There are certain items of interest which have been observed in the course of treatment of these cases which do not lend themselves to statistical statement. There has been no trouble in patients with typhoid fever receiving food surreptitiously. They are kept in wards with patients suffering from other diseases, but neither from their mates in the ward nor from their friends do they receive food not allowed, and this with only ordinary watchfulness on the part of the nurses. Complications may or may not influence perceptibly the temperature of a patient with typhoid fever. Phlebitis often does; in 2 cases with marked phlebitis there has been a step-like rise of the temperature, coinciding in the onset with the occurrence of the phlebitis, resembling in every way the temperature of a relapse, and these cases have been counted as relapses although no enlargement of the spleen and no fresh eruption of the rose rash was detected. Menstruation has, in one or two instances, apparently caused a rise of temperature in convalescence, but has frequently failed to produce any dis-

turbance. Earlier in the paper the fact that at the apparent completion of defervescence the temperature at times fails to become (sub)normal, but ranges almost indefinitely at from 97° to 99° or even 99.5° F was mentioned. This is so uniformly the case with patients who are unruly and cannot be induced to lie quietly in bed, but jump around, prop themselves up on their elbows, etc., that we are confident that restlessness is a very certain cause for such irregularities in temperature. In the same connection it may be interesting to note that a patient who has had the subnormal temperature that is to be expected in convalescence will have a temperature that goes up to 99° F or higher when he first gets up. Ordinarily one looks upon this as a return of the temperature to the normal range, but in such cases the quieter a patient is kept the lower will be the temperature, and the true cause of the greater range is probably to be found in exertion in advance of complete recovery of strength. The greatest instability of temperature seems to be found in patients with the most considerable degree of post-typhoidal anemia and the poorest general condition. There have been three or four patients in the series who have entered much below par, and while gaining on generous diet, have not gained as the majority of patients do; in these cases we have been confronted by an elevation of temperature every time the patients have been allowed to sit up, and when they have been sent back to bed again the temperature has dropped to subnormal at once. In general the condition of patients who are being fed is very satisfactory, they begin to put on flesh at once, and show a continuous gain in strength and spirits as well as in flesh. It is possible that patients fed a little less early would be more manageable, for these feel so very well that it is often hard to keep them quiet. A fair proportion of all the cases have been heard from since discharge, and they usually report themselves as having returned to their ordinary employment shortly after discharge, and as never having felt better, the inference being that as regards recovery of normal condition liberal feeding is a distinct advantage, and I think that I may make this statement as voicing the impressions of the visiting staff.

The conclusion that a more generous diet in typhoid fever is advisable will be made or rejected after a consideration of its effects upon mortality, upon the general condition of the patient both during the progress of the disease and after his discharge from the care of the physician, and furthermore as to whether it increases the chances of hemorrhage, perforation, or relapse. Whatever information is given on these points by this series of 150 cases of typhoid fever treated in the course of seventeen months is here presented for your consideration.

The writer wishes to thank the visiting physicians to the hospital for the opportunity to feed these patients early, as well as for permission to report the cases.

A CITY PLAGUE LABORATORY. — The New York City Board of Health, at a recent meeting, awarded a contract for the building of the laboratory for the study of the bubonic plague on the Willard Parker Hospital grounds. The cost of the building will be \$19,893. The laboratory is to be built in three months. — *Medical Record*.

²² Practice of Medicine.

THE CO-OPERATION OF THE MEDICAL AND LEGAL PROFESSIONS.¹

BY GEORGE A. SANDERSON, ESQ., BOSTON.

"Of law there can be no loss acknowledged than that her seat is in the bosom of God, her voice the harmony of the world. All things in heaven and earth do her homage—the very least as feeling her care; the greatest as not exempted from her power."

This definition of law by Hooker is comprehensive enough to include all the professions.

The law as it is practised today is the outgrowth of human experience. The rights which it enforces and the wrongs which it redresses were based in the first instance on expediency, and they have in time become a system of principles. The development has been usually in line with moral principles, although the law does not undertake to enforce every moral obligation as a legal duty.

The problems of the physician as well as his daily occupation lie almost wholly outside the range of the lawyer's experience. It is not often that a physician is in a position in his profession where he cannot do the work in hand without the assistance of an attorney, but the lawyer constantly has work to do which it is impossible for him to accomplish without the assistance of the medical expert. It is here that the two professions most often and most closely meet. The points of contact are so many and so important that a knowledge of medical jurisprudence, which has been defined to be "the application of every branch of medicine to the purposes of the law," becomes almost indispensable.

The purpose of the Massachusetts Medico-Legal Society should be, in part at least, that the legal aspects of the physician's work may be emphasized, and that the medical and legal professions may be brought into closer relations with each other.

The complete dependence of the courts and attorneys on the physician's knowledge is illustrated in the most important trials known to our State courts, namely, trials for murder. I doubt if a murder case is ever tried or can be properly tried without the testimony of one or more men specially trained and skilled in medicine.

In *Commonwealth vs. Rogers*, the defendant was indicted in 1843 for the murder of Charles Lincoln, Jr., warden of the State Prison. The defence was insanity. Chief Justice Shaw, one of the most eminent of the men who have held judicial position in this Commonwealth, defined certain tests of insanity. "A man is not to be excused from responsibility if he has capacity and reason sufficient to enable him to distinguish between right and wrong as to the particular act he is then doing, a knowledge and consciousness that the act he is doing is wrong and criminal, and will subject him to punishment. In order to be responsible, he must have sufficient power of memory to recollect the relation in which he stands to others, and in which others stand to him; that the act he is doing is contrary to the plain dictates of justice and right, injurious to others and a violation of the dictates of duty."

The court also said that an insane delusion will be an excuse for a criminal act if it "is such that the person under its influence has a real and firm belief of some fact, not true in itself, but which if it were true would excuse his act."

This case has a special interest for medical men, because the chief justice discussed the question of medical evidence. He said: "In general, it is the opinion of the jury which is to govern, and this is to be formed upon the proof of facts laid before them. But some questions lie beyond the scope of the observation and experience of men in general, but are quite within the observation and experience of those whose peculiar pursuits and profession have brought that class of facts frequently and habitually under their consideration. . . . A familiar instance of the application of this principle occurs very often in cases of homicide when, upon certain facts being testified to by other witnesses, medical persons are asked whether in their opinion a particular wound described would be an adequate cause, or whether such wound was, in their opinion, the actual cause of the death in the particular case. Such question is commonly asked without objection; and the judicial proof of the fact of killing often depends wholly or mainly upon such testimony of opinion. It is upon this ground that the opinions of witnesses who have long been conversant with insanity in its various forms, and who have had the care and superintendence of insane persons, are received as competent evidence, even though they have not had opportunity to examine the particular patient, and observe the symptoms and indications of disease at the time of its supposed existence. It is designed to aid the judgment of the jury in regard to the influence and effect of certain facts which lie out of the observation and experience of persons in general. And such opinions, when they come from persons of great experience, and in whose correctness and sobriety of judgment just confidence can be had, are of great weight and deserve the respectful consideration of a jury. But the opinion of a medical man of small experience, or of one who has crude and visionary notions, or who has some favorite theory to support, is entitled to very little consideration. The value of such testimony will depend mainly upon the experience, fidelity and impartiality of the witness who gives it."

The chief justice further said: "One caution in regard to this point it is proper to give. Even where the medical or other professional witnesses have attended the whole trial and heard the testimony of the other witnesses as to the facts and circumstances of the case, they are not to judge of the credit of the witnesses or of the truth of the facts testified by others. It is for the jury to decide whether such facts are satisfactorily proved. And the proper question to be put to the professional witness is this: 'If the symptoms and indications testified to by other witnesses are proved, and if the jury are satisfied of the truth of them, whether, in their opinion, the party was insane, and what was the nature and character of that insanity, what state of mind did they indicate, and what they would expect would be the conduct of such a person in any supposed circumstances?'"

The case of the *Commonwealth vs. Lorenzo W. Barnes*, tried in Middlesex in May, 1897, illustrates how several distinct lines of medical inquiry may be involved in one case. Barnes was charged with the murder of John Deane by striking him with an axe at Maynard, on December 17, 1896. Mr. Deane was left alone in his house by his daughters, who went to work in the morning of the day of the murder. They returned in the evening and found their father dead in

¹ Read before the Massachusetts Medico-Legal Society, October 3, 1900.

a pool of blood on the kitchen floor. Two cuts with an axe had been made in the head and neck, one of which severed the spinal cord. No one had seen the murder committed, and no one had been seen going to or from the house.

Late in the afternoon of the day of the murder, about twilight, Barnes asked for a ride into Maynard from a short distance outside the town. He was on the road which led from Mr. Deane's house, and was some distance from it. He visited a bar room and washed his hands. He bought a new pair of boots and threw his old ones over a bridge. These boots remained on the ice of the river until the next day, when they were taken by one of the witnesses and given, with Barnes's other clothing and the axe, to Professor Wood for examination. He was able to point out many spots on the boots, trousers and coat worn by Barnes that were consistent with being human blood; and he also showed by the shape and appearance of many of the spots the direction from which the blood had come and something of the force with which it hit the object.

He was able to testify from investigations that an invariable rule is that in pear-shaped blood stains the stem of the pear is away from the source from which the blood comes; that the bulk of the blood in a stain is at the farther point from the source except in cases where the blood impinges upon a smooth surface, and then the force of gravitation will carry the bulk of the blood to the lower portion of the stain.

The blood stains on the boots were explained so fully that they made a very important part of the evidence. The direction from which the blood must have come and its distribution on the boots were consistent with results which would be expected if the boots were worn by the man who struck Mr. Deane with the axe.

The professor was able also to testify that some of the blood marks on the axe handle were finger-print marks. There was another matter along this line which was to be developed, namely, to take impressions of the hands of Barnes and, comparing them with the finger prints on the axe, to prove that the hand of Barnes must have made the marks upon the axe. The results of this experiment could not be known before the trial, because it seemed better not to take an impression of Barnes's hands while he was in jail awaiting trial. I understand that the impressions were obtained with Barnes's consent after the verdict, but I do not know what conclusions, if any, Professor Wood has reached in the matter.

The medical examiner gave in great detail the condition of the body, its position in the room when he arrived, as well as many important facts about the table, stove, axe, chairs and blood stains in the room. He, of course, stated the results of his autopsy, giving the condition and appearance of the different organs of the body, the exact nature and extent of the wounds in the head and neck, and the cause of death. A model made or procured by him showing the place of the wounds greatly assisted the jury in understanding his statements.

The case was also interesting and important because of the issue of insanity that was raised and tried. Two experts on insanity were called by the defendant and four by the Commonwealth. The claim was made by the defence that the defendant received a sunstroke when three years old, which caused

a lesion of the brain, and that he had always been weak mentally since that time. The defendant was lame in one leg, and it was claimed that the lameness was caused by the sunstroke. It was said to be an interference with the nervous structure which showed itself in the leg which was supplied by those nervous connections.

The position of the experts for the defence was not that the defendant could not understand the difference between right and wrong, but that his responsibility was of a limited kind. One purpose of this evidence was to show that the defendant's guilty conduct after the murder had no significance, because of his deficient mental condition. Another was that if he committed the crime, he had not mind enough to form that deliberate premeditation which is required in murder in the first degree.

The experts for the Commonwealth testified that in their opinion the lameness was caused by spinal paralysis.

They all testified that they had examined the defendant; that he could distinguish between right and wrong, and that he did not seem to have any irresistible impulses or delusion.

The defendant was convicted of murder in the first degree. An effort was made to have the sentence commuted to life imprisonment by the governor, based principally upon the ground of Barnes's mental condition. The governor appointed other experts in mental diseases, who examined the defendant and the evidence, and made report to him. The sentence was not commuted, and Barnes was hanged at East Cambridge on March 4, 1898.

In the case of *Commonwealth vs. Barrett*, tried in Middlesex in 1894, there was opportunity for special investigation into powder marks, and Dr. Mead's interesting account of the experiments which he performed with powder in connection with that case is contained in a published pamphlet which must have been read by many of you.

Each important criminal case seems to present some unsolved problem in medical jurisprudence, the solution of which must depend largely upon the medical witness.

The time of our civil courts which try cases with juries is largely taken up with tort cases, in which damages are claimed for physical injuries. In almost every case physicians testify on each side. The conflict of evidence between the physicians is usually great, both as to their observations of the symptoms and as to their opinions of the nature and extent of the injury. This class of cases cannot be properly tried without medical evidence. The facts to be established are outside the range of the jury's observations and knowledge. They must rely for the most important evidence bearing on the question of damages upon the testimony of the physician. It would be in the interest of obtaining proper verdicts if the best medical witnesses could be obtained to testify in these cases. But many times the best men will not attend court, because the waste of time is so great and such attendance makes a serious interruption in their regular work. The best experts deserve and demand for their time so large a compensation that the poor man cannot afford to employ them. Irresponsible witnesses often mean verdicts out of all proportion to the injury. It is not unusual that the court sets aside or reduces the findings of the jury.

The most apparent objections to the present methods of trying these cases are, (1) the great waste of time on the part of the physician; (2) the tendency to have in these cases incompetent and irresponsible experts, who enter the case without expectation of pay unless their side wins, and (3) the improbability of the award of proper damages either by a court or jury, even when the present system is working under the best conditions.

It is well known that the courts are assisted in reaching just conclusions in many civil cases, outside of this class of torts, by the appointment of masters, auditors, referees, or commissioners. This system saves the time of the court. It does not deprive a party of his right to a trial by the court or jury after the report of the master or other person appointed, but it does result in the settlement of many cases upon the finding of the master or auditor, and it tends to prevent either excessive or insufficient damages in the cases that afterwards go to the court.

If the court could in the same way refer to some physician of known ability and standing cases in which a medical question is involved for his investigation, either by personal observation or the taking of testimony or both, and for his findings of fact to be reported to the court, there would be a closer correspondence than exists today between the facts and the damages awarded in this class of cases. If a case thus investigated should afterwards go to a jury, the report of the physician to whom it had been referred might be given the same weight as is given to an auditor's report; namely, it would be *prima facie* evidence of the facts therein found. In other words, the facts so found would be decisive of that part of the case unless rebutted and controlled by other evidence.

If such a system should be introduced and adopted, matters of detail, such as whether the governor and council should appoint a number of physicians to whom cases could be referred, or whether some system of civil service rules should apply to their appointment, or whether the judge should be left free to select such competent physician as he should think best, could be determined. The demand for some such system as this has sometimes been recognized by judges and attorneys in referring cases to physicians to fix the damages, or to investigate and report the facts.

In the case of *Copson vs. N. Y., N. H. & H. R. R.*, heard in 1898 by a single justice of the Superior Court without a jury, the claim was made that the injury to the plaintiff had caused a permanent condition of imbecility. The judge, after hearing the evidence, arranged that the plaintiff should be sent to an asylum to be constantly for some months under the supervision of a competent specialist in mental diseases. The judge delayed his finding as to the amount of damages to be awarded until he had received the report of this specialist.

In the case of *Robbins vs. Fitchburg R. R.*, tried in 1894, the judge of the Superior Court ruled that on the evidence the plaintiff could not recover, and ordered the jury to find a verdict for the defendant. The full court decided that this ruling was erroneous, and that the question of liability should have been left to the jury. The case then being in order for trial by jury, the counsel for the parties agreed to leave the amount of the damages to the two physicians in the

case, one of whom had been employed by the plaintiff and one by the defendant.

Another class of cases in which a medical tribunal would save the time and increase the effectiveness of our courts is that in which questions of sanity or mental and moral responsibility are involved. In most cases of committal to an insane asylum there is no contest, and the court simply accepts and acts upon the opinion of the physician. In all such cases it would be as well if the certificate of the physician could be used as evidence, and the expert be saved the trouble of attending court in the matter.

One of our best specialists on insanity said recently that physicians of standing in this specialty generally agree upon the essential facts, and also in their opinions, after they have made a thorough investigation of a case, and that he hoped the time would soon come when the certificates of such experts stating their opinions and reasons would be received as evidence.

A more comprehensive plan for dealing with cases of insanity would be to establish a court or board of physicians, with power to try questions of insanity, and to commit those who were found to be *non compos mentis*. Such a court might be given authority to investigate and pass upon questions of sanity which arise in cases in any court, their decision to be evidence if the case should go to trial before a jury.

Some such system would undoubtedly prevent the defence of insanity in most cases where this tribunal, after investigation, found the party sane. It would be a great convenience in criminal cases in which the question of sanity is raised if the case could be referred at once to such a court or board for its investigation and finding. Courts having probate jurisdiction and civil courts generally would often call upon such a tribunal to investigate the questions which it would be especially qualified to answer correctly. This plan would not prevent the trial of the issue of sanity before a jury in criminal cases in which the defendant still desired to make the defence of insanity after the finding of this new tribunal that he was sane. In such case he would have a right to try this issue, and the witnesses on this question would be obliged to attend court and testify because of the constitutional provision which gives the person charged with crime the right to meet witnesses against him face to face.

I believe, however, that in the years to come there will be many improvements in our procedure in courts and in our methods of finding facts; that this improvement must be brought about by abolishing antiquated and circuitous methods and rules of evidence that prevent rather than assist in reaching the truth, and introducing more simple, more direct, more natural methods, excluding as far as possible all chance of error. It is because the medical man should decide medical questions and is most likely to decide correctly that the suggestions herein made seem to be in the line of progress.

Meanwhile we must make the best of existing conditions, and whether we have reforms in our methods of procedure or not, the demands upon the lawyer to know something of the medical side of the law, and the demands upon the physician to know something of the legal side of medicine must be met.

The physician cannot tell at the beginning of any day's work that he may not be obliged to qualify in court to testify to the medical facts connected with

some case which he treats that day, and he would be expected to know not only what is necessary for a proper treatment of the case medically, but also what is required by the law for proper treatment in court of the medical side of the case.

If the physician knows what is required and permitted as evidence in court, he can note many facts which would otherwise go unnoted. It is often true that we see only what we are looking for, and it is only when we know what is evidence that we can look most intelligently for it. The medical examiner usually has a good working knowledge of proper evidence and I doubt not that every prosecuting officer in the State would say that the community is indebted to our medical examiners for their ability, their fairness, their thoroughness, and their care in making note of every point which may assist in arriving at the truth. It is often true that the medical examiner is the most important witness in our most important cases, and that his care in observing and stating facts has many times prevented a miscarriage of justice. His work requires him to be a specialist in many branches of medicine.

But the whole case has not been stated when we say that medical jurisprudence is a matter of great importance to both professions. A more significant fact than that to the man who wants to know what should be done now is that every branch of medical jurisprudence is *growing* in importance and becoming a more essential part of our judicial system. The phenomenal growth of tort cases has been accomplished within a few years, and this class of cases must continue to increase with our greater industrial and commercial development.

The increase in the number of inmates of our insane asylums is ample evidence that this branch of medical jurisprudence must be constantly occupying a larger place in our courts.

The laws to regulate health and prevent the spread of disease must be greatly multiplied and systematized, as our population grows in the large centres, and our latest census returns almost alarm us with the great growth of all our cities. The increase of population must bring with it an increase of crime, although for some reason, and undoubtedly a temporary one, for the last one or two years there seems to have been a falling off in crimes and criminal prosecutions.

The embarrassment of the physician who is unable to meet the demands of a case in which he is called to testify is only exceeded by that of the attorney who knows little of the medical aspects of his case and little of the bearings of the medical testimony which he is required to present. His examination is likely to lead only to a confusion in the minds of the jury like that which exists in his own mind.

Notwithstanding the great change in the medical and legal courses in our universities, still it would seem that the importance of courses in medical jurisprudence has not been emphasized in either the school of medicine or the school of law. The neglect of this subject, in view of the increasing demand for the physician in court and the corresponding growing necessity that the attorney be able to properly present the medical testimony in a case, cannot be justified nor long excused.

