGBERT H. GRANDIN, M.D., Gynecologist to the Columbus Hospital; Consulting Gynecologist to the French Hospital; late Consulting Obstetrician and Obstetric Surgeon of the New York Maternity Hospital; Fellow of the American Gynecological Society, etc. With the collaboration of GEORGE W. JARMAN, M. D., Gynecologist to the Cancer Hospital; instructor in Gynecology in the Medical Department of the Columbia University; late Obstetric Surgeon of the New York Maternity Hospital; Fellow of the American Gynecological Society, etc. Second Edition. Revised and Enlarged. Illustrated with 64 full-page Photographic Plates and 86 Illustrations in the Text. 6½x9½ inches. Pages xiv+461. Extra Cloth, \$4.00, net; Sheep, \$4.75, net. Philadelphia: The F. A. Davis Co.

The book has for its reason of publication, as the authors state in their preface, the modern requirements of clinical instruction in obstetrics. It would appear from examination that it meets these requirements, giving the essential and practical points, but leaving the vast amount of anatomic and other collateral facts that occupy so much space in most obstetric text-books to be learned elsewhere. Indeed, it is to be assumed that these have been already acquired by the student. It is, therefore, a work that is especially adapted to the student and practitioner who are already qualified in these regards. In some respects the treatment of certain subjects seems brief, but clearness and reasonable fullness are really the essentials. The work will probably meet with deserved success.

International Directory of Laryngologists and Otolologists, containing Names and Addresses of Practitioners engaged in the Study and Practice of Laryngology and Otolology. Compiled by RICHARD LAKE, F.R.C.S. Published under the auspices of the *Journal of Laryng. and Otol.* Pp. 111; 12mo. Cloth. London: The Rehman Publishing Co. (Ltd.). 1899.

This little book is supposed to contain the names of practically all the specialists in these two branches throughout the world. While completeness is not claimed, the list seems to be nearly as complete as it is possible for such a work to be. It contains a list alphabetically arranged by names; and also a list of the important cities, alphabetically arranged, with the names of the specialists residing in each. There is also a list of journals devoted to laryngology and otology. The book will be found of great value to those who are interested in reaching the laryngologists of the world.

Newer Remedies: Including their Synonyms, Sources, Methods of Preparation Tests, Solubilities, Incompatibles, Medicinal Properties, and Doses as far as Known, Together with Sections on Organotherapeutic Agents and Indifferent Compounds of Iron. A Reference Manual for Physicians, Pharmacists and Students. By VIRGIL COBLENTZ, A.M., Ph.D., Ph.D., F.C.S., etc. Third Edition, revised and very much enlarged. Philadelphia: P. Blakiston's Son & Co. 1899.

The above lengthy title of this little work gives a very correct notion of its contents and value. The omissions are very few among the newer remedies, and it will be found a very useful and satisfactory reference manual.

Massage and the Original Swedish Movements; Their Application to the Various Diseases of the Body. By KURNE W. OSTRUM. Fourth Edition, revised and enlarged, with 105 illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

The appearance, within ten years, of the fourth edition of this little work shows clearly enough that it has in it elements that bring it in demand. It is certainly a very convenient, handy book on its special subject, but it can hardly fill the place of larger works that go more deeply and fully into the matters. For a large class, however, it will be found useful, and it has enough in it peculiar to itself to render it a convenient addition to the literature of the subject already in our possession.

International Medical Annual and Practitioner Index. A work of reference for Medical Practitioners. New York and Chicago: E. B. Treat & Co. 1899.

The seventeenth volume of this well-known annual sustains its already earned reputation, and contains a very large amount of well-selected and condensed medical information, well up to the date of its publication. If we are to make any criticism it is for the lack of mention of psychiatric subjects; in other respects it is quite full and complete.

Practical Materia Medica for Nurses. With an Appendix Containing Poisons and Their Antidotes, with Poison Emergencies, Mineral Waters, Weights and Measures: Dose List; and a Glossary of the Terms used in Materia Medica and Therapeutics. By EMILY A. M. STONEY, Graduate of the Training School for Nurses, Lawrence, Mass.; late head nurse Mercy Hospital, Chicago, etc. \$1.00 net. Philadelphia: W. B. Saunders. 1899.

So far as we can see from a rapid examination of this work it contains about everything that a nurse ought to know in regard to drugs. It gives the name, dose, therapeutic and toxic action, and preparations of nearly all the well-known and of many of the newer substances used in medicine, and so far as we have been able to see, correctly. As a reference book for nurses, when they need such, it will without question be very useful.

Laboratory Work in Bacteriology. By FREDERICK G. NOVY, Sc.D., M.D., Junior Professor of Hygiene and Physiological Chemistry, University of Michigan. Second Edition, Revised and Enlarged, with frontispiece and 76 illustrations. Ann Arbor: George Wehe. 1899.

As a students' laboratory guide, which is daily standing the

test of use, this work can be cordially recommended. It does not, as the author states in his preface, give full consideration to certain subjects, like the questions of immunity and the individual pathogenic bacteria, as these subjects are treated by him, in his course, in lectures that are altogether distinct from the laboratory work. It contains, however, in its opening chapters, the necessary general information for laboratory work, and the concluding chapters describe special methods and tests suitable for advanced student work. The value as a student's manual is enhanced by the blank pages opposite the specific descriptions for notes, illustrations, etc.

Surgery of the Head and Neck. By LEVI COOPER LANE, A.M., M.D. (Berol.), M.R.C.S. (Eng.), LL.D. Professor of Surgery in Cooper Medical College, San Francisco. Second Edition. Philadelphia: P. Blakiston's Son & Co. 1899.

The author's modest preface disarms criticism of this work, were we inclined to offer it. As it has reached a second edition in three years, it is fair to assume that its merits have been appreciated. It is certainly a work of much labor, though it does not impress us as being quite up to date in a few points. There is nothing to indicate any special change or revision in this edition.

Cyclopaedia of the Diseases of Children. MEDICAL AND SURGICAL. The articles written especially for the work by American, British, and Canadian authors. Vol. v. Supplement. Edited by WILLIAM A. EDWARDS, M.D. Illustrated. Philadelphia: J. B. Lippincott & Co. 1899.

Since the appearance of the last volume of Keating's Cyclopaedia a number of years have intervened, and this supplemental volume is, therefore, the more welcome to its readers. The articles here published are certainly not less meritorious or valuable than those in the earlier volume, and they bring our knowledge of the subjects fairly up to the year 1898. Some omissions of subjects are noticeable, but the work is as a whole a comprehensive and very valuable addition to literature of children's diseases. The list of the authors, including as it does such names as those of Hare, Osler, Lennox Browne, Jacobi, DaCosta, Starr, Ashhurst, Kelly, and others hardly if any less well and favorably known, would promise this, and careful perusal will confirm all expectations.

Atlas of the External Diseases of the Eye. Including a Brief Treatise on the Pathology and Treatment. By PROF. DR. O. HAAB. Authorized Translation from the German. Price \$3.00. Edited by G. E. DE SCHWEINITZ, A.M., M.D. Illustrated. Octavo. Cloth. Pp. 288. Philadelphia: W. B. Saunders. 1899.

This is another of Saunders' Medical Hand-Atlases, and is as fully deserving of praise as any of its predecessors in the series. The illustrations are beautifully graphic, most of them being true to nature. The descriptive text covers the whole field in a thoroughly practical manner. Dr. G. E. De Schweinitz, the American editor, has added much of value, and has made the work a reliable one.

Deaths and Obituaries.

DANIEL G. BRINTON, M.D., Philadelphia, died while on a visit to Atlantic City, N. J., July 31. Dr. Brinton was born in Westchester, Pa., 62 years ago, and was a graduate of Yale, and subsequently of Jefferson Medical College. During the Civil War he served as medical director until disabled by sunstroke, afterward receiving appointment as superintendent of hospitals in Quincy and Springfield, Ill. For a time he was editor of the *Medical and Surgical Reporter*, and of the *Compendium of Medical Science*. In 1886 Dr. Brinton was awarded a medal for his researches in American ethnology, by the Société Américaine de France. He was professor of ethnology and archeology in the Academy of Natural Sciences of Philadelphia and of American archeology and linguistics in the University of Pennsylvania. He gathered together a library of original American literature printed in the original. Very recently he

gave to the University of Pennsylvania his entire collection of books and manuscripts relating to the aboriginal languages of North and South America, consisting of nearly 2000 titles and 200 bound volumes. The collection will be named after him.

FRANCIS C. GREENE, M.D., Yale, 1851, long a practicing physician in East Hampton, Mass., died there August 2, aged 72 years. During the Civil War he served as a surgeon under General McClellan in the Peninsular campaign. A widow survives him.

D. O. DAVIS, M.D., for twenty-five years a resident of Baltimore, died in that city August 3, aged 53 years. He was a native of Wales and came to America in 1866, and first engaged in the drug business in Washington, D. C. He moved to Baltimore in 1875 and received the degree of M.D. from the College of Physicians and Surgeons, Baltimore, in 1880.

CHAS. W. ADAMS, M.D., Kansas City, Mo., died suddenly August 3. Dr. Adams was one of the founders of the University Medical College of that city, and its dean from 1880 to 1895. He was a member of the AMERICAN MEDICAL ASSOCIATION, the Missouri State Medical Association, Jackson County Medical Society and the Association of Military Surgeons of the United States. He was born in Rochester, N. Y., in 1854.

ROSS DUNN, M.D., Nashville, Tenn., aged 33 years, a graduate of the medical department of the University of Tennessee, in which institution he was afterward demonstrator of anatomy, died July 29.

JOHN H. GILBERT, M.D., Quincy, Mass., a graduate of Dartmouth and Tremont Medical College, aged 63 years, died at his home August 3.

Robert Hunter, M.D., Netherwood, N. J., died while on his vacation in Canada, July 29, aged 75 years. . . . D. A. Linthicum, M.D., Helena, Ark., August 1, aged 80 years. . . . W. W. Parker, M.D., Richmond, Va., August 3, aged 75 years. . . . G. W. Ryan, M.D., Niantic, Ill., July 30, aged 51 years. . . . Rudolph H. Schmidt, Seymour, Wis., July 29, aged 53 years.

Association News.

Practice of Ophthalmology.—The resolution in regard to the practice of ophthalmology, as originally introduced and printed in the JOURNAL (see vol. xxxii, pages 1337, 1373), was revised as follows by the special committee, composed of Drs. Thomas H. Fenton and Louis J. Lautenbach, Philadelphia; and Dudley S. Reynolds, Louisville, endorsed by the ophthalmologic section and adopted by the ASSOCIATION at the third general session.

Resolved. That the application of lenses in such cases is treatment of errors of refraction in the eyes requires a knowledge of pathology and therapeutics.

Resolved. That the application of lenses in such cases is a part of the practice of medicine to be undertaken by no one not qualified to practice medicine and surgery.

New Instrument.

New Form of Portable Battery.

W. N. SHERMAN, Ph.D., M.D.
MERCED, CAL.

The faradic current, being the one most frequently used in general practice, has stimulated the manufacturer of batteries to offer them in as small and compact form as possible, consistent with efficiency. In presenting this new form of portable battery the desire has been to combine efficiency, compactness and novelty.

A faradic battery in the form of a cane would at first thought appear an impossible combination, but when we consider the principle and the construction of faradic batteries in general, it will be seen that the principle of scientific construction has not been altered, but simply a change made in

mechanical construction. We may carry this around with us, concealed in such a way that it can not attract attention, and in a form that is rather a personal ornament than an unsightly burden. Its form does not prevent the scientific electric construction as in other forms, nor affect its efficiency, when compared to other small faradic batteries, while for portability, novelty and convenience it far surpasses any form yet constructed or offered to the profession or the public.

The cuts here presented will give the reader a very good idea of the form of construction, both mechanical and electric. The first illustration, Fig. A, shows the cane one-half its actual size, with the form and outline complete, except its length. The head is not made in the chased design illustrated, but in plain roman gold or polished gold finish, more attractive and durable than the chased heads. The edges of the two end caps

Fig A

Fig 1

are milled to facilitate their easy removal, and are attached by a half turn, and lock tightly in place. The head is four inches long and one in diameter. It has a lock joint between the head and stick that is a convenient and quick method of removing the coil for adjustment of the vibrator, should it become necessary.

Fig. 1 shows a longitudinal section of the battery and electric parts, and nicely illustrates its internal arrangement. The cylindrical gold head is in the form of a polo handle or cane head, and affords a container for *b b*, the nickel-plated hand electrodes, sponges *c c*, and cords *d*. At the opposite end is the hard rubber disc switch-board *B*, adjusted to a slotted ring, so that it is easily removed by pushing it inward. It has three

sockets—*e, e, e*—for the fastening of the cord tips, and a small lever switch at *f*. The connections between this switch-board and the hard rubber head of the induction coil are made by cable wire, well insulated and so arranged as to give the three currents usually given by hand batteries.

A sliding rheotome *E* is provided, which pulls out at the top of the handle and nicely graduates the current. The coil sets down into the wooden well and rests on its top edge by a shoulder, as seen at the joint *l*. The primary coil *g*, the secondary coil *h*, and the core *c*, of soft iron wire, are combined and adjusted to give the greatest strength of current with the least waste of energy from the cells. The vibrator arm and the ad-

justing screw *k* are of delicate construction and perfect mechanism. The connection of the cells is made by contact of the positive or carbon pole at *l*, and the negative or zinc pole at *n*. A thin copper ribbon leads from the zinc of the lower cell to a contact connection made at *n*. The coil and cells are easily removed and new cells can be replaced in a moment.

Fig. 2 shows coil and cells, removed from cane. The length of coil and cells is about 9½ inches. One of these cells alone has run the coil continuously for seven hours, and after a rest of twelve hours showed a current of .026 amperes. The normal capacity of the cells is 1.5 volts, .5 amperes, internal resistance 20 ohms, which is a marvelous showing for so small a cell (see cut, full size). These cells are renewed at a cost of 30 cents each, and should operate the coil for at least fifty sances of ten minutes each.

The cane is a highly-polished, well-finished stick, one inch in diameter at the top, gradually tapering to five-eighths of an inch at the bottom. The wood is furnished in ebony or imitation ebony, which is a hard, heavy wood, weighing five ounces more than the lighter wood. From the outside they can not be distinguished, and the writer prefers the lighter stick.

At the point is provided a screw cap ferrule (*X*), under which is carried a hypodermic syringe (Robinson-Dettmers), which is all-metal and aseptic, with but three parts, barrel, piston and needle (Fig. 3). The piston is hollow, to admit the carrying of tablets (*H*). The complete cane weighs eighteen ounces.

Miscellany.

United Twins.—*O Brazil Medico* of July 1, reproduces photographs of a pair of twins, bright, fairly well-developed girls of 6 years, who are connected together from the umbilicus to the level of the axilla. The parents have applied to Dr. Ramos to separate them, and he is now studying the case to determine the feasibility of an operation.

Frictions with Hot Salt Before the Douche.—Cooking salt is mixed with hot water to a semifluid mass with which the limbs and trunk are rubbed for a few seconds before applying the douche, as a hydrotherapeutic measure in cases where a defective reaction is anticipated.—*Semaine Med.*, July 5.

Electric Treatment of Gout.—Further experience is confirming the efficacy of Gnilloz' method of treating gout by

autoconduction of a long-continued high-frequency current combined with the electrolytic administration of lithium directly to the affected joints. Acute attacks are aborted, and chronic gout attenuated.—*Progress Med.*, No. 20.

Types and Tuberculosis.—Professor Landouzy formally states that the most marked predisposition to tuberculosis infection occurs in persons with white, delicate, transparent skin, marbled with veins, freckles usually, the hair on the head or body, or both, Auburn or red, iris blue, flesh soft, sweat easily induced, graceful outlines. This type is called Venetian in Europe, but not for any special prevalence of tuberculosis at Venice, which has rather a low death-rate from this disease, but probably on account of Titian's women. All or very nearly all of this type are tuberculous, in Paris at least, he asserts. Next in order come the scrofulolymphatic, persons who have been tracheotomized or have undergone other trauma, etc., and especially persons who have had smallpox. Delpeuch calls attention to a passage in Hippocrates' "Epidemics" describing tuberculosis and the persons affected as all having red hair and blue eyes, in his experience, the description almost identical with Landouzy's conclusions 2329 years later.

A Christian Science Druggist's Fate.—*The N. Y. Medical Journal* quotes the following from the *Pharmaceutical Era* for July 13: "The Christian science fantasy has claimed many dupes and victims. These have generally been those individuals who would be cranks anyhow upon some subject or other, so that it is only occasionally that the crimes of this sect have come to public notice through their effects upon the general public. It is therefore very startling to learn that one of a class of men who, it would seem, would be the very last to be duped by this fanatical faith, has succumbed to it, and lost his reason in consequence. Christian science does not believe in drugs; therefore a druggist who is also a Christian scientist must be regarded as a strange anomaly. It is a most incompatible mixture. Such a druggist can not practice what he preaches in both professions. If he is true to the science he can not sell drugs; if he can not sell drugs he must starve, and this is just the position of an unfortunate druggist in an Illinois town. He has gone crazy over Christian science. He lost his business because he advised his customers to leave drugs alone; and not only this, but his sister and niece have also become demented upon the same subject, and the former has died in an insane asylum."

Legal Status of Physicians in Indiana.—The State Board of Medical Registration of Indiana, through its secretary, Dr. Currier, recently asked Attorney-General Taylor for an opinion in regard to the standing of the faith eruders, Christian scientists, Dowieites, osteopaths, etc. The attorney-general gave the opinion on August 4. He first reviewed the standing of these various sects in the different states, giving the various decisions, and concluded with the following opinion: "In view of these authorities, and especially of the decision of the supreme court of Indiana, in the Benham case, it is my opinion that it is a violation of the law for an unlicensed person assuming the title of a doctor to prescribe or pursue any practices for the cure or relief of diseases, injury, or deformity, especially where any fee is charged for such services. It is perfectly obvious that the non-treatment of disease requiring treatment by an unqualified person may be as injurious as the administering of erroneous treatment or remedies, and it is my opinion that in enacting the statute of 1887 the General Assembly contemplated the protection of the public from the evil of non-treatment or non-action where necessary as fully as it did from wrong treatment. In so far then, as Christian scientists, faith curists, mental healers, and metaphysical mediators advertise themselves as physicians, and accept fees for treating disease, by silent or other forms of prayers, or by moral advice, or by profound thought, or by absolute non-

action, they unquestionably, in my opinion, violate the law. On the other hand, osteopaths and magnetic healers who hold themselves out as physicians, and advertise an ability to cure diseases, or who accept fees for the treatment of diseases, by prescribing for them either medicines or the simple laying on of hands, are, if unlicensed, violating the law. On the other hand, if they abstain from claiming to be doctors and from advising treatment, but simply administer massage under another name, there is nothing in the law which forbids them giving to their treatment what name they please, and there is nothing in the law which requires masseurs to be licensed, and one who administers massage, whether recommended by a physician or voluntarily sought by an afflicted person, is at liberty to charge for his services whatever he deems them to be worth."

Cerebrospinal Fever.—We have learned from the public health reports published by the United States Marine-Hospital Service, that during the past year this disease has existed in twenty-seven states and in the District of Columbia. During this period, too, examination of the mortality returns of our large cities has shown a marked increase in the number of cases styled meningitis. While many of these cases are, as formerly, instances of tubercular meningitis, results of ear disease, complications of typhoid and pneumonia masking the original trouble, yet some of them must be looked on as cases of genuine cerebrospinal fever, in that in many of the laboratories of these cities the specific germ as insisted on by Weichselbaum, the diplococcus intracellularis meningitidis, has been isolated. The work of Weichselbaum has been confirmed in this country by Councilman, and Mallory and Wright, the latter observers giving in their late book on "Pathological Technique," a most masterly account which would readily separate this from any other micro-organism. Suffice it to say here that, as the name of the disease indicates, the organisms occur in pairs, are present within the pus cells and even in the nucleus. They are decolorized by Gram's method.

Lately, before the Cincinnati Academy of Medicine, Greive demonstrated a tetracoccus which was isolated from the fluid of the spinal canal, obtained both before and after death. Examination of the fluid itself showed both tetrads and diplococci, and both were present within the cells. But one growth was obtained on culture-media, and examinations of these cultures showed mainly a tetracoccus, but a few diplococci were present. It is extremely probable that they were merely different forms of the same organisms, possibly the preparation of the slide being sufficient to convert here and there a tetracoccus into two pair of diplococci. Certainly these germs bore the closest relation morphologically to one another, and their behavior on culture-media greatly resembled that of the diplococcus intracellularis meningitidis. It seems improbable, considering the comparative infrequency of this form of meningitis of late years, to within the last few months, that the Cincinnati cases which presented the same complex symptomatology that has existed in patients scattered all over the Union, should be due to a distinct micro-organism, while the other cases show the specific diplococcus that has pretty definitely been settled on as the cause of the disease. More probable it is that the diplococcus may sometimes exist as a tetracoccus.

The close relation existing between pneumonia and meningitis has long been a subject of great interest on account of the frequency with which one occurs as a complication of the other. The chief point of difference is that pneumonia is spread widely all over the world; then, too, pneumonia as a rule runs a typical course ending by crisis. Still there are many who still maintain that the meningococcus is merely a variety of degenerative form of the pneumococcus.

The observations of Osler, as cited in his late Cavendish lecture (see *JOURNAL*, July 8, p. 98), are mainly confirmatory of the work of Weichselbaum, and give at the same time a care-

ful review of the subject. Osler's experience covered 21 cases, in 16 of which lumbar puncture was made. In 13 of these the diplococcus intracerebralis meningitidis was isolated, in 2 the cultures remained sterile, and in 1 staphylococci appeared in culture while the fresh cover-glass specimens are described as doubtful. All authors agree on what might be called the "fulness" of the symptoms; symptoms, cerebral, spinal, peripheral, and of course general, are all usually well pronounced in the same case, more so, indeed, than in any other variety of meningitis. Another point in which this variety is distinctive is the extremely abrupt onset, as abrupt as the onset of asthenic pneumonia. The fever shows no constant features, except perhaps irregularly; occasionally, however, it may be continuous, resembling that of typhoid; again it may be markedly intermittent, even accompanied by chills and rigors and give the impression of a malarial fever. The blood shows nothing very distinctive; leucocytosis is an almost invariable accompaniment, the count being as a rule over 15,000. The skin eruptions of the disease were, in Osler's cases, well marked: 13 out of the whole series showed a rash of some sort, herpes taking the lead with 8 cases, bearing out the statement of some authorities that herpes occurs more frequently in this than in any other acute affection. The other rashes included diffuse erythema, petechiæ, and a peculiar purpuric herpes over a livid erythema. Two of the most important points discovered in late years in regard to meningitis are the presence of the so-called Kernig sign, and the release of a considerable amount of fluid by lumbar puncture, the so-called Quinke puncture. The former test is elicited in the following manner: the patient is placed in a sitting position, and an attempt made to straighten the leg, which is in a position of flexion; inability to do this on account of contraction of the flexors constitutes the sign. When the patient is unable to assume the sitting position the test is made by flexing the thigh on the abdomen, when rigid resistance is met on attempting extension. This was present in all of Osler's cases, and in those the writer has recently seen as well. Netter's explanation of this phenomenon is that flexion elongates the spinal nerve roots and so increases their irritability; already greatly irritated by the inflammatory process, this increase of irritation is sufficient to cause reflex contraction of the flexors, particularly when the sitting position is assumed, as this latter augments the nerve stretching. The lumbar puncture is even more interesting, and is also of greater value. According to Osler, "during the past ten years no single measure of greater value in diagnosis has been introduced than Quinke's lumbar puncture." It is usually made between the third and fourth lumbar vertebra. By its aid we are not only able to make a diagnosis that meningitis is present but by examination of the exudate and inoculation of culture-media we are very frequently enabled to tell the specific cause. The amount of fluid varies from a few drops to several ounces and may be serous, serofibrinous, purulent or hemorrhagic. As to the therapeutic value of the Quinke puncture there is some variance of opinion. In the cases the writer has seen, the improvement has been prompt and marked, but unfortunately temporary. Usually the improvement has been in a lessening of the delirium, a better character to the pulse, and a lowering of the temperature. In one of Osler's cases numerous punctures were made at intervals entirely on account of supposed benefit. The clinical notes invariably described the patient as improved after a "wet tap." In all, seventeen punctures were made during a period of a little over a month, and undoubtedly this measure served to prolong the patient's life. It is to be hoped that this measure will be even more extensively used in the future: a single tap for diagnostic purposes; frequent puncture for the relief of the symptoms. Clearly, many of the symptoms from which the patient is suffering are from pressure, and equally clear is the indication for relief from this pressure. This can only be well done by tapping, just as when fluid in the pleura or pericardium can only be effectively done by the same means. The operation is not difficult nor is it likely to be attended with as much danger as the tapping of the pericardium.

The New Illinois Medical Practice Act.—We print below the questions submitted at the first examination held under the new law to the applicants for license to practice in Illinois. The first series of questions are those used in examining physicians; the second, those for "other practitioners." "Other practitioners" refer to those which Section 2 of the law calls "those who desire to practice any other system or science of treating human ailments, who do not use medicines internally or externally, and who do not practice operative surgery." Under this the osteopaths come in, and these—fourteen of them—were the only ones who applied for special license and took the examination. "Osteopathy" is, however, not recognized by the law, any more than any other sect which treats without medicine. Those who pass the examination will be licensed to treat human ailments without the use of medicines, and without the use of surgical procedures. The questions submitted for the specially favored class are certainly elementary enough. The very important subject of physical diagnosis was not taken up, but we understand it will be in the future examinations.

SERIES I.—FOR PHYSICIANS.
ANATOMY.

1. Trace the femoral artery from its origin through its large branches to the ankle. Describe the anatomical relations in the upper third.
2. How many tarsal bones are there? Name the largest and one of the smallest.
3. Name the muscles affected in torticollis, also state the origin and insertion of the principal muscle affected.
4. Name the largest arteries divided in amputation below the knee-joint.
5. Describe the diaphragm, its attachments, number and name of openings in it.
6. What are the number and names of the lobes of the liver?
7. What are the branches of the axillary artery?
8. Name the nerves forming the sacral plexus and its branches.
9. What is the sympathetic nerve system, and what parts of the body does it reach? Name and locate its chief nervous centers.
10. Give boundaries and contents of the popliteal space.

PHYSIOLOGY.

1. Give the physical properties and histologic characteristics of blood, and describe the process of coagulation.
2. What are proteids? What elements do they contain?
3. Describe the mechanism of the heart's action, and the sounds of the heart and their cause, also describe the manner in which the blood circulates through the heart.
4. State the differences between the adult and the fetal circulation.
5. Describe the liver, naming its functions, also state the use of glycogen in the body.
6. Describe the manner in which the nervous system affects blood-pressure.
7. Describe the mechanism of respiration.
8. State of what the spinal cord consists, and name the functions of the membranes of the brain and of the spinal cord.
9. Describe the three forms of digestion.
10. What is the source and what is the function of the saliva?

CHEMISTRY.

1. Define an element and a compound. Give examples of each and their symbol.
2. What is hydrochloric acid. Give synonym and chemical formula.
3. Name the different forms in which matter exists, and define each. Examples.
4. What is meant by qualitative analysis? Quantitative analysis? Structural analysis?
5. Give formula for normal acid, basic and a double salt.
6. What is oxygen, and how is it prepared from $KClO_3$?
7. What is the process termed when oxygen unites with another element, and amidst what phenomena does it usually take place?
8. What is an aldehyde, chemically speaking? From what and how is formaldehyde most readily prepared?
9. What is peroxid of hydrogen? Give properties and formula.
10. What is starch? How is it obtained? Mention a test by which starch can be recognized.

MATERIA MEDICA AND THERAPEUTICS.

1. Describe the therapeutic value of iethyol, and name its principal ingredients.
2. Give the action and uses of menthol.
3. Give doses, therapeutics and dangers of three coal-tar products most used as antipruritics.
4. Give the composition of Hoffman's anodyne, and Monsel's solution.
5. Name a few local and systemic emetics.
6. Compare atropin with morphin in physiologic effects.
7. Name the active principle of colchicum, and describe the therapeutic action.
8. Ergot, its physiologic and therapeutic action.
9. What would you do in a case of arsenic poisoning?
10. Write what you know of the urine as to: 1, its normal and abnormal pathologic constituents, and the manner of detecting the principal abnormal matters; 2, its specific gravity, stating upon what this depends, and the important information obtained through a knowledge of the specific gravity. Also state what the following conditions indicate: a, a high specific gravity, and a small amount of urine; b, a high specific gravity and a large volume of urine; c, a low specific gravity and a small amount of urine; d, a low specific gravity and a large amount of urine.

PATHOLOGY AND BACTERIOLOGY.

1. Describe calcareous degeneration, and give causes.
2. Describe the histologic structure of sarcomata.
3. What are the morbid changes that take place in the vessels in arteriosclerosis?
4. What are blood-changes in leucemia?
5. Differentiate between fatty degeneration and fatty infiltration.
6. Make a brief statement of the bacteriology of diphtheria, describing the micro-organism and the local and general tissue-changes produced by it.
7. Describe the bacillus of typhoid, giving its action and stating where found.
8. Describe the tubercle bacillus. How would you determine its existence in sputum?
9. Name the principal cocci which occur in suppurative process.
10. In what way do bacteria affect the animal organism? Is the nitrogen in the body affected by bacteria, and if so, in what manner?

SURGERY.

1. Describe spina bifida and spina ventosa.
2. Which do you consider more important in bone repair, the periosteum or the medulla?
3. Of what importance is the medulla in the formation of red blood-corpuscles?
4. Describe and differentiate between the hard and soft canerae.
5. Give the chief varieties of spinal curvature—non-tubercular. Name causes and give treatment.
6. Symptoms, diagnosis and treatment of Colles' fracture.
7. If a pistol-ball penetrated the skin and did not fracture the skull where would you search for the ball?
8. Give the treatment for penetrating wounds of the abdomen.
9. Give signs, symptoms and common varieties of dislocation of the shoulder-joint, and method of reduction of anterior dislocation.
10. Which wounds do you consider the more dangerous, those of the brain or those of the intestines? Why?

PRACTICE.

1. Describe the morbid anatomy and treatment of acute enterocolitis.
2. Give the causes, symptoms and treatment of cholelithiasis.
3. Name the various forms of stomatitis, and outline the general treatment.
4. Give the prompt and immediate treatment in a case of acute asthmatic attack of dyspnea.
5. Vesicular emphysema, its causes, symptoms and treatment.
6. Give the different diagnosis between cerebral hemorrhage, embolism, thrombosis and uremia.
7. Describe the pathology and treatment of thermic fever.
8. Give the common names, incubation period, period of eruption and duration of: a, rubella; b, rotheln; c, variola; d, varicella; and e, pertussis.
9. Diagnosis and treatment of typhoid fever.
10. Write what you know of catalepsy.

OBSTETRICS.

1. Describe the uterus, its normal position, its relationship to the other organs, and the means by which it is held in place.

2. How would you diagnose pregnancy before the fourth month? After the fifth month?
3. What means would you take to arrest a threatened abortion, and if abortion occurred, how would you know it was complete?
4. What is the most serious displacement of the uterus in pregnancy? How should it be treated?
5. What are the causes of, and how would you treat ante-partum hemorrhage?
6. Describe normal labor, giving the clinical characteristics and mechanism of each stage.
7. What would you do in a case of rupture of the uterus in the first stage of labor? What in the second stage?
8. What would you do if the head should be arrested in the inferior strait in pelvic presentation?
9. How would you manage a case of shoulder presentation after labor has begun?
10. Etiology, prognosis and treatment of puerperal fever.

GYNECOLOGY.

1. Give the blood-supply of the ovaries.
2. Give the causes of suppression of the menses, and describe menorrhagia and metrorrhagia.
3. Give the contraindications for the use of the sound.
4. Give the treatment of endometritis.
5. Give the symptoms and treatment of pelvic peritonitis.
6. Differentiate hematocoele from other pelvic lesions.
7. What are the causes and terminations of salpingitis?
8. Discuss the pathologic results of laceration of the perineum.
9. Give the differential diagnosis of: a, salpingitis from appendicitis; b, fibroid of uterus from pregnancy.
10. What are the causes of prolapsus uteri?

HYGIENE.

1. What is an antiseptic? A deodorant? A disinfectant? A germicide?
2. Name the three chemical germicides most commonly used, and state in what proportions employed.
3. Name: a, the disinfectant a solution of which should never be made in a tin vessel; b, the disinfectant which precipitates when brought in contact with albumin.
4. If called to a case of diphtheria in a family where there are other children, by what hygienic means would you hope to prevent the latter from contracting the disease? What precautions would you take to prevent your carrying the disease elsewhere?
5. What aerial disinfectant would you use for disinfecting an apartment after the occurrence of a communicable disease? Describe the manner in which it should be used.
6. Describe in full the manner in which you would disinfect a room in which a patient has been sick with scarlet fever.
7. What is the incubation period of: a, variola; b, varicella; c, rubella; d, scarlatina; e, scarlet fever?
8. What effect has ground air and ground water on health?
9. What diseases are due to impure water?
10. Give the minimum of cubic space to be allotted to each individual in: a, tenement houses; b, school-rooms; c, ordinary hospital wards; d, in a fever, surgical or obstetric ward.

MEDICAL JURISPRUDENCE.

1. What is the difference between the spasms of arsenic and strychnia poisoning?
2. When does complete ossification of the os innominatum take place?
3. When a male and female are found dead from asphyxia, which was more probably the survivor? Why?
4. In the case of both dying from the same accident, which would be the probable survivor?
5. In poisoning with prussic acid what symptoms would you expect to find?
6. What relation to insanity has remorse?
7. Define insanity.
8. What is the difference between paranoia and pseudo-mania?
9. What is the age of consent in Illinois?
10. Define a degenerate.

SERIES II—OTHER PRACTITIONERS.

ANATOMY.

1. Name the vertebrae forming the spinal column.
2. What is the scapula? Over what rib does it lie?
3. Name the ligaments of the hip-joint.
4. Describe the trapezius and the deltoid muscles, and give their action.
5. Where does the aorta commence, and into what does it divide and where?
6. Describe and locate the liver.
7. Between what ribs does the apex of the heart pulsate normally?

8. Describe the lungs, and state which lung is the shorter, and why? Also name the structures forming the root of the lung by which the lung is connected with the heart and trachea.

9. What is the sympathetic-nerve system, and what parts of the body does it reach?

10. Trace the internal saphenous vein from its commencement to its termination.

PHYSIOLOGY.

1. What is hemoglobin? Where does it occur in the body?

2. What are leucocytes? Where are they found in the body?

3. The difference in the substances contained in arterial and in venous blood?

4. The cause of the first sound of the heart? Of the second?

5. The number of normal respirations in the adult per minute.

6. The composition of the gastric juice.

7. Describe the systemic circulation of the blood. The pulmonary circulation.

8. Describe the mechanism of respiration, and state on what the movement of the lungs depends.

9. What is the function of the cerebellum?

10. Describe the tissue and nerve-fibers entering into the structure and arrangement of muscles, and discuss the stimuli affecting muscular substances.

PHYSIOLOGIC CHEMISTRY.

1. What are proteids? What elements do they contain?

2. State the occurrence of glycogen in the body and its chief source.

3. From what is the fat deposited in the body derived?

4. What is bile? From what is it derived? Name some of its characteristics, constituents, and two important pigments.

5. From what is the hydrochloric acid in the stomach derived?

6. What is the part oxygen takes in the physiologic process?

7. What is carbon dioxide? How is it formed in the body, and how got rid of?

8. Of what is the atmosphere especially composed? State proportions.

9. Describe the tissue changes in the spinal cord in locomotor ataxia (tabes dorsalis, posterior sclerosis).

10. Write what you know of the urine as to: 1, its normal and abnormal or pathologic constituents, and the manner of detecting the principal abnormal matters; 2, its specific gravity, stating upon what this depends, and the important information obtained through a knowledge of the specific gravity. Also state what the following conditions indicate: a, a high s. g. and a small amount of u.; b, a high s. g. and a large volume of u.; c, a low s. g. and a small amount of u.; d, a low s. g. and a large amount of u.?

HYGIENE.

1. What is meant by ventilation?

2. What precautions would you take relative to the matter coughed or spit up by consumptives? What danger, if any, will result if these discharges are deposited on the floor?

3. In hospital wards for ordinary cases, what cubic air-space should be allowed to each bed?

4. Why is milk so nearly perfect food? Why are eggs so highly valued for food?

5. What effect has the contraction of a muscle on the flow of the blood through it?

6. What is the incubation period of typhoid fever? Of measles?

7. What is meant by disinfection? How would you disinfect a room after the death or recovery of a patient suffering from diphtheria?

8. How is corrosive sublimate, bichlorid of mercury or carbolic acid used as a disinfectant, and in what proportions?

9. Give the size of a model school-room accommodating forty pupils. On what side of the pupil should the light be admitted, and why?

10. After attending a case of scarlet fever, for instance, what precautions would you take to prevent carrying the disease to your family, friends or patients?