If this subject is to be given its proper place in the training schools and among the members of both pro-

fessions, it can most effectually be brought about by this organization, which stands between and unites the two.

May the time soon come when it shall be true not only that the physician shall know everything about his special branch of medicine and the lawyer shall know everything about his special branch of the law, but also when it shall be true that each shall know something of the whole range of medical jurisprudence.

CRIMINAL NEGLIGENCE; REPORT OF A CASE.¹

BY A. W. BUCK, M.D., FALL RIVER, MASS.

THE choice of this subject is the result of experience not alone in the case to be reported, but from the impression, very firmly fixed, that in spite of maternal affection, which is an almost unailing attribute of a mother, no matter how destitute or depraved, there still are cases where one's suspicions must be aroused that the neglect, though apparently due largely to ignorance, is in some degree wilful. Especially is this true where illegitimate children are concerned. The industrial insurance companies recognize the lack of care which these unwelcome guests receive in the majority of cases, and refuse to accept them as risks under the age of five years. Frequently enough we are called to certify as to the cause of death where it is evident that ignorance and wilful persistence in unfortunate methods has brought about the untoward result, where intended kindness has in reality been murderous. To such cases I do not refer, but to those in which the motive is apparently relief from a wearisome burden.

Infanticide has a harsh, barbaric sound, but I believe deaths sometimes assigned to natural causes could justly be attributed to the neglect (semiwilful, if it may be so called) of the mother, who, worn out and discouraged in the struggle to provide for herself and her offspring, is willing to yield the babe to the forces ever waiting for its destruction.

So far as I know, we do not have today in Massachusetts to any great extent the unhygienic "baby farms," which have at times appeared as most potent factors in carrying out the Malthusian theory. On the contrary, the summer home and hospital for sick and poor children have reduced the infant mortality to an appreciable extent. Frequently, however, we find the babe of a few weeks, whose mother must work ten hours of the day, consigned to the care of a neighbor whose only interest is to collect the dollar a week which is paid for the board of the little one.

It is difficult, almost impossible, to say just where negligence approaches criminality. Inquiry reveals more than autopsies can affirm. Starvation may be due to disease. Emaciation occurs in spite of the most carefully prepared diet. Cleanliness is a relative term among infants of the poor. The most anxious mother does not succeed in preventing sores unless she can intelligently devote all her time to her sick babe. Bruises are common to all children able to seek for them. These things will not prove lack of ordinary care, and one must seek further. The failure to provide medical attendance may be but an expression of the mother's lack of confidence in the

¹ Read before the Massachusetts Medico-Legal Society, October 3, 1900.

efficacy of medicine or the skill of the physician. These things combined may nevertheless be of value in determining the intent of the mother. And it is the intent, the motive, which the law recognizes as of prime importance.

The case I wish to report is that of a child aged seven months. The mother was a woman of twenty-five who was working in a cheap hotel as helper in the kitchen. She claimed to have been married five years. Her husband, however, had left her three years before, though she claimed he had been to visit her about a year and a half before the present time. The babe had been for six weeks at the Seaside Home, and though in a forlorn condition on its admission, had gained sufficiently to be thought ready to be discharged from the hospital. The mother was notified, but failed to call for it. During the six weeks of the child's stay at the home she had never been to see it, though opportunities were frequent. Repeated requests had no effect. Then the babe was taken by the overseers of the poor to the almshouse, where it remained two weeks. Our pauper methods, however, do not provide for maintaining a child in the poorhouse while its parent or parents remain outside. This mother, then, who was now supporting a child two years old, was told that she must either declare herself destitute and join her younger babe in the almshouse, or she must support it herself outside. And being summoned before the officers at the police station she declared herself able and willing to provide for both children.

As before stated, she was working at a cheap hotel, and this was within a stone's throw of the office of the overseers of the poor and the city physician. Evidently fearing that the proprietor might object to the presence of two infants, she said nothing of the younger child, but took it to her room, which was poorly lighted and ventilated. There for sixteen days the child was kept, never was taken from the room, no one was told of its existence. The mother manifested marked indifference as to the loss of the babe. She acknowledged that it had been sick for two weeks, but had not thought it necessary to send for a doctor. She knew the method of applying for the city physician, and had previously had him for the other child. She said that she had fed the younger child with milk when it would take food. She had given it soothing syrup when it cried. In the room there was a bottle labelled "soothing syrup," and a man who worked in the hotel said that he had been out for medicine (soothing syrup) several times. This he had supposed was for the two-year-old child. These facts were ascertained after noting the unusually filthy and neglected appearance of the body of the infant, and as a result an autopsy was held September 14th, forty-four hours after death.

The body was that of a male child twenty-five inches in length. It was extremely emaciated. Rigor mortis was present. The buttocks and genitals were red and inflamed. Vermin were present in the sores on the buttocks. The oral mucous membrane was apparently normal. Almost complete absence of subcutaneous fat; skin dry and shrivelled; face pale and wrinkled. Heart and lungs were normal, though all the organs were markedly anemic. Stomach empty save for small amount of white, slimy deposit which was accepted as milk; bowels distended with gas, the walls thin and friable; the small intestine empty for

its entire length; no signs of any inflammatory condition; large intestine also empty, but descending colon and rectum showed slightly inflamed mucous membrane which was everywhere else very pale. Gall bladder was full. Kidneys, spleen, liver and pancreas appeared normal. Brain was normal.

So far as could be ascertained from the autopsy, death had resulted from starvation, but the slight indications of colitis were sufficient to raise a possible doubt as to whether the starvation was due to disease or to the restraint of proper food. The mother was held by the district court on the charge of manslaughter, but she was not indicted by the grand jury.

Reese says that although starvation "is rarely the cause of homicidal death, it should always be remembered that the law does not require the absolute deprivation of food to be proved, but only the necessary quantity and quality to be withheld, provided this has been done with an evil intent." It is important to know that the evidence of organic disease does not disprove that criminal starvation may have been the cause of death. This because the defence set up is invariably that admitting the cause of death, it was the result of disease and not of malice on the part of the one accused. Tidy quotes the statement of Hippocrates that "The old bear want of nourishment best; those who have attained the middle period of life the next in degree; those who have just arrived at puberty are less able to endure it; but that of all ages, childhood is the least capable of enduring hunger." It takes very little to kill an infant by refusing it the breast or giving it insufficient or improper food.

The burden of proof that the fatal result has been the outcome of wilful neglect on the part of the one having the care of a helpless child may at times not be light. The points particularly to be observed in these cases are those usually indicative of starvation. In chronic cases the body is invariably shrunken and greatly emaciated. A contracted state of stomach and bladder, a shrunken and transparent condition of intestines and omentum, with a more or less atrophied, but otherwise healthy condition of the viscus, appear to be the prominent post-mortem symptoms. In acute starvation, however, one may find a considerable layer of fat, as in the case of the Welsh fasting girl.

Clinical Department.

THREE CASES OF GUNSHOT WOUNDS.

BY PASSED ASSISTANT SURGEON A. FARENHOLT, U. S. NAVY.

CASE I. M. M. N., apprentice second class, U. S. Navy, age sixteen and one-half years, was shot through the head at Kabalition Island, P. I., September 2, 1899. The wound was made by a Spanish Mauser, calibre 8 millimetres, ball, and the distance from muzzle to head was but 2 feet. Death occurred in about two hours after the receipt of injury, and the following conditions were observed at necropsy: The posterior, or wound of entrance, was situated a little above the centre of right parietal bone, the anterior, 9 centimetres above nasion in median line of frontal bone; both wounds admitted little finger only to first joint. No staining of powder grains. Exophthalmos of left eye, pupils equal and moderately contracted. Slight movement of bones under scalp.

Coronal suture patent; fractures from posterior to anterior opening, and about 8 centimetres beyond each; several small fractures from posterior wound in right parietal bone. Calvarium removed; brain substance found disintegrated along path of bullet, and into surrounding tissues through a diameter of 5 centimetres. Injury chiefly to right hemisphere except near anterior wound, where left was found injured; much blood clot and oozing from path of bullet. Surfaces of both hemispheres injected, base apparently undisturbed.

This case is interesting in showing that a modern, high-power bullet, passing through a bony cavity at very short range, may not cause a "ragged and enlarged opening" at the wound of exit, as we are so often reminded it does at somewhat greater ranges.

These two wounds were identical in size and character, admitting the little finger only to the first joint, and although fractures radiated from their bony parts, there was no movement in their immediate vicinity.

The so-called explosive effect was, however, apparent, the calvarium being extensively fractured and movable in places, and besides the complete disintegration of brain substance along the path of the bullet, that organ showed clearly by the marked injection and hemorrhage the severe pressure, hydrodynamic, to which it had been subjected.

CASE II. A. H., landsman, U. S. Navy, age twenty-two years, was wounded near Iloilo, P. I., October 6, 1899. He was probably shot by a 45-calibre Remington ball, the wound involving both thoracic and abdominal cavities. The patient lived, perfectly conscious, suffering only moderate pain, but paralyzed below the twelfth dorsal vertebra, for nine hours. The following conditions were found after death: Wound of entrance in axillary line at eighth rib, and that of exit 2 inches to right of median line of back and opposite the last dorsal vertebra. On section the abdomen and pleural sac of left side were found to contain considerable blood. Bullet in entering had gouged away a portion of eighth rib, left axillary line, and immediately perforated diaphragm without injury to lung; continuing, it lacerated the upper portion of spleen near its centre, and then entered the stomach at about the centre of the greater curvature. Emerging in the lesser curvature it lacerated extensively the head of the pancreas, impinged upon and glanced backward from the eleventh dorsal vertebra, fractured its body, transverse, articular and spinous processes with those of the adjoining vertebrae, opened the spinal canal, lacerated the cord and emerged as noted. The wound of entrance in this case was round and clear cut, being $1\frac{1}{2}$ centimetres in diameter, while that of exit was gouged out and ragged and fully $2\frac{1}{2}$ centimetres across.

CASE III. In the same engagement F. A., apprentice, U. S. Navy, age eighteen years, was wounded by a Mauser ball, which passed directly through the body just below the brim of the pelvis. When seen several hours later patient was in fair condition, very little shock. It was decided, after consultation, not to operate, and the patient rallied well, notwithstanding the obvious fact that the rectum had been perforated, and continued to improve during the subsequent ten days, exhibiting no signs of peritonitis or hemorrhage. Suddenly, on the night of the eleventh day, a severe hemorrhage from the posterior wound occurred, from which he reacted

but partially under transfusion, only to succumb a few hours later to another uncontrollable hemorrhage.

The following is the report of the necropsy: The wound of entrance was on the right side through the body of the pubes, just external to the pubic spine; it was of a drilled nature and but slightly larger than the 8-millimetre ball itself. The wound of exit was on the same side, 3 centimetres internal from a point midway on a line from the posterior superior spine of the ilium to the tuber ischii, the ball passing out through the greater sacrosciatic foramen. The latter wound was $1\frac{1}{2}$ centimetres in diameter and rather ragged. The rectum was perforated laterally with considerable loss of substance; the peritoneal cavity was not involved. A cavity, corresponding to the path of the bullet, was filled with blood clots and feces and walled off above by thickened peritoneum which was adherent to the abdominal parietes. The bladder was displaced to the left and bound down by adhesions; the caput coli, ascending colon and sigmoid flexure were surrounded by adhesions, binding them to the abdominal walls and to adjacent structures. The cause of death was secondary hemorrhage from branches of the internal iliac artery. Wound was received at distance of about 70 yards.

Medical Progress.

RECENT PROGRESS IN THERAPEUTICS.

BY ELLIOTT P. JOSLIN, M.D., BOSTON.

(Concluded from No. 19, p. 479.)

OXYBUTYRIC ACID AND ITS RELATION TO DIABETIC COMA.

ACETONE and diacetic acid receive attention far beyond their due in the study of diabetes, and oxybutyric acid, though next to sugar in importance, is overlooked. The amount of acetone and diacetic acid seldom exceeds 10 grammes per day even in the severest cases of diabetes, while that of oxybutyric acid may reach 20 or 30 grammes, and in coma has risen to 160 grammes in the twenty-four hours. Oxybutyric acid has been neglected because its estimation is difficult. It is to be hoped that Dr. Magnus-Levy, who has devoted so much of his time during the last three years to its study, will be able to offer a more simple and accurate method for its isolation than now exists. It is from his first publication of 90 pages on oxybutyric acid that the following partial résumé has been made.

The growth of our knowledge regarding B-oxybutyric acid has gone on in an exceptionally logical manner. In 1880 Hallervorden discovered a marked increase in the excretion of ammonia in diabetes. This amounted to six to eight times the quantity excreted by normal individuals on the same diet. Since the urine was always acid, he believed the increase in ammonia was chiefly due to an increase in the output of inorganic acids in the form of ammonia salts. Stadelmann investigated this point in 1883, and found it was the organic acids, not the inorganic, which were responsible for this excess. He was also able to show that the organic acid in question was one that yielded, on decomposition, crotonic acid. One year later Minkowski succeeded in isolating the original acid in pure form, and characterized it as B-oxybutyric acid. Si-

multaneously E. Kütz discovered it in another manner.

But even before the true nature of the acid was known, Stadelmann recognized its importance in the pathology of diabetes, and especially in its relation to diabetic coma. Patients died of coma in whose urine he found large amounts of the acid, and their symptoms resembled the phenomena in rabbits which Walter in 1877 had produced experimentally by acid poisoning. Since it had been already shown that in human beings there was an excess of acids in the body in diabetes, Stadelmann advanced the conclusion that diabetic coma was an acid intoxication and consequently recommended the treatment of the same with large doses of alkalis. His suggestion was adopted, but we now know that the amount of alkalis given was entirely too small.

B-oxybutyric acid occurs in nearly all severe cases of diabetes. It has also been found in small amounts in scurvy, in the urine of starving insane patients, in that of cancer patients dying with coma, and in the urine of individuals living on an exclusive meat and fat diet. In one of Nannyn's cases it was found five years before coma caused the death of the patient. B-oxybutyric acid is the mother substance of diacetic acid and acetone and when given experimentally is either wholly oxidized, while these bodies appear in its stead in the urine, or if large amounts are given it may appear coincidentally with them. The connection between the three is seen by their graphic formulae.

B-oxybutyric acid	$\begin{array}{l} \text{CH}_3 \\ \\ \text{CHOH} \\ \\ \text{CH}_2\text{COOH} \end{array}$
Diacetic acid	$\begin{array}{l} \text{CH}_3 \\ \\ \text{CO} \\ \\ \text{CH}_2\text{COOH} \end{array}$
Acetone	$\begin{array}{l} \text{CH}_3 \\ \\ \text{CO} \\ \\ \text{CH}_3 \end{array}$

B-oxybutyric acid does not possess a specific toxic action any more than other of the higher fatty acids, for example, palmitic, stearic, etc., nor can one give enough of it by the mouth to produce coma. Its action in the body is purely due to its acid qualities.

Injections of .9 gramme HCl per kilo body weight are necessary to cause death from acid intoxication in a rabbit. As the molecular weight of B-oxybutyric acid is nearly three times as great, 2.6 grammes B-oxybutyric acid per kilo body weight would be necessary to produce this same result. And if one worked by analogy, to cause an acid intoxication or "air hunger" in a man of 60 kilos (132 pounds) at least 160 grammes of B-oxybutyric acid would be required. If 160 grammes are necessary to produce a fatal result in a healthy individual with normal alkalinity of the blood, still less would be necessary in a diabetic, the alkalinity of whose blood is already lowered.

Now the alkalinity of the blood of coma patients is diminished, and it is interesting to compare the alkalinity of the blood under such conditions with the normal values. Magnus-Levy did this, and found a lowering of alkalinity which if produced wholly by B-oxybutyric acid would require .57 gramme per 100 cubic centimetres blood, or as serum is of lower alkalinity, it might be estimated as .3 gramme or 3 grammes B-oxybutyric acid per kilo. For the individual of 60 kilos (132 pounds) this would amount to 180 grammes, which approximates closely to the

weight of B-oxybutyric acid we found by our calculations above was required to produce acid intoxication. Though in a way this settled the question that there was sufficient acid in the bodies of coma patients to account for the coma, it did not directly demonstrate the acid. Moreover, up to this time no such amounts have been found in a diabetic. With the purpose of accomplishing this task Magnus-Levy undertook an "inquiry into the amounts of B-oxybutyric acid produced by the diabetic before and during coma." To do this he was obliged to determine both the amount secreted in the urine and that retained in the system, for only in this way could one secure a clear idea of the relations of the acid to coma.

Magnus-Levy succeeded in his undertaking, and was able to show that even more B-oxybutyric acid was formed per kilo body weight in one of his diabetic patients than was necessary to produce an acid intoxication in a rabbit. The patient was a boy of thirteen, who weighed 32 kilos, and in addition to his diabetes had nephritis with ascites. On the 5th and 6th of July, and again on the 2d and 3d of August, he went into diabetic coma, but lived through both attacks, taking 210 grammes bicarbonate of soda during the day. On the 10th and 11th of August signs of coma again appeared, but yielded to 160 grammes of the soda. As a rule he took 40 grammes daily, but during the coma 210 and 200, and in the next three following days 90, 80 and 60 respectively. The urine remained acid for the whole time. His diet consisted of 40 to 80 grammes carbohydrates in bread and 60 to 80 grammes in milk, or a total of 100 to 160 grammes per day. On days free from coma the acid (B-oxybutyric and diacetic combined) varied between 35 and 60 grammes. On coma days and the three days following it reached 74, 110, 157, 88 and 99 grammes. In five normal days the total amount was 200 to 250 grammes; in five coma days 528 grammes, that is, 300 grammes more than on previous days. The day following the coma the amount of acid was the highest. But for a boy of 30 kilos, theoretically 80 to 150 grammes of acid would be enough to cause coma, yet here we have 157 grammes.

This then establishes what has been suspected since Stadelmann's first work, namely, that diabetic coma is an acid intoxication. But the diabetic does not die of the acid excreted in the neutralized condition in the urine, but of that which remains in the body. So Magnus-Levy analyzed different portions of the body of diabetic patients, and determined the amount of acid which they contained. Calculating from his results the amount for the whole body, the sum total of acids reached 100 grammes.

Patients may live for several years with the production of B-oxybutyric and diacetic acids going on constantly. This is possible because the alkalis of the food and the ordinary store of alkalis in the body neutralize these acids. But the surplus of such alkalis in the body is limited and amounts only to 82 grammes for an individual of 50 kilos. But nature can get around this obstacle for a time because in the metabolism of albumin she can form ammonia and this helps the other bases to neutralize the acid. Indeed the most ready approximate method of estimating the B-oxybutyric acid is by determining the ammonia in the urine, since it has been found empirically that every gramme secreted in the twenty-

four hours over one gramme has probably been formed to neutralize the B-oxybutyric acid. As each gramme of ammonia can neutralize 6.12 grammes of the acid, it is a simple matter to get a rough estimate of the total amount produced, providing the patient is taking no other alkalies.

The indications for treatment of the acidosis (acid intoxication) of diabetic patients are plain. Prevent the onset of coma by the administration of alkalies; in coma combat the acidosis by enormous doses — 200 grammes or more — of the same.

I. *Prevention of onset.* — If a patient is forming considerable acid in the body, and this may be concluded if Gerhard's ferric-chloride reaction for diacetic acid is strong, the diet should only be very gradually changed from one rich in carbohydrates to one exclusively composed of albumin and fat. Such a gradual alteration is necessary, because a sudden change from a free to a strict diet favors coma in three ways: (1) The results of the metabolism of the larger amount of proteid food directly increase the acids in the body; (2) the exclusion of vegetables lowers the ordinary supply of alkalies, and (3) in a normal person as well as in a diabetic the exclusion of carbohydrates increases the amount of acids produced in the system.

A further precaution should be taken at such times, namely, the prevention of increased acidity by the administration of soda. By such a treatment the dangers are averted, and so considerably that Naunyn says that since he has systematically employed this method he has not lost a case during the transition to an exclusively animal diet.

If patients are forming much acid, they feel better when they are taking alkalies, and if no alkali is taken depressive disturbances often occur which lead directly to coma. The longest duration of life after the demonstration of B-oxybutyric acid in the urine has been without the alkaline treatment three years. Naunyn's case, T., who took the alkalies daily, lived six years.

How much bicarbonate of soda is to be given? This depends on the ferric-chloride reaction and the acidity of the urine. Usually 3 heaping teaspoonfuls (30 grammes) daily are sufficient to cause a disappearance of the Burgundy red color. Often much more is required; occasionally after very large doses the urine still remains acid.

II. *Treatment of coma.* — Following the general advice of Professor Naunyn and Dr. Magnus-Levy, I insert the following suggestions:

Overcome the acid intoxication at once, before the system is weakened by it. This is best done by giving intravenously on the approach of the earliest symptoms 3 pints of a 3% solution of bicarbonate of soda dissolved in normal salt solution. In 12 hours, notwithstanding improvement in the patient, repeat the same. In the meantime give 1 teaspoonful (5 grammes) of the soda by mouth every hour. Thus one gives intravenously 90 grammes and by the mouth 120 grammes on the first day. Even if the patient comes out of the coma and feels well, continue the alkalies in somewhat smaller doses for the succeeding days, bearing in mind that the production of acid is constantly going on. The diet during this time is unavoidably reduced to milk and egg-nogs, as the patient cares for nothing else. Under such treatment a few cases have recovered from coma, among them that of Magnus-Levy.

Reports of Societies.

MASSACHUSETTS MEDICO-LEGAL SOCIETY.

FRED E. JONES, M.D., SECRETARY.

MEETING of October 3, 1900, DR. JULIAN A. MEAD in the chair.

GEORGE A. SANDERSON, Esq., read a paper on

THE CO-OPERATION OF THE MEDICAL AND LEGAL PROFESSIONS.¹

THE PRESIDENT: Gentlemen, you have listened to this very interesting paper by Mr. Sanderson which he has kindly brought here and read to us. I hope we shall have a full discussion, and I am sure that Mr. Sanderson will be glad to answer any questions that may have troubled you, both on this general subject that he has discussed or any particular subject that may occur to you. The paper is now open for discussion.

DR. HOUGH: In these cases of suits for damages for personal injuries that are so common, I think the one element that has impressed me as of the greatest importance is the speedy settlement of the cases in one way or another. It is, I think, the general rule that the law's delays are extremely detrimental to the patient. Not that the patient, as a rule, tries to stay sick or lame or feeble as long as possible, but because there is something in the nature of the human mind that does retard recovery as long as a suit for damages is pending, and, so far as the speedy recovery of the patient is concerned, a settlement of the suit is quite as important in many cases as skilful treatment.

Perhaps that is taking an extreme view, but I want to impress upon you what I think is so important in those cases. It has been my fortune a good many times to have the opportunity to examine patients in these cases in conjunction with the physician representing the other party to a suit, and I am happy to say that almost without exception the medical gentlemen are able to agree as to the facts, and agree as to the probable outcome. The differences, if any, have been minor differences, in nearly every case where the physicians for the two sides have been able to meet and examine the patient and discuss the case. The greatest difficulty that I find is that the lawyer on each side considers the medical expert whom he employs as an assistant counsel in the case as retained for the purpose of bringing out, not the truth, the whole truth and nothing but the truth, but only that part of the truth which shall be an assistance to his side of the case. And the lawyers impress that upon the physicians to such an extent as to make it difficult for the best intentioned man to have that eye for the truth, the whole truth and nothing but the truth, which every one of us wishes to have in these cases.

DR. ADAMS: I have listened with great interest to Mr. Sanderson's paper. It seems to me he covers all the points, and I do not feel as though I could add anything to it or say anything of assistance in the discussion.

DR. HARTWELL: Mr. President, I am sure we can profit by what our essayist has said in relation to questions that come before the medical profession. There is a question that is constantly before them,

¹ See page 499 of the Journal.

that will not down, and that is the question of what shall be done with expert medical testimony. You will remember, Mr. President, in a very able paper presented by Dr. Irish, of Lowell, a few years ago, he stated that the whole matter depended upon the character and ability of the expert himself, and that reference to a court of justice composed of medical experts, or any other manner of disposition by the judge of the court, was secondary to that. I feel, as Dr. Hough has stated it, that there is a very strong tendency at the present time to leave these matters out to some medical man appointed by the defendant's and by the plaintiff's attending physician, and it is, I think, for reasons which are plain. The defendant feels — and this refers particularly to actions of tort in the case of our railway companies, perhaps — that he is not properly represented by the jury; a jury capable of being influenced very largely, and mixed up, if I may use the term, by the medical experts on the different sides, and by the attorneys when they come before the jury with a summing up of such testimony. It is left to twelve men who know very little about medical subjects, and I believe Mr. Sanderson has touched upon a very important elucidation, that it can be or should be left to the court to appoint those who may investigate.

One of our most celebrated experts in mental diseases in Massachusetts told me the other day of a tort case, in which a certain railway company in the State was the defendant, that was left out to him. He has had the patient two or three months now under his supervision, boarding in a private family near his home, and, with the consent of both parties, is trying to get at the exact truth, and will make a report to the judge in the case.

It seems to me, Mr. President, where cases cannot be decided between the defendant's physician and the plaintiff's family physician, that if the court can have power to give more authority to the expert than he has at present, that will place the matter where it will be more satisfactory to the parties involved. I believe there is a good deal in what Dr. Irish said, however. We have a law compelling all medical men practising in the State to be educated in medical matters, and I believe that a very great deal depends upon the honesty and integrity and capacity in medical subjects of the expert in question.

DR. DRAPER: Mr. President, I have nothing to say except to thank Mr. Sanderson, the reader, for his very acceptable method of meeting matters which for many years, and at present, have been not so acceptable as they ought to be. It seems to me that he has touched a way to which we, as physicians, can all give our ardent approval, and, if need be, our help toward getting the matter out of the rut in which so long it has been. The trouble, as we all know, is that, under present methods, partisanship is not only common but inevitable. I do not care how conscientious a man may be who is employed as an expert. From the very beginning of his employment, from the very moment when the lawyer comes to him to ask if he will take the case, his conscience is necessarily laid one side and partisanship has the right of way with him. He cannot help it. It is unconscious, it is inevitable. To meet that sort of thing, the suggestion made by Mr. Sanderson seems to me a very pertinent one and a very acceptable one.

I do not know that I have anything further to say,

Mr. President, except a single word of gratification that the essayist, himself representing the legal profession, appears to indicate that the legal profession is having its eyes opened a little bit to the very unsatisfactory way in which experts are employed by them out of and in the court; and if, in the future, these cases, in actions of tort where injuries are in question, where physical conditions are to be decided, can be left out to physicians as masters or as auditors, then we shall have taken a direct step toward results which I am sure we shall all approve.

DR. PRESBURY: Mr. President, we have all been taught that it is good to hear the other side. We have had an opportunity today, as between the lawyer and the physician, again to hear the other side; and I am gratified at being able to call your attention to the fact that today it doesn't altogether appear that all the faults in medical expert work are the faults of the medical side. I think we have had a very just and fair presentation of the difficulties and the faults, and a good and honest suggestion of what may prove a way out of our difficulties. We are all of us troubled, as physicians, with this system of advocacy which has been mentioned by all who have spoken before me, and our desire, I am sure, is to have that put one side, in order that we may, by whomever employed, seek wholly the truth and state wholly the truth. The reader, when he said that it was well that the medical men themselves should be the ones to pass upon medical subjects, because they were the ones best qualified, really touched the keynote of our whole existence. Without that there would have been no medical examiner. The whole idea in the work of the medical examiner was to put the investigation of certain unexplained deaths into the hands of men who had special qualifications for the investigation of such matters, and I think unknowingly he probably hit the real cause of our existence and the essence of our being. It is for us, then, if that is the cause of our being, so to conduct our work as to justify the plan which has made our existence possible. I am very much pleased with the paper that has been read. I think it is good for us to hear a statement of facts from lawyers as well as from physicians, and particularly gratifying to hear them so kindly and pleasantly made as in the paper of today.

DR. ABBOTT: I have been much pleased with the clear method in which this paper has been presented, and I hope it is a sort of harbinger of something better to come as years go on. There is one case I call to mind which is an illustration of just this difficulty, and that occurred some twenty years ago at least. It was the case of the Smith Paper Company's dam on the Housatonic River. I think the number of medical experts called in that case was larger than has appeared in any other trial in the State or in New England. There must have been forty or fifty. The question was whether that dam should come down or not in consequence of the flats above it having produced malaria in that region. What was remarkable about the matter was that no one then knew anything about the cause of malaria. Those gentlemen went on the stand and they testified just according to which side they were paid for, and nothing came of the trial. The dam stands there now. It is only within the past ten years that light has begun to come to us upon this subject, and we do know now something about the causes of malaria; but that is only one of the instances

showing a radical wrong in the present method of trials along this line.

DR. BROWN: I do not know that I can add anything more. One thought occurred to me, however, during the reading of the paper, when reference was made to the disagreement of experts so often, and that point is this: that we, as medical examiners, at least, should never let it appear before the eyes of a jury that we are partisans, however hard the attorney on either side may try to make it appear so. I know several times I have had the question asked me by the attorney, "You are a witness on the other side of this case?" and I take pleasure in replying, "No, sir, I am a witness for the Commonwealth, to tell the truth, the whole truth, and nothing but the truth. I am here to testify in behalf of one side just as much as the other." I try to make it a point to impress the jury that I am not a partisan, and I try to impress upon myself that I will not be a partisan in a case, and I think we should all take that moral ground, and not allow ourselves to be partisans in a case, not to go in with any premeditated view, anything more than to get at the right and truth in the matter.

DR. ADAMS: Mr. President, a curious case comes to my mind, from my own experience, with regard to the lawyers. We have been talking, in what has been said, about the prejudice with which the doctor goes on the stand. It is certain that the lawyer that employs them expects the doctors to give evidence on their side, and I had a curious example of that once.

A friend of mine was a lawyer of some distinction, and he had a case which he was bringing for various riparian owners, of which he was one, to recover damages for the building of a dam. Now, without asking my opinion about it, he summoned me as a witness, and it so happened that my testimony, the moment I began to give it, was entirely against him. His case was, I feel sure, an unjust one. But, however that may be, it is certain that my testimony went entirely against him; and the result was that after I had returned from giving my testimony he said to me in the hearing of the court and loud enough for anybody to hear, "The witness on the stand has knocked our testimony all to pieces." I thought that a most extraordinary exhibition of partisanship, and the feeling with which he entered upon it when he put me on the stand was that I was certain to testify in his favor, assuming that a doctor who was summoned by him—his doctor—must necessarily testify for him, without having previously asked me what my testimony would be; showing that lawyers certainly enter upon cases of that sort, where they summon medical testimony with the idea that the physician is to testify for them whether it is the truth or not.

THE PRESIDENT: Mr. Sanderson, have you any desire to say anything in closing this discussion?

MR. SANDERSON: I think I have had my turn.

THE PRESIDENT: Then unless some gentleman has something to say we will consider the discussion at an end.

DR. F. E. JONES moved that a vote of thanks be given to Mr. Sanderson for his very interesting paper.

THE PRESIDENT: I am very glad, gentlemen, to put that motion, because I personally have enjoyed the paper very much, and I know this society will profit by it.

The motion was put and unanimously carried.

DR. A. W. BUCK read a paper on

CRIMINAL NEGLIGENCE; REPORT OF A CASE.²

THE PRESIDENT: This paper by Dr. Buck is now open for discussion, gentlemen. I think Dr. Abbott once wrote a very instructive paper on infanticide in the early days of this society.

DR. ABBOTT: It was an allied subject—still birth.

DR. HARTWELL: I would like to know if the soothing syrup used was Mrs. W's?

DR. BUCK: Yes, it was. I expressed my wrath.

DR. HARTWELL: Some twelve years ago the legislature passed an act authorizing the State Board of Health to investigate the use and abuse of opium in the State of Massachusetts. In the report made at that time I think you will find Mrs. W's soothing syrup was put down as a morphine simple syrup. I presume he considered that as a factor possibly in the infanticide in this case.

THE PRESIDENT: Has any other gentleman anything to say on this subject? If not, we will consider the discussion at an end.

Recent Literature.

Elements of Clinical Bacteriology. For Physicians and Students. By DR. ERNST LEVY, Professor in the University of Strasburg, I. E., and DR. FELIX KLEMPERER, Privat Dozent in the University of Strasburg, I. E. Authorized translation by AUGUSTUS A. ESHNER, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, Physician to the Philadelphia Hospital, etc. Second enlarged and revised edition. Philadelphia: W. B. Saunders & Co. 1900.

The aim of this book is to present what is known concerning bacteria and the lower organized forms of life, with special reference to the bearing of such knowledge upon clinical medicine. It also has an appendix dealing with the bacteria of the air, soil and water, together with a section on the subject of disinfection.

It is a book for the library rather than for the laboratory and should be useful to physicians. The contents of the book justify the good reputation of the authors as bacteriologists.

Saunders' Question Compend. Essentials of Histology. By LOUIS LEROY, B.S., M.D., Professor of Histology and Pathology in Vanderbilt University, etc. Arranged with questions following each chapter. Seventy-two illustrations. Philadelphia: W. B. Saunders & Co. 1900.

This, even for a quiz compend, is a small book, comprising with an index but 231 pages. It is profusely illustrated with diagrammatic cuts for the most part, and treats in a necessarily brief way of the various structures of which the body is composed. Although we do not in general approve this method of gaining knowledge, we are quite ready to admit that such a compend may at times serve as a useful guide.

INTRADURAL INJECTIONS OF COCAINE FOR
 SURGICAL ANESTHESIA.

THE recent widespread interest in surgical anesthesia by the intradural injections of cocaine, first aroused by the work of Bier in 1898, and again by the extensive demonstrations made by Tuffier and others at the International Congress of Surgery at Paris this summer, has resulted in another of those curious reminders that there is nothing new under the sun, namely, the recognition that the method was practised and published by an American, Dr. J. Leonard Corning, of New York, in 1885. At that time the procedure of lumbar puncture for obtaining the spinal fluid for diagnostic purposes had not been published by Quincke, and the facility with which fluid could be withdrawn from or introduced directly into the spinal canal was not known. Corning found by experimental work on animals that the injection of a 2% solution of cocaine into the subdural space in the lumbar region produced anesthesia of the lower extremities, the anesthetic probably reaching the subarachnoid space and cord by means of the free communication between the two by the veins and lymphatics. In the human subject also, he produced anesthesia sufficient to allow the painless passage of a urethral sound by injecting a 3% solution of cocaine hydrochlorate into the space between the spinous processes of the eleventh and twelfth dorsal vertebrae. In his original article, published in the *New York Medical Journal* for October 31, 1885, he made the following statement, interesting in the light of recent developments: "Whether the method will ever find an application as a substitute for etherization in genito-urinary or other branches of surgery, further experience alone can show. Be the destiny of the observation what it may, it has seemed to me on the whole worth recording." Now that the intradural cocainization is being in some quarters extensively practised, this record gives Dr. Corning the position of pioneer in this method of local anesthesia, as he is acknowledged to have been in the discovery that anesthesia in the distribution of a nerve

could be produced by cocainization of its trunk, and that constriction by elastic ligature of a cocainized member prolongs and intensifies the action of the drug.

Important steps in rendering practicable the methods of local anesthesia by cocaine injections were the discovery by Schleich and others that by thorough infiltration of the tissues with the fluid solutions as weak as 1 to 1,000, or even 1 to 10,000, of the drug could be employed, thus avoiding the danger of cocaine intoxication, and making possible the performance of extensive operations under local anesthesia. The demonstration of the fact that the tissues of the body, excepting the skin and mucous membranes and the nerve trunks, were themselves anesthetic and could be surgically handled without pain, provided the skin were infiltrated (Schleich) and the nerve trunks cocainized (Corning) has rendered possible the excellent elaboration of the application of local anesthesia to herniotomy published by Cushing. Latterly the researches of Bier, in 1898, demonstrating the practicability of surgical anesthesia by intradural injections through a lumbar puncture, followed by the demonstrations by Tuffier, by his pupils alluded to above, have resulted in considerable activity in the practice of this method, which was briefly discussed in our editorial of August 23d.

Since then numerous articles embodying the personal experiences with the method of certain surgeons in this country, and describing the technique, have appeared in the journals. Fowler, in the *Philadelphia Medical Journal* for November 3d, reports the successful performance of such major pelvic operations as hysterectomy, and even operations upon the gall bladder, and the resection of ribs for empyema, the anesthesia extending as high as the fourth rib. Fowler reports forty-two cases with no mortality and no serious after effects, but concludes from his experience that the method could not be applied in abdominal sections for inflammatory conditions of the peritoneum, as the manipulations of the inflamed peritoneum always caused marked pain. He remarks that this is unfortunate, since it is in this class of cases that the surgeon most often wishes to dispense with ether and chloroform.

A review of the experience of Fowler, Matas (Goldan and others who have employed this method in this country shows much in its favor, and on the whole, when it is carefully used, comparatively little against it. It certainly should be employed only in carefully selected cases, and the technique must be scrupulously carried out. Owing to the greater danger of poisoning resulting from the direct conduction of the drug to important nervous centres by the cerebrospinal fluid, great care must be taken with the dosage. The method should not be employed in cases where the older and safer methods of purely local anesthesia will suffice.

The use of the method will always be limited to a comparatively small field by reason of the fact that it

is applicable only to the lower portions of the body and the lower extremities, and that unconsciousness as well as anesthesia is desired by the vast majority of patients, as well as surgeons, during major operative procedures.

In the rare cases in which, owing to pulmonary or renal complications, general anesthesia is dangerous, this method may find a useful place, by securing the painless performance of major operations upon the trunk and lower extremities.

In the excitement attending the exploitation of a new method, it is well for the profession to remember that the dangers attending the bringing of cocaine in direct contact with the central nervous system are sufficient to contraindicate its use in cases which it is known may take ether with perfect safety, and that the new method can be, in fairness to the patients, employed upon cases in which ether would be dangerous or in which the patient so earnestly desires local anesthesia as to prefer to take the risk. The practice of this new and comparatively untried method upon routine cases as they come to the surgeon, which seems to be the present habit in some quarters, cannot be too strongly condemned. Even if due conservatism be practised in the use of the method, we shall soon acquire experience enough to judge of its value. It is emphatically a case where the advantages to be gained do not justify great risks. For in major surgery any method of local anesthesia to deserve extensive practice must possess very definite advantages to compensate for the disadvantage of consciousness on the part of the patient.

The older methods of local anesthesia will suffice for the majority even of major surgical procedures where ether is contraindicated, and, as simpler and safer, should be adopted where possible.

In a certain small number of carefully selected cases, in operations upon the trunk and lower extremities, the new method will probably prove of occasional value.

"The ideal anesthetic," says Keen, and his words are worth remembering, "is not one which abolishes sensation, leaving consciousness intact, but one which will abolish consciousness and sensation without the slightest danger to life."

PRIZES AS A STIMULUS TO RESEARCH.