HISTOLOGY AND PATHOLOGY.

1. What is epithelium? Where is ciliated epithelium found in man?

2. Describe hyaline cartilage, and state in what situations it principally occurs.

3. In what manner is true bone essentially formed, or of what is it always made up?

4. Describe the histologic structure of an artery. Of a vein.

5. What are medullated nerve fibers? What important nerves are composed of these fibers?

6. Describe the manner in which fractured bone unites.

7. Give the definition of necrosis and definition of gangrene.

8. What histologic elements are directly concerned in inflammatory processes?

9. What are the structural changes in the blood-vessels in arterial sclerosis?

10. Enumerate the different stages of acute lobar pneumonia, and describe the gross appearance of the lungs in some one of these stages.

San Francisco Notes.

POLITICS AND HEALTH.—The conflict between the Board of Health and the Supervisors, backed by the auditor, has assumed a phase that promises much harm to the city of San Francisco. The auditor refused to audit the Board of Health's warrants for employes not definitely specified by the statute, and consequently many of the Board's employes, a number of them useless political burdens, were forced out of their jobs. The Board has retaliated by closing all the receiving hospitals of the city, under the excuse that they can not operate them on the money allowance granted by the Board of Supervisors. To-day there is not a hospital open, save the City and County Hospital and the pest-house. A daily paper has taken the matter up, and opened the water-front receiving hospital, which it proposes to operate on its own account and for advertising purposes, until the present muddle is cleared up. Already the evil effects of certain changes and reductions on the Board of Health staff are being felt. An unscrupulous cattle-dealer has gone about through the nearby counties and bought up, very cheap, a lot of tuberculous cattle, which he shipped to the city of San Francisco in the most open and barefaced manner. Fortunately, a meat inspector happened to see the lot, and got the former veterinary of the Board of Health to volunteer his services as inspector of this bunch of cattle; they were condemned and sent into quarantine to be subsequently killed and burned. But, if within the short space of a few days this much has been attempted, one can but imagine what may follow. The root of the whole trouble lies in the fact that in the fall there will be held an election under a new charter, and the political bosses are all striving to secure as much patronage as they can in order to influence things at that election. If they can appoint a hundred or two of their political friends to jobs in the Board of Health office, then this hundred or two can do a good deal of electioneering, and help on the party through which they secured their appointments. The truth of the whole matter is fully understood by every one, yet the maneuvering for political advantage goes on all the time. Under the new charter these city offices will be appointed by the mayor, who will control almost all the patronage, and consequently the strife is a particularly bitter one.

A DISGRACE ENDED.—An order of the Board of Supervisors has recently brought to a sudden end what promised to be a most unique business enterprise in the line of houses of prostitution. Some few months ago certain men in San Francisco conceived and brought forth a scheme which was very simple, yet truly unique. They obtained a large piece of property in a rather poor section of the city, not far from the section known as "Chinatown." On this they built a two-story building, or rather nest of buildings. From the street it looked like a simple two-story building without windows. There were two large doorways, opening upon an alley-way that led all around the four sides of the building. Within the outside enclosing wall, and opening from these alleys, were 250 "cribs" which rented for the sum of \$15 per week, so that the income from them alone was something over \$16,000 per month. Besides this, each occupant paid a certain doctor—she was not allowed to choose her own—the sum of \$1.00 per week. The doctor's income from this source therefore came to a little over \$1100 per month. The natural inference is that the doctor was directly interested, to no small extent, in the building. Whatever the truth of that may be, it is cer-

tain that the "cribs" were in great demand, for the reason that a number of alleys in the city, heretofore given up to that sort of tenantry entirely, have within a short time been closed by the police department, after a long and strenuous work on the part of nearby property-owners and certain churches. The scheme was but short-lived, for the property-owners in the vicinity brought the matter to the attention of the Board of Supervisors, with the result that it was closed. The latest development in the question is the statement that the aforesaid property-owners are to have the "Corporation," or the members thereof, arrested and prosecuted on the ground that they have violated a certain statute, which makes it a misdemeanor to rent property for purposes of prostitution. It is possible that in the course of the case the name of the doctor who was so much interested in the success of the business may come out. Your correspondent is aware of the doctor's name, but unless it transpires in some other connection, he is not at liberty to disclose it.

August 2, 1899.

London.

From Our Special Correspondent.

ROYAL COLLEGE OF SURGEONS.—The chief topic of interest in the English profession at present is the situation at the Royal College of Surgeons, between the Members and the Council, mentioned in previous issues of the JOURNAL. A moderate, powerful and widely-signed memorial has just been presented to the Council, which carries such weight, by reason both of the standing of its signatories and the wide-spread attention which it has attracted, that even that body can no longer evade or loftily shelve the issue. Their only reasons for hesitating to grant the representation asked for are that they themselves are—naturally—satisfied with the present state of affairs, as illustrated by their president's childishly feeble appeal to the Members, at the annual meeting, not to insist on their rights, because many of the Fellows were opposed to granting them, and the harmony of the Centenary would be disturbed! Their other, the sacredness of ancient custom—always a telling argument—has received its death-blow in the present memorial, in which the uncomfortable fact is shown that, from the foundation of the College in 1800, until 1843, the only alumni of the College were Members, who, of course, controlled its affairs, and it was only on the creation of the higher rank of Fellows in that year that all the power was turned over to the present "aristocracy." The injustice of the present position demonstrates itself in a simple statement of numbers. Some 1300 Fellows absolutely control the affairs of a College consisting of nearly 25,000 Members. The Council could give points to "Oom Paul." The moderateness of the appeal of the Members may be judged from the fact that they do not even ask for direct representation, but merely for the right to elect a certain number of Fellows, to represent them on the Council. They make no complaint of, or even reflections on, the competence or fairness of the Fellows' government, but when we remember that the great majority of this ruling class are either city consultants or specialists, we can easily see how little such a body is capable of legislating intelligently on questions involving the interests of the great body of general practitioners, even with the best intentions. And no more favorable or becoming opportunity for granting fair representation to all will ever come than the new charter which is to mark the coming Centenary.

FOOD ADULTERATION.—A curious form of "adulteration" of food was brought to light, created, in fact, in Parliament this week. A most extraordinary clause was introduced in the new Food and Drugs bill, making it illegal for oleomargarin to contain more than 11 per cent. of genuine butter. This strange provision was defended on the ground that if more than this proportion of butter is added to the oleo "bren" it interferes with the simpler tests of the official analysts and renders its distinction from butter quite difficult. In short, the public are not to be allowed more than a certain standard of goodness in

their food, for fear of inconveniencing the Government analysts. The question at once suggests itself, if neither the taste of the consumer nor the tests of the chemist can detect any difference between margarin and butter, and they are both equally wholesome—as most experts are agreed—why legislate against the former, in the interests of public health? In point of fact, most of this legislation, in both England and America, is a political sop to conciliate the farmer vote—wherefore the Government summoned its irrational majority and drove the offensive clause through, in spite of the vigorous criticism of the House.

NURSES IN ENGLAND.—The largest school for nurses in England, indeed probably in the world, is that attached to the London Hospital, where no less than 400 probationers are at work under the leadership of Miss Eva Luckes, the gifted superintendent. The school receives an average of nearly 2000 applications per annum for nurses.

CANCER.—The Government has declined to appoint a commission to investigate the prevalence and causation of cancer, saying, not unreasonably, that in the present state of our knowledge of the causation of the disease, but little of practical value could be hoped from such a commission. And, indeed, if the commission is to be necessarily after the type of most of its predecessors, consisting of a majority of titled and political duffers and a minority of scientists, which aggregation, after three years' cogitation, announces as its findings the commonplaces of professional knowledge, not much is to be hoped from it; but a real research commission, whose chief object was to enable skilled investigators to devote their entire attention to the investigation of the problem for two or three years, might make some valuable changes in the "present state of our knowledge." The interest of the public has been so thoroughly aroused that the authorities will probably be obliged to take some step in this direction, even the Church Sanitary Congress, having recently passed a resolution severely censuring their refusal to appoint a commission.

MYSTERIOUS POISONING.—A curious case of mysterious poisoning at Greenwich has caused some excitement in London, on account of the number involved. A party of some 200 children who were out on a school treat, sat down to a simple picnic lunch of cherries, small cakes and milk. Within twenty minutes of the end of the meal complaints of "belyache" began, and before three-quarters of an hour had passed no less than eighty or ninety were rolling on the grass in severe pain. Fortunately medical assistance was promptly secured, the vans which had brought the children to the park were utilized as ambulances, and the worst cases taken to the great Dreadnought Hospital, which was providentially near. Here most of them recovered sufficiently promptly to be taken home by their parents that night, only two having to remain in the Hospital, and they were reported out of danger next morning. The cause of the trouble is still a complete mystery.

MARY ANSELL.—Now that Mary Ansell is executed and the excitement subsiding the truth about the wretched girl is beginning to leak out. The papers assured us that everyone who had had anything to do with the family regarded her as of unsound mind, or as a "degenerate." Now comes her school teacher, in a quiet little letter, and states that since her name has been mentioned in that category, although she kept silence as long as the unfortunate girl had any chance of reprieve, she now feels that she ought to say that she knows of nothing which would justify her in regarding her as defective in any way. She was in her school six years, during which time she passed through every grade prescribed in the course and never failed in a single examination, in fact, passed most of them with credit. Her scholarship was slightly above the average of girls at her age. The teacher thinks that many people have confused her with her victim, who was only a few years younger and unquestionably defective.

SPOILED FRUIT.—A startling illustration of the protection to the public health afforded by sanitary inspectors and medical officers of health has just been afforded in the seizure, in the great Lipton's canning factory in South London, of no less than 250 tubs of spoiled fruit about to be made into jam. Think of the number of cases of "sporadic" gastro-enteritis, etc., which this two and a half hundred tons of decaying fruit changed into "jam" would have caused in the community; and then say, if you can, that "preventive medicine" is a fad.

Queries and Minor Notes.

CALCULUS IN LUNG.

OMAHA, NEB., July 30, 1899.

To the Editor:—I have just had a very interesting case in which a man coughed up a calculus from the lungs. I can find absolutely nothing on the subject of the bronchial calculus in any of the text-books or periodicals available here. Can you give me any reference on the subject? LER. C.

ANSWER:—Calculi of the bronchi appear to be rare, though they have quite a little "casuistic" literature of their own, going back as far as the sixteenth century. In the last series, Vol. iii, of the "Index Catalogue of the Library of the Surgeon-General, U. S. A.," there are eighteen separate articles on the subject, and still larger a number in the first series. The only separate monograph noticed is that of Pavalion: "Leo Pierres du Ponnon, etc., Paris, 1891." Modern text-books apparently have little to say on the subject. It is only barely mentioned in Thomas' "Pathology," for example, and is entirely omitted in some others. A report of our correspondent's case would be of interest. Most of the literature of the subject appears to be French, the only American case in the last volume of the "Index Catalogue" being Munson's, in 1788. The latest article in the English language then given is that of Ross, *Australian Med. Jour.*, 1892, xiv, p. 300.

CONTRACT PRACTICE.

ST. LOUIS, MO., August 3, 1899.

To the Editor:—I wish to consult you on a question of ethics. I am offered the practice of a large manufactory on a salary to look after the operatives and their families, and a still larger one obtained by taking on a monthly a fixed amount of their operatives' wages. I am just starting out in my professional life and wish to be on the right side. L. E. B.

ANSWER:—The question of ethics here involved would probably depend largely on details not given in our correspondent's letter. It is undoubtedly the legal right of a company to employ medical service for its employees, whether or not it is for the best interests of the physicians. If the pay is equivalent to the average that would be derived from a medical practice covering an equal population, and the physician therefore is not cheapening himself by accepting it, the case is different from that where the service demanded is such that the average remuneration is reduced. This contract business, on general principles is bad, demoralizing to the profession, and has worked most disadvantageously to the profession in Europe, as it will in this country if allowed to extend too much. The spirit as well as the letter is the guide to the "Code of Ethics," and where the letter is silent the spirit of the Code to do as one would be done by should be the ruling motive.

DETERMINATION OF SEX.

SEDALIA, MO., July 27, 1899.

To the Editor:—It would be a great favor to me if you would inform me where or how I could get the complete works of sex determination by Dr. Schenck, as I would like to make a further study of the subject.

G. A. C.
ANSWER:—Dr. Schenck's work, "The Determination of Sex," has been translated and is published by the Werner Company, Akron, Ohio, Chicago and New York. Price \$1.50. It gives his theory and the substance of what he has written on the subject.

The Public Service.

Movements of Army Medical Officers under orders from the Adjutant-General's Office, Washington, D. C., to and including August 2, 1899:

- Thomas B. Anderson, appointed captain and asst.-surgeon Vols., July 5, 1899, and assigned to the 37th Vol. Infantry in the Philippines.
- Isaac W. Brewer, appointed lieutenant and asst.-surgeon Vols., July 5, 1899, and assigned to the 36th Vol. Infantry in the Philippines.
- Edwin F. Gardner, major and surgeon, U. S. Army, leave of absence extended.
- John C. Greenwald, appointed lieutenant and asst.-surgeon Vols., July 5, 1899, and assigned to the 35th Vol. Infantry at Fort Sam Houston, Texas.
- Frederick Hadra, appointed captain and asst.-surgeon, July 5, 1899, and assigned to the 33d Vol. Infantry, Fort Sam Houston, Texas.
- Deane C. Howard, captain and asst.-surgeon, U. S. Army, from temporary duty at West Point, N. Y., to Fort Columbus, N. Y.
- D. J. Johnson, acting asst.-surgeon, from Fort Terry, N. Y., to San Francisco, Cal., for duty in the Department of California.
- P. S. Kellogg, acting asst.-surgeon, from Battle Creek, Mich., to San Francisco, Cal., for duty in the Department of California.
- T. H. Landon, acting asst.-surgeon, from Canton, Ohio, to San Francisco, Cal., for duty in the Department of California.
- Henry Lippincott, lieutenant-colonel and deputy surgeon-general, U. S. Army, member of an army retiring board convened in San Francisco, Cal.
- George W. Matthews, appointed captain and asst.-surgeon Vols., July 5, 1899, and assigned to the 36th Vol. Infantry in the Philippines.
- James Mitchell, acting asst.-surgeon, from Lancaster, Pa., to San Francisco, Cal., for duty in the Department of California.
- Curtis E. Munn, major and surgeon, U. S. Army, member of a retiring board convened in San Francisco, Cal.
- Seaton Norman, acting asst.-surgeon, to temporary duty at Fort Monroe, Va.
- Orden Rafferty, major and surgeon 27th Vol. Infantry, former orders

revoked. He is relieved from further duty and station at Willet's Point, N. Y.

- William Redin Kirk, acting asst.-surgeon, from Washington, D. C., to San Francisco, Cal., for duty in the Department of California.
- Maxwell S. Simpson, acting asst.-surgeon, from Plainfield, N. J., to San Francisco, Cal., for duty in the Department of California.
- George W. Sims, acting asst.-surgeon, from Corpus Christi, Texas, to San Francisco, Cal., for duty in the Department of California.
- Dwight B. Taylor, acting asst.-surgeon, sick leave extended.
- F. H. Titus, appointed major and surgeon Vols., July 5, 1899, and assigned to the 36th Vol. Infantry in the Philippines.
- William Mc Van Patton, captain and asst.-surgeon 1st Washington Infantry, discharged for disability.
- Walter R. Washburn, acting asst.-surgeon, from Denison, Texas, to San Francisco, Cal., for duty in the Department of California.
- F. A. Winter, appointed major and surgeon Vols., July 5, 1899, and assigned to the 37th Vol. Infantry in the Philippines.

Movements of Navy Medical Officers.—Changes in the medical corps of the U. S. Navy for the week ending August 3, 1899:

- Asst.-Surgeon, C. A. Crawford, detached from the *Wabash* and ordered to the *Massachusetts*.
- Asst.-Surgeon, E. J. Grow, detached from the *Massachusetts* and ordered to the *New Orleans* immediately.
- Asst.-Surgeon M. S. Elliott, detached from the marine examining board, August 2 and ordered to temporary duty at the marine recruiting rendezvous, New York, during leave of P. A. Surgeon E. S. Hoger; upon completion of this duty, directed to await orders.
- Surgeon C. G. Herndon, ordered to the museum of hygiene for temporary duty.
- P. A. Surgeon J. C. Rosenbleuth, detached from the *Vermont* and ordered to the *Nashville*.
- Asst.-Surgeon, F. L. Pleadwell, detached from the *Nashville* and ordered to the bureau of medicine and surgery.

Health Reports.—The following cases of smallpox, yellow fever, cholera and plague, have been reported to the Surgeon-General of the U. S. Marine-Hospital Service, during the week ended August 5, 1899:

- SMALLPOX.—
 - Florida: Jacksonville, July 23 to 30, 4 cases.
 - Kentucky: Louisville, July 20 to 27, 2 cases.
 - Louisiana: New Orleans, July 15 to 21, 1 case.
 - Ohio: Cleveland, July 22 to 29, 7 cases; Dayton, July 22 to 29, 3 cases.
 - Pennsylvania: Philadelphia, July 22 to 29, 1 case; 1 death; Pittsburgh, July 22 to 29, 1 case.
 - Virginia: Portsmouth, July 22 to 29, 4 cases.
 - Washington: Seattle, July 15 to 22, 1 case; Tacoma, July 15 to 29, 2 cases.

- SMALLPOX—FOREIGN.
 - Brazil: Bahia, July 1 to 15, 1 case.
 - China: Hongkong, June 7 to 24, 3 cases.
 - Greece: Athens, July 7 to 15, 16 cases, 5 deaths.
 - India: Bombay, June 27 to July 4, 8 deaths; Madras, June 24 to 30, 1 death.
 - Mexico: Chihuahua, July 15 to 29, 3 deaths.
 - Russia: Moscow, July 1 to 8, 5 cases, 3 deaths; Odessa, July 1 to 8, 6 cases; St. Petersburg, July 1 to 8, 7 cases, 2 deaths.
 - Turkey: Beirut, June 27 to July 1, 1 case; Smyrna, June 28 to July 16, 3 deaths.

YELLOW FEVER—UNITED STATES.

- Virginia: Soldiers' Home, Hampton, July 21 to August 1, 49 cases, 8 deaths.

YELLOW FEVER—FOREIGN.

- Brazil: Bahia, July 1 to 15, 28 cases, 14 deaths.
- Colombia: Panama, July 16 to 23, 14 cases, 8 deaths.
- Cuba: Manzanillo, July 1 to 8, 1 death; Matanzas, July 27, 1 case; Santiago, July 1 to 8, 7 deaths.
- Mexico: Progreso, July 26, 2 cases; Vera Cruz, July 20 to 27, 20 deaths.

CHOLERA.

- India: Calcutta, June 17 to 24, 3 deaths.
- PLAGUE.
 - China: Hongkong, June 10 to 24, 257 cases, 255 deaths.
 - India: Bombay, June 28 to July 4, 45 deaths; Calcutta, July 17 to 24, 7 deaths.
 - Japan: Tamsui, May 24 to 31, 90 cases, 66 deaths.

CHANGE OF ADDRESS.

- Braselton, B. E., from Weatherford to Vineyard, Texas.
- Cass, W. E., from Dayton, Ohio, to 1604 Locust St., St. Louis, Mo.
- Cannon, Jas., from 529 Walnut to P. O. Box 324, Des Moines, Iowa.
- Dubell, A. E., from Burlington to Columbus, N. J.
- Drosier, G. W., from Danville to 1645 14th Ave., So., San Francisco, Cal.
- Gill, H. Z., from Topeka to Pittsburg, Kan.
- Houston, I. M., from Nebraska City to Falls City, Neb.
- Johnson, H. P., from Long Prairie, Minn., to Fairmont, Minn.
- Kimball, A. L., from Ann Arbor, to 744 Col. Ave., Racine, Wis.
- King, P. H., from Niantic to Kyle, W. Va.
- Kloke, W. E., from 372 Blue Island Ave. to 235 S. Lincoln St., Chicago.
- McLaren, J. J., from Seymour to Grand Rapids, Wis.
- McLaren, J. L., from Los Angeles, Cal. to Saginaw, Mich.
- Payment, R. C., from Wilcox to 1011 River Ave., Detroit, Mich.
- Phillips, W. L., from Cleveland, Ohio, to Univ. of Virginia, Charlottesville, Va.
- Quinn, W. E., from Lyndon, Kan. to Las Cruces, N. M.
- Simonton, A. C., from Seattle to Roslyn, Wash.
- Shaw, W. E., from 481 to 274 Colerain Ave., Cincinnati, Ohio.
- Townsend, W. R., from 28 N. 59th to 23 W. 53d St., New York City.
- Tenney, J. T., from Wabasha to Kellogg, Minn.
- Wiedrich, J. W., from 14 Platt to 417 W. 33d St., New York City.
- Watson, S. H., from Vinton to Blairtown, Iowa.
- Westervelt, J. Douglas, 215 Main St. to Suite 205 No. Texas Bank Building, Dallas, Texas.

THE PNEUMONIA QUESTION.

SOME INTRODUCTORY CONSIDERATIONS.*

BY EDWARD F. WELLS, M.D.

CHICAGO.

Pneumonia is the greatest medical problem of the day. In temperate regions it is chargeable with more deaths than any other disease, with a single exception—only pulmonary tuberculosis leading it in the mortality bills. It is, moreover, one of the most dangerous of the acute diseases and has an appalling death-rate. It is not only a malady which is ubiquitous, frequent, severe and dangerous, but now, in these waning days of the 19th century, we must frankly confess that its prevalence, frequency, severity and dangers have not been one whit diminished by our immediate predecessors or ourselves.

In opening the discussion on this important question it will be clearly impossible for me to cover, however superficially, the entire subject, or even to deal exhaustively with any part of it. My endeavor, therefore, shall be to consider, suggestively if possible, a few of the numerous practical points which seem to be of greatest present interest.

In order that there may be no confusion or misunderstanding it may be well for me to state that my remarks will refer to one malady, ordinary pneumonia—febris pneumoniae—an acute infectious disease of bacterial origin, having well-defined symptoms and positive anatomical changes; an affection which is readily recognizable during life and leaving unequivocal evidences of its presence after death.

In typical cases the access is sudden, with a chill, followed by fever, pain, cough, characteristic expectoration, increased frequency of respiration, disturbance of circulation, changes in the blood and urine, and evidences of the solidification of one or more lobes of the lungs. The disease quickly attains a high degree of severity and steadily maintains this for about a week, with rapid entrance upon convalescence while the lung is yet completely hepatized; or death in a few hours after the onset of alarming symptoms. Post-mortem section shows the affected pulmonary area peculiarly inflamed, with the alveoli filled with a solidified fibrinous exudate and the pleural covering the seat of a sero-fibrinous inflammation. In the expectoration and in the alveolar exudate is found the etiologic morbid organism.

The essential cause of pneumonia is the diplococcus pneumoniae—the pneumococcus of Fränkel. This assertion can be made, at this day, and before this audience, without appeal to either argument or authority.

The pneumococcus is rounded or tapered at both ends and has a mucinous capsule. It is found single, often

paired, or frequently in groups, enclosed in the same or in adhering capsules. It colors readily with aniline dyes and is not affected by the Gram method. It is cultivated with difficulty, and much care is required to obtain pure growths. It does not lend itself kindly to saprophytic existence, and has not yet been found in the air. It will not grow in acid media and cultures produce an albumose and an acid. Its capsule is lost by cultivation. It varies in size, appearance and virility. Its virulence diminishes as convalescence advances. It loses virulence by cultivation, but this may be restored by passage through the rabbit. An organism which can not now be differentiated from the pneumococcus is present in the mouth and upper air-passages in a large proportion of healthy persons. Diplococci from the mouth are less active and can not be made as virulent as those from pneumonic sputum or exudate. To round out our knowledge of the pneumococcus we need definite answers to the following questions: Is the diplococcus found so frequently in health in the mouth and upper air-passages identical with that found in the pneumonic exudate and sputum? If so, how does the organism obtain entrance into the mouth and nostrils? Has it a wide-spread saprophytic existence, finding its way into the body with the inspired air, or does it pass from one person to another only by direct conveyance of the moist or dried secretions? If it is not identical, whence comes the pneumococcus, and what is its life's history outside the body? What measures can be instituted to destroy the germ outside the body, prevent its entrance into the system, or render it innocuous after entrance? Any intelligent prophylaxis will depend upon full and complete answers to these questions.

The blood is markedly and distinctively altered by the pneumococcal infection. As the attack advances, the specific gravity and hemoglobin are increased, to fall to or below the normal for the individual as resolution progresses. The white blood-corpuscles, especially the polynuclear cells, are usually largely increased in number. This leucocytosis begins as early as the chill, and may be of diagnostic value in those cases in which the inflammation begins deeply within the lung. It corresponds roughly with the extent of pulmonary involvement, the temperature curve and the vehemence of the attack. Its continuance after crisis often indicates the presence of complications. The presence of leucocytosis has no great prognostic value, but its absence, except in the very mildest cases, is an ominous circumstance. The consensus of opinion seems to be that there is an advance into the general blood-current of pre-existent leucocytes and not a greatly increased formation of these cells. Does leucocytosis protect the blood current from the pneumococcus and its toxins? It may be that the near future will demonstrate that the leucocytes form a large and effective portion of the sanguinary army of defense, acting as bacterial phagocytes, by saturating the serum with protective and neutralizing and germicidal substances—a hidden force, held in reserve in the

*Presented to the Section on Practice of Medicine, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

lymph-spaces or by contracted capillaries, ready to rush out and do battle with the first appearance of the pneumonia fœc.

The fibrin, or fibrin-forming material, is greatly increased, probably running parallel with the leucocytosis. The proportion of fibrin in the shed blood, which in health is 2 or 3 parts per 1000, rises at the height of the attack, to 4, or even 10 parts per 1000. The density of the network of fibrinous threads in cover-glass preparations is notably increased, and if the Thoma-Zeiss cell is employed the estimate of comparative coagulation may be fairly accurate. The rouleaux formation of red blood-corpuscles upon the slide is due in the presence of an agglutinating substance, presumably fibrin, and in pneumonia rouleaux formation is exaggerated. If healthy blood is acted upon by pneumonic serum rouleaux formation is also exaggerated, with a peculiar clumping of cells, which latter, however, is not distinctive.

Cardiac thrombosis is met with oftener in pneumonia than in any other disease, and is one of the most serious contingencies which may occur. In analyzing the records of 777 pneumonic post-mortem examinations, I found that ante-mortem heart-clots were present in 169, or 21.7 per cent. If we assume that the death-rate of pneumonia is about 21 per cent. and that all the cases with thrombosis are fatal, we may conclude that ante-mortem clotting of blood in the heart occurs in about 4.5 per cent. of all cases. These clots may be small or they may be so large as to weigh up to two ounces; they may be a mere patch upon the endocardium, a rounded mass within one of the cavities, or a thick or thin elongated clot originating in the auricle, passing through the ventricle and extending several inches into the afferent vessels on one or both sides. Although a cardiac thrombus may become organized or, possibly, undergo solution, with recovery, yet the fact remains that post-mortem examinations of persons recently subjects of pneumonia do not, with very rare exceptions, disclose such conditions. We must infer, therefore, that the formation of such a thrombus is an event which usually leads to death. The condition is seldom recognized during life, and here is a diagnostic problem of great practical importance which the clinician is called upon to solve.

The blood may, and probably always does, contain pneumococci. If they are present in sufficient numbers to be readily found during life, the case is attended with more than ordinary danger, and if they are numerous, death within twenty-four to forty-eight hours is the rule.

The toxemia of pneumonia is due to the development of pneumococcal toxins and, probably, antitoxins; to destructive changes in the normal constituents of the blood; to the withdrawal, by the exudate, of important elements; to diminished aëration; to contamination by the excessive waste products of the body in general and of the inflamed lung in particular; and to interference with excretion.

The hemic changes affect particularly the nervous system. The initial effect of the pneumococcus toxins, necessarily infinitesimal in amount and diluted beyond computation, upon the thermogenic center is to produce a profound chill and incite a raging fever. The vasomotor system of nerves is instantly affected. The pulse is accelerated in direct proportion to the danger. A comparatively slow pulse is of good import, while very few adults will recover after the 140 mark has been gradually reached and crossed.

The arterial tension is always lowered, the diminution measuring with accuracy the severity and danger of the case. This lowering of arterial tension is due to capillary paresis, and not to any primary heart failure. This selective inhibiting action upon the vasomotor system is one of the most remarkable effects of the pneumococcus toxins. Whether the primary action is upon the terminal nerve-fibers in the vascular walls, or upon the vasomotor center in the cerebral extension of the spinal cord, I am not prepared to say. The fact remains that the arterioles and capillaries are relaxed, and in serious cases they are so parietic as to afford the slightest resistance to the passage of blood through them. In many serious cases of pneumonia careful observation will show that the contracting left ventricle is throwing blood into nearly empty arteries and that this fluid passes through the capillaries with such force that the veins beyond pulsate, as may be easily detected in the dependent hand. The body is nourished by the osmosis of fluid portions of the blood through the capillaries, the rate being regulated by a delicate adjustment of the intravascular tension. Under the circumstances above mentioned every tissue of the body must lack in nourishment, the heart, because of the source of its blood-supply, perhaps more markedly than other parts. It may be said, and possibly with truth, that the relaxation of the capillaries is a defensive measure intended to prevent the poisoning of tissues without, but, in any case nutrition fails, the soft tissues become loaded with the poisons of their own waste and the patient falls between the lines of his two enemies. Herein, I believe, lies the most imminent danger, and the chief determining cause of death in pneumonia.

The interesting and important questions which cluster around such of the phenomena of this disease as the forcible contraction of the heart against an increased resistance on one side and a diminished resistance upon the other; the increased frequency of respiration, irrespective of the extent of the hepatization and out of proportion to the exaltation of temperature; the peculiar character of the expectoration; the diversion of the chlorids from the blood to the exudate; the suddenness of symptomatic convalescence while the lung remains solidified; the uniformity of the symptomatology in general; and others of equal moment, must be passed for lack of time.

A moment's attention, however, is asked to two symptoms of prognostic import: During the pneumonic attack reflex sensations are weakened in proportion to the danger. Now, a dyspnea, which is readily recognized by the observer, but which is not appreciated by the patient, is of grave augury, and when accompanied by a rising and falling of the trachea and a non-obtrusive clicking noise with respiration, which persists after coughing, the patient has, in my experience, invariably died. The prognostic value of this syndrome lies in the fact that it antedates all others which certainly denote the approach of death. On the other hand when, late in the attack, the patient awakens from a sound sleep and sneezes, his safety may be assured.

The death-rate of pneumonia is very great. Eight years ago I published a table showing the mortality of pneumonia, embodying the statistics of 223,730 cases, of which number 40,276, or 18.1 per cent. died. This inquiry has been continued, and I have collected 134,705 other cases, with a mortality of 37,715, or 28 per cent. My full table now comprises 358,435 cases, with 77,991 deaths, or a death-rate of 21.7 per cent. From a careful consideration of the materials upon which these statis-

tics are based, I am convinced that the mortality-rate here shown is not overestimated.

Fatal cases of pneumonia are readily divisible into three classes: 1. Those in which the pulmonary involvement is so extensive, or the toxemia is so profound, or because of other conditions, we instinctively feel, from a clinical stand-point, that death was inevitable. 2. Those in which, upon post-mortem examination, we stand astounded that life should have been so long continued in the face of the most extensive involvement and destruction of vital organs. 3. Those in which the clinical phenomena and morbid changes in the tissues are of such slight extent and degree as to excite our wonder why and how death occurred.

There is an art, as well as a science of medicine, and, usually, medical inquiries end in the consideration of methods of management. In pneumonia the treatment should resolve itself into reasonable prophylaxis; in making the patient comfortable; in preventing excessive formation of toxins, in neutralizing them, in encouraging their elimination and increasing the resisting powers of the system against their action; in preventing, or managing properly, the complications which may arise. I regret that time will allow me to consider, cursorily, only one of the many interesting and important questions here presented.

Bleeding in pneumonia has been discussed for so many generations and from points of view so diverse that I approach the subject with reluctance, and it is only because I believe it a remedial resource which has no efficient substitute that I ask you to consider it at this time. It is not desirable that the former routine treatment of pneumonia by excessive bleedings should ever be restored to professional favor, yet I am sure that the physician who wholly abstains from venesection deprives his patient of a most potent remedy.

Venesection is not necessary in every case of pneumonia, and the patient, time and conditions should be carefully selected. The very young and the very old, the weak and the anemic, should not, as a rule, be bled; nor should those in whom the evidences of obstruction of the pulmonary circulation, or of increasing toxemia, is not marked, but in others in whom these conditions exist, the lancet should not be spared.

With an obstructed pulmonary circulation there is a damming back of the blood into the right cavities of the heart and general venous system. The pulse is not rapid and has considerable tension; the breathing is oppressed, accelerated and laborious; the patient is alarmed, and his anxiety is depicted in his countenance. This condition is usually met with only early and in plethoric and robust patients. In my experience the relief afforded in such cases by venesection has been immediate and remarkable. Should the patient have passed into a dull or comatose condition with the first brunt of the attack, imminent danger is clearly present. Here successful treatment depends upon ridding the system as speedily as possible of the poisonous matters circulating in the blood and overwhelming the central nervous system, and free bleeding is the remedy par excellence.

In another and much larger class of cases the patient successfully withstands the first onslaughts of the disease, but after a few days shows the indubitable signs of a profound toxemia, in a pulse which gradually increases in frequency while it loses in sustained force; in a high temperature; in restlessness and delirium; in salowness or duskiness of the surface, and these cases de-

mand not only venesection, but a cleansing of the blood as well. If blood is simply abstracted from the general circulation, the serum is quickly replaced by the absorption of fluids from the soft tissues. At this stage of the disease, however, these fluids are loaded with toxins and leucomains and bleeding alone may fail in its object as a blood-purifier. But if, in addition to venesection there is introduced into the circulation a bland and non-toxic fluid, equivalent in quantity to that withdrawn, we not only remove a great and oppressive quantity of offending material, but we dilute that which remains behind.

The method of procedure is of importance. My own practice is as follows: Venesection, to the extent of removing from four to sixteen or twenty ounces of blood, is done. If the symptoms of intoxication are profound, or if it is clearly evident that the patient will, and does, bear well the loss of blood, the bleeding should be a free one. If, on the contrary, opposite conditions prevail, the amount of blood withdrawn should be small. Indeed, in some of these cases, with profuse perspiration, free excretion of urine or, perhaps, diarrhea, bleeding may be omitted.

Simultaneously with the venesection, or immediately before or after, a solution, in distilled water, of chlorid of sodium, .7 per cent., chlorid of potassium, .23 per cent. and chlorid of calcium, .03 per cent., is injected, subcutaneously, in quantity approximating that of the blood withdrawn. Often four or six ounces may be injected later, and repeated at intervals, according to the effects produced. The injections are multiple and are made with a large-bore needle, preferably by gravity, into the subcutaneous tissues of the chest. The fluid is warmed, and ordinary precautions are taken. In some cases high enemata of the saline solution may be substituted for the subcutaneous injections, and, when well borne and retained, with equally good results.

If this method is followed as detailed it is quite free from danger. I have employed it in a number of cases and have seen absolutely no undesirable results—no chill; no rapid rise nor profound fall of temperature; no restlessness nor excitement; no collapse. On the contrary there has usually followed a gentle or profuse, but warm, perspiration; a free action of the kidneys; a clearing of the intellect and an abatement of cerebral excitement; a lessening of dyspnea; an improvement of the circulation. Such has been my experience when these measures have been resorted to in the early stages of the late toxemia, but if they have been delayed until evidences of approaching death were manifest the effects have been negative. In the one case the results of treatment have been satisfactory, and a fair proportion of patients have recovered; in the other they have, with this, as under every other plan of management with which I am acquainted, uniformly died.

In parenthesis: From first to last in pneumonia the vasomotor system, as reflected in the state of the capillaries, must be given assiduous attention. Failure in this direction, with capillary paresis, should be anticipated and met with efficient doses of digitalis and strychnia, and an occasional, carefully gauged, dose of morphia.

In conclusion: In spite of the fact that the ordinary management of this affection, in times past—recent as well as remote—has been, on the whole, signally unsatisfactory, and that that in vogue today is scarcely a promise of the advances of tomorrow, I believe that the immediate future will demonstrate pneumonia to be, certainly, a preventable and, largely, a curable disease; and that, in this field, the morning light of the 20th

century will see every reasonable hope of medical optimism abundantly realized.

[The series of papers on Pneumonia will be completed next week, when discussion will follow.]

THE BLOOD IN PNEUMONIA.*

BY ALFRED STENGEL, M.D.
PHILADELPHIA.

In discussing this aspect of the question before the Section I shall address myself only to the clinical examinations of the blood possible to the general practitioner. The bacteriologist has been able to isolate the pneumococcus from the blood of pneumonic cases, especially such as are complicated by secondary infectious foci; but this can only be accomplished by skilled investigators and in clinical laboratories. Similarly, the determination of the amount of fibrin in the blood is a matter that must be left to proficient chemists. The French have taught that the quantity of fibrin may be determined by a study of the reticulum formed under a cover-glass. This teaching is certainly very far from accurate. Even if the method were reliable, the quantity of fibrin in the blood is of little practical importance. The recent studies of Pfeiffer and others have shown that there is a notably increased amount of fibrin in the blood in leucocytosis, but there are many causes of leucocytosis and there is nothing peculiar to that of pneumonia, as far as its influence on fibrin is concerned. We are limited then in our study of the blood of pneumonia to the ordinary clinical examinations.

The points of importance that have been recognized by writers and investigators are these: In croupous pneumonia and in bronchopneumonia there is usually leucocytosis. This varies in degree and in duration. When the disease subsides, the leucocytes return to the normal number more or less quickly. There is rarely a critical decline in the leucocyte count comparable to that in temperature, further it is known that the leucocytosis is of the active polymorphous variety of Ehrlich, that is the actively ameboid corpuscles are increased more than the other forms—in other words, the leucocytosis is a chemotactic one. The eosinophilous cells are usually greatly reduced in numbers and some have claimed that they are absent. Finally, there is an undoubted relationship between the leucocyte count and prognosis, cases in which the number of white cells is normal or subnormal usually terminating fatally.

These facts have all been established, and in the main my observations tend to confirm each one of them. Going back somewhat to the consideration of the nature of leucocytosis, I may state with positiveness that this condition, at least when of the forms described in pneumonia, is the result of chemotactic influences. The toxic substances elaborated by the pneumococcus are positively chemotactic and attract to the circulation the ameboid polymorphous corpuscles. This, however, does not express all of the conditions, else there would probably be leucocytosis in every case. The additional element is the reaction of the tissues themselves to the irritant influence of toxic agents. I can not now go into the matter of the pathogenesis of leucocytosis at length, but suffice it to say that experimenters have been able to demonstrate that varying systemic conditions and varying doses of toxins, such as that of the bacillus pyocyaneus, occasion different grades of leucocytosis.

As a matter of practical experience, it has been found that when the systemic condition is bad, and the dose of intoxications over-powering, leucocytosis does not occur. This is an all but uniform relation; but that it is not universal appears from such cases as one under my observation in which a man of 34 years of age, with pneumonia of the left base, made a speedy recovery, with crisis on the eighth day, though his leucocyte count was only 6000. It is possible, of course, that in such instances, the absence of leucocytosis was due to mildness of the systemic intoxication, rather than to the general condition. It must not be forgotten, however, that the leucocytosis may be directly advantageous.

The opinion of bacteriologists, even in Germany, is moving in the direction of Metchnikoff's theory, and it is not improbable that the leucocytosis of pneumonia is a conservative process. Some color is lent to this view by the results obtained by the induction of artificial abscesses and leucocytosis in the treatment of pneumonia. This treatment, suggested by Fochier and first practiced by Lepine, consists in producing local suppuration by injection of turpentin. There results a leucocytosis that may have some connection with the favorable results of the treatment. In one case in which I employed it on account of delayed resolution, the good result was apparently due directly to this treatment. This result, however, might be due to the local relief afforded by abstraction of large numbers of leucocytes from the lungs rather than to phagocytic influence.

I must, however, return to the practical clinical observations in pneumonia. It has been found, as I have stated, that leucocytosis is usually an indication of an unfavorable outcome. The reverse, however, can not be asserted. I have repeatedly seen death occur in pneumonia, particularly in children, when there was enormous leucocytosis. One case in an adult in whom there were 30,000 leucocytes per c.mm. and 98.5 per cent. of polymorphous leucocytes, and another in a child in whom I found 80,000 white cells, may be cited.

As to the differential count, little can be said in addition to what has been said. The leucocytosis is simply of the ordinary inflammatory type. In some cases, I have found a considerable proportion of eosinophilous cells, but in the great majority these forms are reduced in number.

I have not spoken of the attempts to produce an anti-pneumococcal serum, because this subject is after all largely in the experimental stage, and no practically useful results have as yet been obtained.

[The series of papers on pneumonia will be completed next week, when discussion will follow.]

PNEUMONIA OF THE AGED.*

BY ROBERT H. BABCOCK, M.D.
CHICAGO.

This paper is presented with no expectation of its offering anything new, but because the importance of the subject should lend it interest. This importance arises from the fact that pneumonia is far more prevalent among old people than is generally supposed, while the mortality for which it is responsible is so great that in the language of William Osler, "pneumonia may be said to be the natural end of old people in this country." Moreover, the phraseology of the title "pneumonia of the aged" rather than "in the aged" was

*Presented to the Section on Practice of Medicine at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

chosen because of my conviction that the form which so mercilessly strikes down those already enfeebled by senility is due to the pneumococcus and not to an extension of bronchitis. We have been so accustomed to think of the intimate association of old age and bronchitis in the causation of catarrhal pneumonia that I fear the statement in the foregoing sentence will impress many as extreme. For years my conception of the pathology of the affection under consideration was dominated by the statements of earlier writers, that bronchopneumonia is likely to attack either extreme of life as the result of extension of bronchitis.

I do not wish to ignore the occurrence, nay, the frequency, of bronchopneumonia in the aged. I would only insist that when it occurs it is caused by pneumococcus or other infection and should not be regarded as an extension of an already existing bronchitis. Nevertheless, it is my conviction that the pneumonia excited by the pneumococcus is lobar rather than lobular, and that a failure to clinically distinguish these two forms may readily occur because the lobar pneumonia is not frank and typical in its manifestations. It is attended with profound exhaustion and debility, and in other respects displays a symptomatology not unlike that of the lobular form. Moreover, its physical signs are so often obscured by an associated bronchitis as to make it still more closely resemble a catarrhal inflammation. Finally confusion of one with the other may be favored in those cases in which bronchitis precedes, indeed, prepares the soil for the development of the lobar pneumonia. In a word, although the decrepitude of old age predisposes to bronchopneumonia, nevertheless, the form that chiefly attacks aged persons the same as hearty young adults is lobar.

Its prevalence is well shown in the statistics collected and published by E. F. Wells¹ as follows: Of 12,147 cases in 1889, from fourteen different authors, 11 per cent. occurred in persons over 60. In proportion to other diseases in persons over 60, 29.2 per cent. were cases of pneumonia. Per 1000 of population 10.36 per cent. of persons died of pneumonia, whereas of all ages together below 60 only 8.38 per cent. died of this disease. A further study of the figures collected by Wells shows that the mortality from pneumonia in old age exceeds that of any other. Of the authors thus tabulated the range of mortality is from 10 to 80 per cent., some being manifestly too low as others are too high. Wells himself gives it as his opinion that the death-rate is probably from 60 to 75 per cent. This is truly awful, and when one considers also the very great prevalence of this malady among the senile, it is obvious how just is Osler's statement that pneumonia is the special enemy of the aged.

These considerations emphasize the importance of an early recognition and prompt treatment of this disease in the old. The prime essential in its diagnosis is the remembrance of the fact stated by most authors that senile pneumonia is often latent and comes on insidiously. It may be ushered in by a chill or ill-defined chilly sensations, a chilliness creeping up the back, but often these sensations are too indefinite to attract attention. Sometimes there is nothing more than coldness of the extremities and nose, which we all know is a common experience on the part of old people with feeble circulation. Likewise pronounced rigors may or may not be present, or there might be a slight shivering, or even this last may escape attention. In short, the onset of

the disease may be declared by nothing more marked than a feeling of malaise or unusual lassitude, in consequence of which the patient takes to the bed. Such was the declaration of one case seen by me recently in a lady of 78. Pain is also a very variable symptom, as to seat, character and intensity. In some persons it may be absent altogether; in others it may be a quite characteristic cutting pain in the affected side; by some this may be complained of in regions below the diaphragm—in the epigastrium or hypochondrium—while not infrequently aching pains "in the bones" may be felt in the back and legs, with stiffness of the joints. Similarly there may be all possible gradations in the severity of these diverse pains, from mildness to a degree of almost unbearable severity causing the patient to groan or even cry out. The patient mentioned above declared she suffered no pain at all, while in another lady, 77 years of age, the disease was ushered in by mental and physical torpor, a feeling of general coldness and increasing pain throughout the body. Her headache, backache and aching of the lower extremities finally grew so intense that she sought her bed. At no time, however, did she complain of a defined pain in her chest, although a few days subsequently she spoke of it hurting her to cough. Yet in still a third old lady of 78 years, seen about that same time and in whom pneumonia was much more typical in both signs and symptoms, there was considerable pain in the affected side.

Like the other symptoms, cough is subject to considerable diversity in both frequency and severity. It may be so slight and infrequent as to hardly attract attention. Indeed a troublesome cough of the initial bronchitis may become almost suppressed upon the occurrence of the pneumonia.

On the other hand it may be both frequent and severe, or it may be violent but infrequent, being quite paroxysmal in character. In the first patient I have mentioned, the cough was sufficiently troublesome to require occasional doses of codein, while in the second it was also quite frequent. In a fourth old lady of 87 years, who succumbed, the cough was almost incessant for several nights, and did much to wear out her strength.

These four cases also illustrate the differences in regard to the sputum. In the last this was abundant, mucoserous, so tenacious and stringy that the patient often had to take it from her mouth with her fingers. In the third case expectoration, while not copious, was yet rusty; while in the other two, sputum was scanty and somewhat frothy, with sticky pellets. I recall an old man who died in my care years ago, who never had any expectoration. Regarding the sputum it is well to remember that it may be entirely wanting in the pneumonia of the aged, and even when present is most often not rusty.

Dyspnea is another symptom which may be said to be notable chiefly for its absence, or if present at all is insignificant. It was not noticed in any of the four old ladies I have selected as typifying the features of senile pneumonia. The respirations were accelerated, ranging from 28 to 32 and were shallow. In only one case, that with rusty sputum, did they appear hurried to casual inspection.

In respect, therefore, to the trifling respiratory embarrassment manifested in the course of senile pneumonia, these four patients illustrated well the general rule.

I believe it is a fact that persons of feeble vitality exhibit but slight febrile reaction to those affections

¹Jour. A. M. A., June 22, 1889.

characterized by fever. In my experience, old people with pneumonia rarely show much elevation of body temperature, except perhaps at the outset. And yet, Grissolle says that of all acute affections attacking the old, pneumonia produces the highest temperature. Some fever is always present, probably; but it frequently is so slight and the surface of the body, particularly those parts exposed to the air, feels so cool to the hand that unless the physician make thermometric observations, he is likely to be deceived into thinking the patient has no fever. In my old lady with the most nearly classic symptoms of pneumonia the temperature averaged between 101 and 102 F., while in the others it ranged not far from 100F. In No. 2 it fluctuated considerably and often quite abruptly, mounting a few times to 102 F., or more, and then falling to its previously low mark. The practitioner, therefore, should not be lured by such low temperatures into the belief that a pneumonia has not yet set in. It will be the exception when his aged pneumonia patient manifests a febrile range of 103 F.

The heart of the old, even when adequate to all demands of health, quickly shows weakness under conditions of disease or accident. It is not strange, therefore, if when pneumonia, which often overpowers the heart of the young and robust, attacks the aged, the pulse should denote cardiac feebleness. Of course, this will differ in degree in individual cases, being determined no doubt by the intensity of the toxemia as much as, or perhaps even more than, by the condition of the heart muscle. In my experience it is not so likely to be the acceleration of the pulse that will arrest attention, as it is its irregularity in force, perchance intermittence, and its want of strength. Its rate may vary considerably in different cases and even in the same case from time to time, but it will always show more or less weakness. In all cases, even if cardiac asthenia is not striking, it is well to remember that the senile heart is apt to give out suddenly and unexpectedly.

General prostration is also a noticeable feature of this disease in the old. It is very common for the patient to complain of feeling tired and weak, even when still capable of putting forth considerable exertion. The old lady of 87 whom I saw in consultation in a distant Michigan town, insisted on getting out of bed to use the night stool, although she spoke repeatedly of her weakness and fatigue. The prostration, so pronounced a feature of this class of cases, is undoubtedly an expression of the toxic action of the specific infection on the nervous system.

Cerebral disturbances, such as low, muttering delirium, may be observed, but in the cases seen by me this past winter the mind remained unaffected.

Anorexia was present in all, but in the old, desire for food, usually slight at all times, is readily lost altogether. In two there was more or less gastric uneasiness and in the patient of 87 vomiting was very distressing for the first few days. Such disturbance, however, is rather to be expected than otherwise; and the same remark can be made regarding the changes in the urine. They are incident to the pneumonia in part and also in part to the age. It should always be remembered that the senile are particularly prone to renal inadequacy, and therefore it is the kidneys and the heart that should be closely watched in this affection of the aged. Important as this is in pneumonia in all ages, it is especially important in old people.

From the preceding rather cursory description of its symptomatology, it is plain that pneumonia in the aged is often very unlike the same malady in healthy

young adults. Indeed it is so atypical in the large majority of instances that one might not inaccurately say that pneumonia in the old displays a type peculiar to itself and quite distinctive. In fact, my experience leads me to agree with the great French clinician, Grissolle, who has said in effect that pneumonia is so prevalent among the aged that, although it is often latent, and distinctive physical signs are wanting, the symptoms alone of chill, fever and prostration, unless due to some other very obvious cause, will warrant a diagnosis of pneumonia.

Although the disease may and generally does terminate by crisis, yet this is likely not to be so striking as in the sthenic type of the affection. If pyrexia has been low, the critical defervescence may be readily overlooked and is quite likely to be if the temperature has been remittent or has not been recorded with frequency and regularity. The profuseness of perspiration and the relief from pain will be commensurate with the previous intensity of the symptoms.

If one depends for diagnosis on the discovery of the usual physical signs of pneumonia, he will often find himself left in the lurch. In but one of my four patients so frequently alluded to was dulness over the greater part of a lobe, with bronchial breathing and fine moist râles, crepitant and subcrepitant, discovered. In the others a small circumscribed patch of solidified lung at one or the other base behind was recognized, on firm pressure and deep percussion, but a sense of increased resistance and impaired resonance rather than by distinct dulness. This was confirmed by the recognition of bronchial respiration and pectoriloquy over the suspected area. Careful comparison of the two sides is always advisable and generally necessary. In one instance crepitant râles were detected; in another no râles, while in the others the extensive bronchitis obscured the breath-sounds and crepitant râles except over a very limited patch where there were also impaired resonance and bronchial breathing. In a word, one may consider himself most fortunate if he derive any definite information or assistance from the examination of the chest. Reliance must be placed often on the history, the symptoms, and, if a little sputum can be obtained, on its tenacity and the presence therein of the specific diplococcus.

The gravity of the prognosis in all cases is sufficiently indicated by the high death-rate. But to prognosticate correctly in individual instances will often require ripe judgment and great experience. Aside from complications and the condition of the heart, the importance of which is too well known to make a detailed statement necessary here, it is the degree of toxemia, shown by delirium, cardiac feebleness and general exhaustion, also the patient's ability to take food, on which a prediction should be based. Profound prostration coming on early and increasing in spite of generous stimulation is of evil import since it is an indication of the effect of the toxins on the nerve-centers. If the patient can not take and assimilate sufficient nourishment the case is hopeless from the start. In a word, the more adynamic the type of the disease, the worse the prospect of recovery. How much reliance can be placed on leucocytosis or on different degrees of the same has not yet been determined. Cases in which this has been very marked have yet proved fatal.

Time forbids my discussion of the treatment *in extenso*. I will only emphasize four points:

1. It is my conviction that aged pneumonia patients bear well and require large doses of strychnin.

2. Stimulants, as alcohol, in small or moderate doses, and ammonia in frequently repeated doses are usually highly beneficial.

3. As little medicine as will meet the indications should be given, for fear of upsetting the stomach and thereby destroying what few chances the patients have at the best.

4. Because of the tendency to renal insufficiency, the nourishment should be largely fluid, and nothing is so suitable as milk and properly prepared beef juice.

[The series of papers on Pneumonia will be completed next week, when discussion will follow.]

PNEUMONIA.

ITS COMPLICATIONS AND SEQUELAE*

BY R. B. PREHLE, M.D.

CHICAGO.

The frequency with which pneumonia is associated with inflammatory processes in certain other organs, notably the meninges and the endocardium, has been known to physicians almost since the beginning of medicine, and while some suggested that there must be some relation closer than merely accidental between them, this could not be proven until the discovery of the active causal agent by Fraenkel, Weichselbaum, Talamon, Sternberg and others. This discovery has not, however, solved all the problems, and there are to-day many complications for which we are forced to adopt explanations which, as Jurgensen says, explained x by y . The proposed division of the complications into three groups—mechanical, infectious and toxic—is not to be understood as final or exclusive, for certain complications placed by me in one group would be placed equally well by another in another group. For example, I have placed the cardiac dilatation in the mechanical group, believing that the obstruction to the flow of blood through the lungs is the main factor in the causation of the cardiac dilatation and insufficiency, but there can be no doubt that myocardial degeneration due to the action of toxins is also an important element, and indeed is regarded by some as the main element. The renal changes, also, can be matters of dispute, for it is by no means certain whether they are exclusively infectious, or toxic, or what is more likely, both.

The first complication which I will mention, while not common, causes such a marked change from the physical signs common to pneumonia that it is of more than ordinary interest, i. e., the plugging of the large bronchi by fibrinous exudate. So far as etiology and pathology are concerned, these cases do not differ from an ordinary case, and there is, in my opinion, no justification for the effort of Grancher and Faisan and other French authors to make it a morbid entity. From theoretical grounds it is easy to understand what effect this filling of the bronchi would have upon the physical signs. Palpation would show the absence of the vocal fremitus; percussion would yield the intense dullness and resistance which comes from solid organs; auscultation sounds. In a word, in place of the signs of pneumonia would show an absence of the respiratory and voice we would find those of a pleural effusion. These are indeed the physical signs which these cases of massive pneumonia or splenopneumonia present. There are certain points about them which usually lead to a suspicion of their true nature; the mode of onset with a well-

marked chill and rise of temperature is that of a pneumonia rather than of a pleurisy. The dyspnea and cyanosis are more marked than ordinarily seen with pleurisy. There is a more or less abundant sticky expectorate. Closer attention to the physical signs will show differences from those ordinarily found in pleurisy. The pressure symptoms are practically always absent. There is no displacement of the heart or liver. The sternal deviation described by Pietres as a sign of pleurisy with effusion is wanting; Traube's half-moon space, when the process is left-sided. The vocal fremitus, completely absent over the lower portion of the dullness, becomes gradually more manifest as one passes upward, and does not show the sudden increase in intensity so often seen with pleural effusions. These numerous points strongly suggest the presence of a pneumonia rather than a pleurisy, but they do no more than suggest. Exploratory puncture is the only way to remove the doubt. Such cases as these are considerably more common in the male than in the female; 24 to 3 in the 27 cases collected by Queyrat. They are also more common on the left than on the right; 23 left to 4 right. Their course does not differ from that of the ordinary pneumonia, except that the evolution is somewhat slower, running from eight to ten days, and the resolution is usually somewhat delayed; recovery is the rule; 24 in 27 cases. The two following cases well illustrate the points of likeness and difference between this condition and pleurisy, and also the possibility of mistaking this condition for pericarditis and effusion:

CASE 1.—C. H., male, 37 years of age, a laborer, moderate alcoholic, had pneumonia when very young. Three days ago he had a chill, followed by pain in the right chest, labored breathing, fever and loss of appetite. He coughs slightly, but raises nothing.

Examination shows a strong well-nourished man, markedly cyanotic with icterus. He lies on the right side; is suffering from marked dyspnea; has occasional spasmodic cough, without expectoration. His chest is well developed; the right side is fuller than the left and shows less excussion. Percussion on right side shows area of hyper-resonance above the third rib anteriorly; below this intense dullness and resistance; the same posteriorly. Percussion of the left lung unchanged; vocal fremitus lost over the right side, retained over the left. Auscultation shows entire absence of breath and voice-sounds on the right side. The heart is normal in size, position and sounds; the abdomen negative; liver and spleen not palpable; nervous system negative. The urine is high-colored, sp. gr. 1030, and contains no albumin, but shows many granular casts. Pulse is 106; temperature 101.2; respirations 56. The pulse ranged from 156 to 152; the temperature from 101.2 to 105; the respirations from 40 to 64, for forty-eight hours, until death.

We have here the common history for the onset of pneumonia, but had the physical signs of a large pleural effusion, minus the usual pressure effects upon the heart and liver. The only physical signs which could be interpreted as due to pressure were the fullness of the right side of the chest, and the hyper-resonance anteriorly and above. The dyspnea and cyanosis were extraordinary, even for an effusion reaching the third rib. Exploratory puncture yielded no fluid.

Diagnosis, massive pneumonia.

An autopsy, by Dr. Hektoen, revealed the right pleural cavity obliterated by old adhesions; the right lung solid, weighing 2100 grams, with grayish granular surface; many fibrous casts in the bronchi. The left pleural cavity and lung were normal, also the heart and pericardium. The kidneys weighed 375 grams and were smooth; capsule not adherent; grayish red color; cut surface vascular, with distinct cortical markings. Examination otherwise was negative.

The autopsy thus confirms the clinical diagnosis. The plugging of the bronchi sufficiently explains the marked variation from the usual physical signs of pneumonia.

CASE 2.—A male, Italian, about 22 years of age; present illness began suddenly with a chill followed by fever, cough and pain in the chest.

Examination shows an area of absolute dullness, leaving the liver dullness and passing obliquely upward and crossing the

*Presented to the Section on Practice of Medicine, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1899.

sternum at the third rib, then passing in a slightly curved line downward and outward an inch and a half to the left of the easily visible apex-beat in the fifth intercostal space, and well within the nipple line. This dullness was very intense and the resistance great. No breath or voice-sounds were heard over this area. Heart-sounds were regular but feeble; no friction.

The diagnosis of pericarditis with effusion was made, while at the same time it was noted that the dullness crossed the sternum at a very low level for pericardial effusion, reaching the right nipple line and passing an inch and a half beyond the apex.

The patient died three hours after entrance, and the autopsy showed an intact pericardium. The dullness was due to two pneumonic areas, one right and one left, bordering on the heart. The afferent bronchi to these foci were plugged. A correct diagnosis might perhaps have been made had the patient been longer under observation, but with the conditions such as they were, it is evident that the massive pneumonia may simulate a pericarditis as well as a pleurisy.

The cardiac complications belonging in this group are common, and, in view of Jurgensen's statement that the immediate cause of the majority of deaths in pneumonia is cardiac insufficiency, must be regarded as important. The explanation of the frequency of the cardiac dilatation is plain. The presence of the infiltration of the lungs greatly increases the work of the heart, and at the same time, by decreasing the supply of oxygen, impairs the nutrition of the heart muscle. It increases the demand and lessens the supply. This is, I believe, the *modus operandi* in most cases, but were it the only *modus* the cardiac insufficiency should be directly proportional to the extent of the pneumonic process, providing the heart was primarily intact. Exceptionally, however, there is a manifest disproportion between the intensity of the cardiac symptoms and the extent of the pneumonia. In these cases it is necessary to assume that some third influence is at work, and doubtless this is the intoxication of the organism as a whole, and the heart muscle in particular, with the specific toxins of the pneumococcus. In the days previous to the development of bacteriology the cardiac insufficiency was referred to the action of the fever upon the heart muscle, although it was known then even that there was no direct relation between the degree of the temperature and the danger of the heart failure. They noted, as we do today, the often marked disproportion between the general and local symptoms.

The symptoms pointing to threatening cardiac failure are in general such as occur under like circumstances, irrespective of the cause. The pulse-rate is of some significance. In 100 cases I found the average maximum pulse-rate to be 134; the average for 30 fatal cases was 144; the average for 70 non-fatal cases was 131, but 8 of these passed the average for the fatal cases. Griesinger states that more than one-third of the cases where the pulse-rate reaches 120 die. Of 73 cases in which the pulse passed this point, 30, that is 41 per cent., died. The highest pulse-rate reached by a case which recovered was 160, with a pneumonia on the left upper lobe. Such figures as these have only a very general value, for the individual characteristics of the patient influence the pulse-rate to a marked degree. A pulse of 160 means much less in a nervous individual than in one who is a phlegmatic; much less in a small individual than in a large.

Irregularity of the pulse previous to the crisis should always cause anxiety, suggesting as it does an antecedent or developing myocarditis, or other cardiac complications. Certain forms of arrhythmia, as the pulsus paradoxus, are of no significance when accompanying

upper-lobe pneumonia. Here, too, we sometimes find asymmetry of the radial pulses. Bradycardia even to 40 after the crisis is not uncommon, and should excite no especial anxiety.

Examination of the heart often shows changes which, according to their degree and character, are to be regarded as symptoms or complications. A moderate increase in the cardiac dullness to the right can scarcely be regarded as a complication unless accompanied by other symptoms pointing toward cardiac insufficiency. We must mention that Aufrecht draws attention to the fact that in left-sided pneumonias the heart may be displaced to the right, thus simulating a dilatation of the heart.

Certain auscultatory changes are so common that their absence should arouse more attention than their presence. Accentuation of the second pulmonary tone is frequent and is the expression of the increased blood-pressure in the pulmonary system. The degree of the accentuation is dependent upon so many factors, especially upon the conditions of conductivity, that no inference can be drawn from the intensity of the tone alone. If, however, during the course of the pneumonia the accentuation of the second tone decreases markedly without any improvement in the condition of the lung, it must be regarded as a sign of threatening failure of the right heart.

Systolic murmurs frequently appear over the heart, and their interpretation requires considerable care, and often an absolute differentiation between organic and accidental murmurs can be made only after the lapse of days or weeks. The difficulty lies in the fact that the same patient will present an increase of the heart dullness to the right, an accentuation of the second pulmonary tone, and a systolic murmur, i. e., all the cardinal symptoms of the mitral insufficiency appear in the course of the disease, frequently accompanied by endocarditis. We must remember that this combination of findings means less in the pneumonias than in the other febrile diseases.

Fraentzel has drawn attention to the appearance of the gallop rhythm over the heart, and here as elsewhere it is a sign of impending heart failure. Fraentzel has noted it in 25 cases of pneumonia, 4 times in conjunction with other disturbing symptoms just before the crisis; 7 times during the day after the crisis with general collapse. In other cases it was either the first or an early symptom of cardiac weakness at the height of the disease. Among the last mentioned cases only one lived for two days after the gallop rhythm was first heard.

ICTERUS.

The frequency with which icterus complicates pneumonia varies greatly according to the statements of the various authors. This variation is due in part to the difference in the epidemics recorded, and in part to the attention paid to the jaundice. In many cases the jaundice is so slight and evidently of so little significance that it is not noted. There can also be no doubt of the fact that jaundice occurs more frequently in some epidemics than in others. In the table given by Jurgensen the figures vary over an astonishing range; 0.6 per cent. for Vienna; 0.9 per cent. for Stockholm, and 28.3 per cent. for Basel. In one list of cases from Basel the icterus was found in 5.5 per cent. of the cases, and in a later list, in which especial attention was paid to the icterus, the above figure of 28.3 per cent. was found. Aufrecht found 15 cases of icterus in 1501 cases of pneumonia, that is, 1 per cent. From personal experience I would say that 28 per cent. is much more nearly cor-

rect than 1 per cent., if one includes all patients who show conjunctival icterus.

The pathogenesis of the complicating icterus has been, and still is, a matter of dispute, and probably there are several ways in which the icterus develops. Some of the proposed theories can be quite readily excluded. Venous stasis, with resultant compression of the fine bile capillaries, has been suggested, but this is liable to the objection that jaundice results in this way only when the venous stasis is very marked, and it should be accompanied by the other results of the same cause. The jaundice seen in pneumonia usually occurs without any signs of venous stasis elsewhere, and the autopsies on icteric pneumonics do not show venous stasis.

Retention of bile consequent upon lessened movement of the diaphragm is another suggestion, but were this so, jaundice should occur in other conditions of lessened respiratory movement, such as pleurisy, with equal frequency. Jaundice ought also to be more common in pneumonias of the right lower lobe, while it is not proportionately so. Pétrow studied 67 cases of right-sided pneumonia with attention to this point, and found only 6 were icteric, and in all of these there was some lesion of the bile-duct.

Formation of the bile pigments from the red blood-corpuscles broken down during the absorption of the exudate is another suggestion, but may be excluded by the fact that the icterus occurs usually before the absorption of the exudate.

Banti, basing his opinion upon 15 cases, studied in an epidemic of pneumonia in Florence, believes that the diplococcus of pneumonia has a peculiar hemolytic power, and that the icterus is the result of this hemolytic power, and that the icterus is the result of this hemolysis. More than one-half of these cases died, and at the autopsies the bile-ducts were patent, the bile thick, and the feces deeply stained. Cultures from these cases produced hemoglobinuria in animals, while cultures from cases without icterus did not.

Lastly, the icterus has been referred to a catarrh of the bile-ducts or duodenum, or both, and this doubtless is the cause of many cases. Pétrow, in 1897, reports the result of autopsies in 13 cases of pneumonia with jaundice, and in all cases found a lesion of the biliary duct—in 8 cases duodenitis, in 2 cases accompanied by hypertrophic cirrhosis, in 5 cases an angiolitis. Gilbert and Grénet report three autopsies with inflammation of the gall-ducts, in each case due to the infection of the ducts with the bacillus coli communis.

From this review it would seem that the icterus complicating pneumonia may be due to an obstructing inflammation of the bile-ducts, or it may be the so-called hematogenous or toxic jaundice, remembering always that the experiments of Naunyn and Minkowsky have shown that this form of jaundice is only apparently hematogenous, and that all are really hepatogenous. It seems probable that these cases also are really cases of obstructive jaundice, but here the obstruction is in an infinite number of small ducts instead of one or a few large ones. We can not agree with Pétrow, who considers the jaundice as an accidental complication, the frequency with which it occurs being sufficient to exclude this. The experiments of Banti and the well-known clinical fact that jaundice is more common in some epidemics than in others suggests differences in the virulence of the infective agent.

The effect of jaundice upon the clinical source of the pneumonia is dependent in part upon the intensity and in part on the immediate cause of the jaundice. In

cases of duodenitis and localized angiolitis we need consider only the intensity, but where there is reason to believe that the jaundice is due to the character of the infection the intensity is of less importance. The effect upon the mortality is variously estimated by various authors. Traube regarded it as a very dangerous complication. Mosler puts the mortality at 73 per cent., Fisser at 20 per cent., and Banti lost more than one-half of 15 cases. Others, as Huss and Lebert, say that the jaundice has no injurious influence upon the course of the pneumonia. The effect on the mortality is determined by the intensity and the cause.

Jaundice affects the course of the pneumonia by the influence which it exerts upon the nervous system, the heart, the gastro-intestinal tract and the kidneys. It affects especially the sensorium, causing a stupor which appears very early; lessens the sensibility and excites delirium. Traube notes that these patients are very often entirely insensible to the pain caused by the accompanying pleurisy. The effect on the heart may be still more serious. French authors have drawn attention to the fact that jaundice, irrespective of its cause, may excite considerable dilatation of the right ventricle, and I have personally been able to repeatedly confirm this observation. It is at once manifest how dangerous a jaundice may be when added to a disease which, like pneumonia, usually causes some dilatation of the right heart.

The gastro-intestinal symptoms are nausea, vomiting, diarrhea, and meteorism. Any or even all of these may, however, be absent. Meteorism is said by Traube to be of unfavorable prognostic significance. The color of the stools is important as throwing some light upon the site of the obstruction to the outflow of bile. They are clay-colored when the obstruction is at the duodenum, but may be quite dark, as in Banti's cases, when the obstruction is at the smaller ducts. The kidneys may be affected in such a way that albuminuria or even nephritis results. Another interesting manifestation of the jaundice sometimes seen is green-colored sputum.

In the second, or infectious, group are placed those complications due to the presence of the pneumococcus in organs other than the lungs. The infective agent reaches these organs in a variety of ways; by the blood or lymph vessels, or by extension along ducts or by direct extension. Certain organs, as the joints and remote soft parts, are infected only by means of the blood-current. The pleura and pericardium may be infected in this way, or more often by direct extension. The meninges may be infected through the blood, by extension from the middle-ear or nasal air-spaces, or, according to Weichselbaum, by extension through the cervical lymph-channels from the mediastinum. The middle ear is oftentimes affected by extension along the Eustachian tube; the parotid gland by extension along Steno's duct. The method of extension is important, for when the extension is along the blood-channels there is usually, but by no means always, multiple secondary localization of the bacteria, while the extension by lymph-channels or ducts is a local process.

The pneumococcus has been repeatedly demonstrated in the circulating blood in cases of pneumonia without affecting the clinical symptoms of the primary disease. They are doubtless present in many cases without their presence being suspected, and inasmuch as the number of record cases is still small, no very definite statements can be made. Sello examined 48 cases by venous puncture, during life, with negative results in 26, of whom 9 died; 12 positiv results, with 10 deaths. Of the two patients who recovered, one had a pneumococcus

emphyema, and one a pyemia. These cases, with others reported, show what one would expect, that the presence of the pneumococcus in the blood makes the prognosis unfavorable and complications due to secondary localization of the pneumococcus common.

After entering the blood the pneumococcus may cause either a general infection in the shape of a septicemia or pyemia, or may localize itself in one focus, causing a meningitis, a paronychia, a panophthalmitis, and so forth. The clinical picture resulting from such infection is too manifold to permit of general description, but the following clinical cases will serve as illustrations:

CASE 3.—Mrs. N. S., a widow, aged 25 years, entered Dec. 31, 1898. She had had the measles and whooping-cough as a

Case 3.—Pneumococcus pneumonia, septicemia and other otitis media.

child; pneumonia one and two years ago, and had been feeling poorly for a week, with "a cold in the head" and loose cough. Two days before entering she had a chill lasting fifteen or twenty minutes, followed by fever. Immediately after the

chill sharp pain was felt in the right side, in the axillary region, aggravated by coughing or deep breathing; a hard, painful cough, later expectoration of white tenacious material.

Examination showed her to be poorly nourished; slender and small; mind clear; skin moist; eyes showing some exophthalmus; pupils reacting to light and accommodation; lips dry; cyanosis and icterus. Her chest was small and narrow, respirations rapid and jerky. There was friction fremitus in the right axilla; dullness over the right lower lobe posteriorly, and over the same area crepitant râles. Friction and tubular breathing. Over the left lower lobe posteriorly there were fine mucous râles. The heart was negative; pulse rapid, full and of medium tension. The liver extended two finger-lengths below the costal arch and was tender. The spleen was not palpable; urine 1020, acid, clear yellow, containing no albumin nor formed elements. Temperature, pulse and respiration were as in chart.

Diagnosis, pneumonia of the right lower lobe.

January 9, a spot of consolidation was noted in the left lower lobe, and in the left upper lobe, with a temperature of 98.7; pulse 112, and respirations, 44. Pneumococci appeared in the sputum.

January 13, an area of consolidation appeared in the right upper lobe.

January 17, cultures from the blood obtained by venous puncture showed pneumococci.

January 18, there was purulent discharge from the left ear; pneumococci in the pus. From then on gradual recovery, leaving the hospital one month after entrance.

We have here what at first seemed to be an ordinary pneumococcus pneumonia. Its course was prolonged by later transient localization in other lobes than the one primarily involved. Without there being any special reason to suspect the presence of the pneumococci in the blood, they were found easily and in large numbers, being present also in blood smears. Whether or not the complicating otitis media was due to localization from the blood or extension through the throat could not be determined, but was probably the latter.

CASE 4.—Grace K., single, entered Dec. 4, 1898. Had scarlet fever as a child; had cholera ten years ago, lasting for some months. Since then she has had trouble with her heart. She had been fairly well, until five weeks previous to entrance, when illness began with a dull pain in the fingers, thighs, and muscles generally, but not involving the joints. For a few nights after the onset she had night sweats, and when these stopped the cough began and continued with yellow mucopurulent expectorate. Has had dyspnea on lying down and on exertion; no swelling of the feet; appetite fair, but had distress after eating.

Examination showed a small, poorly nourished woman, about 25 years of age. She had slight cyanosis on lying down; no edema. Examination of the lungs showed only generally diffused moist râles. Apex-beat of the heart was external to the nipple line in the fifth interspace, first tone at apex easily palpable; presystolic thrill over the apex; second pulmonary tone palpable. There was absolute cardiac dullness to the third rib above, to and a little beyond the right border of the sternum to the apex-beat, with systolic and presystolic murmurs at apex. The first tone at the apex and the second pulmonary tone were accentuated; aortic tones pure. The liver was slightly enlarged; spleen not palpable. Urine, 1030; contained no albumin nor casts. Temperature was 101; pulse 96; respirations 32. Course of the temperature and so forth is shown in chart.

Diagnosis, acute exacerbation of an old mitral endocarditis. December 7, diffuse moist and crepitant râles over both lungs; no bronchial breathing; cough, but no expectorate.

December 12, after a normal temperature for three days, the temperature rose suddenly to 104; the pulse 120; respirations 24. Crepitant râles appeared over the right middle and lower lobe without dullness or bronchial breathing. There was bloody sputum containing pneumococci.