As is now generally known, a prize of \$200, known as the "Craig Colony Prize for Original Research in Epilepsy," has been offered for several years by Dr. Frederick Peterson, president of the Board of Managers. It may not be so generally known, however, that for two years no prize has been awarded, because of the poor quality of the essays presented in competition. This year, in fact, but one essay was submitted. The committee in charge of the matter make the following statement of the reason for this anomalous state of affairs, as they see it: "In view of the fertility of the field, or the constantly increas-

ing number of investigators and of the present perfected facilities of research, your committee believes that the prize having failed to attract more meritorious contributions is to be explained by its not having been sufficiently called to the attention of original workers. It would recommend, therefore, that for the ensuing year no pains be spared to have the existence of the Craig Colony Prize made known to all qualified to compete for it."

We are inclined to think the foregoing is not the essential reason for the lack of interest in competing for this or any other prize. As a matter of fact there are already far too many money prizes offered on a great variety of subjects connected more or less directly with medicine. It is perfectly clear that as such rewards for original research multiply, the credit attaching to the successful competition becomes proportionately less. The prize essayist is no longer looked upon as necessarily a man of distinguished attainment, and as a perfectly natural consequence we find fewer really able men competing. This brings us to the other point, that it too often happens that the men who compete for prizes do so in great measure from mercenary motives. The money is, and is intended to be, a temptation; of that there can be no question. The moment this is acknowledged, research becomes a means and not an end in itself, and thereby loses at once in dignity.

We are convinced that the present situation with regard to prizes is bad and constantly growing worse. The experience which the Craig Colony Committee has just had could no doubt be paralleled in many other instances if all the facts were known. Even the money is apparently no longer attracting competition. It is very much to be hoped that the near future may see a tendency toward a more worthy conception of the significance and proper rewards of scientific research, and dispense with prizes which are doing much more to cultivate a mercenary spirit than to develop true research. As regards the particular prize which we have happened to take as a text for these remarks, we can only say that in our opinion the study of epilepsy is not being promoted by its existence. While quite ready to spread the knowledge of the existence of such a prize as far as lies in our power, we cannot help wishing that the money might be devoted to some other more useful purpose connected with the important work which the Craig Colony is doing.

MEDICAL NOTES.

FILTHY STREETS AND DIPHtherIA IN PHILADELPHIA. — An inspection of the streets in the sections of the city where diphtheria is most prevalent, according to the *Medical News*, has shown some of them to be horribly filthy in spite of the efforts of the Board of Health to guard against such insanitary conditions. The paved streets are kept in good condition, but the unpaved streets and alleys are not. The

superintendent of street cleaning states that the latter do not come under his jurisdiction. The cases of diphtheria during the last week number 120.

ANOTHER PROPOSED HOSPITAL FOR TUBERCULOSIS.—The *New York Medical Journal* states that Dr. Louis Bazet, a member of the San Francisco Board of Health, has entered upon a vigorous campaign for the establishment of a separate hospital in San Francisco for the care of patients suffering from tuberculosis.

PLAGUE AT ALEXANDRIA, EGYPT.—Two new cases of plague are reported from Alexandria, Egypt.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, November 14, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 148, scarlatina 33, measles 18, typhoid fever 19.

WOMEN DIPSOMANIACS.—A complaint has been entered, and a test case heard in the Supreme Court regarding the commitment of women dipsomaniacs to insane hospitals, on the ground that such commitments under the existing statute are in violation of the United States Constitution. It was contended by counsel for the complainant that while men are given an opportunity to be heard before being committed, women are deprived of that privilege. The complainant was committed on an allegation and complaint that she was an habitual drunkard. The court made the commitment after hearing expert witnesses.

HARVARD VETERINARY SCHOOL AND HOSPITAL TO BE CLOSED.—The corporation of Harvard University has voted to close its Veterinary School and Hospital permanently June 1, 1901.

NEW YORK.

A DECISION REGARDING THE RIGHT OF RESIDENTS OF HOSPITALS TO VOTE.—Writs of habeas corpus and certiorari obtained on behalf of Dr. Albert Sellenings, of the house staff of Bellevue Hospital, and of two trained nurses and two hired helpers at that institution, who had been held by Magistrate Deuel on the charge of having illegally registered, inasmuch as they gave their place of residence as Bellevue Hospital, were sustained by Justice Andrews in the Supreme Court on November 5th. The cases were in the nature of test cases, and affected 143 voters from Bellevue Hospital and 413 in other city institutions. The result of the decision was that the persons objected to had the right to vote. It had been claimed that under Article II of the State Constitution such persons did not have the right. In the course of his opinion Justice Andrews said: "I am at a loss to understand how either of these classes of persons is disqualified from voting by reason of the provision of the Constitution quoted. The term, 'kept' as there used means 'supported,' and as used in the Constitution evidently refers to paupers, pa-

tients, and other persons who are maintained at the expense of the public. It cannot be truthfully said that the physicians, hired helpers, or pupil nurses are supported by the public. The physicians render most valuable services to the patients in the hospital, and are allowed to lodge and eat there, not as a matter of charity, but as a matter of convenience and almost of necessity, owing to the nature of the duties which they are at all times called on to perform." Then, having spoken in a similar way of the relations of the hired helpers and nurses, he ordered the discharge of the prisoners.

ANOTHER DEATH UNDER CHRISTIAN SCIENCE TREATMENT.—On the night of November 5th, Coroner's Physician Wuest, of Brooklyn, made an autopsy upon the body of Mrs. Augusta Hubbell, of Kingston Avenue, in that borough, who had died that day, and found that her death was due to appendicitis and peritonitis. She had been attended for a considerable time by two Christian Scientists, but on the morning that she died Dr. Herman Street was called in by the patient's husband. He saw at once that the case was hopeless, and while he did all that was possible under the circumstances, refused to assume any responsibility. He very properly declined to make out a death certificate, and called the coroner's attention to the matter. Dr. Street expressed the opinion that the patient's life might have been saved if she had received proper treatment.

DEATH FROM CHLOROFORM ANESTHESIA.—A boy nine years old died at the Polyclinic Hospital on November 8th from the effects of chloroform, which was being given for the removal of a diseased gland in the axilla. The operation, which had not as yet been begun, was to have been performed by Dr. John A. Wyeth. The hospital surgeons were entirely exonerated by Dr. Philip F. O'Hanlon, coroner's physician, who made the autopsy in the case. The patient was the subject of septicemia, and he found the entire glandular system involved to an extent which could not have been suspected during life, but which in reality rendered the use of any anesthetic more than ordinarily risky.

APPOINTMENTS AT THE COLLEGE OF PHYSICIANS AND SURGEONS.—At the monthly meeting of the Trustees of Columbia University held November 5th, the following appointments in the Medical Department (the College of Physicians and Surgeons) were announced: Prof. Edwin B. Cragin, secretary of the Faculty of Medicine; Dr. Charles E. Banker, assistant in normal histology; Dr. Carleton P. Flint, assistant demonstrator of anatomy.

OLDEST VOTERS IN NEW YORK.—The two oldest voters in New York State at the recent election were Joseph La Bonté, a French Canadian living in Ogdensburg, St. Lawrence County, who is one hundred and one years old, and George Olley, of Wilna, Jefferson County, who will be one hundred and three next Christmas Day.

SCHOOLS CLOSED ON ACCOUNT OF DIPHThERIA.—On November 8th the public schools of Lyons, N. Y., were closed by direction of Health Officer Veeder to prevent the spread of diphtheria. Within ten days there were two deaths from the disease in the town, and a number of serious cases were reported.

Miscellany.

BIAS IN CLINICAL MEDICINE.

UNDER this heading Dr. Judson S. Bury, of Manchester, according to the *Lancet*, has recently delivered an address before the Medical Society of University College, London. After describing the errors into which a diagnostician is likely to fall, through poor equipment or one-sided training, he concludes as follows: "A patient was not an automatic machine into which a penny could be dropped to pull out a particular disease ready for treatment. On the contrary, the organs by which he moved and lived were composed of living tissues which had a past history and a future development, both of which required consideration before the case could be properly grappled with. The thoughtful qualified man began to find out that he must study other things than mere medicine to acquire that knowledge of humanity so essential to a just appreciation of the many ills to which flesh was heir. The man who got into the habit of regarding every patient as merely a "case" and who ignored the look of icebleness or of distress, or the expression of anguish, and thought only of physical examination, was not well equipped for the diagnosis of obscure disease—he became a machine which was totally unable to unravel the complicated problem of human pathology. Three things were essential for the preventive treatment of the disorder known as bias—namely, care, doubt and truth, and if one thing helped more than another to avoid the pitfalls of bias and of hurried unscientific work, it was that practitioners should put themselves in sympathy with their patients and that they should care for them in the way that Dr. James Jackson, the hero of Oliver Wendell Holmes, cared for his patients. Jackson would have it that to cure a patient was simply to care for him. Such devotion was only to be looked for in the man who gave himself wholly to medicine, the noblest of arts, which the gods of ancient religions did not disdain to practise and to teach."

GENERAL REMARKS ON THE GUNSHOT WOUNDS OF 1898 AND 1899.

THE following extract from the forthcoming annual report of the Surgeon-General of the United States Army, now in press, will interest many surgeons and certainly all those who have followed recent discussions on gunshot injuries:

Of the 4,919 men injured by gunshot during the years 1898 and 1899, 586 were killed and 4,333 were wounded and received into the field and other hospitals. The killed constituted 11.9% of those struck, the wounded 88.1%. In other words, 1 man was killed for every 7.4 wounded. The Mauser bul-

let must therefore be regarded as less deadly than the larger missile used during the Civil War. The medical and surgical history of the Civil War shows the following casualties:

	Killed.	Wounded.
United States troops	59,860	280,040
Confederate troops	51,425	227,871
Total	111,285	507,911

In percentages the casualties were: Killed 17.97; wounded 82.03, or 1 man killed to every 4.56 wounded. The relative proportion of killed was therefore considerably larger during the Civil War than during our recent experiences. It is to be noted also that many of the wounds of the past two years were made by missiles of large calibre. Of those reported in 1899, 471 were specially stated as having been caused by the Remington bullet of calibre .45. It is safe to say that had the whole number of wounds received been inflicted by the smaller Mauser or Krag-Jorgensen bullet the percentage of immediately fatal wounds would have been materially lessened.

The less deadly character of the injuries inflicted by the modern bullet is manifested also when we exclude the killed and regard only those wounds which came under the care of the surgeons. Of these, during the two years, there were 4,333, and 259 of the patients, or 6% of the whole number, died. The corresponding percentage from the records of the Civil War was 14.3. Table C in Part I of the medical volume of the "Medical and Surgical History of the War of the Rebellion," shows that among the white troops of the army there were borne on the reports of sick and wounded 230,018 gunshot wounds, of which 32,907, or 14.3%, proved fatal. The marked reduction of the ratio of killed to wounded may be placed to the credit of the small-calibre bullet; but the lessened mortality among the cases which came into hospital may not wholly be attributed to the humane character of the wounds inflicted by this missile. Due credit must be given to the improved surgical methods of the present day. Wounds of any region of the body may be taken in comparison and the result will always be found to show a decided lessening in the percentage of cases ending fatally among those of the past two years, as compared with those of the Civil War. Take, for instance, gunshot wounds of the femur. During the Civil War surgeons in the field hospitals regarded a fractured femur as a serious menace to life, the danger from which was believed to be materially lessened by an immediate amputation. The field hospital surgical work after a battle consisted in great part of amputations, excisions and resections. Of 6,576 fractures of the femur, 2,923 cases were treated by primary amputation, 186 by resection, and the remaining 3,467 by conservative or expectant measures, this conservative action being due in many cases to a want of favorable conditions for the performance of primary operations. The limb was promptly amputated in 44.4% of these gunshot fractures.

On the other hand, during the past two years 82 cases of gunshot fracture of the femur were reported, 6 of which were treated by primary amputation and 2 by resection, the remaining 74 cases being treated by conservative methods, not because the conditions were not favorable for the performance of primary operations, but because of a conviction that under present methods of treatment the limb could be preserved without adding materially to the danger to life. The

limb was lost through surgical intervention in only 7.3% of the cases.

Not only limbs but lives were saved by the surgical practice of the past two years. In the 82 gunshot fractures of the femur the upper third was involved in 32, of which 5 were fatal, the middle third in 27, of which 3 were fatal, and the lower third in 23, of which 1 was fatal. The mortality varied from 4.3% of the cases in which the lower third was fractured to 15.6% of the cases in which the upper third was the site of the injury, whereas the corresponding percentages of fatal cases during the Civil War were respectively 42.8% and 49.7%. The whole of the lessened mortality in these serious fractures may be credited to the protection given to the wound by the first-aid dressing and to the care exercised in the subsequent aseptic treatment of the fractured limb.

In penetrating wounds of the thorax the rate of mortality fell from 62.6% during the Civil War to 27.8% during the years 1898 and 1899. The Civil War reports show 8,403 cases in which the results were determined; 5,260 deaths occurred among the number. The reports for the later years, as already stated, show 198 cases, of which 55 were fatal.

There were during the Civil War 3,475 penetrating wounds of the abdomen in which the ultimate results were determined; 3,031 of these, or 87.2% of the total, proved fatal. During the years 1898 and 1899 116 cases, 81 fatal, were recorded, the fatal cases constituting 70% of the total. Of 10 cases in which laparotomy was performed, 9 were fatal.

The alteration in the percentages of mortality in fractures of the cranium is less marked than in wounds of other parts of the body. Of 4,243 cases of cranial fracture during the Civil War, 2,514, or 59.2%, were fatal. In 1898 and 1899 68 cases were recorded, with 37 deaths, the latter forming 54.4% of the whole number.

THE ELEVATOR DISEASE.

The *London News* is responsible for the following warning, which we believe may have a element of truth: "It looks as though people with weak hearts had, after all, better climb ten flights of stairs than effect the ascent by means of the lift. This convenient institution is becoming ubiquitous. We soar up to the topmost story of the sky-scraping flat, we descend through geological strata to the twopenny tube by its assistance. We thought we were thereby saving our vital energies and lengthening our lives. The doctors seem to hold another opinion. Lift attendants have died sudden deaths; people with weak hearts have noticed ominous sensations when in the elevator. We are told the sudden transition from the heavier air at the foot to the lighter air at the top is extremely trying to the constitution. Even millionaires and bishops and aldermen are now voluntarily tramping up stairs and avoiding the swifter but insidious route. In fact, a new disease has swung into our ken, 'lift-man's heart.' We have all of us been risking this malady without knowing it. It is true most people have experienced the singular sensation of internal collapse when the lift floor sinks beneath the feet, but none of us suspected the results might be so serious. Every new notion for health and comfort seems to bring its particular Nemesis."

METEOROLOGICAL RECORD

For the week ending November 3d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Melrose	15,411	3	—	—	—	—	—	—	
Newburyport	15,157	6	—	16.66	16.66	—	16.66	—	

Deaths reported 1,792; under five years of age 556; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 418, acute lung diseases 232, consumption 202, diarrheal diseases 90, diphtheria and croup 60, typhoid fever 47, whooping cough 9, cerebrospinal meningitis 7, scarlet fever 2, measles 1.

From whooping cough New York 5, Baltimore 2, Boston and Medford 1 each. From cerebrospinal meningitis New York and Boston 2 each, Baltimore, Worcester and Lowell 1 each. From scarlet fever Boston and Lynn 1 each. From measles New York 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending October 20th, the death rate was 17.1. Deaths reported 3,815; acute diseases of the respiratory organs (London) 182, diarrhea 197, diphtheria 85, fever 71, whooping cough 43, measles 37, scarlet fever 35.

The death rates ranged from 10.4 in Halifax to 28.6 in Gateshead; Birmingham 19.0, Bradford 14.3, Cardiff 10.7, Derby 12.6, Hull 17.9, Leeds 16.7, Liverpool 21.9, London 15.8, Manchester 22.3, Newcastle-on-Tyne 18.2, Nottingham 20.2, Portsmouth 17.4, Sheffield 22.7, Sunderland 21.2, West Ham 15.3.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 10, 1900.

J. C. BOYD, medical inspector, detached from the "New York" when out of commission and ordered to the "Kearsarge."

E. S. BOGERT, JR., passed assistant surgeon, detached from the "New York" when out of commission and ordered to the "Massachusetts."

M. S. ELLIOTT, passed assistant surgeon, detached from Naval Station, Port Royal, and to duty on the "Annapolis" when placed in commission.

W. M. CARTON, assistant surgeon, detached from the "Massachusetts" and ordered to the "Indiana."

J. ST. J. BUTLER, assistant surgeon, appointed assistant surgeon from October 26, 1900.

J. M. MOORE, passed assistant surgeon, ordered to Naval Station, Port Royal.

E. M. SHIPP, passed assistant surgeon, detached from Norfolk Hospital and ordered to the "Michigan."

H. D. WILSON, passed assistant surgeon, detached from the "Michigan" and ordered to Naval Hospital, Norfolk, Va.

L. W. SPATLING, passed assistant surgeon, detached from Yokohama Hospital and ordered to Naval Station, Cavite, P. I.

S. DOUGLASS, pharmacist, ordered to additional duty on the "Massasoit."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOVEMBER 8, 1900.

CARMICHAEL, D. A., surgeon. Granted leave of absence for thirty days from October 23d. November 7, 1900.

MAGRUDER, G. M., surgeon. Granted leave of absence for seven days from November 17th. November 8, 1900.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Natchez and Jackson, Miss., on special temporary duty. November 7, 1900.

YOUNG, G. B., passed assistant surgeon. Granted leave of absence for two days. November 3, 1900. Granted leave of absence for five days, on account of sickness. November 8, 1900.

FOSTER, M. H., assistant surgeon. To proceed to Seattle and Tacoma, Washington., on special temporary duty. November 3, 1900.

GIBSON, R. H., hospital steward. Granted leave of absence for thirty days from December 7th. November 7, 1900.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold its meeting at 19 Boylston Place, Wednesday, November 19, 1900, at 8 P. M. At 8 o'clock: Dr. J. L. Morse, "Leucocyte Count in Serous Pleurisy."

At 8.15 o'clock: Dr. G. G. Sears will read a paper entitled "Pericarditis with Effusion."

HENRY F. HEWES, M.D., Secretary.

THE CRAIG COLONY PRIZE FOR ORIGINAL RESEARCH IN EPILEPSY.

Dr. Frederick Peterson, president of the Board of Managers of the Craig Colony for Epileptics at Sonyea, N. Y., offers a prize of \$200 for the best original unpublished contribution to the pathology and treatment of epilepsy. Originality is the main condition. All manuscript should be submitted in English. The prize is open to universal competition. Each essay must be accompanied by a sealed envelope, containing the name and address of the author and bearing upon the outside a motto or device, which is to be inscribed also upon the essay. All papers received will be submitted to a committee, consisting of three members of the New York Neurological Society, and the award will be made upon its recommendation at the annual meeting of the Board of Managers of the Craig Colony, October 8, 1901.

Manuscripts should be sent to Dr. Frederick Peterson, 4 West 50th St., New York City, on or before September 30, 1901. The successful essay becomes the property of the Craig Colony and will be published in its annual report.

BOOKS AND PAMPHLETS RECEIVED.

Eleventh Report of the State Board of Health of the State of Maine for the Two Years ending December 31, 1899. 1898-99.

Transactions of the Medical Society of the State of West Virginia, held at Morgantown, May 9, 10 and 11, 1900. Instituted April 10, 1867.

DIPHTHERIA BACILLI IN HEALTHY THROATS AND NOSES, WITH REPORT OF CASES.¹

BY FRANCIS P. DENNY, M.D., BROOKLINE, MASS.,

Assistant in Bacteriology, Harvard Medical School; Bacteriologist of the Brookline Board of Health.

The occurrence of virulent Klebs-Löffler bacilli in the throats of healthy individuals who have never shown any symptoms of diphtheria has given rise to much misunderstanding. It has led many to doubt the value of the diagnosis of diphtheria based on bacteriological examinations, and it has even been used as an argument against the Klebs-Löffler bacillus being the specific organism of the disease. It has given rise to many perplexing questions for boards of health. Many incorrect statements in regard to the significance and frequency of these cases are in circulation among the laity, as well as among the profession.