December 15, dullness of the right middle and part of the left lower lobe was noted, with bronchial breathing and crepitant râles; cardiac dullness increased beyond the size at entrance, with pericardial friction. Blood shows 24,541 leucocytes. Smears and cultures show pneumococci.

December 17, blood smears show pneumococci. The condition gradually improved, the temperature fell by lysis, but the pulse and respiration kept up. The lungs gradually cleared, heart condition did not change. Pneumococci found at intervals until December 31, when the blood examination

left; reacted to light. There was rigidity of the neck; no paralysis; no Kernig sign. Pulse was 96; axillary temperature 99; respirations 28. Lumbar puncture showed diplococci answering the description of the pneumococcus; extracellular.

December 2, pulse was 120; axillary temperature 100.3; respirations 48. There was coma; slight icterus; no eruption; retraction of the head and rigidity of the neck; joints as before; no paralyses. Bilateral choked disc was more marked in the left.

December 3, pulse was 120; temperature 100.3 per rectum; respirations 60. Resonance over both lower lobes was impaired; more marked in left than right; breath-sounds loud and accompanied by a few crepitant râles. The heart was not enlarged; both basal tones were pure and accentuated; pericardial friction. There was slight external strabismus; right-sided ptosis; head turned to the right; beginning herpes labialis on the right side. Left wrist was punctured, yielding a few drops of thick whitish mucopus, showing pneumococci. Blood smears show the same organism. Lumbar puncture was repeated, but no fluid obtained.

Diagnosis: Diffuse infection by the pneumococci, causing meningitis, pericarditis, and multiple arthritis. Autopsy, by Dr. Hektoen, showed a small amount of purulent fluid in the pericardium; lungs showed hypostasis below and an old healed tuberculosis in the right apex. The kidneys showed an acute degeneration; brain and cord, diffuse purulent meningitis, and multiple arthritis. Bacteriologic examination showed pneumococci in the blood, pericardium, meninges and joints.

CASE 6.—J. M., male, a patient of Dr. Billings, entered March 2, 1899. He was comatose and unable to give any account of himself.

Examination showed right eye closed; left held open; heart negative. Lungs showed dulness, with high-pitched breathing over the left lower lobe with friction. Abdomen: Liver was palpable; spleen, not. Pulse 80; temperature 102 in the axilla; respirations 22. All rose gradually till death on the sixth day.

Lumbar puncture yielded a diplococcus which by stain, culture and inoculation proved to be the diplococcus of pneumonia. Anatomical diagnosis at autopsy: Purulent cerebrospinal meningitis, acute endocarditis, pulmonary edema, cloudy swelling of the kidneys.

(To be continued.)

[This series of papers on Pneumonia will be completed next week when discussion will follow.]

ASEPSIS OF HANDS OF THE SURGEON AND SKIN OF THE PATIENT.*

BY CARL BECK, M.D.

NEW YORK CITY.

1. Ideal asepsis has become an established fact as far as all objects are concerned which stand boiling well.

2. The atmosphere has no pernicious effects on wounds, as pathogenic bacteria fortunately have a tendency to settle, so they can only come into contact with a wound when the dust in the room is immoderately stirred up. To avoid this possibility, the air in the operating-room is saturated with moisture, at least during two hours before the operation. This can be done simply by originating steam in a kettle.

3. Asepsis of the hands of the surgeon as well as of the skin of the patient is still imperfect, total destruction of the bacteria of the skin being practically impossible.

4. Asepsis must be attained principally by physical, especially mechanical, methods. Chemical processes should play but a very subordinate part.

5. The means with which asepsis should be attained must be aseptic. This refers particularly to the water used for washing, and the soap, which must have been prepared by the boiling process. If brushes are used special care has to be taken. They can only with

difficulty be rendered aseptic, thorough cleaning impeding their usefulness.

6. The surface of the human body is impregnated with many different bacterial species. Some of them adhere to the skin surface, others are imbedded in the dried cells of the epidermis. They do not need destruction, but removal. This can be done by simple mechanical means, viz., scrubbing with soap and hot water. Two kinds of soap are used for this purpose. First with linen compresses, dipped into fluid soap, which is mixed with soft sand (Stuttgart sand), the skin is energetically scrubbed for two minutes, a stream of very warm water always flowing over the surface. Then aseptized green soap is used in the same manner, for the same length of time. Particular attention is given to the folds and creases of the skin and to the subungual space. The latter requires the use of a nail-cleaner and energetic wiping with the sand-soap. Now the skin is dried with an aseptic towel and rubbed with a gauze compress, saturated with 50 per cent. alcohol for about one minute. The alcohol is used for the purpose of dissolving the fat of the skin, which shelters the bacteria; and by dissolving the shelter, the bacteria are removed at the same time. Whether washing with bichlorid of mercury is needed after these procedures is open to discussion; it will certainly not do any harm.

There is no doubt that the surface of the skin can thus be rendered absolutely aseptic by this method, as well as by a few other similar ones. But there remain still a number of bacteria imbedded in the glands of the skin—the secretions of which offer a favorable soil for their development—which cannot be removed. But they will do as little harm as the dust in the room, if cared for properly, viz.: In the incising of the skin a number of glands are naturally dissected, and the bacteria contained by them are freely exposed. The dissecting-knife also comes in intimate contact with them and must therefore be considered infected. This undeniable fact explains thoroughly the so-called supuration of the stitch-canal, as well as the bad reputation of the catgut, and many cases of infection under the supervision of the "extremely careful aseptic surgeon." It also explains supuration after most laboratory tests, carried out under "the most minute aseptic precautions."

How do we get around this salient point?

The knife used for the skin-incision must not be used for further incisions.

The wound-margins of the skin are covered with sterile napkins, with are fastened to the wound surface with small miniature forceps, so that the skin-wound is not touched at all during the subsequent manipulations.

Surgeon and assistants wear sterilized linen gloves. The surgeon changes gloves after the skin-incision is completed.

For uniting the wound-margins of the skin the subcutaneous method should be preferred. The superficial surface of the skin of the patient had been rendered aseptic beforehand by having been given a warm bath twenty-four hours before the operation, a rigid scrubbing with soap and shaving having taken place at the same time. A poultice of green soap had been applied to the skin-surface for twenty-four hours in order to secure thorough permeation of the epidermis, which is macerated to some extent by this procedure. The surface being aseptic, and the skin-glands, which contain bacteria, being *hors de combat*, it becomes evident that the only possible source of infection remaining then,

*Presented to the Section on Surgery and Anatomy, at the Fiftieth Annual Meeting of the American Medical Association, held at Columbus Ohio, June 6-9, 1898.

suffice to protect the woman, as absorption of micro-organisms or their ptomains will sometimes show itself as a putrefactive intoxication with the constitutional evidence of sepsis usual to this affection. In other words puerperal sepsis is wound fever, as the Germans call it. Primarily it is infection which takes place in an abraded or torn surface. It differs in degree with the character of the infection. It may start in the favorable medium of decomposing retained membrane, or it may be due to bacteriologic infection in the external genitalia. Therefore at first it is a local* or at least is a circumscribed process, and is at this time most amenable to treatment. If allowed to pass this stage in its development, we may meet any or all of the complicated and extremely dangerous conditions of full-fledged puerperal sepsis.

The writer has seen fit to speak of the different forms of puerperal sepsis as he has met and is constantly meeting with it. This condition follows abortion and labor at term. In the majority of cases of sepsis following abortion, early recognition will confine the operative treatment to the vagina and the uterus and necessitate simply, thorough cleansing of both cavities, including the removal of the retained decidua, and proper disinfection and packing with iodoform or some antiseptic gauze. Each year, in both hospital and private practice, I see a number of these cases, which if seen early enough usually recover.

In another class of cases following abortion, not only the uterus but the Fallopian tubes are involved. These, however, are seen at a later stage of the disease, when abdominal section and supravaginal removal of the uterus with the uterine appendages, being able to occasionally save one and sometimes both ovaries, suffice to establish a cure. Another class of cases met with after labor at full term have as their most prominent feature a large purulent collection in one or other side of the pelvis, a condition frequently described as cellulitis and abscess. To this term the writer takes exception, for I am convinced that these cases originate from sepsis carried into the Fallopian tube, and through the Fallopian tube into the pelvis, where the inflammatory exudate breaks down and forms an abscess, which is circumscribed by an adventitious membrane so closely resembling peritoneum that operators pronounce it as such, and record the case as one of abscess of the broad ligament. I have studied these cases very carefully and from an anatomic standpoint I have never been able to make them out other than cases of circumscribed peritonitis, and not suppurating cellulitis. This class of cases frequently occasions a bulging of the recto-uterine cul-de-sac so far as to make it feasible to evacuate it through an incision in the vault of the vagina. That they can be so evacuated does not disprove their true nature.

As I have referred to cleansing the uterus I will say a word about the uterine curette. On general principles this instrument is resorted to too often; on the other hand, there are conditions for the relief of which the use of it is essential. I beg to put myself on record, however, by stating that this instrument should be handled with the greatest care and gentleness. In short, it requires as delicate a manipulative skill to use the curette with safety as it does the lithotrite. In the use of either of these instruments the operator should be so deft that, through the medium of the hand manipulating the instrument, and secondarily through the instrument, he should, as it were, be able to carry on a conversation with the part being operated on, and so

be able to tell dangerous places, where it will be necessary to scarcely bring the instrument into contact with the part, while at other points a slight pressure will be necessary. I beg of you, gentlemen, to understand that I am conscious of the importance of this statement, but I feel regarding this as I do about many other operative measures about which much is said, that it is not the operation which is at fault, but the operator.

A woman, aged 26, white, married seven years, had two children, one miscarriage. Menstruation began at the age of 15. She had the usual diseases of childhood; health previous to present trouble had been fairly good; was pregnant about six weeks when present illness began, on the afternoon of March 11, 1899, with sudden sharp abdominal pain referred particularly to the pelvic region, with symptoms of shock, cold clammy skin, pale conjunctiva, weak pulse and feeble sighing respiration. I saw the patient in the evening of the same day, in consultation with my brother, Dr. H. C. Deaver, whose diagnosis was internal hemorrhage, with which I concurred. The operation the same night revealed a "belly full" of blood with a perforated uterus, the perforation being about one-half an inch in its longest diameter. Supravaginal amputation of the uterus, with removal of left tube and ovary and right tube was performed, the right ovary left *in situ*. The patient was very much depressed after the operation. Immediately following the operation 2000 c.c. of normal saline solution were given in the left basilic vein; 3.30 a. m., same night, 1800 c.c. in right basilic vein. Recovery was complete and from this on uneventful.

Another patient, aged 38, white, was seen by me in consultation with her physician, on the evening of Feb. 28, 1899. She had recently aborted and had been curetted. On the arrival of her physician, examination revealed the presence of a loop of intestine in the vagina; this was replaced and consultation called. When I saw her she had rapid pulse, high temperature, distended and rigid abdomen. Operation was performed the same night. On opening the abdomen there we found diffuse peritonitis with pus, the great omentum greatly infiltrated, blood clots in the recto-uterine cul-de-sac, a knuckle of a small bowel six inches in length, semigangrenous and devoid of mensentery. The uterus was the seat of perforation about the size of a five-cent piece. Supravaginal amputation of the uterus was done, with removal of the tubes. The involved portion of the ileum was resected and end-to-end suture with needle and thread made. The ovaries were not removed. The abdominal cavity was thoroughly irrigated and drained. Death occurred on the evening of the fourth day from peritonitis.

Sepsis following labor at term manifests itself in two ways: 1. By infection of the external genitalia, the result of bruises, tears, etc., and if recognized early and free drainage is established few lives will be lost. The practice of immediately sewing up a torn perineum, which often involves the posterior vaginal wall, if not done with the strictest cleanliness, is responsible for many of these conditions. Better leave a torn peritoneum or vagina alone than to coapt all torn parts ever so nicely, if not done with strict cleanliness, because the rents may furnish avenues of drainage sufficient to carry off the infection, which is not only added to by lack of cleanliness but is increased by the introduction of too many sutures. Not uncommonly too many sutures are used, and tied too tightly, subjecting the tissues to dangerous degrees of tension. 2. By infection of the internal genitalia which manifests itself in the shape of

septic endometritis, septic phlebitis of the uterine sinuses, and of the veins of the broad ligament; septic inflammation of the Fallopian tubes and, through fimbriated extremities, septic peritonitis. Very radical operation in infection of the internal genitalia, barring that of septic endometritis is, in the majority of instances, attended by disastrous results.

Septic endometritis, in the majority of instances, if seen early is amenable to gentle curetting, douching with a warm solution of bichlorid, 1-4000, and carbolic acid, 1-80, and packing the uterus lightly with 5 per cent. iodoform gauze, moistened with the above solution. The preparation of the field of operation is as essential here as elsewhere. The vulva and pubic region are to be shaven, and the vagina thoroughly cleansed. During the operation the external parts are bathed constantly by the bichlorid and carbolic solution, which is allowed to flow from an irrigator. The operation being completed, an antiseptic pad is adjusted. After each urination the parts are to be washed with bichlorid, etc. I think it safer to allow the patient to pass her urine than to use the catheter: 1, because I believe it bad practice to suspend the function of the bladder, and 2, the use of the catheter is too often followed by cystitis, a condition I have seen quite as troublesome to correct as the one for which the operation was done. If a catheter is used it should only be a glass or a metal instrument, for these are the only instruments that can be sterilized. It is fitting to say a word here relative to lysol as an antiseptic wash. Personally I regard it of little use compared with bichlorid and carbolic acid. In short, to use lysol I consider sending a boy on a man's errand.

To defer curetting, cleansing, etc., until the patient is constitutionally infected with perhaps a septic peritonitis is virtually locking the stable after the horse is stolen. Early recognition of the danger and the immediate institution of the only proper treatment is the *sine qua non* to a successful issue in the majority of cases. Conservative treatment is the early institution of radical measures which results in saving life, and is not waiting until the "eleventh hour" in hope that Nature, by establishing a leucocytosis or what not, will by chance accomplish a cure.

That postpuerperal sepsis manifests itself in some cases as a phlebitis of the uterine sinuses and of the veins of the broad ligaments, we must agree. In this type of the disease the constitutional symptoms are pronounced; rapid pulse, high temperature, irritable stomach, with, in some cases, a disposition to diarrhea; associated with this condition of the vessels there is endometritis, giving rise to an offensive purulent discharge, often blood-stained. Local examination shows a hot vagina, an enlarged, painful and movable uterus, which offers more or less resistance to touch, suggestive of infiltration, fulness and increased resistance in either vaginal vault indicative of a like condition of the broad ligaments; and the absence of fulness in either the recto-uterine or vesico-uterine pouch. In this condition operation promises nothing; on the contrary it may do much harm by breaking down septic thrombi, often favoring foci of inflammation, to say nothing about the risk of cerebral or ptomainic emboli.

Mrs. C., aged 35, with a history of miscarriage occurring four weeks previously, presented the symptoms of pelvic abscess following premature birth. The uterus was subdivided; a large hard mass could be detected to the left of the uterus extending from the floor of the pelvis to the abdominal wall. Diagnosis: Peritoneal uterine exudate from sepsis with abscess. Incision

through the left rectus muscles disclosed a large deposit of lymph which contained a small purulent collection. Drainage was introduced and resolution followed, with recovery.

Mrs. L., aged 32, gave a history of miscarriage. A mass was found, on vaginal examination, to the right and behind the uterus, fluctuating and very tender to touch; uterus subinvolved with a discharge from cervical canal. Diagnosis: Pelvic abscess from infection. The abscess was evacuated through the vagina by means of incision into the mass; curettement of the uterus, drainage of both the abscess cavity and of the uterine canal. Recovery was uninterrupted.

Mrs. A., aged 38, gave a history of infection occurring three weeks after labor. A mass was detected above the pubis and slightly to the left of the median line, as well as by vaginal touch. Diagnosis: Pelvic abscess following infection from uterus. An attempt was made to evacuate the collection through the vagina, by opening the recto-uterine cul-de-sac. The cul-de-sac opened, the mass was found to occupy too high a position to warrant further attempt by way of this avenue. Incision was next made along Poupart's ligament, the peritoneum exposed and pushed out of the way, the mass of lymph felt anterior to the bladder, which was opened and found to contain an abscess. The cavity was irrigated, drainage introduced and the wound allowed to close by granulation. Recovery followed.

The treatment which promises most under these circumstances is supporting: stimulants, large doses of tincture of iron, 30 grs. every three hours, quinin, grs. x. in twenty-four hours, plenty of milk and concentrated nourishment; locally vaginal and intra-uterine douching with bichlorid and carbolic solution, antiseptic pads, etc., and ice-bags are constantly applied to the lower quadrant of the abdomen. The bowels are to be opened two or three times daily, with salines. Convalescence is usually prolonged. In a percentage of these cases convalescence is interrupted by the development of foci of suppuration which, in my experience, has usually occurred in the broad ligaments, one more often than both being affected. This manifests itself as a unilateral swelling, which can be detected by vaginal, rectal and abdominal examination, and to the sense of touch presents a boggy feeling, a sense of resiliency or perhaps fluctuation. The general condition of the patient usually bespeaks the presence of pus. We find a hectic temperature, and moist skin; the tongue is usually red, but not always so; chilly sensations are complained of, or a decided chill may occur. The selection of the best avenue to evacuate the collection will depend on the point at which it is most accessible; this may be through the vagina or immediately above Poupart's ligament. It is my experience that these cases usually recover. I have seen spontaneous evacuation above Poupart's ligament take place in a number of cases followed by recovery.

The treatment, generally speaking, depends on the stage of the disease, whether it is still localized or circumscribed to the point or place of infection, or whether it is more advanced and associated with constitutional symptoms. If taken early, local treatment will, if thorough, be sufficient for a cure. If, however, it becomes advanced and the body of the uterus, or the internal genitalia be involved, we may have to meet and treat any or all of the conditions I have described here. This class of cases illustrates a point I wish to make, i. e., the early institution of so-called radical measures is true conservatism in surgery.

UTERINE FIBROIDS.*

BY THOS. FITZGIBBON, A.M., M.D.

Professor of Gynecology and Clinical Gynecology in the Wisconsin College of Physicians and Surgeons; Attending Gynecologist at St. Joseph's Hospital.
MILWAUKEE, WIS.

Fibroid tumors of the uterus originate in its muscular walls. These tumors, as we shall observe, are composed of muscle and connective tissues; hence the names myofibroma and fibromyoma, the prefix designating the more abundant tissue. Uterine tumors composed exclusively of muscular tissue rarely occur.

PATHOLOGY.

Fibroids may be classified from the position they maintain, viz: subserous, interstitial and submucous. As a rule they grow very slowly, may be single or multiple and attain various sizes from a pea to 140 lbs. "Dr. Hunter of New York removed one weighing 140 pounds, which was 55 pounds more than the woman weighed after operation."

The subserous variety develops beneath the peritoneal covering of the uterus, usually, invested by loose cellular tissue, blood-vessels of small size that connect the tumor with the capsule; and, should dense adhesions occur between the capsule and the tumor, they have been caused by inflammatory processes. Large pedunculated tumors may extend into the cul-de-sac and become adherent to the rectum and surrounding tissues, and may produce obstruction to the bowel.

The submucous variety lies just beneath the mucous membrane of the uterus, usually causing a hypertrophy or atrophy of this structure. The breadth of these tumors varies; often they are attached by a slender pedicle, but frequently by a sessile base.

The interstitial variety develops within the walls of the uterus and forms part of it; and the natural tendency of this variety is to change into one of the preceding varieties, and become pedunculated. In all varieties of fibroma the uterus is hypertrophied and the mucous membrane is in a state of inflammation. To the eye the tumor appears white or red, the latter color being due to excessive amount of muscular tissue.

Uterine fibroids may undergo various degenerations and alterations during sexual activity and after the menopause. Calcareous degeneration may occur in old women after the menopause; fatty, suppurative, cystic and malignant degeneration may also occur.

"Martin made an interesting analysis of 205 cases of uterine fibroids, fatty degeneration existed in 7, calcification was present in 3, suppurative in 10, in 8 cases the tumor has become cystic, and carcinomatous degeneration had taken place in six cases."

ETIOLOGY.

Although several theories have been advanced we must admit that nothing positive is known as to the direct causation of uterine fibroids. "Byford says the direct cause may be due to a microparasite. Other authors claim that long-continued irritation may be the cause of these neoplasms." While the greatest number are discovered during the menstrual activity, it is nevertheless true that they are also found before puberty. Dr. Jos. Price of Philadelphia has discovered uterine fibroids among the colored women of the South in a large percentage of cases, and during my observation in the past seventeen years I have found these neoplasms in a large percentage of women suffering with uterine symptoms.

*Presented to the Section on Obstetrics and Diseases of Women, at the Fifth Annual Meeting of the American Medical Association, held at Columbus, Ohio, June 6-9, 1896.

SYMPTOMS.

The symptoms of uterine fibroids may be divided into three kinds: 1, constitutional; 2, those that originate in the uterus; 3, those resulting from pressure.

The chief symptom of the submucous and interstitial variety is hemorrhage. This symptom is rarely, if ever, present in the subserous variety. The next symptom of importance is pain, always greatest during the time of menstruation, and consisting of backache and bearing down pain. Suppression of urine may be produced by direct pressure on the ureters, which in turn will produce serious kidney disturbance. We may also have local peritonitis produced by pressure, and the various displacements of the uterus resulting from the position of the growth.

Menorrhagia, metrorrhagia, leucorrhœa, backache, pain in the pelvis, down the thighs, sometimes hemorrhoids and serious disturbances of bladder are nearly always present in cases of large fibroids. We have fatty degeneration of the heart, a condition which should not be overlooked, should an operation be demanded. Anemia from great loss of blood and digestive disturbances is present in a majority of cases. Martin has called attention to the liability to embolism and thrombosis, which may cause sudden death several weeks after hysterectomy.

DIAGNOSIS.

To make a positive diagnosis of uterine fibroid in the early stages of its development is not always an easy task, even though our experience may be ever so great. The following differential condition should be considered, viz: 1, pregnancy; 2, retained menses; 3, flexions; 4, malignant disease; 5, subinvolution; 6, inflammatory exudates.

A fibroid uterus is harder and more elastic than the pregnant, grows more slowly, and does not present the positive signs of pregnancy.

Retained menses cause a tenesmus of the uterine walls, but not the hardness of fibroids, and the os will be found closed in cases of retained menses.

Flexions may be differentiated by the use of the sound, which should always be resorted to under the strictest antiseptic precautions.

Malignant disease may be known by the character of the discharge, age of the patient; and, to make a positive diagnosis, the scrapings of the endometrium should be examined with the microscope.

Subinvolution is known by an enlarged cervix, and the history of infection. Inflammatory exudates should not cause much hesitation in diagnosis, as they are accompanied by more or less febrile reaction, sudden onset and acute pain.

PROGNOSIS.

The prognosis in the great majority of cases, in so far as life is concerned, is good, providing the growth does not begin too early in life, and grow so large as to cause death by pressure, or in the submucous or interstitial varieties does not cause death by oft-repeated hemorrhages, or by some malignant or cystic degeneration taking place in the tumor.

TREATMENT.

The treatment is non-surgical and surgical. Under the former we have: medication, manipulation, intra-uterine tampons, intrauterine styptics and electrolysis.

Ergot stands at the head of all drugs in the treatment of fibroids. If of the submucous variety, it may cause its expulsion. It may also diminish the blood-supply by contracting the muscles and blood-vessels and thereby causing atrophy.

Hydrastis canadensis has a very beneficial effect in controlling the hemorrhage. The ergot treatment was faithfully tried by the author in one case, and although a considerable portion of a large submucous fibroid was expelled, the tumor reappeared in a few months, and was removed with the uterus later. Ergot is not always well borne by the stomach, and should then be given hypodermically or in rectal suppositories.

Manipulation is sometimes necessary in order to elevate an incarcerated tumor in the pelvis, intrauterine tampons by means of long strips of iodoform gauze, every forty-eight hours during the periods, and it may be necessary while the patient is being prepared for operation. Intrauterine injections of tincture of iodine or persulphate of iron. The latter is mentioned only to be condemned, as there is great danger of sepsis following.

I have used electrolysis in two cases, with no reduction of tumor; besides, when a strong current is used, it causes the patient great pain, and is often accompanied with danger of sepsis.

Under the head of surgical treatment we may divide as follows: palliative, vaginal, and abdominal operations. In the palliative we curette, ligate the uterine arteries and remove the appendages. Curetting is always indicated from the fact that in nearly all cases the mucous lining of the uterus is in a state of inflammation and, although it must be often repeated, it always gives temporary relief, but should be done with the greatest antiseptic care.

Ligation of the uterine arteries and broad ligaments was lauded to the skies by Martin and Robinson, but recently there has been very little praise for this procedure.

The removal of ovaries and tubes, which was so commonly done a few years ago, by such men as Battey, Hegar and Tait, is now rarely done unless some special reason exists against a hysterectomy or myomectomy. I have performed two operations of this kind the past winter, when a hysterectomy was deemed inadvisable; both patients have been freed from their severe floodings. In order to bring about a cessation of the periods, it is absolutely necessary to remove all the ovary, and the tubes must be tied close to the uterus, otherwise the hemorrhage will occur. The radical operation is preferable per vaginam, when the tumor is small. Vaginal morcellement is practiced in some cases. This operation was performed by Dr. Thos. Addis Emmet thirty years ago. This, too, is accompanied by the great danger of cutting through the walls of the uterus. Radical abdominal operations are adapted to the large subperitoneal and interstitial tumors. Which shall we select, extraperitoneal or intraperitoneal hemostasis? The consensus of opinion at the present time favors the intraperitoneal method. When the ovarian and uterine arteries are ligated on either side, the field of operation is, comparatively speaking, a bloodless one. This procedure was first practiced by Baer and Eastman. The clamp may be used when there is danger to the patient by a prolonged operation. The fact that there is no danger of adhesions, and it affords us the best drainage, should not be lost sight of.

Subserous fibroids, if pedunculated, may be removed by myomectomy, thereby saving the uterus. To control the hemorrhage during operation a ligature may be thrown around the upper part of the cervix, a wedge-shaped incision made, and the parts drawn together after removal of the tumor, by one or more rows of interrupted catgut sutures. In cases where drainage is necessary, this may be done through the vagina or

stitching the uterine wound into the abdominal incision and packing with gauze.

In supravaginal hysterectomy the usual preliminary preparation of abdomen, bowels and vagina is necessary; the latter precaution is especially so, should you find the removal of the cervix necessary, or vaginal drainage be indicated. The abdominal incision should be made high, lest the bladder be injured on account of its malposition. Bring the tumor through the wound, ligate the arteries, ovarian and uterine, remove the tumor and supravaginal portion of uterus. Make the toilet of the peritoneum over the stump and close the abdominal wound. As the toilet of the peritoneum is very important, first ligate all bleeding points, cauterize the cervical canal with carbolic acid, close the canal and cover the stump with peritoneum, which is best done with a continuous suture of silk or catgut. Complete removal is indicated when the uterus is septic, or undergoing malignant degeneration, or when a thorough vaginal drainage is needed. The greatest danger to be avoided is tearing or cutting one or both ureters. The mortality of complete abdominal hysterectomy in the hands of the average operator should not be more than 5 or 10 per cent.

The following cases are from my hospital records of the past three years:

LARGE SOLID SUBSEROUS FIBROID, 33 LBS.; SUPRAVAGINAL HYSTERECTOMY; RECOVERY.

Miss F., aged 28, entered St. Joseph's Hospital July 30, 1898. She had sought relief in many quarters, but in vain. The tumor was large and very hard, and had not been diagnosed until just prior to entering the hospital. She weighed 270 lbs., with girth of abdomen 49 inches at the umbilicus; heart, lungs, and kidneys normal. For several years no great inconvenience resulted, except the pressure symptoms and great discomfort in going about.

A hypodermic of morphin, $\frac{1}{4}$ gr. and 1-150 atropin was given ten minutes before the patient was taken to the operating-room. Sulphuric ether was given by Dr. Jermain, and I was assisted by Drs. P. H. Jobse, G. Fitzgibbon and W. J. Cronyn.

The first incision was about twelve inches in length about four inches above the symphysis, lest the bladder be wounded. It was found impossible to remove the tumor through this incision; it therefore was continued up to the ensiform cartilage, which made the incision twenty-four inches in length. Three omental adhesions on the right side were tied, and with great difficulty the tumor was turned out of the abdominal cavity.

Both ovaries were considerably enlarged and cystic. To expedite the operation a copper wire was thrown about the cervix and fastened with the écraseur. The uterus and ovaries were then cut away, the peritoneum was stitched to the stump beneath the wire, and the abdominal wall closed by three rows of sutures from within outward, continuous silk sutures closing the peritoneum. Chromicized catgut was used to close the muscles and fascia and integument by interrupted silk-worm gut. Immediately after the operation the temperature was 101 F., pulse 90. On the second day after operation the temperature and pulse were normal and remained so until she left the hospital, which was four weeks later.

Three weeks after operation the clamp was removed, and there remained a small fistula, which subsequently closed. The stitches were removed on the twelfth day and the abdomen was closed perfectly. The only an-

noying symptom which followed was an irritability of the bladder at the time of her menses. She is now a strong woman in perfect health and can do her own work.

A LARGE SUBMUCOUS MYOFIBROMA WITH SESSILE BASE, TREATED FIRST BY ERGOT, LATER BY MORCELLATION AND FINALLY BY SUPRAVAGINAL HYSTERECTOMY.

Mrs. R., aged 24, presented normal lungs and kidneys, anemic heart murmur, and herself very anemic from loss of blood. Large doses of fluid extract of ergot were given, and brought on severe uterine contraction, which expelled large masses of tumor, enough to fill a large fruit-jar. The patient's hemorrhages reappeared in two months, whereupon she was removed to the Presbyterian Hospital, and with the assistance of Drs. G. A. Kletzsch and L. Jermain an effort was made to remove the tumor by morcellation. With the hope that all the tumor had been removed, she returned home one week after operation.

Three months later the tumor was as large as ever. Menorrhagia and metrorrhagia were worse than at any time previous; therefore a supravaginal hysterectomy was advised, and she was again sent to the Presbyterian Hospital for operation, and was ordered to drink large quantities of milk and given 1-20 gr. strychn. nit., hypodermically, every six hours for three days previous to operation.

Abdominal incision, 8 inches, resulted in the extraction of a 5-lb. uterus and tumor; clamp applied.

As in the first case, the patient recovered very promptly, and is well and doing her household duties, with no hernia at the present writing.

A CASE OF INTERSTITIAL FIBROMA IN WHICH PREGNANCY PROGRESSED TO FULL TERM. PORRO'S OPERATION. RECOVERY.

Miss R., aged 29, height 3 ft., weight 100 lbs., has antero-post. diameter of brim of pelvis $2\frac{1}{2}$ in., lateral 5 in. Although a dwarf in stature, she has never suffered with hemorrhages or pressure symptoms, and no tumor was suspected until she entered hospital for Cesarean operation. After the gravid uterus was rolled out on the abdomen, it was decided to remove the uterus on account of the presence of fibroid. There were present, at operation, Drs. Kletzsch, Jermain, Scollard, Fitzgibbon, and Hayes. The clamp was also applied in this case and the stump was entirely healed in four weeks. The patient made an uneventful recovery, and is well and able to work to-day. No hernia has resulted.

DISCUSSION.

DR. G. B. MASSEY, Philadelphia—The Doctor used the word electrolysis in describing the various methods employed in the treatment of fibroids. Although this word is very frequently used in connection with the electric treatment of fibroids, yet I think it is an unfortunate one. Its use probably accounts for some of the poor technic in the electric treatment of fibroids. It gives the impression that the tumor is to be destroyed by the electric current. Electrolysis is the chemical dissolution of the electrolyte. Although electrolysis always accompanies the direct current and is a most important portion of the Apostolic treatment, it is by no means the whole element. We must get the greatest amount of electrolysis in the shortest time; we must have the contracting effect of the current. I avoid the word electrolysis and simply use the word electricity. The trophic action is what we want, and the trophic action on the peculiar growths of which we know so little must be gotten by careful testing and patient methods. We can not rush in and dissolve these tumors without getting ourselves into trouble; hence we have those hasty reports of a method so highly recommended by Keith and others throughout the world. I myself have been able to make an addition to the technic which would prevent some of the results of inexperience, among them that of sepsis, from unwise pushing of the current. When I say "unwise pushing of current," I mean using too long an application of

a strong current, making the application twice as much as is necessary. To do this work requires a period of time of from three months to a year. The patient must therefore make some concession, and the physician must concede something in his attempt to make an impression on this growth which will make it innocuous and at the same time preserve to the woman her womanly functions and her abdominal wall intact. The improvement I allude to is the use of mercury on the zinc anode, particularly in hemorrhagic cases where we might have a little septic trouble from unwise pushing of the current. The result of the use of mercury is the production of the oxychlorid of mercury at the seat of application, which makes it absolutely aseptic. Of the kind of tumors that are suited to electric treatment, probably the first are the hemorrhagic cases. These can be cured by patience. The other kind are the little tumors that we have heard so much about in the Section on Surgery and Anatomy. They grow from a minute nodule, and at that time they are treated for prolapsed uteri, etc. Of such cases 100 per cent. can be cured by electricity in from two to four months.

DR. WILLIAM H. WATHEN, Louisville, Ky.—These tumors, in a histogenetic sense, must necessarily be myomatous, the fibrous structure afterward developing and sometimes possibly becoming fibroid. If I understood the gentleman correctly, he used a clamp, and treated the pedicle externally in these operations. Is that correct?

DR. FITZGIBBON—I used it in three cases.

DR. WATHEN—I do not feel we can recognize as a scientific principle the extraperitoneal treatment of the pedicle in any kind of tumors by the clamp. There is either the treatment of the entire removal of the tumor of the uterus, or the removal of the tumor and of the uterus except the cervix. Each of those two methods has its advocates, and it is not possible for any one of us to say that either procedure must take precedence over the other in all operations. There are instances where possibly one procedure is better than the other, and vice versa. I do not believe there is anything in the argument, however, that the leaving of the cervix is of any benefit whatever in furnishing a strong vaginal vault, and it certainly has the disadvantage of leaving a structure in which malignant disease is more liable to develop than in the vagina or the ovary. In these operations we should do as much conservative work as possible, and I was a little surprised to hear the statement made that the so-called fibromyomatous tumors are in every instance amenable to treatment by electricity. I can hardly conceive of a case in which electricity is at all indicated in dealing with this class of tumors, and I think it has done untold harm, and those of us who have treated cases time after time following the use of electric treatment know the mischief it has done, and we know better than anyone else how it emphasizes the belief that there is no field for this method of treatment in dealing with these growths. We should be conservative, but we should resort to surgical treatment when the ordinary medicinal treatment will not relieve the symptoms, or a curettement, etc. In dealing with these cases surgically, we need not necessarily remove the uterus. We have learned in the last two years especially that there are many cases in which we can enucleate one or more fibroid tumors from the substance of the uterus, and by proper suturing leave the uterus so that it is capable of performing its normal function and of bearing children. So the treatment that we ought to develop above all other treatment, when surgical measures are indicated, is that of myomectomy, saving as much of the uterus as possible.

DR. T. A. REAMY, Cincinnati, Ohio—I can not keep my seat any longer after hearing the remarks of my friend from Louisville on the subject of electricity in the treatment of fibroid tumors. I must call a halt. By what authority does Dr. Wathen denounce the use of this agent; proclaim that such treatment ought not to be recognized? I am not an electric expert, but have a fairly clear apprehension of the principles which should guide in its use—with some practical experience. I do not, however, resort to electricity in dealing with uterine fibroma except in carefully selected cases. In most cases demanding treatment I resort to surgery. But certainly in more than fifty cases within the past few years, in which I have employed electricity, the tumors have ceased to grow, have diminished in size, and in some instances have disappeared, these women remaining well. Other men of more skill and larger experience than myself have had even better results. There are many general practitioners who use electricity with intelligence in such cases, and see their cases improve. The hemorrhages cease; the tumor or tumors cease to grow; the patients enjoy good health; and in my judgment many of them are fortunate in avoiding the

unnecessary mutilation ready to be surgically inflicted either by Dr. Wathen, myself or some worthy colleague.

Many of these cases, as is well known, but in some quarters denied, will recover without any treatment whatever. But I repeat that when truthful and competent men report cases cured by the use of electricity we are bound to credit their statements, at least until they are disproven. That the experience of my friend from Louisville is to the contrary does not count, for he has never had sufficient confidence in the remedy to enable him to learn how to use it properly. Gladly do I believe him on other subjects. On this he is not a credible witness. He denounces everything not surgical as unworthy, unscientific, useless. When he or any other surgeon can show a record of 100 per cent. over a long series of cases cured by surgery, then, but not until then, may he denounce all other methods.

In a large percentage of cases surgery is our only refuge; and its possibilities in the field are marvelous. But let us not weaken the arm of surgery or detract from its glory by unnecessary mutilations.

DR. HENRY O. MARCY, Boston.—Little did I think I would have to cross swords with my distinguished friend from Cincinnati, Dr. Reauy, and I am sorry to say that I have to differ with him in regard to the use of electrolysis in the treatment of fibroid tumors. I followed the work of my friend, Dr. Kimball of Massachusetts, and that of his successor, Dr. Cutter, till I was thoroughly satisfied that electrolysis as they advised was a misnomer if it was used at all in the sense of cure. When in London, in later years, I met Apostoli, and became familiar with his work. Ten years ago, after he had attended a meeting of the International Medical Congress, held in Washington, D. C., I invited him to Boston, where patients submitted themselves to his personal treatment. I purchased an electric outfit, made over a thousand applications, and kept careful notes of the cases so treated. The results were unsatisfactory. The surprising thing to me was that every patient declared herself as feeling better; but in a single sense, after careful investigation, I did not find a single patient that I thought was even moderately benefited. I believe the consensus of opinion of two continents is in favor of the surgical rather than the electric treatment of fibroid tumors.

DR. ALBERT GOLDSPOHN, Chicago.—After having heard both sides of the subject of electricity in the treatment of fibroid tumors represented by the opponents and the defenders, I think it is well for one on neutral ground to say something. Electricity does make a patient feel better, and it is not simply a matter of suggestion, either. Electricity does largely do away with that pelvic hyperemia, that venous engorgement of the entire pelvis that exists when such neoplasms are present. We get a beneficial action by electricity without encroaching on the "Holy of Holies"—the endometrium. The introduction of the positive pole into the uterine cavity stands on a par, as far as the danger or good is concerned, with the introduction of a red-hot wire, the actual cautery. It is not rational because we can not evenly apply it to all parts of the endometrium for mechanical reasons, which anyone can see if he thinks for a moment. There is an excessive action in many places and no action at all in others, so that at the end of a week or so there is a culture-bed for germs that are very often septic. The result is a worse condition rather than a better one. The routine introduction of the positive pole into the uterine cavity by the general practitioner is most reprehensible. It is better to use electricity in cases that are dangerous for surgery, that have valvular heart disease, or organic kidney lesions. Use electricity for what it will do in those cases.

With reference to surgical treatment, we should bear in mind that all operators at the present day recognize one ideal standard of tying or clamping of vessels outside of the uterus rather than the use of any constricting ligatures or clamps. If the cases can not be dealt with by myomectomy, where the uterus is to be removed, it is a great deal better to remove the entire uterus, cervix and all, which does not really involve any more labor than to do a supravaginal amputation, and it is for various reasons a decided advantage for the patient in future years.

DR. JOSEPH EASTMAN, Indianapolis, Ind.—There was one point mentioned by Dr. Masser which I can not allow to go unchallenged. He speaks of cases which, after a thorough course of treatment by electricity, etc., may be turned over to the surgeons. I think the surgeon whose diagnostic acumen has been thoroughly cultivated by a few thousand operations in the abdomen, and whose observations of the subjective symptoms and objective signs presented are practical, is much more capable of making a diagnosis and suggesting

what cases should be selected for the surgeon and what cases should be turned over to the electrician than the man who has spent a little of his life in using electricity in connection with fibroid tumors. These cases should be first examined by men of the greatest diagnostic ability, before they are turned over to the electrician. A large number of fibroid tumors contain calcareous deposits, associated with suppurating pus tubes. These are had cases for electricity. I find few cases that are curable by electricity, but a larger number of them are susceptible to surgical treatment rather than to electricity. Electricity has its field in the treatment of fibroid tumors, although it is a very limited one.

DR. C. D. PALMER, Cincinnati, Ohio.—This is an interesting, yet serious, question. I do not believe any one method of treatment is suitable for all cases. The patients must be individualized, and the treatment adapted to the individual case. The first thing to consider in the management of a fibroid tumor is to ask ourselves what will Nature do? Nature is perfectly competent to manage some of these cases; a number of them will get well if left alone, and the best thing for us in some cases is to do nothing. In the second place, let us ask ourselves, after we have found out a reply to that question by the history of the case, what will medicines do? I have very little confidence in medicines, as recommended by a Philadelphia physician, such as bichlorid of mercury, muriate of ammonium, and iodid of potassium. Iodid of potassium is excellent if a patient is syphilitic, but all medicines do very little good in the treatment or dissipation of these tumors. I will except that remedy which seems best adapted for interstitial fibroids or those that are intramural. I refer to hydrastis canadensis. As to surgical treatment, we again must individualize our cases. It is true, we may have to take out the whole tumor, including the cervix, provided the cervix is diseased also. Myomectomy should be resorted to whenever it is possible, and practically when all of the fibroid infiltration can be removed, and the essential structures of the uterus remain undisturbed. A pregnancy and parturition may follow a most thorough myomectomy. A myomectomy only will do if the fibroid infiltration, although small, is left behind. Curettement of the uterus is a most admirable remedy for the treatment of these tumors; nearly all cases are more or less benefited by it. The tumor may be reduced in size after a curettement has been done. In interstitial or intramural fibroids, electricity may be used with benefit; it not only makes the patient more comfortable, but arrests hemorrhage. The main point is to study each case, find out the size of the place and kind of tumor, and govern the treatment accordingly. I consider the Baer operation the best to employ when an abdominal section is made, unless, in very rare cases, the cervix uteri has also undergone fibroid infiltration.

DR. J. WESLEY BOVEE, Washington, D. C.—I want to call attention to the danger of septic infection following curettement in many of these cases. I do not consider it by any means a simple operation. I have seen three or four cases of septic infection following curettement for fibroid tumors where there was encroachment on the uterine cavity by growths sufficient to cause considerable bulging, so that the parts above could not be curetted. It is only a partial operation and is certainly attended with some danger.

DR. T. FITZGERIBSON, closing the discussion.—In order to go over such an immense subject as this I had to skip many important points. I reported three cases as having been operated on by the extraperitoneal method, believing that this is the best method for those cases. My experience with electrolysis has not been sufficient to commend the treatment, but I am pleased to know that some of the members of the ASSOCIATION have had better results than I have in the few cases I have treated with it.

THE LIFE of a talented, successful, unscrupulous, young Paris surgeon is sketched with remarkable technical fidelity in a recent French novel, "Le Mal Necessaire," by A. Couvreur. To supply his insatiable need for money, the young surgeon operates right and left, regardless of everything save the purse of his patients. He takes advantage of a young woman in a cataleptic condition, and when consulted by her parents a few months later, diagnoses a tumor and operates. The chief interest in the story is the psychologic study of his assistant, an honorable man, who learns the circumstances.

SOME RADICAL CHANGES IN THE AFTER-TREATMENT OF CELIOTOMY CASES.*

BY EMIL RIES, M.D.

PROFESSOR OF GYNECOLOGY, POST-GRADUATE MEDICAL SCHOOL,
CHICAGO.

The purpose of the changes which I have worked out within the last four years has been to free the patients from many irksome and disagreeable features of the after-treatment as usually carried out, and at the same time to make their recovery more rapid and more complete, so that they are able to leave the hospital at a much earlier date than has been customary and in such a condition of strength that they can follow their wonted occupations within a few days after their discharge from the hospital.

The first impulse for these changes has been given by the observation of patients on whom vaginal celiotomy had been performed. I found, just as other surgeons did who used this method, that after intra-abdominal work done by the vaginal route with subsequent complete closure of the peritoneum and vagina by sutures, the patients could be fed like perfectly healthy persons and could be allowed to be up and walking about in a remarkably short time. Very soon I found that the period for which it was advisable to confine such cases to bed could be counted by hours instead of days, so that of late I have allowed my patients to get up within twenty-four to forty-eight hours and to leave the hospital four to six days after their vaginal celiotomy. I could not fail to notice that these same patients did not present the picture of listlessness and muscular weakness which the same category of patients present after the performance of the same operations by the abdomen with the usual after-treatment. I refer here to operations on the uterus and appendages, from the simple salpingostomy or retroflexion operation to the extirpation of uterus and appendages.

Though these intra-abdominal operations very frequently necessitate manipulation of the intestines and the omentum, I have never insisted on causing the bowels to move within the first few hours after such operations, and I have found it easy to make them move with a simple enema on the first or second day after the operation. Very often I have found that if left alone they would move naturally. This is infinitely more comfortable for the patient than to be filled with salts as soon as the operation is finished, as some operators recommend. I must add, however, that in the preparation of the patient for the operation I omit the customary efforts toward getting the bowel as empty as possible, because I fail to see how we can expect the bowel to move easily if, previous to the operation, we have insisted on producing a condition of as complete emptiness of the bowels as possible. Many text-books still contain the statement that early action of the bowel is a preventive of peritonitis. This statement is another example of how frequently the cause is mistaken for the effect. If there is no infection of the peritoneum it is easy to move the bowel. If there is infection it is extremely hard to produce a good bowel movement. In the first case it is not the bowel movement which prevents the infection; it is rather the absence of infection which permits of the easy action of the bowel. In the case of infection of the peritoneum it is not the absence of the bowel movement which causes the peritonitis; it is rather the peritonitis which prevents the free action of the bowel. The study of this question in the light of modern research makes this perfectly clear, so that we need not hesitate to establish the maxim

that early action of the bowel is a point of diagnostic or prognostic importance rather than a therapeutic or prophylactic factor with reference to peritonitis.

While these rules were being established by my observations I found that patients who got up early and whose bowels acted regularly and easily presented another symptom which necessitated a further change of the customary after-treatment. These patients were hungry. They were not satisfied with milk and soup or liquid diet generally. They had some muscular exercise, being permitted and encouraged to turn over in bed immediately after their operations, being allowed to be up and about as early as twenty-four hours after the operation. They became hungry and the question arose: could it be permitted to give them something more nutritious? The intraperitoneal stump of organs removed by this method and the suture of the peritoneum and vagina did not seem to form any objection to having a little more fecal matter in the bowel, and so I began to give them meat, bread, vegetables as soon as peritonitis was proven to be absent by the observation of the general condition, pulse and temperature and by an easy bowel movement about twenty-four hours after the operation. To my gratification the patients thrived under this treatment so well that now I allow them every reasonable kind of food in liberal quantities as early as twenty-four hours after the operation. Two things are achieved thereby: the bowel containing fecal matter in moderate quantities experiences the most physiologic impulse to regard action and requires very little attention, and the patients are not being starved and can keep up this muscular activity, which in its part contributes toward the physiologic action of the bowel.

Where cases presented adhesions, where more or less raw surfaces were left on parietal peritoneum or bowel or pelvic organs, such liberality at first seemed little short of temerity. But when I thought the matter over, I remembered how often it had been observed that enormous, apparently inseparable adhesions found in one celiotomy had in a subsequent celiotomy on the same patient been discovered to have disappeared completely and solely by the peristaltic motion of the intestines. I, therefore, arrived at the conclusion that a well-filled intestinal canal and regular peristaltic motion, far from being detrimental, are really the only reliable means of breaking up old and preventing the formation of new adhesions. The practical consequence was that in cases where extensive adhesions were found, whether they were broken up in the course of the operation or not, I gave the patients solid food in liberal quantities very soon after the operation, and my patients have fared well under this treatment. I have yet to see my first case of ileus after a vaginal operation, be it hysterectomy or whatever else it may be. I have not had one single death from vaginal celiotomies in four years, though I have had over a hundred of them. I have had only one death in over sixty vaginal hysterectomies within the last four years, and this was a case of puerperal streptococcus-sepsis with very little pus, a case in which operation was performed as a last resort, with a temperature of 105, death ensuing twenty-four hours after the operation. On the other hand, I have had the pleasure of seeing these cases leave the hospital within a week from the operation in cases of vaginal celiotomy, and within ten days from the date of the operation in the case of vaginal hysterectomies, if they were done with the suture method. The patients go home not as anemic, stooping wrecks with backache, dizziness and general muscular weakness, but as erect as any of us, and able to work the day after they come home.

I have frequently been asked by our Post Graduate students how I manage to render my patients able to be about so early after the operation; whether I give them any special tonics and so on. I do nothing of the kind; they do not even get the much-beloved strychnia. All I do is what the general surgeons nowadays attempt to do in cases of fractures and dislocations, etc. I am telling the surgical Section of the ASSOCIATION nothing new if I speak of the prevention of muscular atrophy in operations on joints, muscles, bones, etc., and they will easily understand me if I compare the work under discussion with their work in general surgery. Put a patient to bed for six weeks and tell the patient to move as little as possible and after the expiration of the six weeks let that patient get up. Would you be astonished if that patient's muscles after general inactivity for six weeks are unable to perform physical functions? Is it not rather exactly what you have seen and see every day in general surgery when a joint and its muscles have been out of use for some length of time? Patients with intra-abdominal operations do not need any special treatment or any special tonic in order to prevent that atrophy, but what they do need is the use of their muscles, and if we do not prevent them from using their muscles we have no atrophy. I am glad to report these observations to the surgical Section, because this special point will, I am sure, be appreciated by the general surgeon.

The objections which might be raised against this régime in vaginal celiotomies have proven to be without foundation in my work. I have seen neither vaginal hernias nor hemorrhages, external or internal, nor any other subsequent trouble that could be attributed to this kind of after-treatment.

So far we have discussed vaginal celiotomies exclusively. But when I had observed the course of convalescence of these cases for some time I began to doubt the wisdom of the customary after-treatment of our ventral celiotomy cases. The only difference that I can see between a vaginal celiotomy and a ventral celiotomy, aside from the question of the organs operated on or removed, lies in the ventral incision. The incision in vaginal celiotomy or vaginal extirpation of the uterus and appendages is small in comparison with the ventral incision necessary in many of the abdominal operations and the chances of a vaginal hernia are correspondingly smaller. But the recent work of Abel on hernia after ventral celiotomy has furnished conclusive evidence that the occurrence of ventral hernia depends entirely on the accuracy of the suture in layers and the absence of infection, while all other factors, including the wearing of a binder, are of secondary importance only. With regard to the firmness of the suture it is entirely indifferent how early the patient leaves the bed, though we have been accustomed to being afraid of putting the suture on a strain soon after the operation. Here again I wish to remind you of conditions prevailing in the work of the general surgeon. Suppose you operate on a neck or a chest, do you forbid the patient to use the muscles of his neck or his chest in breathing or coughing? Suppose you operate on a tongue, can you keep that tongue absolutely quiet? Suppose you operate on a bladder or on a bowel, do you believe you can keep them at absolute rest? Or suppose you perform a suture of a vein, do you propose to prevent the blood from flowing through that vein? You certainly do none of these things, and what about the healing of these wounds? Do you or do you not expect primary union and therewith a firm, reliable cicatrix? Well, that being the case, how about the abdominal incision? First of all, remem-

ber that if you attempt to keep the abdominal suture absolutely quiet, you must know that you cannot do it. Every breath, every heart-beat, every variation in the quantity of the abdominal contents, every filling and emptying of the bladder, of the intestines, moves the abdominal wall, not to mention at all that it is impossible for a patient to maintain absolute rest. Secondly, you know from operations on organs which you cannot keep at absolute rest that primary union of operative wounds in these organs takes place all the same if you keep out infection. So, theoretically, we must arrive at the conclusion that it is not necessary to keep up strict injunction of rest. Practically I have tested this in many cases and the result corresponds absolutely to that observed in cases of vaginal celiotomies. Many of my patients with ventral or inguinal or lumbar incisions have sat up as early as three days after their operations; others I have kept in bed until after the removal of the stitches on the sixth to the eighth day, the superficial layer of stitches which comprises skin and subcutaneous fat alone and which I usually make with silkworm being removed at that time, the deep layers sutured with catgut having by this time united firmly. All the patients, however, are permitted to turn over and move about in bed as soon and as often as they want to. The consequence here as in vaginal celiotomy is prevention of muscular atrophy, rapid recovery of strength and discharge from the hospital about twelve days after the operation.

The intestinal canal is managed in ventral celiotomies as in vaginal celiotomies, no efforts at complete evacuation before the operation and no effort at artificial diarrheas after the operation. As to the relation between peritonitis and early action of the bowel, the same principle holds good as in vaginal celiotomy. The feeding of the patient is also carried out after the same rules as described above. Intestinal operations make no exception to this rule. Patients with bowel sutures or with mechanical appliances in their bowels are permitted solid food after the first bowel-movement, the only special precaution which I use in these cases being a strict order that the patient must chew the food very carefully.

My patients do not wear any binder of any shape or kind after their ventral incisions, and I have still to see the first hernia. I have to add that I do not use any drainage in order to be able to close the abdominal wound completely. I have to use packing sometimes, which is an entirely different thing. I know, however, beforehand that where packing is used and brought out through the abdominal incision I have to expect hernia and I have seen small hernias develop in every one of the very few cases where I have used packing. But in these cases I keep the patient in bed longer than in the cases in which the abdomen has been closed completely, because I know that I have to deal with an imperfect abdominal wall, through which prolapse of the intestines might take place. When the abdominal incision suppurates—and I am sorry to have to confess that I am probably the only surgeon here in whose cases suppuration takes place sometimes—I let the patient be up and about, but I put on adhesive plaster strips in order to approximate the edges of the suppurating wound and incidentally in order to reinforce the abdominal wall.

The changes which I have reported here have not to my knowledge been carried out anywhere else to this extent. I can assure you that with the proper asepsis and with the proper method of suture they can be introduced everywhere, not only without detriment to our patients, but to their positive gain and advantage. It means a great thing for a business man or a laborer or their wives

to be able to attend to their work two or three weeks after an abdominal operation, and it means a great deal to the nervous, cosseted millionaire or his wife to be put on their own feet in a short time, rather than to be confined to bed, having their weak backs and general debility increase rather than disappear after the operation which was to cure them.

100 State Street.

DISCUSSION.

DR. THOS. H. MANLEY, NEW YORK CITY.—It occurs to me that of all the papers that I have heard to-day the last one has not been the least one in importance to the practical surgeon, because it opens up in its way practically a new epoch in the therapy of a very serious, and, as it has become recently, a very large class of lesions; it certainly is one of the most valuable contributions to practical surgery that I have listened to or read for a long while and I regard it as most valuable, because my experience leads me to believe that the observations contained therein are correct. It is valuable, because it points to the improvement accomplished in a very little time by observing simple principles. You all know how we are chained down by authority and tradition in a great many ways. The Doctor makes a plunge here, and shows that it is not only not necessary but harmful to keep a patient in bed four or five days after many a laparotomy, unless we have such conditions as to point to the necessity for it; that as soon as the patient has an appetite she should have something to eat, and such food and in such quantities as agrees. He shows us great saving of time and money, which is a vast object to poor people going in to expensive hospitals.

There is another point—dispensing with drainage. Ten or fifteen years ago every kind of incision was packed with drainage-tubes, by which we killed a great many. The Doctor showed in certain cases the importance of dispensing with the drainage-tube. I would like to ask him whether, in cases where there has been an extensive operation, where it has been found that there has been a considerable parenchymatous hemorrhage, he would let his patients get up?

DR. FREDERICK HOLME WIGGIN, NEW YORK CITY.—It has been my experience that the tendency in treating patients on whom an abdominal operation has been performed, is to withhold food too long a time, and when it is supplied to give it in insufficient quantities. It has been my custom to give these patients nourishment as soon as they are able to take it, and in such quantity and quality as they are able to digest. I have also found, as a result of my work, that it is not necessary to keep these patients very still after the performance of either vaginal or abdominal operations—by incision through the abdominal wall. Last year a patient on whom I performed vaginal hysterectomy left her bed while the nurse's back was turned, within six hours after the performance of the operation, went to the closet, removed the dressings and returned to bed again, without any ill effects following. Another patient on whom laparotomy had been performed, fell out of bed the evening following the operation, and notwithstanding this accident the abdominal wound healed primarily.

As to the action of the bowels after the operation, it is a matter of considerable importance to patients when they are doing well that the bowels should not be moved too soon. The patient is necessarily somewhat weak, and suffers from more or less nervous reaction, and if the nausea incident to the administration of the anesthetic ceases, and the patient begins to desire food or nourishment, it should be given, and it is well in such cases to omit cathartic medicine for a day or two. If, on the other hand, the patient continues to vomit, or is more or less disgusted with food, eighteen hours or so after conclusion of the operation, then the quicker we get the bowels to act, the better it will be for the patient. I have seen many instances where a neglect of this procedure for a few hours, meant the death of the patient, for as a rule, this condition indicates the beginning of intestinal paresis, which condition can not be overcome if it is allowed to get much headway. The symptoms of this condition are, beginning eighteen hours or so after the performance of an abdominal operation, first a tendency of the patient to constantly vomit a light-colored fluid which next becomes tinged with yellow, and later darkens to a brown, accompanied by increasing abdominal distension, prognosis becoming less favorable with the darkening of the fluid, and the degree of abdominal distension. As soon as the condition is recognized, a rectal tube should be passed into the patient's bowel and a seditif powder immediately given. If this is rejected, it has been my custom to give another within fifteen minutes, and if this second powder is not retained, then to pass

a tube into the patient's stomach, and after letting all the gas escape through it that will, to wash out the stomach with saline solution, and then to leave there from two to four ounces of saturated solution of sulphate of magnesia, when the tube is withdrawn. Since I have come to recognize this condition in its early stage, and have followed the line of treatment already indicated, none of my patients, to the best of my recollection, have died of intestinal paresis, although formerly many of those on whom abdominal operations had been performed died as a result of this complication.

DR. F. C. SCHAEFER, Chicago.—I simply rise to make the statement that I have been familiar with Dr. Ries's work. He has certainly obtained remarkable results. The work has interested me to such an extent that I have followed the same course with satisfaction.

DR. C. L. BONFIELD, Cincinnati, Ohio.—I regard this paper as a very interesting one, but interesting as showing a possible method of treatment after abdominal section, rather than the proper one. The Doctor has proven that the incision will heal if the patient is not kept in bed. Few of us doubted that. A dog breaks his leg; the fragments are not held together by any kind of splint; union takes place. The result, however, is not such as to induce surgeons to adopt this method of treatment for their patients with similar injuries. The fact that the incision in the abdominal wall will unite after a manner if the patient is not kept quiet should not lead us to respect this measure, which common sense dictated and experience has sanctioned.

The experience of ages is not to be thrust aside in a minute. But there is a limit to all things. A patient may be kept too long in bed. Many operators doubtless have done this, and many more will now let them up too soon, for doctors are prone to believe that anything new is an improvement. We are not unlike a flock of sheep that follow the bell-wether wherever he may lead.

DR. EMIL RIES, Chicago.—The first question I have to answer is the following: You say it can be done. Is that any reason why it should be done? Yes; if you can save a patient three or four weeks' stay at the hospital, don't you try to do it? If you can save the patient money or discomfort isn't it worth while? Whatever we can do toward alleviating the suffering of our fellow-beings, isn't it our duty to do that? We have to do it as soon as we can; it is our duty—that is what we are physicians for.

I have also to answer Dr. Manley's very kind remarks, and in answer to his question, I would say that I have used in the deep layers formaldehyde catgut, boiled and kept in alcohol; you can boil it as long as you wish, and it will not become brittle.

As to packing, rather than put in a packing, I would leave small bleeding surfaces, or try to stop them by the customary means of a hot sponge or of the cautery applied a certain distance above the bleeding surface, because in this way I can close the abdomen completely. You can not operate on a peritoneal cavity full of adhesions without having some exudate, but in these cases especially I insist on early, liberal feeding, so as to get the bowel full; as long as it moves it does not become adherent; if it is kept quiet it will become adherent.

Dr. Wiggin very properly mentioned cases of patients who get up without the advice of the physician. Six years ago I was in Naples, and in Morisani's clinic the assistant showed me a case of symphysiostomy that had got up the night after the operation, and had walked through the ward to get some water, and all the dressing she had on was a towel around the pelvis. I saw the case once more than a week after that escape, and she had a firm pelvis. Similar observations of laparotomy patients getting up without permission, have demonstrated time and again, that the incisions heal all the same. I must repeat, if it can be done it ought to be done.

Health in Indiana.—The report of the state Board of Health concerning disease in Indiana for July shows that the diseases which increased in area of prevalence during that month were: diarrhæa, cholera morbus, dysentery, cholera infantum and malarial fever. All of these, except malarial fever, are called filth diseases, and would not appear in the hot months if we would but so dispose of all excreta as to prevent access of flies, and prevent the same from getting into the water-supply. The diseases decreasing in area of prevalence were: typhoid fever, erysipelas, measles, bronchitis, pleuritis, whooping-cough, diphtheria, pneumonia and scarlet fever. Dysentery has been epidemic in several towns, notably in Liberty Center and Covington. The total deaths so far, at these two places, have been 26, with probably 100 cases.

THE PROGRESS OF SURGERY.*

BY HERMAN E. PEARSE, M.D.

Chairman of Committee on Progress of Surgery.

KANSAS CITY, MO.

Standing on the threshold of the twentieth century, and looking with the eyes of hope at the future of our noble profession, let us remember that the splendid progress of the past fifteen years has been made possible only by the solid foundation builded by those whose hands have laid down their scalps forever; who watch us now from the great unknown, let us hope, in our feeble struggles to attain perfection in our art. These surgeons who upheld the profession in the long past struggled against a series of obstacles, and with a succession of handicaps that are appalling to contemplate at the present day. They had no method of controlling hemorrhage save by the cautery or direct pressure. They were compelled to operate without anesthesia. Their knowledge of anatomy was as limited as one would expect from the strenuous opposition offered to human body dissection. They knew nothing of infection as applied to surgical wounds. They were powerless to follow by the perfect microscopes, now at our command, the tissue-changes incident to growth, repair, death and morbid change in living tissue. In the face of such appalling conditions, who of us would have accomplished more than they?

In scanning the work of the past, three strongly marked epochs have been pointed out by medical historians. Prior to 1552, or until within 350 years, there was almost no progress in surgical art. At this date Ambroise Paré, then a barber, used ligatures for tying vessels and controlling hemorrhages, instead of the cautery, as his predecessors had done. This enabled the surgeon to work boldly, and beyond the former limits of his craft. He cut more freely, he feared fatal hemorrhage less, and has been increasing the usefulness of Ambroise Paré's invention by new modifications of the ligature, up to the present year, when the formalin preparation of catgut and kangaroo tendon has enabled him to do plastic work in hernia, and indeed, all kinds of surgery of finer grade of manual work, with an ease and a certainty of cure heretofore not to be hoped for.

The second epoch in the progress of surgery was marked 300 years later and only forty-three years ago, when, in 1846, Morton, the Boston dentist, gave to the world the ether anesthesia, and one year later the discovery of chloroform rounded out the measure of this great boon to mankind, and "opened wide the throttle" for the surging advances of operative procedure.

The third epoch was ushered in by Pasteur, in 1856, when he discovered and proved that fermentation could occur only as a result of the presence of certain microorganisms, some of which he isolated and fully described. It was fully completed by Sir Joseph Lister, who in 1867 gave to the world his theory of wound infection and elaborated the antiseptic methods of wound dressing. Nothing was now lacking. Hemorrhage, the dread of all conscientious surgeons, was conquered, pain was banished and quiet insured; inflammation and suppuration were held in the grasp of the surgeon's strong hand, and eliminated at his will.

Progress in surgery may be measured along these three lines. Our diagnostic skill, to be sure, is increasing, but only in connection with the splendid work, even better than our own, coming from the purely medical branch of our profession—the internal medicine men.

New routes of attack in special cases have been devised and perfected, many of them by the gynecologist—who is a surgeon first, and a specialist afterward, and who has solved many of our most vexing problems, laying them as free offerings upon the common altar of professional attainment—but for all these, we may yet, as surgeons, measure our successes, measure our advancement, control our death-rate and raise the percentage of perfect cures by observations along these three lines: 1, the ligature and suture; 2, the anesthetic; 3, the technic as ushered in by Lister and simplified by the many who have followed him.

LIGATURES AND SUTURES.

The profession is coming away from silk more and more, as catgut is perfected. The preparation of this material by the cumol process and by the formalin process, with or without chromicization, makes a suture so strong, so flexible, so surely and certainly sterile, that we are with one accord dropping all else. The use of silver wire in infected regions and for certain plastic work is still much in vogue and to be recommended. The silkworm gut is likewise a fixture under some conditions. In true surgical work, however, in aseptic surroundings and where perfect results are hoped for, catgut has no rival. The use of kangaroo tendon and allied animal sutures in such work as the repair of hernia and ruptured peritoneum has become general. Under its beneficent influence the ratio of perfect cures of hernia has so risen that it is rare indeed, to find an advocate of any other material for use in the union of the more powerful structures to be approximated and held in hernial operation.

Anesthetics.—Perhaps the most notable progress in the art of anesthesia rests in the application of nitrous oxid—"laughing gas"—to general and prolonged narcosis. Children, and patients who have recently filled their stomachs, patients known to suffer badly from the after-nausea of chloroform, or whose lungs and kidneys are too badly damaged to permit either as an anesthetic may be anesthetized by this means quickly and with satisfaction. I have seen Dr. Bennett, formerly of Kansas City, now of the New York Hospital, keep a patient under anesthesia by this agent for half an hour at a time, without bad result, and to the operator's satisfaction. As an adjuvant to ether it is used, on account of its rapidity and its effect in the beginning of the anesthesia, to be followed later by ether, as a less expensive and more permanent agent. Ether, in the old, old controversy between ether and chloroform, still continues to win its way to the front. There can be no doubt in my own mind as to its increased safety and if it were as easily used as chloroform, and if it once acquired its deserved popularity with the mass of physicians, chloroform would be still less often employed than is the case at present. Deaths from chloroform due to paralysis of the heart are still quite common and comparatively unavoidable.

Technic.—As regards technic, the third line along which our progress may be estimated, the energy of the surgical world is now directed to the margin between the ideal death-rate of 3 per cent. and the actual one of 15 per cent. to 20 per cent. The profession have emphasized in the past year that asepsis and not antiseptics is the proper safeguard for the patient, and the latter is used only as a handmaid, so to speak, to the former—a stepping-stone by which it may be reached. The normal salt solution, sterile and non-irritating, has supplanted the bichlorid or carbolic solution as an irrigating material, and for cleansing the hands during the opera-

*Read before the Missouri State Medical Society, Sedalia, May 16 1899.

tion. The autoclave with its tremendous sterilizing power renders it unnecessary to soak towels and instruments in antiseptic fluids. The rubber glove is a permanent innovation. So much is it esteemed that a prominent eastern hospital, finding after 587 hernial operations, 15 cases of suppuration, passed a resolution requiring all operators to wear sterilized rubber gloves when operating, in order to eliminate even this small number of unfavorable cases. This notable innovation is the only exception to simplicity in technic. In all other directions the tendency has been to use less and less paraphernalia in the operating-room and to rigidly limit the number of separate chances for contamination, offered by assistants.

In regard to the cleansing of the hands, I cannot do better than quote Eastman of Indianapolis, Wm. Pryor of New York and others, whose statements coincide entirely with my own experience:

"The greatest objection to any chemical sterilization of the hands and field of operation lies in the probable neglect of that greater virtue which lies in soft water, soft soap and softened elbow grease by much trituration of microbes. Cleaning nails, five minutes of scrubbing; cleaning nails again, five minutes' more scrubbing; then a teaspoonful of powdered chlorid of lime, until the heat of the lime begins to lessen; then sal soda until the hands are cooled; then immersing in alcohol. I have lost faith in the permanganate and oxalic acid. It leaves an acid on the hands last, the lime and soda an alkali last, and the hands that are in the abdomen every day and several times a day will tolerate the lime and soda, whereas the potash and oxalic acid have proven, in my work, very hard upon the skin; and, further, bacteriologic investigation by able eastern surgeons, as well as in our own laboratory, has shown a decided preference for the free chlorine produced by lime and soda."¹

Before closing this report, I wish to speak of some of the surgical procedures that have been to some extent abandoned.

Foremost among them stands the spaying of women—the removal of the ovaries for pelvic pain or because of disease of other structures. The rules of radical destruction that apply to an inflamed appendix do not apply at all to the case of female ovary. Its functions are vital to the welfare, physical and mental, of the woman, and are kept up long after grave changes occur in the connective-tissue portion of its structure. It has been settled that it is better left in situ, even after extensive plastic operations and after resection or removal of the tubes. The appendix is a useless appendage—the ovary a potent and active organ. That its exact manner of influence is not known does not render that influence less powerful upon the physical and mental welfare of the patient. The protest against the wholesale removal of these organs long ago came from the better gynecologists, was echoed by the attentive practitioner of general medicine and now comes from the laity, who see the baneful consequences. While there are still operators so blind to the light of modern pathology, so intent upon "doing something" and that something an easy one, as to perform ovariectomy for pelvic pain in young women, these are rightly denounced as little short of criminal in their disregard of modern views and the lessons of experience so well taught, and at such a bitter cost, by the records of the past decade.

Another operation practically abandoned is that of trephining and craniectomy for epilepsy and idiocy. The results have been so poor, so meager, so bare of

permanent good as to leave us but little choice in the matter—operation should not be advised. These cases belong to the asylum, to the man who can educate the few remaining nerve-cells, who can conserve the little remaining nervous energy and make of these patients useful things—automatons it may be, but self-sustaining and often more. To operate upon these is bad; to exact money for it seems worse. There are indeed a few exceptions to this rule—a very few. The greater part of these cases lie out of the sphere of the surgeon.

It is a pleasure to turn from this picture to the positive grounds fixed by the experience of the year in appendicitis. There is no recession of the surgeon on this line. Operation is imperative, is the only cure, and the earlier done the more certain are the results. Again I would say, as I have said in the past, and as many and better surgeons have said: The contraindications for operation are only a patient too weak or too shocked to bear operation and an operator incapable of doing it. In orthopedic surgery, too, the year has seen great things. Improved methods of treating bone disease; sharper lines of distinction between tubercular and other forms of bone necrosis; improved orthopedic appliances and a broader field of usefulness for the surgeon who would relieve the crippled and the deformed. The conscientious surgeon has reason to be proud of his art, to believe in himself and in the future of his profession.

PROFESSIONAL SECRECY.

ITS LEGAL ASPECTS.

BY WILLIAM C. TAIT, LL.B.,

SAN FRANCISCO.

The ethics as well as the universal custom of the medical profession protect the secrets of the patient from disclosure; the confidence which the relation of physician and surgeon inspires is seldom betrayed. The law, nevertheless, frequently unseals the lips of the physician, and compels him to divulge information which, but for the voice of authority, might never have been disclosed. In the absence of express statutory prohibition, the physician or surgeon may be either permitted or compelled, against the objection of his patient, to testify as to any information concerning the latter's physical or mental condition acquired in a professional capacity, regardless of the nature of the information or the feelings of the patient, for the common law recognized no distinction between professional and ordinary information, at least as far as physician and patient were concerned. Under that system the patient did not enjoy the privileges of the client. The secrets of the latter were sacred and inviolable. If the same protection was not extended to the patient the reason may perhaps be found in the fact that until the last and perhaps the present century, medicine can hardly be spoken of as a profession. The books speak of "physic," and the term is still found upon some of our statute books. The physician shared the fate of the ordinary witness. Neither public policy, the interests of society, nor the confidential character of the information were, to the minds of judges, sufficient inducement to warrant any distinction between professional and non-professional communications. Either plaintiff or defendant might drag from the unwilling physician evidence seldom divulged except to physician or priest. But for the protecting seal of modern statutes, the physician might be compelled to disgrace his patient; it would not be safe to consult a physician. From time immemorial the law, both written and unwritten has closed the mouth of the attorney as to the secrets of his client.

¹ Eastman: West. Med. Review, Jan. 15, 1898, p. 6.

But it did not occur to the lawmaker until a comparatively recent period that the reasons for protecting the client applied with equal, if not greater, force to the patient. How much better is the intimate life of the individual known to the physician than to the attorney. How much does the strength of the domestic tie, the happiness of the individual, the welfare of society, depend upon the silence of the physician. At the present day the statutes of all our states provide substantially that a licensed physician or surgeon cannot be examined as to any information acquired in attending his patient, which was necessary to enable him to prescribe or act for the patient.

These statutes, of which the language is plain and explicit enough, have nevertheless been variously construed. In some jurisdictions they have been interpreted literally and strictly; in others the spirit rather than the letter has been followed. Many interesting questions have arisen, and we propose in the course of this paper to review the most interesting.

First, as to what is to the judicial mind the purpose of the statutes, we will quote the language of Chief Justice Ruger of New York: "To inspire confidence between patient and physician; to enable the latter to prescribe for and advise the former most advantageously, and remove from the patient's mind any fear that he may be exposed to civil or criminal prosecution, or shame and disgrace, by reason of any disclosures thus made."—*McKinney vs. Grand St. R.*, 104 N. Y., 352.

The opinion of the revisers of the New York Code is less complimentary to the profession: "To remove all temptation from the physician during the struggle between legal duty on the one hand, and professional honor on the other. The latter, aided by a strong sense of the injustice and inhumanity of the rule, will in most cases furnish a temptation to the perversion or concealment of the truth, too strong for human resistance."

What do the statutes mean by information? Frequent attempts have been made by ingenious counsel to have the courts confine the rule to the confidential communications of the patient, but so narrow a construction of the broad term "information" has never been countenanced by the courts. On the contrary, the courts have interpreted the term to mean not only communications received from the lips of the patient, but all such knowledge as may be acquired from observation of his appearance and symptoms, for as the New York Court of Appeals once expressed it (*Edington vs. Ins. Co.* 67 N. Y., 185): "Even if the patient could not speak, or his mental powers were so affected that he could not accurately state the nature of his disease, the astute medical observer would readily comprehend his condition. Information thus acquired is within the meaning of the statute."