With our present knowledge the occurrence of these cases can be satisfactorily explained, and they are in no way inconsistent with the generally accepted theories of the disease. It is very desirable that there should be a better understanding of these cases among general practitioners that they may aid the boards of health in detecting these individuals and give their moral support in securing their isolation.

The question of the frequency of diphtheria bacilli in healthy throats is important because of the prevalent belief that there are *many* healthy individuals in any community who have the bacilli in their throats. It is therefore felt that these cases cannot be a great source of danger and that it is unjust to insist on the isolation of the few who are by chance discovered. This belief is supported by most of the reports of cultures from healthy throats which are found in the literature.

Kober¹ in a review of all the reports which he could collect found that 7% of all healthy persons who had *not* been exposed to diphtheria had Klebs-Löffler bacilli in their throats, while among those who had been exposed 18.8 were positive. Kober's own investigations showed only .83% positive among the non-exposed and 8% among the exposed. The cultures which are reported later in this paper show an even lower percentage of positive cases.

The high percentages found in the literature are partly to be explained by the fact that many of the cultures reported were made from individuals living in institutions or in crowded tenements of our large cities. The hygienic conditions under which the individuals are living appear to stand in close relation to the frequency of these cases.

Another reason for the high percentages is that in many of the reports no distinction has been made between those individuals with virulent and those with non-virulent bacilli. It seems probable that in certain localities non-virulent forms of the bacilli are much more frequently found than in others. These non-virulent forms which morphologically are identical with true Klebs-Löffler bacilli may differ only in the absence of virulence, or they may show slight variations in growth on certain media, the most important of which is the failure to produce acid in sugar

bouillon. Persons with non-virulent bacilli are probably not a source of danger. No one has ever succeeded in experimentally raising the virulence of bacilli when it has been entirely absent.

Diphtheria bacilli are most frequently found in healthy persons who have been exposed to the disease. Under these circumstances the bacilli are usually virulent. As cultures will seldom be made except from individuals known to have been exposed, the bacilli found in cultures from healthy throats are usually virulent. It is always well, however, to test the virulence of the bacilli found in those who have shown no symptoms.

The percentage of positive cases among those exposed depends largely on the hygienic conditions under which the individuals are living and also on the degree of exposure, which in any large series of cases cannot be accurately measured. The conditions of institution life seem especially to favor their occurrence.

It is now very generally believed that virulent bacilli may multiply in the throats and noses of certain persons without producing symptoms because these persons have a natural immunity from the disease. The bacilli multiply in their throats without producing symptoms just as they multiply in the throats of those convalescing from diphtheria. During convalescence the individual has a temporary immunity due to the accumulation of antitoxin in the blood during the acute stage. The antitoxin prevents the further development of the disease, although virulent bacilli continue to multiply in the throat. It seems probable that the natural immunity which certain individuals seem to possess is also due in part at least to the antitoxic property of their blood, for Wasserman and others have found antitoxin in the blood of individuals who have never had diphtheria.

Wasserman² obtained blood from different persons by cupping, and inoculated diphtheria toxins in guinea pigs together with small amounts of the human serum so obtained. He found that one or two cubic centimetres of the blood of certain persons was capable of protecting a guinea pig against several times the fatal dose of toxins. The blood of some persons did not have this protective power. Abel,³ Orłowski,⁴ Loos,⁵ and Passini⁶ have confirmed these observations of Wasserman.

In view of the fact that certain individuals have a natural immunity from the disease due to the presence of antitoxin in their blood, it is no more surprising that virulent bacilli should multiply in their throats without producing symptoms than it is that the bacilli should continue to multiply in the throats of those convalescing from diphtheria: the one has a *natural*, the other an *acquired* immunity.

The number of bacilli which may be present in the throat of a healthy person varies greatly. In some of the cultures which I have examined there have been only a few; in others they have been present in almost pure culture. As a rule, they are less than during the acute stage of diphtheria, corresponding in the number of bacilli present to mild or convalescent cases.

To what an extent are healthy individuals with virulent bacilli in their throats a source of danger? We know the Klebs-Löffler bacillus to be the specific organism of the disease. The virulence of the bacilli being the same, an individual is a source of danger in

¹ Read in part at the meeting of the Norfolk District Medical Society, January 30, 1900.

proportion to the number of bacilli which are given off from him. In an acute case of diphtheria when the child is coughing and gagging and the secretions are profuse the bacilli will be disseminated more than they are in the mild or convalescent cases. Still from the mild cases, and equally from healthy individuals, there is abundant opportunity for the bacilli to be disseminated. In coughing and sneezing and even, according to Pflügger, in speaking, the bacilli are scattered abroad. They leave the mouth on towels, handkerchiefs, forks and spoons, drinking cups, etc.

Cases have been reported by Park⁷ and others where the infection can be traced almost with certainty to individuals who have shown no symptoms. Many outbreaks of diphtheria in children's institutions which have persisted for a long time, despite the fact that all the sick children were promptly isolated and the rooms disinfected, have been quickly stamped out when the healthy children's throats were tested and those with the bacilli were isolated. There can be no question that *healthy individuals with virulent bacilli in their throats can give the disease.*

In our search for these cases it is not practicable to make cultures from every healthy individual. We can, however, make cultures from those who are most likely to have virulent bacilli in their throats and those are persons who have been exposed to diphtheria. It is especially desirable that physicians should make cultures from the well members of a family where there has been delay in isolating a case of diphtheria or where the isolation has not been thorough. The poorer the hygienic conditions under which the family are living and the more crowded the rooms the greater the need of making cultures. In institutions also where there have been diphtheria cases it is especially important that cultures should be made.

In examining a healthy person for the presence of the bacilli, cultures should be made from both throat and nose, as the bacilli may be present in the nose, while a culture from the throat is negative.

The giving of immunizing doses of antitoxin to all the well members of a household does not take away the need of making cultures. On the contrary, it is more important to make them under those circumstances. Antitoxin prevents the development of symptoms, but it does not prevent the bacilli multiplying in the throat. Already at the time the antitoxin is given the throat may be infected. The immunity conferred to persons otherwise susceptible prevents the development of symptoms which would lead one to regard these persons as infections. I believe that it often happens that immunized individuals with abundant bacilli in their throats are allowed their freedom, when if no antitoxin had been given, symptoms would have appeared which would have led to their prompt isolation. To a certain extent, therefore, the giving of immunizing doses of antitoxin when not controlled by cultures may favor the spread of diphtheria.

The making of cultures from healthy individuals who have been exposed is especially important when these individuals, by their occupation or habits, are likely to spread the disease; such are school children, persons who handle articles of food, milkmen, servants and nurses.

Nurses who have been taking care of diphtheria patients not infrequently have bacilli in their throats, although not developing the disease themselves. Rit-

ter,⁸ in cultures from 18 nurses who had been caring for diphtheria patients, found Klebs-Löffler bacilli in 2. Washburn and Hopwood⁹ found 2 nurses with the bacilli among 6 from whom they made cultures. The danger from a careful trained nurse is not so much that the bacilli from the case she has been nursing are clinging to her person or clothing, but that the bacilli may be multiplying in her throat, where they may persist for weeks. It is customary to allow a nurse seven days for quarantine before taking another case. Personally, I should prefer to have a nurse two days after leaving a diphtheria case, from whose throat a negative culture had been obtained, than one after two weeks without any bacteriological examination.

Another reason for making cultures from healthy individuals is to determine the source of infection of diphtheria. When a number of cases appear simultaneously among individuals associated together—for instance, in a family or in a schoolroom—and the connection with another case of diphtheria cannot be made out, one should always suspect that there is some individual with whom these cases have been in contact who is carrying the bacilli in his throat. Cultures should be at once made from those persons by whom the patients might have been infected. Often suspicion will point to a single individual as the one most likely to have the bacilli, or, again, it may be necessary to make cultures from a large number of individuals to find the source of infection.

Cultures from 285 healthy individuals were sent to the Brookline Board of Health Laboratory during the past year. The cultures from only 7 showed the presence of diphtheria bacilli. For the information about these cultures I have been dependent largely upon the cards which were filled out and sent in by the physicians who made the cultures. I am also indebted to many of the physicians for information about the cases which has been given orally. With only these data it has been impossible to determine how many of the cases have been exposed, or to measure in any way the degree of exposure. It appears, however, that in a few of the cases only has the exposure been very great; in many it was very slight, and in the larger number only suspected.

These figures, therefore, are of no value as representing the frequency of the bacilli in those who have been exposed to diphtheria. They do show how seldom the bacilli are found where there is not great exposure in persons living in a suburban community under good hygienic conditions. If we exclude the cultures from 50 persons which were made in connection with two outbreaks of diphtheria, where the exposure had been considerable, and among whom 6 positive cases were found, we have cultures from 235 healthy individuals with only 1 positive case (about .43%).

Of these 235 healthy persons, 216 were children, 19 were adults. A large part of them were of the well-to-do class. Most of those of the poorer class from whom cultures were made were living in two and three family tenement houses with air on at least three sides, where the conditions are very much better than they are in any large city. The low percentage of positive cases is to be explained

by the good hygienic surroundings under which the persons were living.

Of the 7 positive cases, 4 were among 38 adults from whom cultures were made by Dr. Chase in connection with an outbreak of diphtheria believed to be due to infected milk. These cases have been reported by Dr. Chase,¹⁰ but as they illustrate very well how infection may be spread by healthy individuals, I shall refer to them briefly.

In October, 1899, 2 children in a milkman's family were taken sick with diphtheria and were sent to the hospital. Realizing that others in the same house who were handling the milk might have diphtheria bacilli in their throats, and that the milk might so be infected, Dr. Chase made cultures from all the well members of the milkman's household. All were negative at that time. About three weeks later a number of cases of diphtheria began to appear among the milkman's customers. Cultures were again made from the well members of the household, and 3 healthy men were found to have the bacilli. Two of these men did the milking. The bacilli in their throats were very abundant, and were shown to be virulent by the inoculation of guinea pigs. In 4 families among the milkman's 8 Brookline customers, there were 12 cases of diphtheria; at least 6 cases occurred among his customers outside of Brookline. Dr. Chase has shown very clearly that these 18 persons were infected through the milk by the bacilli from the 2 healthy milkers. A fourth healthy man with the bacilli in his throat was found by Dr. Chase among 31 adults who were known to have been exposed by drinking the infected milk.

The 3 other positive cases were discovered among 174 healthy children in the public schools, from whom cultures were made by the school inspectors. During the recent epidemic, culture outfits have been kept at all the schools. When a school child has been taken sick with diphtheria the inspectors have made cultures from those children who have been sitting nearest the child. When more than 1 case has occurred in a room cultures have been made from all the children in that room. The cultures have been made under such circumstances with the double object of determining, if possible, the source of infection of the diphtheria cases, as well as to see if there might not be some who had the bacilli in their throats as the result of exposure.

Two of the 7 cases were found in a room in one of the primary schools in which there was a small outbreak. On September 24, 1899, 3 children who had adjoining seats in the room were taken sick with diphtheria. The fact that the 3 became ill simultaneously made it seem probable that they had all been infected from some other child in the room. Accordingly, cultures were made from all the children, and it was found that 2 children sitting in seats adjoining the 3 sick children had positive cultures. Both were perfectly healthy. In 1 there was a doubtful history of a slight nasal discharge. It seemed probable that this child had infected the other 4 children sitting near it. The seventh positive case was a school child in whose throat the bacilli were by chance discovered, although as far as known there had been no connection with any case of diphtheria.

The virulence of 2 of the 7 cases was tested with positive results. Four of the cases were in such close

relation with cases of diphtheria that at the time it did not seem necessary to test the virulence, although for the sake of the record it is much to be regretted that it was not done in all. In the seventh case the bacilli were so few that I did not succeed in isolating them in pure culture. In all of the 7 cases the bacilli were found to be present on more than one day.

The remainder of the cultures which I have to report were from 190 healthy boys in the Parental School in West Roxbury. It is a municipal school for truants. The age of the boys is ten to fourteen years. During the week beginning March 5, 1900, 10 of the 200 boys in the school were taken sick with sore throat, and cultures showed the presence of Klebs-Löffler bacilli. Four of the boys only had membrane. On March 10th and 11th cultures were made for me by Dr. Sleeper, the house physician, from the throats and noses of the 190 healthy boys. The cultures were examined by Dr. Hill at the Boston Board of Health Laboratory. Sixteen of the 190 cultures were positive. The occurrence of this number of positive cases in such an institution is a common experience. These cases are of interest, however, on account of their distribution in the school and the unusual opportunity which was given to determine what are the conditions of institution life which favor the occurrence of diphtheria bacilli in healthy throats.

The 200 boys live in three large new buildings. The cases of diphtheria were quite evenly divided in the three, but of the 16 healthy boys with the bacilli, 15 were living in one of the buildings. Investigations were therefore made to determine what were the conditions under which the boys in this building were living which were not present in the other two.

The boys in the different buildings are of the same age and of the same social class. They are together in the same day school. They do the same sort of work, and lead the same regular life. They have the same food, but have their meals in their own buildings. The only difference appeared to be in the building in which they lived.

Two of the buildings accommodate only 40 boys each. The hygienic conditions in these two buildings are exceptionally good. Each boy has his own separate sleeping room, measuring 10 x 6½ x 9 feet. A window, and an open door leading into a large, airy corridor, give excellent ventilation. The living rooms for day use are large, well ventilated and sunny. Hygienically these two buildings would compare very favorably with the dormitories of most of our large private boarding schools. Among the 80 boys in these two buildings there were 5 cases of diphtheria, or one-half of all the cases that occurred. But among the 75 healthy boys there was only 1 who had bacilli.

Most of the remaining 120 boys live in the third building, which is larger than either of the other two. Here, instead of single rooms, there are large open dormitories in which the boys sleep. Thirty-five boys slept in each of two rooms measuring 40 x 30 x 12½ feet. There were 18 boys in a room proportionately smaller. The remaining 32 boys were scattered about in smaller rooms in the school. The large rooms were high studded and well ventilated. The cubic air space per boy was only one-fifth less than in the buildings with the single rooms, and much larger than the boys would have in their own homes. The living

rooms in the third building were considerably smaller than those in the other two, in proportion to the number of boys. All the buildings are kept exceedingly clean. The plumbing in all is new and in good condition. The boys in the third building appeared to be in as good physical condition as those in the other two.

Among these 120 boys there were 5 cases of diphtheria—2 with membrane and 3 with simple sore throat. Fifteen of the 115 well boys had positive cultures. The virulence of three of these cultures was tested. Two of them were virulent and the third appeared to be non-virulent.

The only difference which could be discovered in the conditions under which the boys were living which would explain the occurrence of the larger number of positive cases is that in the first two buildings the boys have separate sleeping rooms, while in the third building a large number of boys are sleeping together in the same room. The living together of a large number of individuals breathing the same air seems to be the condition of institution life which predisposes to the occurrence of these cases.

It might be supposed that the larger number of positive cultures in the third building could be explained by the greater exposure which must occur where persons are living together in such close contact. If that were so, however, one would expect that there would have been a greater number of diphtheria cases in that building, while in reality there were proportionately fewer.

Evidently the boys in all three buildings had been exposed. One is therefore led to conclude that the bacilli becoming lodged in the mucous membranes of the boys living in the single rooms found the conditions favorable for their growth only in those who were susceptible. In those who had a natural immunity—in other words, in those whose blood possessed antitoxic properties—the conditions were not favorable and the bacilli did not multiply. On the other hand, in the third building, where large numbers of the boys were sleeping together, the bacilli found the conditions favorable for their growth in many of those who were naturally immune. Whether the more favorable conditions for the growth of the bacilli were the result of local changes in the boys' throats, I was unable to determine. On inspection no difference could be noted between the appearance of the boys' throats in the different buildings, or in their general physical condition. Enlarged tonsils were exceedingly common throughout the school, but not more so in one building than in the others.

There is not time now to consider the question of what action boards of health should take in regard to these cases. I can only say that it has been the policy of the Brookline Board to isolate all of those in whose throats virulent bacilli are found. It is believed that no other course can be consistently followed. The local condition of the patient's throat or his constitutional symptoms are of no significance to boards of health. The only criterion of the disease from the point of view of the public health is the presence of the bacilli.

To briefly sum up the principal points which should be emphasized:

(1) Diphtheria bacilli are seldom found in the throats of those who have not been exposed to diphtheria.

(2) The bacilli are more frequently found in those who have been exposed, especially in persons living under poor hygienic conditions or in institutions.

(3) The conditions of institution life which favor the growth of the bacilli in healthy throats are the living together of a large number of persons in a limited air space.

(4) Healthy individuals with virulent bacilli in their throats can spread the disease. They are just as dangerous as mild or convalescent cases of diphtheria, and ought, therefore, to be detected and isolated.

(5) Cultures ought to be made among those who have been exposed to diphtheria: (a) By physicians among the members of a family who have been exposed; (b) by inspectors in the schools; (c) by health officers under any circumstances when they think the disease is being or may be spread by such individuals.

In concluding I wish to express my thanks to Dr. G. S. C. Badger for his help in examining the Brookline cultures, to Dr. Hill for his reports of the cultures from the Parental School, and to Dr. Sleeper, the house physician at the school.

CHRONIC DIFFUSE INTERSTITIAL NEPHRITIS.¹

BY CHARLES J. ENEBUSKE, M.D., BOSTON.

MY reason for addressing you upon this subject is that for a number of years I have had under treatment many patients who have complained of fatigue, diminished working capacity and nervousness, and who have sought my help particularly because they have thought that massage and movements should do them good. In several of these cases I have observed a trace of albumin, small hyaline casts, high-tension pulse and accentuated aortic second sound.

Two of these cases have later developed as typical cases of chronic diffuse interstitial nephritis, and died in uremic symptoms. Some of the cases, after improving during treatment, have passed from my observation. One has recovered functionally and one has recovered entirely. The last one, a single woman of thirty, nursed her mother, who was in the last stages of chronic diffuse interstitial nephritis. During the last weeks of her mother's life, the daughter complained of increasing weakness, and thought that she should give out. On examination I found her anemic, with high-tension pulse, loud accentuation of aortic second, and cardiac dullness extending from right border of sternum to mammillary line. I advised her to take rest, which she could not get; I regulated her diet as in a case of chronic Bright's disease, and prescribed tincture of chloride of iron, which she took

¹ Read before the Clinical Section of the Suffolk District Medical Society, October 17, 1900.

without relief. After her mother's death and after some weeks of rest, I examined her again. She felt strong as usual and there was nothing abnormal about her pulse or heart sounds, and the urine was negative. One year later she was well and strong.

The cases referred to serve to illustrate the uncertainty of diagnosing this disease from signs found at one examination alone, and I wish in addition to bring out some therapeutic points.

The multitude of synonymous denominations of this disease testifies to the variety of attempts that have been made to classify and interpret the renal diseases. Some of these names are derived from etiological considerations, others from clinical manifestations, still others from the gross appearance of the organ, or from the microscopic changes found at the examination of the organ "post mortem." Such names are cirrhosis of the kidney, gouty kidney, contracted kidney, granular kidney, small red kidney, granular atrophy of the kidney, chronic desquamative nephritis, renal sclerosis. Only two varieties of the disease are generally recognized, namely, the genuine inflammatory cirrhotic kidney and the degenerative cirrhotic kidney, of which the former is an independent primary disease, the latter a sequel to arteriosclerosis. It may be added that certain authorities admit and others deny a third variety of the disease, namely, those cases which start as smooth cirrhotic kidney, and in their further development contract into the kidney of chronic diffuse interstitial nephritis. Both forms are characterized clinically by insidious onset and slow development, and anatomically they are marked by atrophy of the parenchyma of the organ, secondary to the formation of new connective tissue, ending with a more or less complete destruction of all the anatomical elements of the organ.