Nor can the rule be confined to information of any particular character; the fact that the particular information would in no way injure or reflect upon the patient makes no difference. The statute is in this respect at least absolutely prohibitive. It applies to information of every kind and nature acquired professionally and necessary to enable the physician to prescribe or act. It includes measles as well as gonorrhoea. It is so strict that when the physician is compelled to sue for his fees he is not permitted to testify to anything beyond the fact that he had treated the patient, and in the course of his employment had made a certain number of visits. Nor would he be permitted to state that he had performed a surgical operation of a particular nature, so long as the patient objected. A consulting physician or

surgeon is equally within the rule. He cannot prove the nature of his services by his books. As it is practically impossible to determine the value of medical services without at least a general account of the condition of the patient, and the nature of the treatment, the physician is, financially speaking, at the mercy of his patient, unless he is able to prove the necessary facts by the testimony of a nurse.

During the trial of a recent suit of a physician to recover the value of his services the writer endeavored to solve the dilemma by calling the defendant and patient to the stand. The court, however, refused to compel the witness to disclose the information sought to be elicited, holding that the physician could not be permitted to prove by the patient what the law forbade the physician to disclose. As far as the decisions go, there is no authority one way or the other. The statute only applies to the physician. Still, to permit the physician to prove his case by the patient would be a clear violation of the spirit of the statute, which was designed to protect the patient. It may be said *en passant* that the duty of the physician to keep secret professional information amounts to an implied contract, and that a suit for damages will lie for a breach of the contract, in case he divulges it without the patient's consent.

A distinction must, of course, be made between professional and other information. In order that the rule may apply, it is necessary: 1, that the relation of physician and patient should exist between the parties; 2, the information must be such as is necessary to enable the physician to prescribe and act. Without these prerequisites the information, although it be of a medical character, is not privileged.

Statutes and city ordinances regulating the actions of boards of health generally require the filing of a certificate by the attending physician as to the cause of death. But it has been held that such police regulations do not make the certificates public records in the sense that they are evidence between private parties of the facts recorded. In the case of *Buffalo Loan & Trust Co. vs. Knights Templars, etc.*, 126 N. Y., 450, decided in 1891, a policy of insurance obligated the company to pay the insurance within sixty days after the notice and satisfactory proof of the death of the insured, without requiring the cause of death to be communicated. The guardian of the insured, however, furnished the company, as part of the proof of death, the certificate of the attending physician of the insured, to the effect that his death was from a cause which would have released the company from liability. Upon the trial of the case the court excluded both the certificate of the physician and the records of the board of health. One of the grounds upon which the court rejected the certificate was that the guardian had no right to waive the statutory privilege of the deceased. In this case the policy did not require the cause of death to be stated. The same thing might well happen to an executor, or administrator, or to the beneficiary of the policy; unless they were allowed to waive the privilege of the deceased, the company could not be compelled to pay the insurance. Under the law of New York, as it existed prior to 1893, when the statute in question was amended, such would have been the result, as the personal representatives of the deceased patient were not permitted to waive the statutory privilege for him.

The statutes should not be understood to mean that the physician may refuse to be sworn in a judicial action or proceeding, or that he is justified under all circumstances in refusing to disclose professional informa-

tion after having been sworn. The statute is intended for the protection of the patient, and he may waive it if he sees fit to do so. If the physician were permitted to maintain absolute silence, the patient might suffer irreparable damage. The latter may, of course, remove the ban of secrecy; the moment he does so the information is no longer privileged, and the physician may be compelled to divulge it. The success of much litigation depends largely upon the testimony of attending and consulting physicians, and they are frequently called into court by their patients. The whole truth, the whole history of the case, and all the physician knows concerning the physical condition of his patient, are seldom disclosed upon an examination in chief. Naturally only such information as is beneficial to the patient's side of the case is brought out. When, however, the adverse party, by means of a searching cross-examination, attempts to elicit further information, the history of litigation shows a tendency on the part of the patient to invoke the statute, to object strenuously to the introduction of further testimony on the part of the physician the moment it bids fair to become unfavorable to his case. This is usually the case in damage suits for personal injuries. It has also happened more than once in malpractice cases that, after having testified, together with the various members of his family, as to the secrets of the sick-room, the plaintiff has claimed the protection of the statute the very moment the defendant opened his mouth in self-defense. But, as Chief Justice Ruger of New York has said: "The rule cannot be used both as a sword and as a shield, to waive when it inures to his advantage and wield when it does not. Once divulged in legal proceedings, it cannot be again hidden or concealed." (*McKinney vs. Grand St. R.*) The principle enunciated by the chief justice is well illustrated by the Indiana case of *Lane vs. Boicourt*, 128 Ind., 420, in which the plaintiff claimed that the defendant, a physician, failed to give his wife proper attendance during parturition, resulting in the lacerating and rupture of the muscles of the genital organs, and that he allowed five days to elapse before attempting to bring the parts together. The plaintiff, his wife and wife's mother, all testified to all that was done by the physician. But when the defendant called the consulting physician to the witness stand and attempted to prove by him the falsity of the plaintiff's testimony the latter claimed the production of the statute. The court very properly admitted the testimony, holding that the patient had waived the statutory rule and that "nothing was privileged, as all had been published." The court, in the course of its decision, says: "If a patient makes public in a court of justice the occurrences of the sick-room for the purpose of obtaining a judgment against his physician, he cannot shut out the physician himself, or any other present at the time. By this voluntary act he breaks down the barriers, and the professional duty of secrecy ceases. It would be monstrous if the patient himself might detail all that occurred and yet compel the physician to remain silent."

Whether by waiving the privilege as to one physician the patient thereby waives it as to others has been variously decided by the courts. Upon both principle and reason, it would seem that by waiving it as to one he waives it as to all. Sometimes the question as to whether or not the privilege has been waived by the patient is a very nice one, as in the case of *Venzke vs. Venzke*, 94 Cal., 225, in which the wife charged her husband with cruelty in having communicated to her a venereal disease (gonorrhoea). Dr. Reuda testified that he had treated her for that disease. The defendant admitted that he had had

the disease, and that he had consulted Dr. Reuda in regard to it, and did not deny that he had advised his wife to consult the doctor, but said that he had taken it from her. When, however, the wife's attorney asked what he knew about the defendant's case, defendant claimed his privilege, and Dr. Reuda was not allowed to testify.

Did the admission of the defendant that he had had the disease warrant the assumption that he had, by disclosing and publishing the secret himself, waived the statutory privilege. The judge who tried the case thought otherwise, and but for his ruling the plaintiff might have been permitted to show by the physician that he had given the disease to his wife, rather than taken it from her. If Chief Justice Ruger's declaration is good law, and it seems to be, then the testimony should have been admitted.

The death of the patient does not release the physician from his obligation of secrecy. Can the patient's executor or administrator release him from this obligation? Do they succeed to his rights to waive the legal privilege? The courts are at variance on this point. In some jurisdictions, notably New York and California, the privilege is a personal one, and no one but the patient can waive it—not even his executor or administrator. The courts of New York have said that any other rule "would permit the living to impair the fame and disgrace the memory of the dead, by dragging into the light communications and disclosures made under the seal of the statutes." Such a strict and literal construction of the statute is often detrimental to the patient's estate. The case of *Harrison vs. Sutter St. R. R. Co.*, 116 Cal., 156, is a good illustration of this. There the administrators of the deceased attempted to prove by the latter's attending physicians that the injuries complained of caused his death. The court refused to allow the physicians to testify. Such a construction becomes particularly harsh and detrimental, when the validity of the patient's will is in question, for in such a case the rule applies to the proponents as well as to the contestants. In spite of these hardships, the courts of New York for years favored the strict construction, and refused to allow the patient's personal representatives to waive the rule, thus considering the personal rights of the deceased as paramount to the property rights of his heirs. Finally, in 1893, the legislature of that state relaxed the rule so as to permit the latter to waive it except as to "confidential communications and such facts as would tend to disgrace the memory of the patient." Code C. P., sec. 836.

The following case is a still better illustration of the hardship of the literal interpretation:

A policy of life insurance provided that the policy should be void if the insured should commit suicide. He hanged himself, and mainly upon that ground the company defended the action brought by the executor of the deceased. The plaintiff gave evidence that the insured hanged himself while insane. In the course of the trial the plaintiff called a physician who had known the deceased for a long time, and who attended him professionally a short time before his death, and asked the physician how he found him. The defense objected on the ground that the information was a privileged communication and prohibited by statute, and that the privilege of the deceased could not be waived by his executor. The trial court overruled the objection; the physician was permitted to testify, and gave important evidence as to the mental and physical condition of the insured at that time and subsequently. The jury

found for the plaintiff. On appeal, the court reversed the verdict on account of the error of the trial judge in admitting the testimony of the physician, holding that "the purpose of the law would be thwarted and the policy intended to be promoted thereby would be defeated, if death removed the seal of secrecy from the communications and disclosures which a patient might make to his physician, or a client to his attorney, or a penitent to his priest. Whenever the evidence comes within the purview of the statutes it is absolutely prohibited, and may be objected to by any one unless it be waived by the person for whose benefit and protection the statutes were enacted. After one has gone to his grave the living are not permitted to impair his fame and disgrace his memory by dragging to the light communications and declarations made under the seal of the statutes. An executor or administrator does not represent the deceased for the purpose of making such a waiver. He represents him simply in respect to rights of property and not in reference to those rights which pertain to the person and character of the testator." *Westover vs. Ins. Co.*, 99 N. Y., 56, decided in 1885.

It is difficult to conceive how the testimony of the physician in the case just cited either "impaired the fame or disgraced the memory" of the deceased. On the contrary it vindicated his memory from the disgrace of an apparent suicide.

Yet it cannot be said that the court erred in its interpretation and application of the statute. Its language was plain and explicit; it was absolute and unambiguous in terms; it provided for no exceptions.

The courts of Indiana, Michigan and Missouri, under a similar statute, allow the personal representatives of the deceased patient to waive the privilege. In California and in some other states, the New York precedents are followed, and the statute strictly construed. In California, however, the statute is, by its express terms, confined to civil actions. In that state the following interesting case arose:

The defendant, a physician, was charged with the murder of a woman, and found guilty and sentenced to imprisonment in the state prison for a term of twenty-five years. The theory of the prosecution was that the deceased was pregnant and went to the defendant to have him procure for her a miscarriage, and that the defendant by some unlawful means did procure a miscarriage, thereby causing her death.

The theory of the defense, on the other hand, was that the miscarriage was effected by some one else before the deceased went to the house of the defendant, and that he, as a physician, received her there, and did all he could to save her life. To sustain this theory, the defendant called as a witness Dr. Johnson, who was willing to testify. No objection was made by the prosecution. The court, however (Judge Wallace), of its own motion, refused to allow the Doctor to be examined. For this error of the trial judge, the supreme court set aside the verdict, and granted the defendant a new trial.—*People vs. West*, 106 Cal., 89.

In this case the testimony was clearly admissible, for the reason that the statute of California applies only to civil actions. Such a statutory distinction between civil and criminal actions is peculiar to California. It is not found elsewhere. Nevertheless, there is considerable authority for the assertion that the rule does not apply to criminal cases. Thus, in New York, under a statute which provided that "a person duly authorized to practice physic or surgery shall not be allowed to disclose any information which he acquired in attending a patient in

a professional capacity, and which was necessary to enable him to act in that capacity"—we cite this particular case because the New York statutory provision has been incorporated bodily into the Codes of most of our states—the court of appeals held in a poisoning case that the physician who had attended the victim at the request of the prisoner, and had examined him and prescribed for him could be allowed to testify for the people, as against the objection of the prisoner, the latter's objection being that it was prohibited by statute. The court, after asserting that the object of the statute was "to place the information of the physician obtained from the patient in a professional way substantially on the same footing with the information obtained by an attorney professionally of his client's affair," saw fit to violate the plain language of the statute, by making a distinction between civil and criminal actions, alleging as a reason for such an arbitrary distinction that, if strictly construed, it would be extremely difficult, if not impossible, in most cases of poisoning to convict the murderer. "The statute," the court said, "was intended to protect the patient and not to shield one who is charged with his murder."—*People vs. Pierson*, 79 N. Y.

In other words, in order to convict the defendant, who is perhaps an innocent man, and who may be acquitted by the jury of the crime charged, it is proper and admissible to compel the physician of the victim to break the rule of professional secrecy, and to divulge information which may "impair the fame and disgrace the memory" of the patient!

Is it not better that the guilty should escape, if they cannot be convicted except by breaking down the barriers which the law has erected for the protection of the confidential relation of physician and patient? The decision in the Pierson case was written by Judge Earl in 1880. In 1886 the same judge, in passing upon the same statute, refused to permit the executors of a deceased patient to waive it, and said "that so important an exception should be engrafted upon the statute by the legislature, and not by the courts; that if the statute excludes the most reliable and vital evidence which is absolutely needed for the ends of justice, particularly in testamentary cases, the remedy is with the legislature, not with the courts. There is no more reason for allowing the secret ailments of a patient to be brought to light in a contest over his will than there is for exposing them in any other case where they become the legitimate subject of inquiry." This was the language of the court in a civil case (*Renihan vs. Dennin*, 103, N. Y., 593). Is it not equally applicable to a criminal case?

In the Edington case, and in the case of Grattan vs. Metropolitan Life Ins. Co., 80 N. Y., 281, Judge Earl thought the statute should be so construed as only to prohibit the disclosure by a physician of any information of a confidential nature, but was overruled by his associates. In the Pierson case, he thought there was nothing of a confidential nature in anything the physician learned, or which was disclosed to him; the symptoms and conditions were such as might be expected to be present in a case of arsenical poisoning.

The legislature of New York, in amending the statute in 1893, adopted his views as far as personal representatives were concerned. It did not see fit, however, to engraft a further exception by confining it to civil cases, as had been done in California.

The question is more squarely presented by the case of *People vs. Brewer*, 53 Hun., 217, in which the defendant was charged with aiding and assisting in procuring an abortion. The physician was called on the trial as a

witness for the prosecution, and was allowed, against the objection of the defendant, to testify that the following conversation took place between himself and the defendant: The defendant said: "For God's sake, hurry up; my wife has a fit, or fainted, or something. I don't know what." He said: "Probably you would like to know what the difficulty is before you leave the office." I said: "Yes, it might be a help to me, because I might need something that I would not take with me." He said: "This lady down to the house I am living with I am not married to, but I expect to get a divorce from my wife and get married. This lady is about three months gone in the family way, and she introduced a catheter with a wire in her womb, and after she had introduced it far enough to hurt her, I blew in it." I said: "What did you blow in it for?" He said: "I done it before, and it worked all right."

The jury found the defendant guilty. The verdict was reversed on appeal, on account of the error in allowing the introduction of the physician's testimony. The court refused to apply to this case the principle of the Pierson case, and said: "The present case is widely different. The defendant employed the physician to save Mrs. Brower's life. His alarm and anxiety were great. He knew what had taken place, and suspected that it was the cause of her sudden prostration, and felt that the physician ought to know it, and to govern his treatment accordingly. The physician did want to know. In this critical moment, with the sole purpose of saving the woman's life, he disclosed the secret to the physician to enable him to act rightly. To have withheld the disclosure would have made the defendant a consenting party to the woman's death. We have no doubt that the statute, both in letter and spirit, protects the confidence thus reposed in the physician, and forbids him to betray it."

Professional intercourse between attorney and client is protected by profound secrecy. The privilege is that of the client, and the prohibition as to the attorney is absolute. The law never unseals his lips in the interests of justice, not even when the client is charged with a crime. The client cannot be convicted out of the mouth of his attorney, any more than can the guilt of the penitent be proved by the testimony of the priest. In the case of the patient the statute may sometimes block the wheels of justice, but as Chief Justice Bigelow of Nevada said in *People vs. Depoister*, 21 Nev., 107: "It is better that such testimony should be lost, than that the confidence which ought to exist between priest and penitent, lawyer and client, and physician and patient, should be destroyed by the knowledge that they may be compelled to divulge the information so obtained from those who have placed trust in them."

MEDICINE.*

ITS PROGRESS, PROBLEMS, AND PROSPECTS.

BY J. BRUYERE, M. S., M.D.

SURGEON TO MERCER HOSPITAL.

TRENTON, N. J.

It has been the request of the committee of arrangements that the president of this Society deliver an address on "The Progress, Problems, and Prospects in Medicine," at this our fiftieth anniversary. With due appreciation, we accept the honor conferred and bespeak your kind attention and indulgence. The subject is so broad and comprehensive that we can not do more than briefly consider the course of medical evolution, and

some of the present medical problems and prospects. In the dim past so many theories, hypotheses and opinions emanated from such a few facts that medical systems flourish in abundance. It would be impossible, in the brief time at our disposal, to describe the medical systems and dogmas of the past, so we will only briefly allude to these and pass on to a brief sketch of the progress in some of the numerous branches of medical science for the last fifty years. The last decade has been a period of advancement without parallel in the world's history. This progress has revolutionized the principles and practice of medicine, hence it would require much patient research and philosophic insight to successfully trace the evolution of medicine during this period. It would require the pen of a medical genius to fittingly portray the good accomplished in preventing suffering and saving life. It is to be hoped, for the honor and glory of medicine, that the time is not far distant when some worthy medical historian will fittingly perform this task.

Throughout the ages medical evolution has kept pace with intellectual development. An infant age bred fear, bigotry, superstition and great credulity. Diseases arose from unseen and mysterious causes, hence remedies were equally mysterious, and charms, sorceries, propitiatory prayers, sacrifices and gifts were offered to appease the wrath of the gods, and to secure the assistance of some health-giving deity. During the age of barbarism, medicine was a species of sorcery, and excited fear in the popular mind. During the age of superstition, medicine was the "mystery of the alchemist," and excited feelings of wonder. During the ecclesiastical age medicine became oracular, and it was accepted with absolute credulity. During the metaphysical age medicine was speculative, and was accepted dogmatically. During the age of experience and superficial observation medicine became empirical, and specifics were demanded. During the present scientific age, fear, sorcery, alchemy, mysticism, dogmatism, empiricism, etc., have vanished, and the scientific spirit and methods have taken their place. For many centuries, owing to bigotry, superstition and the spirit of speculation, there was only progressive accumulation, and but little scientific advance in medicine. There were no laws regulating the practice of medicine, and even as late as the Middle Ages, the regular profession was composed of a mongrel horde of barbers, bath-keepers, bone-setters, butchers, calf-doctors, crystal-mancers, druggists, exorcists, midwives, priests, lithotomists, rat-catchers, shepherds, hermits, magicians, jugglers, gypsies and numerous other charlatans, mountebanks and quacks. General practice was largely in the hands of the priesthood, and surgery in the hands of social outcasts, until the sixteenth century, when there was a separation of the priesthood from medicine.

At this time there was a recognition of the importance of surgery by anatomists and clergy, and a drawing together of medicine and surgery. The ecclesiastical doctors were prone to speculation, and believed in the efficacy of charms and relics, and in the intervention of the martyrs and saints. Among the causes of disease they included demons, witches and ghosts, "the fall of man," "the faculty of appetite seated in the spleen or in the stomach," "the poisoning of the vital spirits," etc. They despised surgery, and regarded operations as beneath their dignity. In the thirteenth century surgical operations were forbidden, dissection was regarded as a sacrilege, and books on medicine were banished from the monasteries. The works of Arnold de Villeneuve, Andreas Vesalius and others "were condemned by the iniqui-

*Read before the Mercer County (N.J.) Medical Society, at its Fiftieth Anniversary, May 23, 1898, and subsequently revised.

sion, because they commended experiments rather than mere speculations." They were thought to be atheists and heretics, and were persecuted by the church, which later ridiculed Boyer, Jenner, Simpson and many others, because they feared them and the effects of their discoveries.

This early persecution by the church is not to be wondered at, if, as Park tells us, many of the clergy "were mere lascivious gluttons, and considered even washing unchristian." They denounced all observations and experimentations, and believed that "wisdom, like the grace of God, was obtainable only by fasting, supplication and poverty." All truth was to be revealed by their inner consciousness; they imagined, they speculated, they dogmatized, and, like Pilate's wife, pronounced judgment from their dreams.

The period previous to the sixteenth century was one of cabalistic theories, of mysticism and occultism, when gods, devils, and stars were supposed to exercise an influence over the conditions and affairs of men. During the Middle Ages occult philosophy consisted of theosophy, magic, astrology and alchemy. At the beginning of the seventeenth century, the natural sciences began to flourish, and observation and experimentation added many new facts to human knowledge. Modern realism, or inductive philosophy, exact methods and originality, were beginning to take effect, and were greatly advanced by such men as Sydenham, Bacon and others.

A new era in medical science commenced when the inductive system of philosophy passed into medicine. Previous to the seventeenth century they philosophized and dogmatized about medicine, and the humble labors of research were held in contempt. Dogmatism was the result of self-confident ignorance, and flourished when the principles underlying the treatment of disease were merely speculative. As we become more thoughtful and rational, dogmatism declines. It is now regarded as an act of supererogation and presumption on the part of any one to assume an autocratic dogmatism and express ex-cathedra opinions on any subject until the evidence is first carefully examined and set forth as a basis of belief. The reason is no longer in subjection to the imagination, and we no longer seek scientific truths by introspection. Men are being taught to leave their minds free to receive the impressions of truth, to interrogate nature by observation and experiment, and inductive reasoning, and to prove all things, and hold nothing for true until the grounds of certitude have been ascertained. Individual experience, deductive reasoning, and many theoretical beliefs are being eliminated by inductive and scientific methods. Sir Astley Cooper's motto: "First observe, and then think," is a good one. Observation and experimentation now precede conclusions, and have overthrown the hypotheses which were sustained only by speculation. Hypotheses must be proven, and beliefs must be founded on evidence and supported by facts. There must be a cause for every effect, and a reason for every belief. Each one must use his own eyes, and must think and observe for himself. The *ipse dixit* or ex-cathedra opinions of the great masters are no longer blindly accepted. We cannot rely upon dogmas, or the inherited opinions and beliefs, which rest solely on authority and not on their own intrinsic merits. We must accept "truth for authority, not authority for truth." Dogmatic authority steeped "in port and prejudice" made of medicine a black art, and shrouded her in mystery.

For long years medicine occupied the realm of mystery, and was accepted on faith. A sanctified faith, that

has a spiritual and intellectual foundation, is commendable, but a blind, unquestioning, superstitious faith, founded on great credulity and ignorance, imprisons the reason and leads not toward knowledge, wisdom or truth. It is said that "a judicious distrust and a wise skepticism are the sinews of the understanding." The great Sydenham was called "a man of many doubts." He was an intelligent and original thinker and investigator, and was loyal to truth rather than to authority. This is the scientific spirit, and has made the present an era of modern science. If we are to have scientists in medicine, the laboratory, hospital, dispensary and clinic must continue to furnish experimental and practical information. True scientific methods are being developed by numerous inquiries, keen experimentation and close research. Medicine is now an inductive as well as a deductive science. The scientific methods now predominate, and special systems with their "isms" and "pathies," are fast disappearing. A broader intelligence recognizes the solid foundation on which medicine rests—a foundation that is laid by research, observation, and experimentation, the same as physics, chemistry, or any other branch of science. Regular, or rational medicine, has received its greatest impulse and development through scientific methods.

Although a broader intelligence demands of medicine observation, positive knowledge, absolute proof, or the scientific spirit and methods, nevertheless there are many who can not distinguish between science and pseudo-science. There are still many pretensions theories that are built on delusions in physics and philosophy. The human mind develops slowly. The faith and belief of the ignorant and credulous "rise by means of heated air—the fevered breath of enthusiastic ignorance." To all such, medicine is "the grand idol of human credulity," and their faith and belief become a port free of entry to all unsupported individual convictions. Over this port of entry is written the motto "*Credo quia impossibile est*"—I believe this because it is impossible. Christian science, osteopathy, and all the other "pathies" and "isms," find easy entry and shelter here. Human ignorance and credulity have ever been the fruitful soil from which have germinated and flourished many pretentious theories. Scientific medicine will never be fully appreciated until the laity more fully understand the scientific tendencies and spirit of the age. But, thanks to the writings of Darwin, Spencer, Haeckel, Wallace, Huxley, Tyndall and others, people are being taught scientific methods of thought, and the importance of investigation by the senses. The pure science of nature, founded upon scientific investigation, is the most influential philosophic doctrine of this century. Of course, medical thought, as well as the popular mind, has been largely guided by these philosophic doctrines. All advance in physics, chemistry, natural history, botany, zoology, comparative anatomy, etc., have advanced the science of medicine. Medicine has ever appreciated and profited by the advance in all the various departments of science, still she has not been entirely receptive. She has found it more blessed to give than to receive, and, during the last fifty years, she has given to science many of the grandest ideas and truths of the century. These we will consider later.

When this Society was founded, May 23, 1848, medicine was an art rather than a science. The *post hoc ergo propter hoc* error which at this time received so much attention, has been discarded through rational observation. We now have more knowledge of, and re-

spect for nature than formerly, and no longer attempt to make art superior to nature. Medical truths are now discovered by applying sound medical observation and judgment to the phenomena of life. Many complaints that were popularly believed to be due to meteoric influences and the appearance of comets or to the "visitations of God," and called by medical men "idiopathic," are now rightly assigned to their real cause. Increased knowledge in the nature and causation of disease has led to more effective treatment. We no longer delight in polypharmacy with its shot-gun prescriptions. It is said that Huxham gave messes to his patients containing more than four hundred ingredients. The empirics prescribed nostrums and panaceas for a name, but now empiricism has largely given way to rationalism and physiologic and pathologic investigation have led to rational therapeutics. The great advance in physical diagnosis, and in the knowledge of the physiologic action of drugs, has banished this pseudo-scientific audacity in the use of remedies. We now use extracts and active principles for a definite physiologic effect, rather than crude drugs and mysterious combinations. Our experimental and physiologic laboratories have greatly increased our knowledge of biology, organic chemistry and the physiologic action of drugs, and have given us the alkaloids—the active principles—and many new and useful remedial agents, which we now prescribe for their physiologic effects, and for this alone. The blind faith in many remedies and methods has disappeared. Calomel was formerly regarded as "the Samson of the materia medica," and bleeding was both a necessity and a virtue. It is said that, in one year—1833—there were "forty-one million, five hundred thousand leeches imported into France." Broussais is said to have used one hundred thousand leeches in his own hospital wards during one year, and Bouillard is said to have surpassed even this. When we consider the amount of blood extracted by the lance, and by cupping, in this country as well as in France, we must conclude that our forefathers were sanguinary heroes, heroic in their faith—a divine quality that is often misplaced. Our Puritan forefathers were martyrs to faith. They believed in the combination of theology and medicine, or the "angelical conjunction" as it was called. They placed great confidence in the medical skill of their spiritual authorities, and Cotton Mather, who believed in witchcraft, etc., "was regarded as an eminent authority on medical subjects." These theologico-medical experts wrote many pamphlets and works on medicine, which must have excited the risibilities of the saints. They believed most intensely in the efficacy of prayer, which they often practiced at the bedside of their patients. Such an act is commendable, but the humor of the situation dawns upon us only when we are informed that the results they sought, by their prayers, was, as they quaintly expressed it, to "give them a lift Heavenward." What would be thought of the doctor to-day who sought such therapeutic results? What sublime faith our forefathers must have had to trust those whose avowed purpose was to give them a lift Heavenward. How different is the faith of their degenerate sons, who do not have even such confidence in those whose avowed purpose it is to keep them out of the bottomless pit. How sublime also was their faith in the justness and generosity of God acting through human instrumentality, or by proxy. Dr. Stafford says: "No man can with a good conscience take a fee or reward before the party received benefit apparent, and then he is not to demand anything but what God shall put into

the heart of the party to give him. And he is not to refuse anything that shall be given him, for it comes from God." *O tempora, O mores!* Such views could do nothing else than breed infidelity and atheism among doctors. But times have changed. The simple faith of childhood fades away as thought and knowledge develop. The primitive faith in medicine has been banished by scientific methods of observation and experimentation, which have caused more progress in medicine during the last fifty years than during all previous time.

Previous to 1848 nothing was known about bacteria, infection, immunity, antiseptics, asepsis, toxins, anti-toxins, etc. Gynecology, dermatology and pathology were in their infancy, and bacteriology was unknown. But little was known about the diseases of the heart, lungs, liver and kidneys. Nervous diseases, and diseases of the nose, throat, eye and ear were comparatively unknown. There were no laboratories, no recitations, no graded course, no ward classes, and no text-books were required. The medical student had no actual contact with disease, but after six months of didactic lectures received his diploma, and went forth to kill or cure as the fates decreed. There were no boards of health, except the microbes and the buzzards; and hygiene, sanitation and preventive medicine were in their swaddling clothes. There were no microscopic or chemical examinations of the blood, or of the secretions and excretions. Dietetics, during the last half century, has been established upon a rational scientific foundation. Pediatrics, which date from "*de morbis puerorum*," 260 B. C., received but little attention until quite recently. The first text-book of diseases of children that was published in this country was written in 1825, by Logan and Dewees. We had no journals treating of pediatrics until 1868, and there was not an exclusively pediatric society until 1888. There was not a hospital, in this country or England, for diseases of children until 1852. In 1854 a child's hospital was founded in New York, and in 1855 one in Philadelphia. These were the first established in America. There was no special chair in pediatrics in any of our medical colleges, until 1860, and this was filled by the distinguished Jacobi. The "humane sciences"—anthropology, psychology, criminology and sociology—have been formed and developed by the investigators in the field of neurology. The study of neurology has done much to explain the cause of degeneracy and the philosophy of reform. It has ameliorated the conditions in our schools, asylums, reformatories, and prisons. It has led to a better knowledge of self, to a better knowledge of the effects of heredity and environment, and to a more sympathetic and more humane treatment of the weak and erring. It has taught us the broad distinction between abnormality and immorality. It has dispelled many harsh and ascetic beliefs, and ameliorated many social conditions. It created such broad sympathies and altruistic sentiments that harsh and inhuman treatment of the degenerate classes no longer prevails. Only a few years ago the insane were supposed to be possessed with a devil, bewitched, or the victims of divine displeasure. They were regarded as heretics, witches, criminals. But the study of neurology, inductive inquiry, and physiologic research, has taught us that insanity, like all forms of degeneracy, is a disease to be treated, rather than a crime to be punished. Great has been the advance during the last fifty years. In 1848 there were about thirty medical colleges and 3500 students; now it is estimated that we have about 170 medical schools, 28,000 students,

and about 186,000 physicians. The libraries, medical journals, societies and scientific associations were few, now they are very numerous, almost universal.

With this broad and general consideration of the subject, which is merely superficial, we will now mention some of the more important discoveries and indicate their effect on general medicine. A short time previous to the organization of this Society, the first great discovery in medicine was made. Anesthesia, a term first suggested by Oliver Wendell Holmes, was at this time running the gauntlet. Holmes tells us that by means of an anesthesia "the fierce extremity of suffering has been steeped in the waters of oblivion, and the deepest furrows in the knotted brow of agony have been smoothed away forever." He, and many others, lauded this great discovery, but some of our ministerial brethren anathematized it as "a decoy of Satan—which will harden society, and rob God of the deep earnest cries which arise at the time of trouble for help." For a long time the clergy did not appreciate the moral and spiritual influences exerted by medicine, but at the present time they are our staunch friends and allies, and no longer fear the results of scientific investigation.

Sulphuric ether was first discovered in the thirteenth century. In 1510 it was called the sweet oil of vitriol, and in 1730 it was first called an ether. In 1796 Beddoes published a work on "Fartitious Airs," in which he says that "Ether in pectoral catarrh gives almost immediate relief both to the oppression and pain in the chest," and further states that "after inhaling two spoonfuls he fell asleep." In 1839, in Pereira's well-known treatise on materia medica, the intoxicating and stupefying qualities of ether are mentioned and its exhilarating effects and its relief of colic and pain were well known. Nothing could better illustrate the unscientific methods of the age than this, and the great need of close observation and experimentation. With all this knowledge before him, it seems strange that Velpaun, in 1839, should write: "To escape pain in surgical operations is a chimera which we are not permitted to look for in our time." At this very time negroes on southern plantations were holding "ether frolics," and knew much about the anesthetic effect of ether. Ether and its blessings might have been obtained centuries before, had there been greater observation and experimentation. At present, with our laboratories for scientific research, medical truths do not slumber so long in the lap of forgetfulness.

On Oct. 16, 1846, occurred the first authentic and public exhibition of anesthesia during a surgical operation, although this was not the first time ether had been used for the purpose of producing insensibility to pain. In May, 1842, Crawford Long of Georgia removed from the neck of a patient a small tumor, while under ether, and without any pain. In 1844 Horace Wells, a dentist of Hartford, first demonstrated the painless extraction of teeth when under the effects of nitrous oxid gas. During this same year Dr. Marcy of Hartford performed a painless operation on a sailor, while under the influence of ether. In 1841 W. T. G. Morton entered the office of Horace Wells, as an assistant, and while there became impressed with the nature and usefulness of nitrous oxid gas. He saw in this a pecuniary reward, so he applied to Dr. C. P. Jackson of Hartford, a noted chemist, to ascertain the best method of manufacturing the nitrous oxid gas, for anesthetic use, and Dr. Jackson first suggested to him the use of ether for this purpose. On Sept. 30, 1846, Morton gave ether for the extraction of a tooth, and the operation proved painless. The next

day he proceeded to have his supposed discovery patented. Then he called upon Warren, at the Massachusetts General Hospital, soliciting his co-operation, and on Oct. 16, 1846, he made his first public experiment with his so-called "lethion," which was simply ether disguised by aromatic oils. Warren succeeded in removing a tumor from the neck of a young man, and the operation was pronounced a great success. Had Morton possessed a scientific and philanthropic spirit instead of one of speculation and cupidity, he would never have disguised the ether or patented his supposed discovery, and sold office rights to dentists. The hospital was the pedestal that caused his borrowed light to shine abroad like a newly discovered sun. Morton, in attempting to find a market for his patent, first publicly proved to the world that ether was a safe anesthetic in surgical operations. Nevertheless, the Medical Society of Paris, in 1848, recognized the claim of Horace Wells as having been the first to apply the use of vapors or gases for painless surgical operations, and on Wells' monument in Hartford, is the following inscription, "Horace Wells, who discovered anesthesia, November, 1844."

Chloroform was discovered in 1831, but was not introduced for anesthetic purposes until 1847, when Simpson used it in his obstetric work. Cocain was discovered by Niemann in 1860, and was first applied as a local anesthetic, or analgesic, in 1862, by Schroff. Karl Koller first demonstrated its use as an ocular analgesic, and reported the same in 1884, when it first came into general prominence. Since this time rhigolin or chlorid of ethyl, Schleich's infiltration method, eucaïn, holocain, aneson, orthoform, etc., have been used as analgesics, in minor surgery. Before anesthesia patients sometimes preferred death to the pain and agony of an operation, which frequently terminated in death from the depressing effects of simple shock and pain. Now there is no more pain, no more agony, and no more incautious haste on the part of the surgeon. Far more difficult and better operations can now be performed. Anesthesia was one of the grandest discoveries of all time, and the human race owes a debt of gratitude to the profession that has done so much toward the relief of suffering and the prolongation of life.

Another grand discovery that has no parallel in the history of medicine was the discovery of bacteriology and antiseptics. We will next, therefore, consider bacteriology, its history and development, its influence over etiology, pathology and the principles and practice of medicine, together with the results that have followed this discovery, such as the knowledge of infection, hygiene, preventive medicine, sanitation, boards of health, antiseptics, asepsis, serum therapy, immunization, etc. The germ theory of disease was anticipated by Terentius Varro, 115 B. C. He advised people to avoid marshy places which "breed certain minute animals, invisible to the eye, and which, carried by the winds, penetrate the mouth and nostrils, and promulgate obstinate diseases." It seems that nearly, if not every, great discovery was anticipated centuries before. For a century or more previous to the experiments of Pasteur, Tyndall, and others, scientists and naturalists believed in the spontaneous generation of life. They knew of the existence of micro-organisms, "monads" or "vibrions" as they were called, but they did not know that all life springs from pre-existing life. They did not know the life history of micro-organisms, or the part they play in nature or disease. Still there were a few early investigators who believed in the germ theory of disease.