Pathological anatomy; gross appearance. — The kidney is small; the weight is sometimes only one ounce each. The capsule is thickened, adherent, the surface irregular, "granular," puckered. The organ is either red, hyperemic (more developed form) or anemic, pale, gray. There are small cysts, containing clear, transparent liquid. The cortex is thin. The pyramids are shorter, redder than normal, the pelvis is wider. The small arteries stand out prominently. In cases associated with gout there are seen deposits of urates of soda as white lines through the medullary portion. The granular elevations correspond to the portions of the cortex which remain healthy; the sunken portions represent the atrophied parts, replaced by connective tissue. The gross appearance is the same in the two varieties of the disease.

Microscopical changes. — Connective tissue is widely distributed, especially in the cortex between the medullary rays and about the veins, less between the pyramids. It begins as a round-cell infiltration in the intertubular tissue and about the tufts. This becomes fibrillated, contracts, and gradually destroys both tubes and tufts. The Bowman's capsules are thickened and compressed by the surrounding new connective tissue. The vasa afferentia are narrowed, the glomeruli atrophy, the capillary epithelium is loosened, that covering the tufts is desquamated, the tufts undergo hyaline degeneration and do not transmit fluid; there is only slight change in the capsular epithelium. In areas free from connective tissue some tufts appear normal, but their cells are increased and the Bowman's cap-

sules are thickened. The changed tufts excrete albuminous urine, which packs together the desquamated epithelium, carrying the granular debris with it.

The tubal cells in the connective-tissue areas are atrophied or replaced by cuboidal cells. Some tubes are denuded, others have cells with granular or fatty change. Many tubes are greatly dilated by being plugged with granular debris in the portions which are constricted by connective tissue. The degeneration of renal epithelium is much less widespread than in the parenchymatous nephritis. There are large areas of normal tubes even in advanced disease, which accounts for the slowness in the development of the disease. Many tubes are collapsed and obliterated by connective tissue. Many contain casts and granular debris, but fewer than in the parenchymatous form.

There is an advanced sclerosis of the vessels. The adventitia is thickened; the intima with inflammatory growth (endarteritis obliterans). The media is thickened by increase of connective tissue, while the muscular fibres are atrophied. The capillaries are obstructed and finally obliterated.

Heart. — The heart is hypertrophied in a marked degree, and sometimes with considerable secondary dilatation. There are atheromatous and calcareous changes along the aorta.

There is a difference between the degenerative cirrhotic and the genuine inflammatory form. The former shows characteristic changes in the small and medium sized arteries of the kidney, and thereby the circulation through the kidneys is impeded. This leads to degeneration of the renal epithelium by insufficient nutrition. It atrophies and new connective tissue develops in its place. Consequently the arterial changes are primary.

In the genuine inflammatory kidney, on the other hand, the primary changes are in the glomeruli.

From both forms the secondary cirrhotic kidney is distinguished by larger size, only moderate adherence of the capsule, the coarseness of the granulations (that is, the surface slightly uneven), and the reddish color mottled with gray patches.

Etiology. — It occurs most frequently in the latter half of life, more frequently in males than in females, but the earlier period of life is not exempt. It is rare in childhood; a few congenital cases are reported. The following are generally recognized causes: Chronic gout; the fibroid diathesis; alcohol in excess, particularly the stronger kinds; excessive eating; too little or too severe exercises; worry and strain, physical as well as mental; chronic lead poisoning; articular rheumatism, acute and chronic; chronic endocarditis; syphilis; urethral stricture; pyelitis; senility. The toxins of the staphylococcus pyogenes and probably the toxic products of numerous pathogenic bacteria may also be causes, according to recent observations. Acute gout is not recognized as a cause, although the chronic is in marked degree.

Symptoms. — The patients complain of general muscular weakness, lassitude, impaired power of application, irritability of temper, fretfulness, deceptive memory, sleeplessness, impairment of the sexual sphere, occipital headache, and sense of pressure in the head, pain in the back of the neck.

Urine. — There is increased amount of urine; the patient has to leave the bed during the night to pass water. The amount of nightly urine generally ex-

ceeds that passed in the daytime. The twenty-four hours' amount may reach 3,000-6,000 cubic centimetres. It is clear, with little or no sediment. Specific gravity 1.006-1.012; acid; albumin is generally present in small quantities (about $\frac{1}{10}$ %). Sometimes albumin is absent for a few days or part of a day. Urea is at first normal, later diminished. There are a few casts, usually small hyaline. A few lymph cells are generally found, but no blood corpuscles unless an acute attack supervenes.

The cardiac dulness is increased both to the left and to the right. There is increased arterial tension, with firm pulse, forcible apex beat and the aortic second sound accentuated, with a ringing quality, even years before the hypertrophy is demonstrable. Later the apex beat is displaced to the left and is of increased force.

So long as the hypertrophy maintains arterial tension and regulates the urinary secretion, the condition is good, but when the heart muscle degenerates, dilatation and cardiac insufficiency set in. Then the pulse loses its tension, becomes smaller, more frequent and irregular. In this condition the patient is much influenced by slight physical exercises, and dyspnea and palpitation are easily produced. At this stage mild bronchitis, congestion of the lower lobes or spots of lobular pneumonia may appear. Edema may appear first at the ankles, later more generally, but is usually slight. Many theories are advanced to explain the development of the hypertrophy of the heart and they are significant not alone from a pathological point of view, but also with reference to the practical therapeutics of the disease. The weight of opinions is on the side of Cohnheim's theory that the increased local resistance in the kidney causes the hypertrophy. In general appearance the patient presents a pale, yellowish face, the expression is weary and listless, the eyelids are slightly swollen, the temporal arteries are tortuous, the skin dry, with little tendency to perspiration, and if the skin is scratched, the stripes remain.

There may be a variety of gastric symptoms: Anorexia, nausea, vomiting, diarrhea.

The eyes may be affected, exhibiting yellowish-white spots, small inflammatory exudates and minute hemorrhages. A variety of cerebral symptoms may occur.

(1) *Motor disturbances.* — Convulsions, tremors, localized contractions.

(2) *Psychical disturbances.* — Delirium, hallucinations, vertigo, coma, melancholia.

(3) *Sensory disturbances.* — Deafness, blindness, hemiopia.

(4) *Respiratory.* — Dyspnea, Cheyne-Stokes respiration, laryngeal spasm.

(5) *Thermic.* — Hypothermia or hyperthermia.

Even when cirrhotic kidney is fully developed, the symptoms may remain mild for many years. The danger is always present that some accidental complication or gradual exhaustion may precipitate uremic symptoms. The involvement of the normal portion of the kidney in an acute nephritis from overwork, exposure, or various influences, is very dangerous. The various ways in which the symptoms combine in the individual cases have led to the recognition of certain more or less defined clinical groups.

(1) *Cardiac.* — The sufferers are generally gouty persons. The cardiac changes appear early and at the autopsy renal sclerosis is revealed (a large proportion of all cases of renal sclerosis).

(2) *Cerebral.* — These are characterized by intense headaches, vertigo, numbness, formication, temporary paresis of a single limb.

(3) *Gastro-intestinal.* — Persistent nausea, vomiting and profuse diarrhea are the leading symptoms in these cases.

(4) *Progressive weakness.* — The leading symptom of the cases under this group is gradually increasing weakness and exhaustion. They are often regarded as cases of neurasthenia, anemia, or senility, and are not recognized as renal sclerosis until later in their development.

The complications of this malady may be numerous, as the following enumeration shows: Scrofulinous pleurisy, inflammation of the serous membranes generally, chronic bronchitis, catarrhal pneumonia, lobar pneumonia, neuroretinitis, or retinal hemorrhage, hemorrhage from the mucous and serous surfaces and in the substance of the organs, and edema glottidis.

Diagnosis. — Not many years ago, if the examination of a patient had revealed a pulse of high tension, an increased area of cardiac dulness, the second aortic sound accentuated, with a ringing quality, the urine of low specific gravity and large amount, with a trace of albumin and some few hyaline or fine granular casts, it would have been justifiable to make the diagnosis of chronic interstitial nephritis.

Reliable observations of a more recent date have made necessary the exercise of more reserve in drawing conclusions from the signs mentioned. It is recognized that a slight amount of albumin and an occasional cast may occur without a renal lesion being demonstrable after continuous observation of the case. On the other hand, the early stage of interstitial nephritis is not always associated with the appearance of albumin and casts. The high-tension pulse and the accentuated aortic second sound have been found to exist apparently as a mere function of years from the early middle age in a number of instances without any demonstrable renal lesion. The dislocated apex beat and increased cardiac dulness area may be an expression of idiopathic hypertrophy of the heart without renal disease.

The diagnosis of this malady cannot be made with certainty from any formula of symptoms and signs. It requires repeated examinations during a sufficient length of time to establish the persistency of the signs mentioned, often with intervening periods of absence of albumin and apparent health, and these facts must be balanced in view of the etiology and the history of insidious onset and slow, progressive development.

If the patient is examined for the first time when symptoms of disturbed compensation are developed, the diagnosis is difficult because the urine is not then characteristic of contracted kidney, but is scanty, darker, richer in albumin, and the condition can scarcely be differentiated from primary heart lesion with secondary congested kidney, particularly if arteriosclerosis exist at the same time. If the first examination is made during sudden uremia or after apoplectic seizure, the condition is with difficulty differentiated from other acute cerebral affections.

Chronic diffuse interstitial nephritis with acute exacerbation is differentiated from acute nephritis by a consideration of the history of the case, especially the first day of onset. In the chronic form the general appearance suggests longer illness. In the acute nephritis the urine is of higher specific gravity and

usually contains blood. In the chronic form there is evidence of hypertrophy of the heart, high arterial tension and retinitis albuminurica.

Chronic interstitial nephritis is differentiated from secondary cirrhotic kidney by a consideration of the etiology, and the fact that the cardiac hypertrophy and the vascular changes are less marked in the secondary cirrhotic kidney. The urine is smaller in amount, of darker color, of higher specific gravity, with more albumin and more cell elements.

Prognosis.—It is generally admitted that the fibrous tissue, once developed, extends until by its contraction the organ is destroyed. In the early stages of the disease, and under good regimen, the patient may live for many years without any apparent disturbance. When the heart fails, weakness, dyspnea and dropsy will appear, amenable to treatment at first, but increasing later in spite of the best care. Severe edema appearing late in the disease indicates a failing heart, and is a serious symptom. Uremic intoxication is a constant danger. It appears late in the disease and is fatal in many cases. Even with severe symptoms (Cheyne-Stokes respiration, persistent vomiting and edema) the patient may live for months.

Drs. Richard C. Cabot and Franklin W. White have found from the Massachusetts General Hospital records that out of 304 cases 17 have completely recovered, and that the average duration of 332 cases was nineteen months. Cases of eight to ten years' duration are not unusual, and cases are recorded of over fourteen years' and up to twenty to twenty-nine years' duration.

Treatment.—The two leading indications are to avoid irritation of the kidney and to avoid overwork of the heart so as to keep off cardiac insufficiency as long as possible. To this end the diet must be adapted to the condition of the individual case. Overeating, like other overexertion, must be precluded. Generally both starches and nitrogenous foods must be restricted and fats given generously, but there is some ground for the theory that an unusually rich nitrogenous diet is required to protect the organism from the loss of nitrogen, when much albumin is excreted, and that such increase in the nitrogenous food does not influence the amount of albumin that escapes through the kidneys. The skin must be kept active by tepid baths and the bowels regulated.

Physical overwork and mental worry should be excluded as far as possible, but moderate exercise and outdoor recreation and rest encouraged. According to most observers, a dry, equable climate is preferable, but actual test must decide in the individual case in which climate the patient "eats well, sleeps well, and feels well" (Delafield).

It is not proven that medication has any influence over the development of connective tissue and the contraction of the kidney, but mercury, iodide of potassium and in anemic cases iodide of iron may be tried.

There is great diversity in the observations as to the effect of iron preparations in this disease. Special symptoms must be treated as they arise. Iodide of potassium, nitroglycerin and chloral hydrate are important for their effect in reducing too high arterial tension and dilating the arteries.

If spasmodic dyspnea arises, the indication is to dilate the arteries and to stimulate the heart. If

disturbance of compensation appears, the indications for the treatment are the same as in chronic heart disease. Headache, vomiting, hemiplegia, convulsion, coma, require such means as diuresis, sweating, purging and blood letting. Massage, resisted movements and passive movements in some form or another are indicated in the various phases of this malady.

In the early stages before special symptoms have developed, but the patient is distressed by sense of fatigue and impaired strength and working capacity, much can be done to relieve the condition and increase the strength by massage and movement, in conjunction with proper regimen in other respects. By a systematic course of gymnastics may be ascertained the proper limits of exertion in the individual case and those limits widened in some measure. It is important that the patient should be made convinced of the fact that such forms of exertion as running and jumping are entirely out of the question, and that the ordinary rate of steps in walking must be reduced from, say, 100 or 120 in a minute to perhaps 50 or 60; that straining on defecation is dangerous; that walking uphill or upstairs is safe only if proper limits are observed, and that the determination of these limits cannot be safely trusted to subjective sensations alone.

Certain experiences from the administration of gymnastics to cardiac cases are worthy of consideration in this connection. It is generally found that simple exercises are less exciting to a delicate heart than exercises that are complex and difficult to learn, even though the latter be not violent or vigorous. Generally exercises which involve action chiefly from the muscles of the lower extremities are more easily borne at a time when the condition precludes a corresponding amount of exertion involving the muscles of the upper arm which have one attachment to the thorax. Gymnastic movements which shift localization from one group of muscles to another in a progressive succession are most beneficial.

Later on, when the compensation is weak, when occasional attacks of dyspnea and precordial oppression appear, or even when the compensation is failing, so long as there is recuperative power behind, much can be done by movement and massage to re-establish compensation and postpone the symptoms.

The leading indication in the early stage is to dilate the arteries and reduce the tension when it is too high. Later, when the compensation is failing, the indications are: (1) To increase the systolic stroke of the heart; (2) to relieve the venous hyperemia of the abdominal organs and the lungs, when such exists, and (3) to relieve the edema.

Experience gathered from the administration of exercises in Swedish medical gymnasia and in the Nauheim and Oertel Institutions has taught methods to meet these indications in recuperative cases. Contra-indications to these methods are advanced arteriosclerosis, aneurism and grave aortic lesions. The details of the methods are scarcely capable of simple description and satisfactory formulation. In general it may be said that:

(1) Dilatation of the small arteries and reduction of too high arterial tension can be obtained in many instances by kneading and stroking of the muscles of the extremities with slow strokes and gentle but rather deep pressure.

(2) Increase of the strength of the systolic stroke

is obtained in many instances by simple movement of the joints of the extremities with gentle resistance, provided that the exertion is limited to that which the recuperative force of the heart can respond to.

(3) Edema is relieved by centripetal strokings with gradually increasing pressure.

(4) The resistive movement must be given while the patient is in a restful horizontal attitude or half reclining.

(5) Passive movement must be attempted with caution in persons who have not good muscular control, because otherwise the effort of the patient to inhibit co-operative or resistive action either fails, or is so great an exertion in itself that the effect of a vigorous active movement is obtained instead of the passive one which is attempted.

A NEW SPINAL JACKET.

BY EDWARD A. TRACY, M.D., BOSTON.

THE jacket herein described is termed new, inasmuch as its technique is for the first time presented to the profession ; but it has been, however, employed in the orthopedic practice of the writer during the past five years. The writer can, therefore, present it to the profession as an instrument of tried efficiency that merits employment in suitable spinal cases.

The distinguishing features of this spinal jacket are its lightness, cleanliness, rigidity, and durability. It is much lighter than either a plaster-of-Paris or a leather jacket. It is more cleanly than either, because it is freely ventilated and permits of thorough washing. Its rigidity is that of board when required, and yet it has resiliency. Its durability is demonstrated by the fact that the writer has had patients wearing jackets for two years with their efficiency unimpaired.

The basic material of this spinal jacket is wood-plastic splint material, described by the writer in a paper entitled "A Brief Splint Technology for Surgeons," contributed to the first Pan-American Medical Congress, at Washington, 1893. This material serves admirably in the splinting of injured joints and broken bones ;¹ for such uses the manipulation of it is so simple as to require no special instructions to one possessing a modicum of mechanical ability ; but when used in the construction of a spinal jacket the technique is of necessity more complicated and requires more careful description and study.

¹ See paper entitled, A Safe and Quick Method of Joint and Bone Fixation, in the Boston Medical and Surgical Journal of August 31, 1899.

There are two ways of moulding the jacket ; one, directly upon the body of the patient, the other, upon a plaster-of-Paris cast. The former method is practicable in those cases where the body curves are not too various and compound. The latter method, moulding the jacket on a plaster cast of the patient's trunk, is advised. The making of the cast is not difficult. Apply roller plaster-of-Paris bandages over a tightly fitting undershirt until a plaster jacket encircles the patient's body. After allowing this to harden for twenty minutes it should be cut carefully down the middle of the front, sprung apart, and removed. It is then to be placed upon the floor, and carefully brought together again so that it has the shape it had while on the patient. A string can be applied so as to cause it to maintain this shape. The inside of this plaster jacket should be well greased with lard ; this prevents the plaster of Paris when poured into it from adhering to the plaster jacket. Plaster of Paris mixed with water to the consistency of molasses is poured into the jacket and forms the cast. In making the cast it is found useful to place a piece of timber $2\frac{1}{2}' \times 3'' \times 4''$ as an upright in the jacket, and to pour the plaster of Paris around it. This timber upright serves as a support for the cast when using it to mould upon it the jacket. The piece of timber used should be moist, otherwise it will absorb moisture from the cast, swell, and split the cast, — not, however, a serious mishap.

The cast having been completed, the jacket should be moulded upon it in the manner described below. The jacket is made principally from four pieces of wood-plastic material, the back piece, the front piece and two side pieces. The back piece extends from the upper border of the cast to the lower border and overlaps the sides of the cast. In the back piece are two incisions on each side directed towards the middle line — these incisions allowing the material to mould over the various curves in the cast. Each side piece extends from the upper to the lower border of the cast and from a point an inch and a half away from the anterior superior spine of the ilium (towards the middle line of the front of the body) to near the middle line of the back ; the side pieces thus overlap the back piece. Two incisions are likewise made in each side piece, in a direction from the back towards the anterior border of each piece. These permit of the perfect moulding of the material upon the cast.

The back piece and the side pieces having been cut and moistened are bandaged in their correct relative positions over the cast and allowed to dry thereon. After drying, they are carefully removed and a layer of glue having been placed between the side pieces and the back piece where they overlap, they are re-applied to the cast, and bandaged upon it till the glue dries. The back piece and the two side pieces glued together form what may be termed the foundation of the jacket. It is now a well-fitting brace or back splint. This brace is covered carefully with cotton cloth, which is glued upon it, inside and outside. Holes are carefully punched into the jacket about two inches apart, and so placed as not to weaken it. These holes are three-eighths of an inch in diameter and permit of excellent ventilation. The jacket can be on the cast when the holes are being punched. The brace is now to be coated with a material that is impervious to moisture. The writer has used two such materials ; one, a solution of gutta percha in car-

bon bisulphide; the other, a solution of celluloid in acetone. The latter is preferable.

The brace portion of the jacket having been finished, the front portion should be moulded upon the cast, so as to overlap the sides about an inch. The front piece is moulded over the cast, after incising the upper half of it in the median line; this permits an overlapping of the upper portion, and causes the upper part to press on the upper chest with any chosen degree of pressure. This pressure appears to the writer to be an important advantage in maintaining a correct position of the spine. The front piece should then be treated in a similar manner to the brace portion, to provide for its ventilation and protection from moisture. It should then be attached by a leather hinge to one side of the brace; strips of leather with eyelets for lacings should be attached to the other side of the front piece and of the brace portion, thus completing the spinal jacket.

SOME OBSERVATIONS ON RENAL CASTS.

BY WALTER E. TOBIE, M.D., PORTLAND, ME.

In making a systematic microscopic examination of urine, one cannot fail to be impressed with the frequent existence of casts, and that, too, in many instances, without a co-existing albuminuria. So closely has the presence of casts become associated with albuminuria that it is far from the universal practice to submit the urine to a microscopic examination unless albumin has been found; and it is only since the centrifuge has come into more general use that the significance of each has begun to be better understood. The advantage of securing the sediment from a freshly voided urine unaffected by fermentative changes is too apparent to require defence. It is noticeable that by so doing hyaline casts are found in many instances where neither clinical history nor chemical examination would seem to point to their presence. The custom of obtaining urinary sediments by allowing the urine to stand for twelve to twenty-four hours in a conical glass has given fair results; but the urine necessarily undergoes bacterial and chemical changes, and it seems not unreasonable to believe that structures so delicate as hyaline casts may by these changes become disintegrated or so altered as to be difficult or impossible of detection. Certainly there is no good reason for believing kidney disease to be increasing to the alarming extent that microscopic examination of urine might imply. The increase is apparent and depends upon better and more systematic urinary examination.

The three theories of cast formation are that they result from the disintegration of renal cells, from a morbid secretion of these cells, or from a leakage of serum albumin into the tubules. All of these theories imply some structural kidney change, temporary or permanent, and we might then expect to find with casts always a greater or less amount of albumin. This, I am convinced, is not the case, notwithstanding the view of many, who contend that casts are never found in urine unless it contains albumin or has recently contained it. Testing for minute traces of albumin is difficult, uncertain and unsatisfactory, as is evidenced by the great number of test solutions and methods of testing, and the opinion is quite general

that an amount of albumin too small to be detected by the boiling or nitric acid contact test is too small to have any clinical importance. Taurer's potassiummercuric iodide test is capable of detecting the most minute trace of albumin. It is oversensitive and valuable, therefore, as a negative test to prove not the presence of albumin, but its absence. Such a non-albuminous urine may contain casts, and, I believe, this condition is much more common than it is possible to ascertain, because urinary examinations are made, as a rule, in general practice only when there are indications pointing to disease of the urinary organs or passages.

From the analysis that I have made in the laboratory of Dr. Alfred King, I have taken two hundred in regular order, without any attempt at selection as regards season of the year, age of the patients, or their diseases. The results as regards albumin and casts are as follows:

Urine containing neither albumin nor casts	109
" " albumin without casts	29
" " " with casts	35
" " casts without albumin	27

It will be seen that the cases of albumin with casts were rather more frequent than either alone. In making these tests, every effort was made to detect minute traces of albumin. Had this not been done, the proportion of cases where casts occurred without albumin would have been very materially increased. The cases of albumin without casts were almost invariably due to blood or pus from the genito-urinary passages.

I have mentioned three influences which might affect a series of urinary examinations as regards casts, the first being the season. This has a bearing only to the extent that diseases affecting the kidneys are more common at certain seasons, notably, the winter and early spring. Age is a decidedly important factor. Although it has long been taught that the kidneys in old age undergo a change comparable to that of cirrhotic kidney, it is not generally appreciated how common this condition is, nor how early in life the change may begin. Repeated examinations of urine from patients between fifty and sixty, certainly far from senile, show the presence of hyaline casts in many instances. Inasmuch as they may be present for many years without symptoms pointing to their existence, these questions naturally suggest themselves. Is the mere presence of hyaline casts necessarily a grave omen? May not the disease be checked or even of itself cease to advance? May they not be present in urine from kidneys whose excreting functions are practically normal?

The occurrence of casts with chronic constitutional diseases is extremely common, but the influences determining their formation are not altogether apparent. Thus in the constitutional disturbance accompanying carcinoma I found, while a house doctor at the Maine General Hospital, that hyaline casts were very common and that the urine was almost invariably free from albumin. This observation became so strikingly frequent that I was led to believe that some relation existed between the carcinoma and the production of casts, and that it resulted from some impairment of nutrition or from poisonous products occurring in the cancer formation. It was noticed, also, that in many of these cases the administration of ether caused no noticeable disturbance of the kidney functions.

Considering the importance attached to kidney disease by life insurance companies, the means employed by their examiners for detecting the same are surprisingly lax, since a microscopic examination is not part of the routine. While I should question very much the advisability of making the presence of casts a standard for refusal, it certainly should constitute a reason for a more searching examination regarding the eliminating functions of the kidneys. I believe that insurance companies will yet issue endowment policies knowingly to applicants whose urine contains casts, even as they have done so for many years unknowingly.

Medical Progress.

PROGRESS IN PATHOLOGY.

BY JAMES H. WRIGHT, M.D., BOSTON,
Director of the Clinico-Pathological Laboratory of the Massachusetts General Hospital.

GUNSHOT WOUNDS AND TETANUS.

THE great frequency of tetanus, following wounds from blank cartridges, is well known. H. Gideon Wells¹ has made a study of the blank cartridges on the market with the object of determining whether tetanus spores were present in them or not. Upon inquiry he found that the blank cartridges on the market were manufactured by five different firms in this country and in Canada, and samples of each of these were obtained for examination. In all about 200 cartridges were examined, but in none of them were tetanus bacilli found.

The method of examination was as follows: (1) The wads, powder and shells were first heated to 85° C. for forty-five minutes and then cultures on glucose agar and other media were made. Cultures were also made without the preliminary heating. (2) A series of animal inoculations of guinea pigs and mice were made, in various series, with wads and powder and with agar and bouillon cultures, both with and without heating. Ultimately for the examination of a large number of cartridges the following plan was adopted. Wads from ten cartridges were broken up into fine pieces and placed in bouillon sufficient to cover them; the fluid was then heated to from 80° to 85° C. for forty-five minutes and grown for one week under anaërobic conditions. The cultures were then inoculated into mice and guinea pigs, and also examined microscopically. Agar cultures were made in deep stabs. The bouillon cultures were covered with paraffine, after a previous boiling. The tissues were then placed in sealed jars with pyrogallic acid.

Cartridge wads were also inserted in the muscular tissue of animals and allowed to remain there for three days to two weeks. They were then removed, or inoculated into other animals, or cultivated anaërobically. These experiments all gave negative results. Microscopical examination of the cartridge wads showed them to be made of wood pulp.

THE NEW FORMATION OF ELASTIC FIBRES IN THE STROMA OF MALIGNANT TUMORS.

The invention of a selective stain for elastic fibres by Weigert has enabled histologists to recognize elas-

tic tissue with a facility which was not possible a few years ago.

It is of considerable histological interest to know whether, in the newly-formed tissue of malignant tumors, elastic fibres are produced as well as white fibrous tissue. The following workers have investigated this question with the aid of Weigert's staining method, with the following results:

H. U. Williams² finds, (1) when the stroma of carcinoma is itself of new formation it is usually free from elastic fibres; (2) newly-formed elastic fibres may occur in the stroma, though rarely, and they are likely to be fine in quality and small in number; (3) the tumors in which newly-formed elastic fibres occurred either contained a large amount of connective-tissue stroma, or the newly-formed fibres were in connection with pre-existing elastic elements of the original parts.

W. C. White³ comes to practically the same conclusions from his study of the subject.

Alice Hamilton,⁴ on the other hand, finds in certain soft epithelial tumors, with relatively small amount of stroma, a rich growth of elastic fibres. Thus, in adenocarcinoma of the uterus, stomach and mammary gland the stroma in many instances consisted largely of such fibres and very seldom were they altogether wanting. In fibrosarcoma, and alveolar sarcoma also, good evidence was obtained of a new formation of elastic fibres, but in subcutaneous fibromata and in a myofibroma of the uterus new-formed elastic fibres were much less numerous than might be expected. In scirrhous carcinomata of the pancreas, mammary gland and liver undoubted evidence of new formation of elastic fibres was obtained.

THE ORIGIN OF SIMPLE CYSTS OF THE OVARY.

At the present time the generally accepted view as to the origin of these cysts is that they are of the nature of retention cysts of the Graafian follicles. This view, probably, is due to the observations of Rokitsky, who claimed to have found ova in some of these cysts. Other observers, however, think that some of them, at least, are new growths. Von Kahl- den,⁵ in a needlessly long and verbose paper without a summary, has submitted the question of the origin of these cysts to a careful examination. He studied cystic ovaries from 19 cases in adult women of varying ages. His conclusions are that these cysts are not derived from Graafian follicles, but arise from solid or tubular ingrowths of the germinal epithelium. His conclusions are based upon (1) the observations of these ingrowths of epithelium; (2) the absence of ova in the smallest of the cysts; (3) the occurrence of cysts in ovaries long after the formation of ova has ceased; (4) the absence of any tendency to form ova, except in 1 case. In this case, however, many ova-like bodies were formed, but never reaching the normal size; (5) the difficulty of explaining these cysts as retention cysts, in view of the fact that they are always superficial, that they have thin walls and that there is no apparent mechanical reason why, if they are retention cysts of Graafian follicles, they should not rupture as readily as the Graafian follicle itself.

² Contributions to the Science of Medicine, Dedicated by his Pupils to William Henry Welch, upon the Twenty-fifth Anniversary of his Doctorate.

³ Bulletin of the Johns Hopkins Hospital, September, 1900.

⁴ The Journal of Experimental Medicine, vol. v, No. 2, October 25, 1900.

⁵ Ziegler's Beiträge, 1900, xxvii, 1.

¹ Philadelphia Medical Journal, June 16, 1900.

According to these observations of von Kalden, the simple cysts of the ovary seem to develop in much the same way as do the Graafian follicles from the germinal epithelium, and these cysts might, in consequence, be regarded as the result of abnormal efforts upon the part of the ovary to form Graafian follicles.

ACUTE AND CHRONIC GONORRHEAL CYSTITIS.

Hugh H. Young⁶ reports these cases. In the first case the gonococcus was found in pure culture in the urine. In the second case the gonococcus was found in the urine in association with the bacillus coli communis. The urine was collected by aspiration of the bladder under strict aseptic precautions.

In reviewing the literature of gonorrhoeal cystitis, Young was able to find only 7 other cases in which the gonococcus had been demonstrated in the urine. In his opinion, this small number of cases by no means represents the frequency of gonococcus infection of the bladder. The principal reasons for this belief are, (1) The difficulty of obtaining urine by aspiration, owing to the acuteness of the inflammation which causes the contraction of the bladder, so that it is difficult to penetrate it with the aspirating needle; (2) because the gonococci will not grow in the urine unless it contains a considerable amount of albumin. In 1 case of gonorrhoea in which there was no cystitis the aspirated urine showed large numbers of gonococci. It thus seems probable that in the production of cystitis the gonococcus is only one of several factors in the process.

In the same paper Young also reports a number of instances in which the gonococcus was found in pure culture in subcutaneous abscesses. These abscesses developed either in the region of the urethra or in the subcutaneous tissue following operations for tenosynovitis or arthritis. For the cultivation of the organism Young recommends a mixture of hydrocele or ascitic fluid and nutrient agar-agar.

ACNE VULGARIS.

Dr. T. Caspar Gilchrist⁷ has arrived at some interesting results from a bacteriological study of this subject. He has examined bacteriologically 96 pustules from 55 patients. In cover-glass preparations from every one of these 96 pustules he found a special bacillus. He obtained cultures of this bacillus in 11 instances. In 31 instances the white staphylococcus of Welch was also present in the pustules. The bacillus found in these cases was short and thick and in cultures often occurred in long forms which, in some instances, showed branching. The bacillus grew in the ordinary culture media. In the original glycerin agar cultures from the pustules growth could only be obtained when considerable quantities of the pus in clumps were placed upon the surface of the culture media. Transplantations from the original cultures were only successful when masses of the growth were used for transplanation, without spreading the same over the surface of the medium. These peculiarities of the bacillus suggest to the reviewer that this organism would probably grow much better under anaërobic conditions. Dr. Gilchrist seems not to have tried anaërobic methods of cultivation.

The bacillus was found to be pathogenic for animals. Experiments on a guinea pig and on two mice showed that it was capable of giving rise to local supuration and a general infection. This organism is probably identical with that seen by Unna in acne pustules. Unna, however, never cultivated it. The branching of the organism was only observed in the cultures and in the local lesions of one of the experimental animals. The fact that it does branch would indicate that it should not be regarded as a bacillus, but as a streptothrix. The author, however, prefers to call it a bacillus, by analogy with the bacillus tuberculosis and the bacillus diphtherie, which, likewise, are known to be capable of branching.

In light of these results of Gilchrist, acne vulgaris is due to an infection with a specific organism. The generally accepted view, that this disease is due to infection with the ordinary pus organisms, is thus shown to be erroneous. Such infection with pus organisms is to be regarded merely as a secondary one.

A NEW PATHOGENIC MOULD.

Ophüls and Mollit⁸ report an interesting case in which the clinical diagnosis was septicæmia.

At the autopsy the following principal lesions were found: Abscesses and pneumonic consolidations of the lungs, encapsulated empyema, suppurative foci in kidneys, liver and spleen, purulent otitis and periostitis of the frontal bone and of the upper part of the left tibia, purulent arthritis in various joints, necroses and abscesses in various lymphatic glands. In the pus from a variety of situations, there were found peculiar spherical parasitic organisms of variable size up to 30 micra in diameter. In some of the lesions these were not associated with bacteria and were apparently the only infecting agent in the process. These bodies appeared not to be possessed of motility. The larger forms acquired a capsule, while the protoplasm broke up into one hundred or more spore-like bodies, which are highly refractile.

Attempts to cultivate this organism resulted in the growth of a mould, composed of a mycelium. By inoculations of this mould into guinea pigs and rabbits suppurative foci in various organs were produced, in which the same spherical parasitic bodies were found in pure culture in variable numbers, but no mycelium. By study of these spherical bodies in bouillon, under special conditions, it was found that mycelium developed from them.

The observations of the authors seem to establish pretty clearly that the infecting organism in this case has thus two stages in its life history which are very unlike one another. The authors suggest that the spherical form of this organism may be identical with the protozoan described by a few others under the name of coccidioides immitis pyogenes or other names. The botanical classification of this organism, as well as a number of organisms apparently more or less closely related to it, is extremely uncertain.

THE ETIOLOGY OF TROPICAL DYSENTERY.

Simon Flexner⁹ considers that there are two forms of tropical dysentery, one due to bacterial infection, the other due to the ameba coli.

From a number of cases of acute tropical dysentery in soldiers in Manila he was able to isolate a bacillus

⁶ Contributions to the Science of Medicine, Dedicated by his Pupils to William Henry Welch, upon the Twenty-fifth Anniversary of his Doctorate.

⁷ Loc. cit.

⁸ Philadelphia Medical Journal, vol. 7, No. 26.

⁹ Middleton Goldsmith Lecture, Bulletin of the Johns Hopkins Hospital, October, 1900.

which was apparently identical with the bacillus described by Shiga in the epidemic dysentery of Japan. This bacillus has a certain resemblance to the bacillus of typhoid fever, but is not identical with that organism. It gave the Widal reaction with the blood serum of the patients from which it was isolated.

Flexner also isolated this same bacillus from a case of chronic dysentery contracted during the Spanish War in Puerto Rico.

THE TYPHOID BACILLUS AND ROSE SPOTS.

Mark W. Richardson¹⁰ has cultivated the typhoid bacillus from the rose spots in 5 out of 6 cases in typhoid fever. In all of the positive cases the Widal reaction did not appear until six days, on the average, after the date of demonstration of the bacilli in the rose spots.

The method of cultivation was essentially that of Neufeld, who diluted the blood from the rose spots with a comparatively large amount of bouillon, thus avoiding the bactericidal action of the blood on the bacilli. By this means Neufeld¹¹ cultivated the typhoid bacillus from the rose spots in 13 out of 14 cases. Neufeld also found that in 7 out of a series of 8 cases the Widal reaction did not appear until, on the average, six days after the finding of the bacilli in the spots.

Curschmann¹² also recently obtained positive cultures of the rose spots in 14 out of 20 cases.

These results show conclusively that the typhoid bacillus invades the circulation early in the disease.

A RARE ENDOTHELIOMA.

Joseph Sailer¹³ describes a neoplasm involving the wall of the left superior pulmonary vein and occluding the lumen of the same. This neoplasm, on microscopical examination, proved to consist, essentially, of proliferated endothelial cells separated into groups or alveoli by connective-tissue stroma. The occlusion of the vein had resulted in atelectasis of the superior lobe of the left lung. That this atelectasis had occurred during adult life was shown by the presence of carbon pigment in the collapsed pulmonary tissue. Sailer gives an elaborate discussion of the nomenclature of tumors originating from lymphatic and blood vessels. He calls the present tumor a primary endothelioma.

COSTOCHONDRAL OSTEOMYELITIS.

Harvey Cushing¹⁴ reports this case, following a probable typhoid fever, from which a peculiar bacillus was isolated. This bacillus was found to have a close relationship to the bacilli of the hog cholera group. This group of bacilli manifest peculiarities which are found both in the typhoid bacillus and in the bacilli of the colon group. The patient's blood serum produced the Widal clump reaction with the bacillus, but did not do so with the typhoid bacillus. The bacillus did not give the clump reaction with the serum of typhoid fever cases. The bacillus in this case may be regarded either as a typhoid bacillus which has undergone modifications during its long res-

idence in the human tissues, or the bacillus may be regarded as a secondary invader from the intestinal canal that made its entrance during the course of the typhoid fever. Cushing seems to be inclined to adopt the latter view on account of the great variety of organisms, more or less closely related to this bacillus, that are to be found in the intestinal canal.

PLAGUE BACILLI IN SPUTUM.

Recovery from the pneumonic form of the bubonic plague has been an exceedingly rare event. The observation of 3 cases of recovery from this form of disease has enabled Gotschlich¹⁵ to study the question of the duration of the persistence of the bacilli in the sputum. In the first case virulent bacilli were found in the sputum up to the seventy-sixth day, and forty-eight days after complete defervescence, and forty-eight days after the patient had left the bed. In the second case the bacilli were found up to the thirty-fifth day of the disease, and six days after the patient had left the bed. In the third case the bacilli were present up to the thirty-third day after defervescence, and nineteen days after the patient had been up and about and had felt completely well.

Dr. Métin, at Oporto,¹⁶ has also studied the virulence of the sputum of plague convalescents. He finds, contrary to Gotschlich, that the virulence of the bacilli contained therein diminish rapidly from the end of the first week, so that after the ninth day the injection of sputum into guinea pigs is no longer fatal.

BACTERIA IN ACUTE RHEUMATISM.

F. J. Poynton and Alexander Paine¹⁷ report that in 9 cases of acute rheumatism they have met with a peculiar micrococcus. This was found in the pericardial fluid, in vegetations on the heart valves, in a rheumatic nodule on the elbow, on the tonsils, and in the urine. In 2 cases it was found in the blood during life.

The organism is a small micrococcus, occurring in pairs and chains. It grows best under anaerobic conditions, in a mixture of milk and bouillon, rendered slightly acid with lactic acid. It was found to be pathogenic for rabbits, producing polyarthritis, bursitis, tenosynovitis, pericarditis, "valvulitis," pleuritis, pneumonia, fatty degeneration of the myocardium, and other lesions.

THE KOCH-WEEKS BACILLUS IN CONJUNCTIVITIS.

The bacillus described by Koch in the epidemic conjunctivitis of Egypt in the eighties, and some years later described by Weeks in the epidemic conjunctivitis in New York, known as "pink eye," has recently received renewed attention.