In 1675 Leuwenhoek described the "animalcules" in water, and in 1683 he discovered micro-organisms in the saliva, in the intestinal evacuations and elsewhere, and this led him to believe in the relation of micro-organisms to disease. He believed that all diseases and pathologic conditions were caused by organisms. In 1762 Plenicz declared that all infectious diseases were due to living substances capable of multiplying within the body, and of transmission through the air. He discovered animalcule in all decomposing matter, and believed that decomposition was always due to organisms, and that each disease had a special germ. The times, unfortunately for posterity, were not ripe for such observations or theories—which at this time were regarded as due to an unbalanced mind. Ozanan, in 1820, refers to Plenicz' theories and calls them "absurd hypotheses." Robert Boyle, in the seventeenth century, believed that a knowledge of the cause of fermentation would explain the phenomena of fevers and other diseases. Many had vague notions about a "*contagium vivum*," or minute organisms capable of spreading and reproducing themselves. In 1835 Bassi discovered the parasitic origin of silk-worm disease. In 1836 Schulze proved the presence of organisms in the air, and in 1837 Schwann found minute globular bodies, which he believed to be the cause of alcoholic fermentation, and later proved that there was nothing in the elements of air to cause fermentation, as heated or sterilized air would not produce fermentation in boiled substances. In 1843 Helmholtz confirmed Schwann's discovery. In 1839 Schönlein discovered that a parasitic fungus caused the contagious disease of the head, called favus. Vogel discovered the *oidium albicans* in 1840, and Gordsir the *sarcina ventriculi* in 1841.

In 1849 and 1850 the first and largest of the pathogenic organisms—the anthrax bacillus—was identified and described by Pollender and Devaine. So important was this discovery that it has been called the key-stone to the arch of bacteriology. Notwithstanding this discovery, and all previous observations, it was still generally believed that micro-organisms might arise *de novo*, or be generated spontaneously. Liebig thought that putrefaction was due "to the absence of oxygen" and disturbed "molecular arrangements." Schroder and Dusch, in 1854, proved that filtered air would not produce fermentation, and Schwann, Helmholtz and others, in 1848, knew that fermentation and putrefaction were intimately connected with the presence of organisms.

But it remained for Pasteur, in 1858, to scientifically explain the mysteries of fermentation and to disprove the theory of spontaneous generation. There were many previous experiments and observations that anticipated Pasteur's work, but with greater zeal, and with scientific methods of research, he did more than any other observer to popularize and give scientific form to the discoveries previously made. Tyndall and Cohn's observation on the micro-organisms in the air, their relation to fermentation and putrefaction, and the results of temperature on germ life, did much to banish the idea of spontaneous generation, and to create an earnest study of the relations of germs to disease. Pasteur, in 1858, showed that lactic, butyric, and acetic fermentation, and the fermentation of the impure tartrate of lime, were due to micro-organisms, and later affirmed that putrefaction is only a special case of fermentation. He investigated the diseases of silk-worms, the cause of splenic fever, etc., and showed that sheep and cows vaccinated with the attenuated bacilli of splenic

fever were made immune. He first scientifically demonstrated that infection is a phenomenon of microbial parasitism, and first discovered the principle of vaccination, and proved that the pathogenic microbes could be so attenuated or weakened as to produce a mild disease and future immunity. Pasteur's experimental work was along the line of fermentation, infection, contagion, and vaccination. These, together with his discovery of the new treatment of hydrophobia, which is said to cure more than 99 per cent. of all cases, have made him a great benefactor to humanity. Pasteur undoubtedly laid the foundation for bacteriology, but many earnest workers aided in erecting the superstructure. Cohn classified and studied the forms of bacteria, which he regarded as constant. His classification and theories were later modified and enlarged by Lankester, Lister, Billroth, Klebs and many others, who added greatly to our knowledge of the morphology of the micro-organism. While these observations in morphology were being made other observers were doing much to establish the relation of micro-organisms to disease. Villemin, in 1865, first demonstrated the fact that tuberculosis is an infectious disease and could be transmitted by inoculation. Cohnheim, in 1877, confirmed these observations, and this led many to search for the bacillus. Baumgarten first discovered the bacillus, but Koch, in 1882, first fully established the identity of the organism, and made successful cultures. In 1866 Rindfleisch described "vibrios" that he found in infectious wounds, and Recklinghausen and Waldeyer record a similar discovery in pyemia. It must be borne in mind that micro-organisms were called by different names at different times. They were called "monads," "vibrios," "animalcule," "infusoria," "schizomyccets," microbes, etc. These micro-organisms were regarded as animals until 1852, when Perty demonstrated that they belonged to the vegetable kingdom. In 1881 Laveran discovered the plasmodium malariae, and Ogston and Rosenbaum discovered pyogenic organisms. Israel and Ponifick, in 1882, first discovered the parasite, or bacillus, of actinomycosis. During this same year Koch identified the micro-organisms of malignant edema, and Friedlander, in 1883, discovered the bacillus of pneumonia. Loeffler and Schultz discovered the specific germ of glanders—the bacillus mallei—and in 1884 Koch discovered the specific organisms of Asiatic cholera. Nicolaier, in 1884, discovered the bacillus of tetanus, and recently the specific bacillus of yellow fever—the bacillus icteroides—has been discovered. Klein and others have also recently isolated a streptococcus that is regarded as the cause of scarlet fever. Eberth, Koch, Gaffky and others, demonstrated the fact that typhoid fever is due to a special micro-organism. In 1870 Klebs described how organisms in wounds enter the circulation, and later Oertel, Klebs, Eberth and others, established the constant presence of bacteria in diphtheritic deposits. Martin, in 1892, describes three forms of the Klebs-Loeffler bacillus—the long, medium, and short—and showed that one or more of these are found with the streptococcus and other germs, in every case of diphtheria. Much was done by Latour, Schwann, Pollender, Davaine, Heme, Oertel, Pasteur, Tyndall, Klebs, Lister, Koch, and other close observers, to firmly establish the relation of micro-organisms to disease.

(To be continued.)

NAPLES is planning for an international antituberculosis congress and a national exhibition of hygienic appliances next spring.

Correspondence.

A Philippine Evil.

PARIS, FRANCE, July 20, 1899.

To the Editor.—The lay as well as the medical public already recognizes that the torrid heat and drenching rains of a tropical climate are more to be dreaded by the American pacificator, than its hostile and treacherous mongrel population, but the non-professional community does not understand that which even the medical fraternity at home is slow to declare—a far greater evil than even these menaces the youthful soldiers, and through them, when they return, the people of our own land with whom they come in contact. Among the harpies, whose nests are in the East Indies and countries bordering the China Sea, there is none more ravenous and destructive than the lues venerea, whose victims are first the young and vigorous males of the race, and through them, those whom they infect, these remotely to poison others.

No amount of religious instruction or moral suasion, except in a few instances, has been found effective in deterring the youth subjected to the allurements of the facile women of this part of the world. Themselves ignorant, indolent, careless, and unclean, as well as amatory, they become the ready propagators of venereal diseases, which, perhaps from climatic influences, here assume their most virulent form. The writer's own professional experience in these regions caused him to look for syphilis underlying almost every ailment, barring accidents alone, that came under his cognizance.

The British medical officers, from the earliest occupancy of the Indian peninsula, proclaimed this danger, and the medical authorities, year after year, pointed to the statistics, which, moreover, only incompletely exposed the extent of this terrible scourge. Finally, parliament passed the "Contagious Disease Acts," the beneficial effects of which were soon apparent throughout the military and naval service of Great Britain. Notwithstanding this, the cry that the government was fostering vice was raised by a set of narrow-minded religionists, which resulted in the repeal of these acts and the immediate increase and spread of venereal diseases and their sequelae in the British army and home. Japan and the French Asiatic colonies alone examine their public women and sequester those found diseased, in Lock hospitals. Among the Chinese, Malayan and hybrid Spanish population, with whom our troops come in contact, these diseases run rife. When passion impels, principles are forgotten, precepts are ignored, and prudence ought to be inculcated. The examination of women who ply the trade of prostitution can be conducted without even a quasi-recognition of it, at least not greater than its tolerance by the authorities, which is of itself a tantamount recognition, since to assume its non-existence is only a hypocritical pretense of ignorance.

Unfortunately, the reckless exposure of the willful, sinful soldier and sailor does not end with their own infection. With equal recklessness and unconcern, they either deliberately communicate their maladies under the traditional belief that they can thereby rid themselves of them, or unconsciously infect innocent women and children, or even men, who use the drinking vessels, table appointments, toilet articles, or utensils which they have soiled by the touch of their lips or hands. The most pernicious case of syphilis I have seen in recent years occurred in an innocent person, who used a comb belonging to an unsuspected syphilitic, the victim not recognizing the nature of the disease until it had progressed so far that cutaneous syphilides were developed.

It is of moment, therefore, to sanitary and medical men to recognize the danger from the importation of those same venereal maladies, which are invalidating an immense proportion of the British Indian troops. If it be impracticable to require the compulsory examination of enlisted men, prior to their com-

plaint of disability, it is, nevertheless, urgent and necessary to institute such examinations, before the men or officer is mustered out of service on return home. Precise figures can not be given of the proportion of such troops so infected, but the number is far greater than supposed, and as every single case becomes a focus of dissemination, its discovery and suppression are of far-reaching sanitary importance. Chaplains may exhort fervently and eloquently—though in fact they avoid the subject—without moving the sinner, who conceals his sinning, but the medical officer who positively says "Thou art the man," serves the cause of God and righteousness to far better effect by secluding the—in it may be innocent—victim from possible, if not certain, contamination, or other innocents among women and children. If syphilis is comparatively infrequent in late years, in the United States, it is because the keepers of brothels recognize the pecuniary advantage of protecting their inmates by instructing them in preliminary inspection of their visitors, and by placing them at once under medical care if, despite their crude precautions, they become infected. There is no such safeguard among the loose females of the Philippines and adjacent groups, whose animal instincts are under no restraint, and who, themselves often in the first place victims of unscrupulous beastly men, scatter their disease far and wide. Were sinners the only sufferers, some reason might be held by those whose own righteousness entitles them to stone these profligates, but since we know that the mucous patch and eczematous vesicle are no respectors of persons, and that the sure and guileless may be innocently defiled, it becomes a solemn duty to extinguish the spark which may lead to such ruin. Hence, it is to be hoped that the surgeons-general of the army and navy will require satisfactory evidence of absence of venereal disease before authorizing the discharge of any soldier, sailor and marine from the national services. The economic consideration concerned in the protection of the pension list from future applications actually due to antecedent venereal disease is an additional reason for this rigid scrutiny.

A. L. G.

Ventrosuspension of Uterus.

HILLSBORO, N. D., Aug. 8, 1899.

To the Editor.—In connection with the recommendation of Dr. J. Wesley Bovee, to utilize a bundle of the rectus for ventrosuspension of the uterus, I wish to draw your attention to the successful performance and result of this idea in a case operated on by me in 1896, reported to the last meeting of the North Dakota State Medical Society and printed in the *Northwestern Lancet* for June 15, 1899. This patient was well one year after. I have endeavored to get the subsequent history as to conceptions, labors, etc., but have not yet succeeded.

Yours very truly,

THOR MOELLER, M.D.

[All the mention we find in the paper referred to is contained in the following very brief report of a case:

"Case 15.—Mrs. S., March 19, 1896. Ventrosuspension of the uterus by a bundle of the rectus muscle and fascia for retroflexion. Discharged in three weeks, was well a year after."

EDITOR.]

Unique (?) Case.

BURLINGTON, IOWA, Aug. 5, 1899.

To the Editor.—Country doctors sometimes see unique cases, and I should like to report the following as having been interesting, at least to me:

Early in May, of this year, I was consulted by Miss W. J., from a neighboring town, for a pathologic condition variously estimated as calculus of the liver, kidneys or bladder. I discovered cystic ovaries, and pyosalpinx of the right Fallopian tube, and advised removal. On account of severe pain, she readily consented, and the following day, after curettage, I removed degenerated tubes, broad ligaments, cystic ovaries,

subserous myoma with appendix vermiformis attached thereto, by adhesive inflammation; rapid and uneventful recovery,

Yours,
C. E. BARNES, M.D.

A. M. A. Week Clinics.

COLUMBUS, OHIO, Aug. 5, 1899.

To the Editor.—During the week of the meeting of the ASSOCIATION in Columbus, I made a number of private abdominal sections. Although there were no public clinics, all the operations were witnessed by numbers of my surgical colleagues who had honored me by asking to see me work. Several of them requested to be informed of the results of the operations, but as I am unable to keep a record of my visitors I have felt that the only way to reach them would be by a note to the JOURNAL.

The abdominal sections were twelve in number, ten of the cases being operated on at the Protestant Hospital and two at St. Anthony. I am happy to state that in all the cases recovery was absolutely uneventful and the patients all left the hospital promptly and in good condition. Very respectfully,

J. F. BALDWIN, M.D.

AMERICAN.

1. Rupture of Colon.—Two cases of traumatic rupture of the colon have within three years come under the observation of Makins. He reports both cases and discusses the symptoms and treatment of intestinal rupture generally. As regards causation, he finds that the one factor of importance is the severity of the violence and its localized action. The small intestine is most liable to injury, owing to its more exposed situation. He thinks that it may be affirmed that blows over the abdomen above the navel are not very likely to cause intestinal rupture unless the violence is directed so as to press the gut against the spinal cord. In such a case injury to the mesentery or omentum is nearly as likely as one of the bowel itself. The analysis of the symptoms is as follows: shock was very variable, in most cases comparatively slight; abdominal pain was constant, always continuous, and often not severe; rigidity of the abdominal wall was constant and not pathognomonic; abdominal distension was rare in the early stages and only occurs with the advent of peritoneal septicæmia. Tenderness may be regarded as a constant sign, though it is not always reported. Percussion signs are variable, but the data are imperfect in regard to them in the cases analyzed. In the two varieties of local resonance, dullness and tympanites, he regards the least extensive one as of the most importance. The importance of dullness depends largely upon its fixity. The pulse shows a steady tendency to rise in frequency and lose in strength. The temperature may be low in the beginning, but subsequently rises. Tendency to defecation or passage of blood is of importance. The diagnosis must in most cases be made by exclusion of injury to the solid viscera or the bladder which have their own special signs. The history as to the location and manner of the injury is also of value. Localized tenderness, dullness, etc., with shock, pain and vomiting are of importance, and such signs especially characteristic of intestinal injury, such as cellular emphysema localizing the injury to the uncovered portions of the duodenum or colon, or possibly free gas in the peritoneal cavity may be present. Any of these signs with a rising pulse above 100 will be indications for abdominal exploration. A definite diagnosis from rupture of the mesentery is often impossible, and the conditions may coexist. One sign, however, is of definite value in localizing injury to the mesentery, namely, the presence of a large quantity of free blood in the peritoneal cavity. The prognosis has been considered bad, but of the twenty cases analyzed, three recovered. Fifteen were operated on, including the recovered cases. The average duration of life in the fatal cases amounted to a little over fifty-nine hours, but excluding other cases which lived four, five, six and nine days, respectively, the average duration of the remainder was just forty-eight hours. Operation can not be too early if the injury is diagnosed or suspected, and the best site for incision is in the median line between the umbilicus and pubes to one or the other side of the linea alba. In all moderate rents the Lembert suture is to be preferred. The peritoneum should be cleaned by a preliminary dry sponging of the affected area followed by irrigation and flushing. Drainage should be avoided if possible. Rectal feeding should be relied on for the first twenty-four hours, after this, in the absence of vomiting, fluid nourishment may be given by the mouth. The paper ends with the brief details of the twenty cases analyzed.

2. Injury of the Spinal Cord.—Bolton's conclusions are as follows: 1. Extradural hemorrhage does not give rise to cord lesions or symptoms, and requires no treatment. 2. Total

Lesions of the cord are irremediable, because the cells and fibers of the entire thickness of the cord are destroyed, are never regenerated, and are replaced by cicatricial tissue. The lesion is thus permanent and needs no treatment. 3. In hematomyelia the clot is absorbed; its site persists as a cavity or is filled by newly formed tissue; irregularities of circulation in the surrounding portions of the cord adjust themselves. There may be great amelioration of the symptoms. There is, therefore, no therapeutic indication, and no remedial treatment is possible.

4. In partial contusion of the cord the lesion results in permanent destruction of the cells and fibers; disturbances of circulation adjust themselves. Repair is accomplished by cicatricial tissue. No treatment is available. 5. In open injuries of the cord there is destruction of cells and fibers and disturbances of the circulation. In addition, infection may occur or a foreign body may be introduced and left in or lodged against the cord, and by its continued presence produce great disturbance of circulation and consequent extensive degeneration and necrosis of cells and fibers. Repair occurs by cicatricial tissue as before. But here active operative interference is indicated to remove foreign bodies, to facilitate disinfection, to prevent more extensive necrosis, and to facilitate drainage.

3. **Detection of Renal Calculi by X-Rays.**—In this paper Abbe has collected 27 cases, including two personal observations in which operation verified the diagnosis of renal calculi by radiographs. He believes that in most people of spare habits, and in young subjects, the stone in the kidney can be found with reasonable certainty. He also thinks that while the technical work of producing a successful radiograph is not yet thoroughly studied out, it seems probable that a quick penetrating focus tube with very short exposure would show stones that would be lost in long exposures.

6. **Congenital Malformation of Clavicle.**—Besides a case of anterior dislocation of the carpal scaphoid bone, King reports a case of a woman who had fractured her right collarbone in childhood, resulting in nonunion through neglect. She had had three children. The first died in infancy, the condition of its clavicle unnoticed. The other two have a congenital ununited apparent fracture of the collar bone on the same side, with the same appearance as that of their mother. There were no accidents during pregnancy, nor to the children, and both labors were natural.

7. **Tuberculosis.**—Trudeau calls attention to a number of yet unsettled questions in regard to tuberculosis, its etiology, the wide variation in the manifestations of the disease, what constitutes virulence in the infecting bacilli, how do they grow out of the body, what is predisposition? As regards its pathology, the problems here suggested are chemical changes in the digestive secretions, condition of the blood, pathologic changes causing cure in peritoneal tuberculosis after laparotomy, the factors determining local immunity, the meaning of the presence of tubercle bacilli in the different secretions, of the production of beading of the tubercle bacilli, within and outside of the body, its relation to spore formation and to the nature of the bacillus itself as regards prophylaxis; we need still further study of the sources of infection, and he mentions a number of questions as regards bacteriology and antitoxins. As regards diagnosis, the mechanism of the tuberculin reaction requires study, and the use of X-rays is recommended, and as to treatment the chemical inoculation, antitoxin and immunizing are questions as yet in many points unanswered. He partially reports his own experiments on guinea-pigs, as yet incomplete.

8. **Salt Solution Infusions and Oxygen Inhalations in Pneumonia.**—Penrose describes the method used in the Johns Hopkins Hospital for infusion of normal salt solution in pneumonia, and reports two cases, also a method of giving oxygen by means of a funnel held by a framework, the oxygen having passed through a hot inhalation mixture. He believes that infusion of salt solution increases the circulation of the lungs and their ability to take in oxygen.

11. **Chronic Malarial Nephritis.**—The two points of special interest in the case reported by Larned are, he states, the rarity of the malarial type, the quartan, and the associated nephritis, which was almost certainly dependent on this or a previous malarial infection. He says: The conclusions to be drawn from this and other cases already on record, especially Thayer's and those of Kelsch and Kiener, are: 1. Certainly

in some localities malarial fever should be given a prominent position in the etiology of chronic as well as acute nephritis. 2. In all cases of malarial fever the urine should be carefully watched. 3. A blood examination should be made in all cases of nephritis occurring in those who have visited or lived in a malarial district, as it often happens that the severe grade of nephritis resulting may entirely mask the clinical picture of malarial fever.

17. **Otitic Brain Abscess.**—Ropke's paper discusses the subject of brain abscess from ear disease, quite thoroughly, noticing the literature in detail. After describing the technic of the operation and discussing the question as to whether brain abscess can disappear spontaneously, which he thinks can be admitted in rare cases, he gives the results of 141 cases operated on, and which he has been able to collect and analyze in detail. Of the 141 operated cases, there were 57 permanent cures or 40.4 per cent., a result which refutes the very unfavorable estimate of some authors as to the curability of this condition. Of the 26 cases following acute otitis, 43.2 per cent. were cured, and we have very nearly the same percentage—43.1 per cent.—of the 109 after chronic otitis. The operation, therefore, has about the same prognosis in either case. The symptoms which give the indications for the operation do not help us very much as regards prognosis. Cases with normal or subnormal temperature are frequently more favorable than those which run a violent course, as the virulence of the infection seems to be less and complications are less likely to occur. The presence of focal symptoms before operation is of no value in estimating the future course. The size and site of the abscess are important. The small abscesses situated near the surface of the brain naturally afford a better prognosis than the larger and deeper ones. It is especially important to note whether the abscess contains pathogenic germs. The color and odor of the pus give no clue as to its virulence. When the abscess lacks lining membrane, and is irregular in its outline, it is more serious, and the more brain tissue disturbed during the operation, the worse. In his 141 cases, 81 were operated on through the squama, with 38.3 per cent. recovered; 43 operated through the tegmen, with 40.2 per cent. cures; in 7, where the combined opening was made through both, 5 or 71.1 per cent. recovered.

18. **Intestinal Disturbances Produced by Otitis Media.**—Hartmann, after noticing the cases reported by others, deduces the following conclusions: 1. Acute febrile otitis causes a diminution in weight, or arrest of increase of weight. 2. Otitis accompanied by grave septic symptoms probably causes diarrhea. 3. An acute febrile otitis occurring during intestinal diseases may act on the general constitution, and by reducing the vitality, aggravate the intestinal affections or retard recovery. 4. Whether there is a direct relation between atrophy and otitis, must be reserved for further observations. He reports nine cases. The latter part of his paper is devoted to the diagnosis of infantile otitis.

26. **Multiple Cavernous Angioma.**—Ohlmacher's article describes, at length, a case of multiple angiomatous tumors of the brain and spinal cord, and a fibro-endothelioma of the dura. The latter gave rise to epilepsy, the spinal tumor, causing transverse destruction of the spinal cord, and ending in an extensive hemorrhage, revealed on autopsy. The pathology is very fully worked out and discussed.

27. **Retardation of Pain Sense in Tabes.**—Musken's has noted a special retardation of pain sense on the borders of analgesic areas in tabes, when the sense of touch is still intact. This border varies much in width, from a millimeter or less to some decimeters; it is widest as a rule in the lower extremities. He thinks this special retardation of pain sense is an important and early symptom of the disease, probably always preceding the analgesia, and probably of differential diagnostic value.

28. **Symptomatology of Intracranial Disease.**—Fraenkel's paper is a painstaking analysis of two cases, one probably of specific thalamic gumma, and the other diagnosed as tubercular disease involving the cerebellar and pontine region. This patient died in uræmic coma. From a careful analysis of the symptoms of the first case, emotional spasticity, mental hebetude, pupillary and ocular symptoms, abolition of the psychic reflex of the seventh nerve, mild and slowly progressing hemiplegia with inconstant spasticity, muscular atrophy and in-

co-ordination, depression of all vegetative reflexes, with absence of hemianopia and sensory disturbances in the opposite side of the body, he concludes that the tumor was in the anterior portion of the thalamus. The autopsy findings in the cranium in the second case were not very decisive, but the suggestion of a tubercular basilar meningitis existing to some extent was rather confirmed than otherwise.

29. Aural Vertigo.—The point made in Mettler's paper is that the nucleus of Deiter is probably the true center of equilibrium, that the sense of equilibrium is essentially a complicated sensory motor phenomenon, and the semicircular canals alone are not especially its organs. He aims to show, by his anatomic and physiologic discussion of the subject, that vertigo may be produced by irritation of any of the ramifications of the apparatus of equilibration, in the eye or stomach for example, as readily as in the ear.

30. Extrapulmonary Coughs.—Noticing first the difficulty of the problem of always giving a careful etiology of a cough, Abrams mentions certain methods of diagnosis, such as the use of iodid of potash, bromoform, etc., and calls attention to the influence of irritation occurring from the skin, ear, nose, nasopharynx, the pharynx, the tonsils, the uvula, and lingual tonsil, as especially producing these symptoms. It may, however, be aroused from the teeth, esophagus, liver, spleen and pleura. The so-called stomach cough is also largely corroborated by clinical observation.

31.—See ¶ 64, below.

38. Asthma.—Hitz suggests that one of the commonest causes of asthma is a reflex from the nasal mucosa, and he states that in every case that has come under his observation immediate relief has been afforded by the direct application on a probe of 10 per cent. solution of cocain to the points of contact of tumors and soft swellings with the septum—a diagnostic measure to which there is no superior. In the vast majority of asthmatics he claims that swellings or points of pressure and irritation appear to be in the region of the middle turbinal and usually greatest in its posterior aspects. He reports seven cases illustrating his views and points out removal of the growths as treatment.

39. Sanitation of Private Houses.—Pritchard calls attention to the sanitary shortcomings in homes; the unhealthy, many-layered wall paper, the carved and cracked or ill joined woodwork, hiding germs, and the defects in ventilation in old houses. He would have painted walls, well-seasoned woodwork with all cracks and holes puttied up, and painted floors laid close and not requiring carpeting, furniture without upholstering that may gather dirt, germs, etc.

47. Sanarelli's Serum in Yellow Fever.—Archinard here reports the results of a series of experiments made on yellow fever patients with Sanarelli's serum, received from Monte Video. The ten cases thus experimented on are recorded in detail. Archinard concludes that this agent has, in his hands, shown no curative power whatever, none of the important and dangerous symptoms having been in any way mitigated or prevented by its administration. In justice to Sanarelli it must be said that he has never claimed his serum curative in severe cases, and most of these were severe. It is not always easy to use it early, and, judging by experience, the great majority of cases are benign and get well under any treatment. Necessarily serum employed at random in these cases would be at great advantage. Archinard is skeptical also in regard to any immunizing property of the serum, judging from his experiments on animals. In the human species he has had no experience.

49.—See abstract in JOURNAL, July 8, p. 102.

51. Danger Signals of Pre-eclamptic State.—Jewett assuming that eclampsia is due to toxemia, adopts the view of Hughes and Carter that it is probable that in addition to the pathogenic poison of uremia there are under certain conditions other secondary ones active in the production of the toxemia; that the poison producing uremia will also produce nephritis, and that it is possible to have uremia without previously existing kidney lesions. He notices, for the sake of brevity, only a few of the leading urinary signs to be noticed as danger signals. The first of these, albuminuria, is especially valuable on account of its ease of detection. Unfortunately, however, too many physicians trust to it alone, and are not sufficiently per-

sistent and frequent in their testing. He believes that it is more frequently found early in the pre-eclamptic state than is commonly recognized. It is a fact, however, that cases of eclampsia occur with no kidney lesions found at the autopsy. How long and to what extent albuminuria may have existed in such is a question he does not attempt to answer. The second sign noticed is the urea, which is especially valuable on account of its ease of determination, but on it too implicit reliance should not be placed, as it may have quite a wide range in normal individuals. These cases, however, are exceptions, and noticeable diminution of this substance in the urine should excite suspicion. A most important and too frequently neglected element in the prognosis as relates to the pre-eclamptic condition is the daily quantity of the urine. It is especially useful, as it is a matter that can be trusted largely to the patient's observation. With necessary precautions, close observation of this element has greater value than urea determination. None of the foregoing should be alone depended on. All must be watched. The urine being normal in amount and character, true puerperal eclampsia need scarcely be feared, but departure from the normal in any of these points demands special vigilance.

53. "Christian Science" Methods.—Dr. Wilson's article is an interesting account of certain "Christian Science" methods, with extensive quotations from a report of a *New York World* reporter who took a course in "Christian Science" in order to be able to enlighten the public in regard to it.

54. Catarrhal Deafness.—The object of Snow's article is to point out that many cases of catarrhal deafness are considered incurable and unnecessarily neglected. He thinks that in most cases we will find a cause which is removable, and that the disorder is a preventable one. His plan in chronic catarrhal inflammation is to see that all removable causes are cared for, and to make a new test of the hearing and then begin with vapor of camphor and iodine in interrupted jets through the Eustachian catheter. It serves the purpose of toning up relaxed or atrophied membranes, increasing ossicular mobility and absorbing inflammatory products. This treatment should be repeated according to the case, every day or twice a week until the sensitiveness of the tubal membranes is removed, relaxed blood-vessels toned up and improvement in hearing ceases. Active treatment may then be discontinued, but the patient is instructed to report on every new sign of deafness. These periods of rest may be regularly increased until three to six months elapse between the treatments. Under this plan he has obtained very satisfactory results in cases where an unfavorable opinion has been given.

56. Slipping of Intrapertoneal Ligature.—Noting the frequency of the unfortunate accident of slipping of the intraperitoneal ligature, Sutton calls attention to the surgical practice of tying en masse, and he thinks it is better surgery to tie the ovarian artery at the big infundibulum pelvium, and the uterine below the cornual extremity of the Fallopian tube, and to strip out the tube and ovary entirely from the ligamentum latum, closing the open edge of the latter with a catgut suture. With this method the conical retracting stump is avoided, with all tension, and the removal of the ovaries and tubes is more complete. In cases where it is not possible to safely secure vessels with a ligature, Doyen's crusher will serve a useful purpose or, where it is desirable, the application of a pair of heavy clamp forceps will prepare a bed for the ligature. It will hold better in the groove of crushed tissue than made.

58. Insurance Decision Following Gastro-Enterostomy.—A case reported by Scott is of interest as showing the decision of a life insurance company in regard to a case of gastro-enterostomy. The patient, a man, 45 years of age, was operated on for non-malignant pyloric stenosis. Simple gastro-enterostomy between the anterior stomach wall and the jejunum was performed, with the result of perfect recovery. The patient's life insurance being nearly run out, and re-examination required, the doctor wrote to the New York Life Insurance Company and stated the nature of the case and the details of the operation, and received in reply the statement that they would admit the patient to examination though only one year and a half had elapsed after operation.

62. Clinical Study of Chorea.—Williams, after noticing

the accepted views and facts in regard to chorea, reports four cases as illustrating the different causes producing the disease. In the first case eye strain seems to have produced it in a boy 11 years old; the second case was apparently caused by fright in a child; the third was a girl 9 years old, with psychopathic family history, she had a fall, injuring her head, and fracture of the skull was diagnosed, but operation was refused. Epilepsy and chorea both followed, the choreic movements being confined exclusively to the left hand and arm. Trephining was performed over the scar on the skull and a spicule of bone pressing down on the ascending parietal lobe of the right hemisphere, $1\frac{1}{2}$ inches below the upper margin of the hemisphere, was removed. Recovery was uninterrupted and both disorders disappeared for as long as the child was under observation. The last case appeared to be due to reflex irritation from adenoids, and on their removal the chorea ceased. Williams emphasizes the importance of close examination as to the causal factors in each individual case.

64.—See abstract in JOURNAL, May 27, p. 1171; also ¶ 31, above.

66.—This paper appeared in full in the JOURNAL of June 24, p. 1420; see also, *Ibid*, May 27, p. 1173.

68.—See abstract in JOURNAL, June 3, p. 1256.

74.—*Ibid*, May 13, p. 1053.

78. **Tuberculosis of Breast.**—Gage reports a case of tuberculosis of the breast in a woman 43 years old, with microscopic examination, and discusses the subject of this tubercular manifestation. Up to date there have been reported 55 cases, besides his. Out of the 56, but 4 were males and more than half of the women had borne children. He thinks, therefore, that functional activity was in some measure a predisposing cause. In 20 per cent. there was a tubercular family history. As regards the mode of introduction of the germ, he believes that it is through the circulation, finding a point of least resistance in the breast. The clinical history is rather vague, there may be pain or there may be the want of it. Constitutional disturbances are slight, and the progress usually slow. The diagnosis must often be left until the breast has been removed, in accordance with the general rule that any-growth in the breast associated with enlarged lymphatics requires excision. The treatment is surgical and the removal should be radical.

80. **Gelato-Glycerin Bougies in Earache.**—Richards calls attention to the value of gelato-glycerin bougies in the treatment of this affection, as they can be inserted in the ear without difficulty, by simply washing off the lycopodium powder, when they slip in readily and dissolve so that the anodyne is brought into immediate contact with the inflamed surface. He gives the following formula, which can be made by any druggist:

Acid carbolic.....	m. 7
Fl. ext. opium.....	m. 6
Cocaine.....	gr. 3
Atropin sulph.....	gr. 3
Water.....	m. 52
Gelatin.....	gr. 18
Cocain.....	gr. 3
Glycerin.....	gr. 158

M. To make 42 bougies.

After making they are covered with lycopodium powder and dispensed in a bottle, as they are somewhat hygroscopic. He believes that if used early enough they will in many cases prevent the need of paracentesis.

83.—This address appeared in the JOURNAL of June 10, p. 1273.

103. **Some Smallpox Statistics.**—Ruhrah reports the statistics of the Quarantine Hospital at Baltimore as regards smallpox. There were 1106 cases; 441 of these had been vaccinated at some previous period, 645 had never been vaccinated, and 20 had been, but unsuccessfully. Of the 441 cases there were 378 recoveries, 63 deaths, and a mortality rate of 14.3 per cent. Of the 645 unvaccinated, there were 330 recoveries, 315 deaths, and a mortality percentage of 48.8. Of the 20 cases of unsuccessful vaccinations, there were 6 deaths and 14 recoveries, and the mortality rate 30 per cent. The total mortality was 34.7 per cent. In 105 cases the variety of the disease was stated; 55 of these cases had been vaccinated, 49 recovered; 43 discrete, 6 confluent; 6 died, discrete 1, confluent 5. Of the unvaccinated cases, 50 in number, 27 recovered;

15 discrete, 12 confluent; 23 died, discrete none, confluent 21, hemorrhagic 2. These figures show that in those who had been vaccinated, how long before not stated, the percentage of recovered was greater and the disease in most of the cases discrete. All but one of the fatal cases were confluent, and that one died of complicating pneumonia. In the unvaccinated most of the cases were confluent.

106. **Meddlesome Instrumentation in Urethral Diseases.**—The unsurgical and disastrous results of meddlesome instrumentation in urethral disorders is the theme of Champion's article. He condemns the use of small steel instruments below 18 or 20 French. Steel sounds for exploring the urethra should be abandoned. If the urethra is sensitive, or there is a discharge from the canal, first treat by irrigation until the sensitive condition has disappeared and the discharge is controlled, before using instruments. Instruments are passed too often in treating stricture, and he states that as a rule it is bad surgery, in treating stricture by dilatation, to reintroduce an instrument—unless it be filiform—before the lapse of at least seventy-two hours, and more rapid progress will be made by waiting ninety-six hours, often even seven to eight days. The practice of doing internal urethrotomy in the office and allowing the patient to go home can not be too strongly condemned. It is a dangerous operation and the patient should be kept in bed for at least five days, better a week. In his opinion, after internal urethrotomy instruments are too frequently passed. Every fourth, fifth or sixth day will give as good results and less pain than the shorter intervals. He emphasizes the importance of irrigating before surgical operation on the urethral canal, whether it be mere passage of the sound or an internal urethrotomy. If this is done there will be fewer cases of urethral fever and less irritation and inflammation. Lately he has used hydrostatic irrigation in the treatment of inflammatory conditions of the urethra and bladder and finds it better than any other method. The container, which holds a prescribed quantity of the fluid to be used, is raised eight to nine feet from the floor. The anterior urethra is first thoroughly washed out and the glass nozzle employed is placed firmly against the meatus and the patient told to breathe deeply or try to urinate and the fluid flows back into the bladder. When the bladder is full, he is allowed to pass it and it is again refilled. The advantage of this is that it distends the urethra completely, and forces the pus and germs from the glands and follicles.

108. **Diverticulitis.**—Wright reports a case of inflammation of Meckel's diverticulum simulating appendicitis, and operated on with success, by excising about three inches of the ileum with the diverticulum. This was done on account of the extreme thinness of the intestinal walls at this point, and from this he concludes there was probably a traumatic origin of the diverticulum. A Murphy's button was used and passed the nineteenth day. The clinical symptoms were entirely those of appendicitis, but the true appendix was found lacking.

115.—See ¶ 83, above.

116. **General Suppurative Peritonitis.**—McGuire reports his method in the treatment of general suppurative peritonitis. He calls attention to the importance of early diagnosis and operation, and the necessity of multiple incisions for thorough work. Primary incision should be made at the point giving the shortest and most direct route to the focus of infection. The secondary ones should be usually three in number, one opposite, below or above, the primary incision, and the other two in the posterior lumbar region. In females an opening through the Douglas sac will be of service. These secondary incisions should be large enough to permit the easy insertion and passage of gauze drains, but not large enough to cause danger of bowel protrusion in coughing, or vomiting. To cleanse the abdomen thoroughly it should be emptied, the intestines should be drawn out through the incision, wrapped in the hot gauze towels and laid to one side. The cavity should then be wiped out with moist gauze compresses and the bowels gone over loop by loop and freed from all infection. This should be done under continuous hot irrigation; plain sterilized water will be sufficient. In many cases the bowels will be found parietic and distended with gas, and it would be fatal to return them in that condition. They should be incised at several points and the tension relieved. As soon as the gas escapes the opening

should be sutured, the surface sponged off, and this operation should be repeated at other points until the distension is done away with and the bowels can be returned without force. Drainage is essential, as it means that we have no other measure available to insure complete asepsis of the cavity. Gauze drains should be left in position as long as they are doing good; usually they can be removed in from three to five days. The after-treatment is the same as in any other case of abdominal section.

122. Modern Use of Synthetics.—The title of this paper is slightly a misnomer, as it is special and not general in its subject. The paper is confined to a statement of benefits and advantages of kryofin, which the author thinks is a very valuable addition to the pharmacopœia.

125. Appendicitis.—Why some severe cases of appendicitis end in recovery without operation is explained by Carstens on anatomic grounds. In several cases observed during the last years, he found some interesting peculiarities which serve to answer this question. In one case the end of the appendix was adherent to the cecum in such a way that there was no peritoneal tissue between them. In this suppurated of the appendix would find an easy outlet into the cecum, readily penetrating the muscular wall. In a second case the appendix was adherent to the cecum throughout its whole extent, and the same condition existed as in the former, only more extensively. He gives tabulated statements of thirty-three operations for appendicitis in 1898, with two deaths.

127. Effects of Influenza on the Eyes.—Oppenheimer gives a long list of ocular complications of influenza, from medical literature, and explains them as follows: As regards glaucoma, he thinks the cases occurring may be accounted for by the general reduction of strength and vitality. The same will account for the lighter grades of paresis of the muscles, especially those of accommodation. In the hemorrhage, in various parts we have the changed condition of the blood as a probable responsible factor, and this without taking into account the septic emboli to be further mentioned. No specific effect is necessary to explain them. They occur in all conditions affecting the condition of the blood. The purulent uveitis and orbital cellulitis and panophthalmitis must be explained by emboli containing pyogenic cocci, but he is not prepared to say how far the Canon-Pfeifer bacillus is responsible. The severe nervous troubles are best accounted for, in his opinion, by malnutrition, using the word in its broader sense, combined at times with localized edema. As an example of this effect, he refers to the ocular symptoms observed in Russian prisons and barracks during the long fast of six weeks enjoined by the Greek church. He says: "Thus, to my mind, the lack of appetite, the vitiated functions of the digestive apparatus, the consequent changes in the blood, lowered nutrition, together with the great depression of the heart's action (which is in all probability due to toxins produced by the yet undiscovered causative microbe), will account for the profound impression upon the nervous system which is so commonly observed, and explain the chromatopsia, scotomata, inflammations and paralyzes of the nerves and muscles supplied by them."

128. Hemoglobinuric Fever.—Feild describes the differential diagnosis of hemoglobinuric fever, yellow fever and ordinary bilious remittent. Between hemoglobinuria and yellow fever we have the following differences. In hemoglobinuria we have no immunity, its occurrence in malarial districts, high external temperature not required; its occurrence at all seasons of the year; its non-infective nature; the excessive amount of urine, high colored and of high specific gravity as opposed to the scanty urine of yellow fever. The peculiar ratio of slow pulse and high temperature so notable in yellow fever is lacking in hemoglobinuric fever. The jaundice is very rapid, no hemorrhage occurs except from the kidneys, remission in a few hours is the rule; lack of violent headache and the characteristic flush and physiognomy of yellow fever, and the fact that negroes are exempt are also distinguishing characteristics. In ordinary bilious remittent, the slower onset and less rapid and intense jaundice, the absence of black vomit, the hemorrhage from mucous surfaces and the heavily white furred tongue are notable points of distinction. The treatment most successful in Feild's cases was the relief of constipation by salines, the withholding of quinin, hypodermics of morphin for the great

pain and restlessness, cold to the head and the administration of arsenic to prevent recurrence of the malarial paroxysm. He thinks that theoretically the flushing out of the kidneys with soft water would seem to be indicated. The other treatment should consist of keeping up the strength of the patient, allaying irritability of the stomach, giving liquids only, etc.

130. Typhoid Fever.—The antiseptic treatment of typhoid fever is strongly advocated by Seufert, who, in addition to the precautions of rest and diet and cold sponging—the Brand method was not utilized—treated his cases with an opening dose of calomel, one grain every two hours, followed by intestinal antiseptics, salol, naphthalin and carbonate of guaiacol. Each was given in the order indicated, for one week, salol in 5-grain doses every two hours, naphthalin in 5-grain doses every three hours in capsules, and the third week guaiacol in 2.5 grain doses every three hours until convalescence. Constipation was relieved by Rubinat water, and diarrhea and meteorism, which occurred in only six cases, were easily controlled by turpentin emulsion with deodorized tincture of opium. In the one case of an 8-year-old sickly child, which was complicated by pneumonia, chorea, pericarditis and endocarditis, the treatment was also with ice bags, Fowler's solution, three drops every four hours in water, and full doses of strychnin. Tonics were used during convalescence. The average duration of the fever was twenty-one days, the longest case nine weeks. An analysis of the symptoms is given.

131. Suprarenal Capsule.—The suprarenal capsule as an astringent is highly recommended by Sharp in diseases of the nose and throat, in a 10 per cent. aqueous extract, made up freshly. He thinks it will contract the mucous membrane of the nose as much as cocaine, without the danger and depressing effect of the latter.

132. Abdomino-Sacral Operation for Rectal Carcinoma.—Sommer describes a case observed by him in Kraske's clinic, in which the latter performed an operation for carcinoma of the rectum situated high up by first opening the abdomen and freeing the adhesions, then packing the cavity with gauze, placing the patient in a right lateral position and performing the sacral operation which goes under his name. He is inclined, the author states, to use this combined operation more generally in such cases. Its chief advantages are the possibility of delaying the opening of the bowel until it has been isolated; shock seems to be a matter of comparatively little consequence, and tumors, which were practically inaccessible by the sacral route alone, become accessible. Another advantage is that the removal of the tumor and resection of the rectum can be done externally, and the complete removal of surrounding infected tissue is made possible, and still another is the facility of ligating the intestinal vessels. The operation observed was perfectly successful.

133. Acute Bronchitis.—In this article Reilly discusses the etiology of bronchitis and thinks that it is due to a toxemia. He strongly suggests its connection with lithemic poisoning. As regards treatment, he objects to the use of expectorants and doubts their curative effects. The rational therapeutics of the disease consist, he holds, in repeated cleansing of the intestinal tract, aiding the skin and kidneys in the elimination of toxic products by repeated diaphoresis and the ingestion of a large quantity of water, and in the neutralizing or hastening the elimination of the so-called lithic acid poisoning. He concludes as follows: 1. Acute bronchitis is a symptom. 2. The diseased condition of which it is a symptom is a toxemia, which may be due: a, to the so-called uric-acid poison; b, to auto-intoxication from the intestinal canal; c, to specific infectious agents. 3. The treatment with nauseous mixtures under the name of expectorants, is illogical, and is opposed to modern therapeutics. 4. In every case we should endeavor to discover the etiologic factor, and treat the same.

134. Asexualism.—Brooks describes a case of approximate sexual neutrality with feminine general contour and tendency and rudimentary external male organs. He thinks these cases are more frequent than supposed, especially in the female type.

135. Epiphora.—The description of this condition by Woodward, and the discussion of its etiology and treatment form the subject of a rather lengthy paper. He classifies the causes as those inducing excessive production of tears and those interfering with the proper functions of the drainage system.

The former include emotional states, conjunctival inflammations, and various ocular irritations, eye strain and reflex irritation from the nose with other things that increase the sensibility of the fifth nerve. The drainage of the eye depends on the perfection of its apparatus, the patency of the punctum, the permeability of canaliculi, the normal condition of the lachrymal sac, the permeability of the duct and the pathologic conditions in the nose. The treatment consists in opening up the punctum by removal of a V-shaped segment from the posterior wall, and he has for many years been in the habit of removing, in cases of insufficiency of the canaliculum, a portion of the whole of its posterior wall. Other details are fully described and aescopsis insisted on.

136. Celiotomy.—Talbot's paper details the methods of celiotomy. He speaks highly of the Tuffier's angiobride for securing the vessels in celiotomy.

137. Typhoid Mortality.—The mortality from typhoid fever in twenty-four American cities given in tabulated form with brief comments, makes up the substance of Crum's paper. It shows that the typhoid mortality-rate is uniformly high, but that there has been an improvement in most cities during the past decade. The percentage of reduction during the last five years ranges from 71 in Newark to 4.7 in Boston. In New Orleans only is there a higher typhoid rate of late years than during the first half of the decade. The reduced rates are in most places directly attributable to improvement in the water-supply, and Newark and Chicago head the list, the percentage of reduction in the latter city being 61.2. The highest mortality-rate is in Pittsburg, the lowest in Brooklyn. The epidemic in Philadelphia, of this present year, is not included in these statistics.

143. See editorial abstract, *JOURNAL*, August 12, p. 419; also London letter in this issue.

144. See abstract, *JOURNAL*, August 5, p. 355.

145. See editorial abstract, *JOURNAL*, August 12, p. 419; also London letter in this issue.

146. *Ibid.*

151. New Remedies.—The multiplicity of new preparations of all kinds is deprecated by the author. He criticizes the acceptance of samples by physicians, and thinks that they do not always represent the average preparations.

152. Yellow Fever.—Sanarelli's paper is a controversial article combating criticisms that have been made against his claims, by Sternberg, Reed and Carroll, and Novy. He maintains that exposure to cold has no effect on his bacillus.

153. Tuberculosis of the Kidney.—The text of Reynold's paper is that tuberculosis of the kidney is not the hopeless bilateral affection which it has been considered, and is often unilateral and suitable for surgical treatment. The symptoms in the cases on which he founds his opinion were simply general debility and urinary discomfort, with tubercular antecedents. The diagnosis was made by palpation over the kidneys and the course of the ureters, visual inspection of the bladder and in the absence of definite lesions of this viscus, a catheterization of the ureters and the submission of the separate urines, not only to microscopic examination, but also to inoculation experiments, the latter being especially important as shown by one of the four cases he here reports.

154. Retention of Testicles.—After noticing in a general way the facts in regard to this condition, Hill reports three cases of operation in which relief was obtained. In the last case there was a reflex epilepsy which seems to have been relieved also.

155. See abstract in *JOURNAL*, April 29, p. 938.

156. Special Schools for Special Children.—Fort's article dwells on the importance of manual training for weak-minded and backward children.

157. Proteids of Urine.—After reporting a couple of cases Hills describes the conditions of globulinuria and peptonuria. The first case was one of pure globulinuria, a rare condition, though globulin is very commonly found in connection with other proteids. In fact, albuminous urines in a great majority of cases contain it, while it is the sole coagulable protein in a small proportion of cases. The same is also in all probability true of albumin. The significance of globulin in the urine is not well known, though there is some reason to think it has some effect as a factor of the proteid quotient. As regards pep-

tonuria, he calls attention to the fact that greater exactness should be observed in nomenclature. Cases of albumosuria should be reported as such and not as cases of peptonuria or propeptonuria, as has been done in the past. The term peptone should be reserved for those proteid products of proteolysis, which are not precipitated by saturation of the liquid containing them with ammonium sulphate.

158. Spinal Osteo-Arthritis.—Goldthwait reports ten cases of spinal osteo-arthritis, and points out the difference between it and rheumatoid arthritis, also its general clinical pathology.

159. Palmar Abscesses.—Brooks recommends a new method of treating palmar abscess by opening up a triangular flap along the natural lines of the palmar surface, forming a sort of open pouch of the palmar bursa. This affords easy exploration of the whole area of the palm, and cleaning out of any pockets of pus. After granulations have appeared the packing is no longer used, and the skin flaps are folded back and a dry dressing applied.

FOREIGN.

British Medical Journal, July 29.

Operative Treatment of Various Internal Derangements of Knee-Joint. W. J. WALSHAM.—In this article the author discusses the diagnosis and operative treatment of the internal derangements of the knee-joint, including loose bodies, detachment and displacement of the semilunar cartilages, enlargement with nipping of hypertrophied synovial fringes and elongation of the ligamentum patellae. All these conditions have somewhat similar symptoms, synovial effusion, weakness of joint, limitation of flexion and extension, pain sudden and severe, and sometimes a sensation of something slipping in and around the joint. If a loose body is the cause of the trouble it can be felt, as a rule, to slip in and about the joint, not only by the surgeon, but by the patient himself. Still, even in a while there are difficulties, and Walsham reports a case where exploration was required. The diagnosis between a detached semilunar cartilage and a hypertrophied fringe is sometimes difficult. The sign stated in text-books of a semilunar cartilage, that is, locking of the joint and sudden projection of the cartilage, is, according to Walsham, not common. He trusts more to a peculiar creaking or sudden click or snap over the inner portion of the joint, combined with a partial locking and some limitation of movement, and perhaps some slight swelling and pain. The cause of the snap is flying back of the flexed cartilage on flexion of the joint. The signs of a hypertrophied synovial fringe are very similar, but there is not, as a rule, locking of the joint, or much limitation of movement, and the fringe may frequently be felt to roll like a soft pad under the finger when applied over the line of articulation. The disability, however, is often equally great, but it will be found that the pain occurs only when the joint is semiflexed with some slight lateral twisting of the tibia or femur. Elongation of the ligamentum patellae is less common, but the symptoms are similar. The loose patella, slipping, sometimes, over the external condyle, allows the patient to fall. When operations are required for these conditions, the author calls attention to the five following points: The thorough preparation of the patient some time before the operation and complete asepticism of the skin, the knee-joint requiring special attention in this regard; arrest of all hemorrhage before the capsule is opened and thorough cleansing of the joint after the operation, from all clots, with warm, mild antiseptic solution; accurate suture of the synovial membrane and capsule, for which he prefers fine strands of kangaroo tail tendon; absolute rest on a well-fitting back splint till the skin wound is soundly healed, firm pressure being applied to prevent oozing; early passive movement and massage, usually beginning on the fourteenth day, and the patient being up and walking about a week later. As regards elongation of the patella, he thinks it is better to transplant the tubercle of the tibia the shortest distance downward than to attempt to divide and shorten the ligament.

Effective Treatment of Vesical Hemorrhage When Caused by Papillomatous Growths. HERBERT T. HERRING.—The author's method is to use injections of 4 ounces of warm water (99°F.), commencing with the addition of .5 dram of a standard solution of nitrate of silver, one grain to the dram

of distilled water, and increasing the strength every day or two till sometimes 2 drams have been added. This treatment at the start may occasionally increase the hemorrhage, but after several applications it decreases and finally disappears. Thorough antiseptic precautions as to instruments and the parts are required. He reports twelve cases.

Note on Blood in Case of Beri Beri. F. W. MOTT and W. B. HALLIBURTON.—This paper gives the results of experiments made with the blood obtained from a case of beri-beri, as to its effect on blood pressure, experimentally injected in cats, and is illustrated by plethysmographic and manometric tracings. The effect seemed to be more pronounced than that obtained by cholin injection obtained from the cerebrospinal fluid of paretics. Attempt was made to obtain a chemical analysis and determine the presence of cholin, but it was not entirely satisfactory.

Treatment of Impermeable Stricture of Urethra by Excision of Strictured Segment and Suture of Divided Ends. EDWARD DEANESLY.—The author recommends, instead of Wheelhouse's operation for impermeable urethral stricture, the complete excision of the segment involved, and bringing together and suturing the normal calibered, healthy ends which are left, as is done in end-to-end union of the bowel. He reports a case where this was carried out without difficulty. He thinks that there are few cases of stricture which can not be treated in this way.

The Mechanical Factors in Surgery. C. HAMILTON WHITEFORD.—Attention is here called to certain facts which the author has named, for want of a better term, "The Mechanical Factors in Surgery." In the ununited fractures of long bones it will frequently be found that a piece of muscle or splinter of bone has interposed itself between the ununited ends. The mechanical obstruction of respiration in anesthesia, as by growths at the base of the tongue and the valve-like action of the lips, is often overlooked. In the treatment of ulcers we often see lint spread with ointment extending over a margin of healthy skin, instead of having it accurately cut to fit the ulcer, which is bad practice. We see also the use of permanent buried silk sutures which frequently refuse to remain permanently buried, and the illogical use of chemical solutions, such as carbolic acid and corrosive sublimate in the irrigating of wounds, instead of the strictly physiologic salt solution. Lastly, he mentions the bad effect of strangulated hernia involving only the omentum, by producing kinking of the intestines. Another factor in peritonitis, not mentioned in text-books, is the loss of fluid by diarrhea and vomiting, causing heart failure, which would be remedied by large intravenous injections of hot normal salt solutions.

An Inoperable Case of Epithelioma of Larynx and Neck Treated with Formalin Injections. J. D. McFEELY.—This is a report of a case of inoperable malignant growth treated by formalin injections with apparent good results for a time, but the patient finally died, and, at the necropsy, it was found that the tumor occupied the entire left side of the neck from near the jaw to the clavicle and sternum, and it was with great difficulty separated from the deep muscles. The death was caused by asphyxia due to filling of the tracheal tube with fluid, from the breaking down of the tumor, which was found to be an epithelioma of the larynx, starting from the aryepiglottic fold. The author ends his paper with the following conclusions:

1. Up to half a dram of pure formalin can be injected into the body without producing toxic symptoms.
2. Although a powerful styptic, it does not seem so liable as other styptics to produce clotting or embolism.
3. It is probably as safe to use formalin undiluted as diluted with water.
4. When used undiluted it seems to produce an anesthetic effect more quickly.
5. Unlike most other powerful antiseptics or irritants, it does not stimulate, but retards cell multiplication or growth in malignant tumors.

In conclusion one may hazard the opinion that formalin, being such a powerful antiseptic and exercising, as it undoubtedly does, such destructive influence on all low forms of organic life, if any of the neoplasms or malignant growths owe their malignancy, as some believe, to any form of organism, not only

palliative but also curative effects may reasonably be expected to follow its judicious application.

Lancet, July 29.

Influence of Heredity on Drink Habit. G. SIMS WOODHEAD.—The point in Woodhead's address is mainly a criticism of the views maintained by Archdall Reed as to intemperance being a useful factor in evolution, and the establishment of national and racial alcoholic immunity.

Practical Aspects of Dorsal Percussion and in Particular of Percussion of the Spine. WILLIAM EWART.—It is not possible to abstract this article, as it covers the subject at considerable length, and is very detailed, but we mention it here for reference, as it treats very thoroughly of a matter that has not so far been extensively discussed in our text-books on diagnosis. The diagrams are also very instructive.

Dermatitis Exfoliativa Neonatorum or Ritter's Disease. KEDARNATH DAS.—This article reports briefly a case of Ritter's disease, and gives a description of the affection, largely taken from Elliott.

Case of Recklinghausen's Disease Complicated with a Sarcomatous Growth Involving the Brachial Plexus. H. D. ROLLESTON.—The case here reported in detail with necropsy is of interest. The author considers the disease as a congenital hyperplasia and tumor formation in the mesoblast at its junction with the epiblast, that is, in the skin and nerves. It appears probable in this case that the growth was at first an innocent neuroma, becoming ultimately a sarcoma similar to the sarcomatous development occasionally observed in other congenital defects, such as pigmented moles.

Practitioner (London), August.

Injuries to Peripheral Nerves. VICTOR HORSLEY.—Beginning his lecture with the statement that nerve injury without irritation causes atrophy and we only have trophic changes other than atrophy with an irritative lesion, Horsley passes on to the statement of the recuperative power of nerves and shows that, according to Kennedy's observations, the same changes take place when a nerve is simply bruised as when it is cut, that is, that regeneration occurs by the growing outward of the axis cylinder of the central portion of the nerve. He has himself seen $1\frac{1}{4}$ inches bridged over in this way, but the ordinary course would be to suture cut ends, and, if this is not possible, insert grafts. He expresses the opinion, a little at variance with that held by some authors, that direct conduction may take place through the graft or suture. As regards prognosis of nerve injury, contusion or otherwise, he thinks it is generally favorable if properly treated. In the conclusion of his paper he speaks of the question of the hysterical or neurasthenic traumatic neuroses and their diagnosis.

Various Aspects of Open Air Treatment of Phthisis. ALBERT HILLIER.—This article discusses the importance of pure air for consumptives, and shows that this is the first consideration, everything else is secondary.

Australasian Medical Gazette (Sydney, N. S. W.), June 20.

Immediate and Ultimate Treatment of the Inebriate. F. NORTON MANNING.—The author advises the immediate and total cutting off of all alcoholics in the treatment of inebriety. He condemns chloral given alone for the insomnia, but advises it combined with the bromids in moderate doses. The one important matter should be that the dose of the bromids should not be too small and of the chloral not too large. It is not necessary to give more than a few large doses or to continue active treatment beyond forty-eight hours, and it is always advisable to watch the urine and administer diuretics when it is scanty or loaded, as is often the case. As regards the ultimate treatment of inebriates, he criticizes palatial asylums or retreats, and thinks that their seclusion should be compulsory and a certain amount of work enforced. He thinks the treatment along what has been called, not inaptly, the "Calvinistic method," is the best, and that drunkenness is not altogether so much of a disease and so little of a vice as some have held.

An Outbreak of Dermatitis Exfoliativa Neonatorum. WALTER SPENCER.—This author describes an epidemic of Ritter's disease occurring in a Sydney institution. Twenty-five cases are reported with five deaths. Two patients were born with the disease. The eldest case attacked was $3\frac{1}{2}$ years old. He thinks that the prognosis, in untainted, healthy infants treated antiseptically under careful supervision, is good. In

infants with bad heredity, constitutional dyscrasia or concurrent ailments, the preliminary eruption is apt to be fatal. His treatment was permanent application of *lotio zinci carb.* combined in the cases of minor exfoliation with *lotio nig. aa.* General treatment was seldom needed except in cases where syphilitic taint existed. These responded well to mercurials.

Annales de l'Institut Pasteur (Paris), April.

Pathogenic Sarcina. LOEWENBERG.—In only one out of 1000 cases of nasal troubles examined, a fetid discharge from the nose, which had persisted for years, with symptoms differing from those of *ozena*, proved to be exclusively caused by a kind of sarcina which was found in enormous numbers in the secretions. It was extremely pathogenic for rabbits, guinea-pigs and white mice, producing intense peritonitis in the former. As the microbes vanished under appropriate treatment the patient was permanently cured.

Bulletin d'Electrotherapie, June.

Pathogenesis of Contractions. GILLES.—The hypothesis advanced in this communication is that peripheral contractions are the result of stimulation of healthy centers by some continuous, involuntary peripheral action; that spinal contractions are the result of the pathologic reaction to normal excitations of injured or defectively connected centers; that cerebral contractions, on the other hand, are essentially peripheral and connected with the appearance of tardy secondary lesions. This theory harmonizes with certain of Grasset's and Van Gehuchten's later propositions.

Gazette Medicale Belge (Liege), June 8.

Mangold's Method of Epidemic Grafting.—The skin is scraped with a razor and the scraps thus obtained are scattered over the defect to be covered, in time forming a covering as perfect as that obtained with a Thiersch flap. Pispoli has found that raking the surface with pins arranged like Wecker's instrument for tattooing, twenty pins in a coil of parchment paper, superior to the razor, and reports a number of cases in which defects 8 by 5 cm., or 8 by 9, healed over completely in two weeks, after thus sowing them with epithelial substance, and covering with tin-foil or gutta-percha to prevent drying. The fifth day the surface is irrigated with salt solution and boricated vaselin applied the tenth day. (See JOURNAL, July 29, par. 60, p. 275.)

Journal des Sciences Medicales de Lille, July 15.

Examining Old Pus for Actinomyces. G. LEMIERE.—The significant fact is reported that typical specimens of actinomyces were found in the pus of a cow affected with actinomycosis, after it had dried to a powder seven years later. The bottle containing it had stood on a dry shelf in the laboratory, exposed to sun and daylight. No cultures could be developed, but the appearance of the micro-organism suggested that merely a specially favorable soil was needed.

Presse Medicale (Paris), June and July.

The Leucocyte Balance. LEREDDE.—"Closer study of the proportions between the numbers of the various types of leucocytes may prove a valuable assistance in the diagnosis and prognosis of many diseases, and also in therapeutics, as the balance can be regulated by medication and leucocytosis promoted." The proportions in the normal adult, Leredde has established to be 60 per cent. for the polymuclear, and 1 to 2 per cent. for the eosinophiles; in the child, 40 to 50 per cent. of the former and 5 per cent. of the latter. In the aged the polymuclear increase to 70 per cent. The physiologic balance in the adult seems to be constant, with slight variations during fasting or digestion, pregnancy, etc. The polymuclear cells increase rapidly in diphtheria and certain cutaneous affections. Mononucleosis is peculiarly frequent and pronounced in acute and chronic leucemia, and is an important aid in differentiating leucemic from tuberculous glandular swellings, as polymucleosis prevails in the latter. Increase in the number of eosinophiles indicates a reaction on the part of the bone marrow; increase of mononuclear cells indicates glandular alterations.

Entero-Anastomosis by Implantation. E. SCHWARTZ.—An elderly woman with an incarcerated femoral hernia and consecutive crural aneurysm, was operated on five months later and the intestine cut off above each end of the V. The long-disused peripheral end, no larger than a pencil, was implanted in a lengthwise incision in the dilated central end. Notwith-

standing the extreme disproportion between the sizes of the portions united, normal conditions were promptly restored.

Acute Appendicitis in the Tuberculous. F. CATHELIN.—Several observations are described to emphasize the fact that tuberculous lesions of any kind reduce the power of resistance, and hence surgical intervention is indicated with special urgency in case of acute appendicitis occurring in a person with a tuberculous predisposition or local lesions.

Epidemic of Icterus in Children. FRINGUET.—Seven children out of thirty attending the same school from various villages were affected with infectious icterus, distinguished by the slow pulse, 55 in one case—a boy of 12. The icterus was the last of the symptoms of the benign infection to subside.

Cold Baths in Delirium Tremens. M. LETULLE.—Cold baths are indorsed as the most effective and harmless means of reducing the temperature and calming the delirium, with three observations reported. The patient is placed in a bath at 18 C. for ten to fifteen minutes every two or three hours, until the delirium and fever have definitely subsided.

Gangrenous Mammitis. ROGER AND GARNIER.—A young woman was attacked with scarlet fever and mammitis a week after normal delivery of a child, who died in two days without discoverable cause. The scarlet fever threatened to be severe, but yielded to cold baths. The mammitis in the left breast became gangrenous, but healed after dressings of oxygenated water were applied. Gangrenous mammitis is of rare occurrence in women, but is more frequently observed in milk animals. In this case a peculiar small coccus was isolated, producing aerobic and anaerobic cultures resembling grains of sand, and in the first cultures distinguished by a fetid odor. It is pathogenic for animals, and does not liquefy gelatin.

Chyle Cyst in the Mesentery. LETULLE.—A child of 7 years was operated on for supposed tuberculous peritonitis, and the symptoms found to proceed from a cyst in the mesentery, containing chyle. The structure of the walls of the cyst indicated a congenital malformation of the excretory lymphatic system connected with the small intestine, with a continuous endothelial layer over the inner surface of the cyst.

Etiology and Treatment of Tuberculosis of Iris. F. LAGRANGE.—According to the writer's research and experimentation, tuberculosis of the eye is frequently local and clinically primary. He also establishes the possibility and danger of generalized infection from the local lesion, and suggests the necessity of enucleating the eye if sight has been lost.

Cancer of the Ampulla of Vater. H. DOMINICI.—This is a report of an observation of a neoplasm developed at the expense of the excretory biliary and pancreatic passages, as opposed to the cancer of the head of the pancreas derived from the pancreatic acini: in one word, a cylinder-celled primary epithelioma of the Vater region, of excretory origin.

Revue Generale d'Ophthalmologie (Paris), June 30.

Essential Hemeralopia Cured by Ingestion of Sheep's Liver. TRANTAS.—Hippocrates used to treat hemeralopia by the administration of beef's liver, and this has been tried in modern times, but so ineffectually that the manuals of ophthalmology no longer mention it. Trantas reports a series of ten cases all cured after the administration of 200 grams a day of cooked sheep's liver, which can not be ascribed to mere chance. In one case of twelve years' standing, with alcoholic antecedents, the patient was relieved of his infirmity in a few days. Light cases are cured almost at once, and the hemeralopia accompanying a hepatic affection is cured even when the latter is incurable, such as an inoperable carcinoma.

Revue Heb. de Laryngologie, etc. (Bordeaux), June 3.

Double Thyrotomy, Double Tracheotomy for Angioma of Larynx. GOMIS.—The angioma located in the left wall of the ventricle in a boy of 4, was successfully removed, but the upward displacement of the ventricular band persisted, requiring a repetition of the operation and resection of the band with an elliptic flap of the mucosa, before respiration became normal.

Semaine Medicale (Paris), July 15.

Hemianesthesia of Cerebral Origin. DEJERINE.—The point that serves to differentiate cerebral from hysterical hemianesthesia is the parallelism between the other cerebral manifestations and the anesthesia: the member most paralyzed is likewise the most anesthetic. In hemiplegia complicated with

hemianesthesia, the disturbances in the sensibility are most marked in the upper member, in the trunk and face, and they are most pronounced the farther from the root of the member. This fact has never been noted before. The anesthesia never occurs in zones as in hysteria; it is usually more intense in hysteria. There is also a subconscious sense that serves to protect the subjects from injury, which is an aid in differentiating hysteria, as also the fact that when the attention is diverted from a point the anesthesia at that point becomes less. The special senses almost always participate more or less in hysterical anesthesia, while the visual field, etc., is not disturbed in organic hemianesthesia. The localization of the cerebral cause, whether cortical or capsular, can not be decided by the symptoms, which are identical in each case. The hemianesthesia is particularly persistent when a lesion in the thalamus has destroyed the terminal fibers of the ribbon of Reil and the fibers of the thalamocortical neuron. It is particularly extensive when, with an intact thalamus, its connections with the sensory-motor corticality have been more or less destroyed. These are the only two conditions, according to Dejerine, in which a central lesion of the hemisphere can cause hemianesthesia of the general sensibility.

Berliner Klinische Wochenschrift, No. 28.

Malignant, Non-Septic Form of Endocarditis Rheumatica. M. LITEN.—The writer adds seven new cases to the eleven he has previously published, in which malignant, fatal endocarditis without suppurative processes appeared in the course of an ordinary articular rheumatism or chorea, only distinguished by their prompt response to salicylic acid. The endocarditis proceeds with the characteristics of general infection, as in the septic form, with objective symptoms similar to those of the usual simple rheumatic variety, but the metastases are exclusively bland infarcts. A chill or cutaneous hemorrhage frequently inaugurates the affection; and weeks and months may elapse before the end. Erratic chills are characteristic; also, usually, enormous acceleration of the heart's action. The retinal hemorrhages sometimes show a white center. Transformation of a simple rheumatic form into the malignant or septic form has never been demonstrated. The affection may sometimes prove difficult to differentiate from peliosis rheumatica, morbus maculosus Werlhofii, etc.

Centralblatt f. Chirurgie (Leipzig), July 29.

Inflammatory Swellings in Lymphangioma. TAVEL.—The inflammatory swellings that occur "in pushes" in a lymphangioma are explained by an observation reported in which the lymph trunco jugularis entered a tumor on the neck of an infant 4 months old, and pure cultures of the streptococcus were obtained from the pus. The circumstances plainly indicated that the infection must have arrived from the nose or mouth and not from the exterior. The infected portions were not accessible by simple puncture. No antiseptics were used, as Tavel is convinced that the tissues in the vicinity of an infectious focus are practically immunized from the dissemination of the bacterial toxins, and antiseptics are not required, while they are injurious and retard recovery. He never uses them even after evacuating a large osteomyelitic cavity.

Valvular Stoppage of Biliary Passages by Calculi. C. LAUENSTEIN.—Fenger and others have called attention to the occlusion of the biliary passages by stones acting as a valve, allowing the passage of bile in one direction and not in the other. Lauenstein states that nothing but such an assumption can explain the gorged condition of the gall-bladder in some cases, the bile not finding an egress, and its emptiness in others, the bile prevented from entering by the reverse valve action of the stones. The influence of this condition is harmful, as the gall-bladder no longer answers its purpose as a reservoir. There is a constant, instead of the normal intermittent flow of bile into the intestine. The sphincter in the ampulla of Vater must be constantly gaping to allow the passage of the continuous stream, and this favors the infection of the biliary passages from the duodenum.

Deutsche Medicinische Wochenschrift (Berlin), July 27.

Is Wood Sorrel Poisonous? L. LEWIN.—Referring to Eichhorst's communication (see JOURNAL, August 5, p. 346), Lewin sifts the evidence and asserts that the possibility of intoxication from wood sorrel is absolutely improbable and unproven.

Case of Diffuse Scleroderma of Lower Limbs With Well-Defined Spinal Segmentary Limitations. I. BRUNS.—The scleroderma commenced in the feet and extended symmetrically on both legs until it reached and stopped at the line corresponding exactly, both front and rear and on both sides, to the upper limit of the cutaneous region ascribed to the first lumbar segment as depicted in Head's diagrams (*Brain*, 1893), etc. Bruns distinguishes, in the disease, first a stadium hyperemicum or vasoparalyticum; then a stadium elevatum, possibly also edematosum, and a third, the stadium atrophicum.

Universal Staining Method for Blood Preparations. L. MICHAELIS.—By this new method one stain simultaneously brings out on one preparation the nuclei, neutrophilous, eosinophilous and basophilous granulations and the blood plates. There are two solutions, each an aqueous, 1 per cent. solution of methylene blue or eosin. They are combined with alcohol and acetone as follows: Solution A (methylene blue), 20.0 and absolute alcohol, 20.0. Solution B (eosin), 12.0; acetone (Sp. 56 to 58), 28.9. The preparation is fixed in alcohol or by the Ehrlich method, from one-half hour to twenty-four hours. One e.c. each of A and B are poured into a block dish and covered. The preparation is dipped into this mixture, as Ziemann recommends for his method. It first turns blue and then red, and the proper length of time for the stain is the moment when the red stain becomes evident, which may be in from one-half to ten minutes.

Muenchener Medicinische Wochenschrift, July 11 and 25.

Phosphorus Necrosis. L. V. STUBENRAUCH.—This affection is not restricted to workers in match factories, but has occurred in bronze works, etc., where phosphorus is used. It is impossible to reproduce in guinea-pigs, rabbits or dogs, a clinical picture similar to that of human phosphorus necrosis, as Stubenrauch has established by three years of experimental research. The fumes of phosphorus have no specific irritating effect on these animals, even when the periosteum is directly exposed. The latest views are that the phosphorus alone is not responsible, but that phosphorus plus infection, causes the decay of the bone. The phosphorus only supplies the disposition, which, he asserts, is a tendency to thrombosis.

Glass Brick Walls for Operating and Work Rooms. F. KUHN.—In building an operating-room facing the east and close to the street, Kuhn employed the Faleonmer glass bricks, which are small cubes or diamonds of glass filled with air, and fitted and mortared together like ordinary bricks. He found that no windows were required, as the light penetrates sufficiently, although it is absolutely impossible to see in or through them, even with a light inside at night. A skylight above supplies the direct light, which is reflected and multiplied by the glass walls, without glare. They also modify the temperature of the room remarkably, modifying both heat and cold, and also deadening the noises without. Still another advantage is that these walls do not frost over in winter, and that they look clean, both out and inside, and can be easily kept aseptic inside, while they are very ornamental.

"Sore Mouth" in Children and Its Relation to "Foot and Mouth Disease." R. POTT.—Reviewing his 553 cases of stomatitis in children during the last twenty years, Pott notes that only 53 under 6 months were affected, and these with exclusively catarrhal manifestations, while from 6 months to 2 years, or during the teething period, the number attained 290; from 2 to 5 years, 161, and from over 5, 49. He considers abrasion of the gums of infants in attempts to clean their mouths, a frequent source of inflammation, also the congestion induced by teething and the injurious custom of allowing children to chew and suck on rubber rings, etc., which rubs off the epithelium and favors fermentative and putrefactive processes in the mouth. He considers stomatitis aphosa or ulceroa as a primary local infection, and calls attention to the fact that uncooked butter or milk from animals affected with foot and mouth disease is capable of producing an analogous disease in man, and especially in children. Boiling the milk and cooking the butter absolutely prevents this. It has been established, however, that the identical affection may appear in children when the possibility of an infection must be excluded unless disseminated long distances through the air. He has observed seven instances of family epidemics.

After Treatment of Sprained Joints. K. HASEBROEK.—Patients often complain of a weakness in a knee, wrist or ankle that has been badly sprained. It gives way when least expected, and may lead to permanent functional disturbances. Hasebroek urges trial of a leather support that he has found extremely useful in supporting the joint and imparting strength and confidence. For the wrist, a leather cuff, made over a plaster cast, and laced snugly, proves an ideal support. A similar contrivance for the knee leaves the cap of the knee bare, but is snugly laced above and below, the two parts connected by a hinge extending almost the entire width of both. For the ankle he uses Marcinovski's simple appliance for flatfoot, which answers the purpose most admirably.

Habitual Dislocation of Shoulder. F. KRUMM.—A healthy man of 49 dislocated his right shoulder and, during the following seven years, the luxation re-occurred again and again, thirty-seven times in all, requiring necrosis for each reduction, and preventing all work. Krumm restored the shoulder to normal function by taking up an equatorial fold in the capsule with a lacing suture from the depths of the axillary cavity forward, thus substituting a stout ridge in place of the stretched and weakened portion of the capsule wall, and making it fit the joint. He insists on the necessity of opening up the capsule first to examine the joint; drainage is not required, but is advisable for the extracapsular wound. Smooth and permanent recovery followed. Over a year has since elapsed.