Kamen,¹⁸ about a year ago, reported finding this bacillus in a small epidemic of conjunctivitis among soldiers, and more recently R. Hoffman¹⁹ has met with a number of instances of conjunctivitis, in which he also has found it. The bacillus is very small and is frequently included inside the leukocytes. In its morphology and cultural peculiarities it has a great resemblance to the bacillus of influenza. The conjunctivitis caused by it has, in some instances, a ten-

REGULAR meeting, Wednesday, October 17, 1900,
DR. H. F. VICKERY in the chair.

DR. H. S. POMEROY described

AN IMPROVEMENT IN INSTRUMENT AND METHOD FOR REMOVING SUPERFLUOUS HAIR BY THE ELECTRIC METHOD.

I feel that some apology is due you for taking any of your time for a matter about which so few of you will feel any specially active interest. When I first began to take out hairs by electricity, some thirteen or fourteen years ago, the very first thing that was impressed upon my mind by my instructor, a Boston physician who had been taking them out for some time, was that I must be very particular about my needle, that it must be a very sharp one, and I was instructed always to apply this test: take a little wad of cotton, fold it tightly and see if the needle would pass through without objection. I was instructed to use steel needles. I have found that steel needles are largely a delusion and a snare, wear out and break, that the points are uncertain, and I find that a sharp point is very unwilling to follow the course of the follicle beside the hair to reach the papilla at the bottom, and I did as most of us do when we find difficulties in modes of procedure—we experiment. I soon made up my mind that a blunt needle was the thing to use and I began to use my needles more and more blunt and finally settled on one made of platinum. Now it is the custom of a good many to have a quantity of needles—six, eight, ten or twelve—on hand. I used to do that myself. As an illustration of what can be done by one needle, I will say that the particular needle in this holder I have used six or seven years, and the only point about it I am very particular about is that it shall be very blunt. Being blunt it will follow the course of a follicle as a finger is pushed into the finger of a glove, and it is curious how this works in some instances. A few days ago I was doing an operation with this needle on one of the large hairs on the chin. The needle fell in of its own weight about half the distance down the papilla and stopped; I then turned it at an angle of 45° and it slipped in to the bottom. That was one of the cases in which the course of the follicle is not straight, but turns an angle of perhaps one-half to two-thirds of a right angle in its course. If I had had a sharp needle the point would have gone through the sheath of the follicle and out, and not at or near the papilla, and I could not have got the hair out.

The second point I want to speak of is that this needle is insulated. Prof. P. S. Hayes, who wrote a

little book of about 125 pages on "Electricity and Facial Blemishes," speaks very decidedly on this point, that it is not possible to insulate a needle need for removing hairs by electrolysis and gives as his reason that the canal is so small that it would not be possible to have the needle sheathed in anything that would be a non-conductor and yet get it in. He seems to assume that it is no use to have any insulation unless your needle is insulated almost to the point, leaving just the least bit of the point exposed. I experimented some time on insulation because I found with all the care I could use I sometimes got rather bad scars and at length I hit some three years ago, I think, on this device. I had a very small cylinder of hard rubber bored by Colman & Shurtleff, with one of the drills they use for boring out needles used for hypodermic purposes, and then this little tube, which was of hard rubber, was slipped over the needle when it was a little hot and shrunken. I have used that particular one with that insulation on for three years. The needle is bare for about the depth of the largest hair follicle. The depths vary from perhaps $\frac{1}{32}$ inch to a large $\frac{1}{4}$ inch. I have compromised just a little and the needle is left bare perhaps $\frac{1}{8}$ inch. The insulation comes a little below what would be the surface, and by rotating the needle a little and crowding—the tissues are elastic and will give—that part of the needle that is insulated enters the opening of the follicle for perhaps $\frac{1}{4}$ inch or less, but enough to hold the part of the needle that is bare away from direct contact with the true skin. It might seem *a priori* that that would not accomplish much, but as a matter of fact it does. Since I have got this insulation I have had almost no trouble with scars. I had a little trouble which came up in a way that rather surprised me. In one case I found a great deal of the tissue destroyed, and finally I found the trouble was this: The work was being done on the lip near the nose, where there is the greatest sensitiveness of any place on the face, and the patient was high-strung and sensitive and suffering very much, and the result was that she perspired very freely, and before I realized it the skin at that point was bathed in perspiration and the perspiration settled down and extended outside, so that I was working in a little water bath and the destruction of tissue reached quite a distance. That is the only instance I have had in three years, and that would not happen again, because I should be forewarned and forearmed. The length of needle in this holder is the most that is ever needed; I have only a few times had to urge the needle a little to get it to the papilla. Sometimes I go a little beyond the papilla. I think it is better to urge this needle than have the trouble of three or four needles, though if I were going to have three or four I should possibly have one that had the bare part of the needle a trifle longer than this and then the others graded down to one that is exposed $\frac{1}{32}$ inch.

There are a good many hairs that worry the ladies and they want them out, and yet they are very fine and the opening to the follicle is very small, and sometimes, unless you have a very strong light and conditions unusually favorable, it is very difficult to enter with the needle, and the attempt annoys the patient, and hurts very much more than it does to go directly into the follicle. I tried the experiment of putting this needle into a hair follicle at the back of the wrist without cocaine or other anesthetic and

crowding the insulated part down into the mouth of the follicle so that it was in perfect condition for working, and have done it repeatedly with scarcely any pain at all. That was when the electricity was not passing; that makes a good deal of difference, and of course it is very important that you should get into the follicle, because if you do not it is almost impossible to destroy the papilla. If a little to one side and you have a very strong current, as you would get from twelve or fifteen cells and leave it to an exposure of thirty to forty-five seconds, you might possibly destroy the papilla without being actually inside of the range of the follicle. I found it difficult to work with a glass. But I thought if I had one that was at hand in position so that I could use it at the moment of getting the point of the needle started it would be a good deal of help and I devised this. It is cut down from one of the little glasses used by watchmakers. The rim is deep enough so that you get the right focal length when it is screwed into the eye like a monocle. I had this cut down and remounted at an angle and it is on a little slide, and it also pulls off if you do not care to use it. It helps me very much about getting the point of the needle started properly. I tested it in this way: I had a cut of something that represented a surface that was mottled, and the mottlings were so fine that with the naked eye it was scarcely possible to distinguish that it was not a surface evenly brushed over. With this little lens I found I could easily plant the tip of the needle in the centre of one of the clear spaces, these spaces being a good deal smaller than the opening to a follicle.

It seems to me that the blunt end, and the platinum for the substance of the needle, and the compromise of insulating in this way, and the little magnifying glass added, make quite a little assistance in some of the difficulties and pitfalls of removing hair by electricity. I have at least found them so, and thinking that possibly some of the members might like to see it, I brought it in. I thank you for your attention.

DR. C. J. ENEBUSKE read a paper entitled

CHRONIC DIFFUSE INTERSTITIAL NEPHRITIS.¹

DR. PUTNAM: I should like to ask if Dr. Enebuske has tried the method I saw recommended by Dr. Jacobi, of New York, of giving massage under the surface of water in cases of arteriosclerosis? It was desired, I suppose, to get the dilatation of small vessels.

DR. ENEBUSKE: No, sir; I have not tried it.

DR. POMEROY: I am very much interested in this paper. I have only a word to say. There are 2 cases I call to mind which are somewhat interesting perhaps, one from the fact that the patient is known to have lived almost twenty years, probably twenty-one or twenty-two years after the disease set in. The disease was first diagnosed by one of my brethren in November, 1880, and was then apparently very far advanced. She was an unmarried lady of about forty-nine years and it was not supposed she would live more than a few months. She was under the care of this physician about five years, and then, he withdrawing from general practice, she came to me and was under my care nearly fifteen years. During about nineteen years of the time that the case was under observation the patient on the whole apparently improved from year to year. There was not very much im-

provement to notice after the first few years, but still a little. She seemed a little more available for society and such philanthropic work as she did to amuse herself until a short time before the close, when the disease took a rather bad turn and she came to Boston to have me give her a thorough looking over. I found that the disease had within a few months made a decided advance and told her friends she probably would not live very long; she died in about six weeks.

The other case is a little amusing, if a case of chronic interstitial nephritis can ever be said to be amusing. The patient is a man about sixty-five years of age, who came to me for treatment about five years ago and after a few months thought he was a great deal better and was not willing to come to my office for more treatment, and for some years now I have seen the patient only about three or four times a year. He does very much like alcohol, and before he came under my care was in the habit of using it a great deal. I took that away from him, of course, and got great credit from the family for doing it. About once in three or four months, on the average, the habit will creep on; he will commence with a glass of beer and soon get to something else and finally send for me. I take away the alcohol, put him to bed for a few days, and then perhaps several months will elapse before he sends for me again, meantime being able to attend to his business as usual.

DR. PUTNAM: I should like to ask if in the cases Dr. Enebuske found to improve so much he could explain the rationale of the improvement through the treatment by exercises, etc.; whether it was accomplished through the general invigoration or improvement in the circulation or in what way.

DR. ENEBUSKE: The case which I mentioned I do not feel sure how to interpret, but my impression has been that it was not at all a case of chronic interstitial nephritis and I mentioned it because I think it illustrates the impossibility of diagnosing a case of chronic interstitial nephritis from the signs found at one examination, because at one moment of time the symptoms are such that one would seem to be justified in making that diagnosis, but the development of the case does not bear out the diagnosis. She recovered after three weeks' rest and one year afterwards was still better. My impression was that it was only the case of a woman under the combined influence of more work than her strength was good for and much mental depression, sometimes doing work involving a great deal of muscular effort, and I thought of the case as one of acute strain of the heart and that might account for all the symptoms. However, I do not make this diagnosis. I have no conclusive theory about it. There are several members of the family who have had chronic interstitial nephritis, judging from the family histories; it is a rheumatic family and it might well be that this woman is going to develop later in life symptoms in the direction of chronic interstitial nephritis. However, at this time there was nothing serious at all; it was simply under the influence of certain circumstances in which she was living that all the symptoms developed, and they passed off very readily without any treatment at all.

DR. MORSE: Dr. Enebuske's paper suggests one or two points to me. The first one is the importance of being continually on the lookout for the combination of high-tension pulse, enlarged left ventricle and accentuated second aortic sound. It seems to me that

¹ See page 518 of the Journal.

the profession at large is hardly enough on the watch for this combination of signs and that when they see it do not recognize its pathogenic significance. Of course what it means is increased arterial tension. That increased arterial tension may or may not be associated with interstitial nephritis.

Then it seemed to me on simply thinking over the cases of interstitial nephritis which I have had without looking them up, that the importance of cardiac failure and dilatation of the left ventricle is not so great as it would seem from Dr. Enebuske's paper. It seems to me it is not the usual terminal process.

Then the point Dr. Enebuske has made that one examination of the urine is not sufficient to make a diagnosis of interstitial nephritis is important. The albumin and casts must be persistent to warrant the diagnosis.

Another point which he made, and which was rather new to me until Dr. Ogden called it to my attention a short time ago, is the relation of the night and day urine, much more being passed in the night than in the day, even when the total amount is not much increased.

DR. VICKERY: It has seemed to me that the time when we can do these patients the most good is very early in the course of their disease, and vigilance is rewarded in that respect. Of late I have had a series of cases in which the urine was apparently all right until a microscopic examination was made, and I have examined such a urine today passed by a man who is pretty well advanced in arteriosclerosis and there was no albumin by nitric-acid test and the faintest possible cloud by acetic acid with a specific gravity of perhaps 1.018, and yet the man is really quite far advanced. And I have in mind another man, a prominent professional man of this city; his pulse is not of high tension and his heart is not enlarged and sometimes there is no albumin in his urine at all, yet I have never failed to find casts in his urine. He came to me because of very obstinate headache. I do not know whether that has any connection—probably it does not—I rather think his headaches belong to the class of migraine. These are men whose nervous systems are strained a great deal, who accomplish a great deal of important work with their brain.

Another one of the same sort I have had is a politician who had a very close and finally successful contest. His urine was an innocent looking thing until you found casts in it. Many of these cases may be temporary and due to some slight irritation, but it seems to me that if we are vigilant in making a careful examination of all the cardiac factors that have been pointed out and also of the urine, that we shall make the prognosis of kidney troubles better than it is now. It has improved within ten years.

DR. PUTNAM: I cannot claim to have kept myself absolutely well posted on the literature of the subject, but I have been quite interested in it, and I should like to ask if there is not a fairly definite distinction to be drawn between the cases of arteriosclerosis with nephritis and those without. Of course they run into each other and either may become complicated with the other, but I have supposed that in cases such as Dr. Vickery has just spoken of, where the specific gravity of the urine remained fairly high, indicating a good quantity of urea presumably, there might be a very marked degree of arteriosclerosis and that it was that which caused the retinal hemorrhages and

cerebral hemorrhages, small and large, so that the patient might die without his kidneys even becoming seriously affected. I supposed that was especially common with young and middle-aged persons. I dare say the distinction is not so sharply drawn as I had supposed.

DR. VICKERY: I think there are cases in which the process either in the arteries of the brain or in the coronary arteries far outstrips in rapidity that which affects the kidney, so that the man does not live long enough to have a very bad kidney. Then, of course, a nephritis may exist entirely independent of an arteriosclerosis, as was pointed out; but my impression is that such a case from the purely pathological standpoint would show some signs in the kidney. The only difference is with regard to treatment of the patient. Perhaps it puts you on the right track if you find these morphological elements in the urine. Certainly I have seen them in cases where the heart was not enlarged and the pulse not of high tension, nor rigid, and yet casts steadily present with an infinitesimal amount of albumin.

I think in this region the adjective "diffuse" is reserved for a kidney which has more of a degenerative character, with a good deal of fat and a good deal of albumin in the urine.

DR. OGDEN: I would endorse what Dr. Vickery has just said in regard to the nomenclature, that is, that the term "chronic diffuse nephritis" is ordinarily applied to the condition where there is a decided amount of parenchymatous change, a large quantity of albumin and a large amount of fat.

There is one point in connection with the albumin that seems to me to be important. I have seen many cases of interstitial nephritis from the laboratory side largely, and I have yet to find a case where the urine did not contain the slightest possible trace or more of albumin. Of course, there may be cases of this disease where the urine does not contain albumin, but I have never happened to see them. With the changes in the kidney and the morphological elements in the sediment, it seems to me that albumin should be a constituent of the urine under those circumstances. In such urines the amount of albumin is exceedingly slight; so is the number of casts very small.

The quantity of urine is of the greatest importance in diagnosis from the urinary point of view, and especially in connection with chronic interstitial nephritis. The day and night quantities, that is, from 7 A. M. to 7 P. M., and 7 P. M. to 7 A. M., should be collected and measured separately. In perhaps 95% of the cases of interstitial nephritis the night quantity will exceed that of the day and sometimes to the extent of three or four times that of the day. Usually, however, the quantity is about twice as much at night as in the day; this fact accounts for the necessity for getting up at night to pass the urine, which, as we all know, is an old sign of chronic interstitial nephritis.

DR. ENEBUSKE spoke of the rarity of the disease in children. I think that is rather a mistaken idea, because it really is not so very uncommon. It is, however, uncommon for the diagnosis of an interstitial nephritis to be made very early in childhood, because the urine cannot be accurately collected, the minute amounts of albumin do not attract attention, and the importance of the small number of casts is not correctly determined at that time. One of the most marked cases of interstitial nephritis I ever saw was

in a child of seven years; that case was diagnosed as diabetes insipidus during life. The patient was passing very large daily quantities of urine—6,000 to 8,000 cubic centimetres—and there were tremendous thirst, marked emaciation, and insomnia. The urea, chlorine and phosphates were all very high. This girl of seven, although emaciated, was eliminating over 40 grammes of urea, more than 12 grammes of chlorine, and a high amount of phosphoric acid. At the autopsy two years later the kidneys were found to be very small and perfectly typical of chronic interstitial nephritis.

SUFFOLK DISTRICT MEDICAL SOCIETY. SEMI-CENTENNIAL ANNIVERSARY.

HOWARD A. LOTHROP, M.D., SECRETARY.

ADDRESSES BY DRs. B. JOY JEFFRIES, A. T. CABOT, J. C. WHITE, D. W. CHEEVER, J. C. WARREN, GEO. B. SHATTUCK, H. L. BURRELL.

REGULAR meeting, Saturday, April 28, 1900, Dr. HERBERT L. BURRELL in the chair.

DR. BURRELL: This meeting has been arranged to commemorate the founding of the society fifty years ago. The committee appointed to arrange the programme for this evening has secured for us the speakers whom you have seen announced, and I will ask Dr. B. Joy Jeffries to give the first address.

DR. JEFFRIES: April 25, 1849, at the Masonic Temple, was held an adjourned meeting of the Fellows of the Massachusetts Medical Society, for Suffolk District, including Chelsea. Dr. John Ware in the chair. Dr. George Hayward for the committee appointed at a previous meeting, "for the purpose of considering the expediency of forming a district medical society," reported the following resolution: "That it is expedient to form a district medical society for Suffolk, and that measures be taken to carry this resolution into effect at as early a period as is possible." The resolution was unanimously adopted.

The committee said in their report, "It is perhaps hardly necessary for the committee to state advantages which they believe would result from a measure that would unite more closely the members of the parent society residing in this district. It could not fail, in their opinion, to promote harmony and good feeling among them. It would enable them to act with more concert, and consequently give them, by a harmonious action, a greater degree of weight and influence in the society at large than they now possess. By bringing the fellows of the society residing in this district more frequently together and thus giving a better opportunity than they now enjoy for an exchange of views and opinions on topics of common interest, it would tend to break down the jealousy and ill feeling that too often exist among the members of our profession."

At a special meeting of the Councillors of the Massachusetts Medical Society, May 29, 1849, it was voted: "That permission be given to the fellows residing in Suffolk County to form a district society." Nine had been previously formed. Worcester and Essex South, June 7, 1804; Berkshire, October 7, 1807; Hampshire, October 5, 1831; Bristol South, April 3, 1839; Barnstable and Hampden, May 28,

1840; Essex North, October 6, 1841; Middlesex North, October 2, 1844; Suffolk, May 29, 1849; Bristol North, May 31, 1849; Middlesex East, October 2, 1850, and semicentennial next October; Middlesex South, Plymouth and Norfolk, October 2, 1850, and May 8th, semicentennial; Franklin, May 27, 1851; Worcester, May 25, 1858; Norfolk South, October 1, 1884; Suffolk tenth, eight since formed, making eighteen districts at present.

Monday, September 17, 1849, at a meeting of the Fellows of the Massachusetts Medical Society residing in Boston and Chelsea, Dr. Z. B. Adams in the chair, it was voted: "To accept the charter granted by the Councillors of the Massachusetts Medical Society." At a subsequent meeting held September 24, 1849, the following gentlemen were elected as officers for the current year: John Jeffries, President; Samuel Cabot, Jr., Vice President; E. Whitney Blake, Secretary; Ephraim Buck, Treasurer; Wm. E. Coale, Librarian; Z. B. Adams and N. B. Shurtleff, Committee of Supervision. Certain by-laws were then passed.

SUFFOLK DISTRICT MEDICAL SOCIETY:—This society has recently been organized in Boston, and seems to have been considered by many gentlemen to embrace the essentials of the Boston Medical Association. In fact at a meeting of the District Society, on Monday, October 1st, it was announced that the venerable association was defunct, when some, having a larger share of attachment than others for old institutions, thought it a very strange affair—indeed quite revolutionary—for a new society that had been in existence but a single week to declare another one, embracing nearly 300 members, extinct, without asking leave of anybody. The Boston Association had never been civilly asked to die, and it was, therefore, concluded to reflect a little and through a committee ascertain what the new Suffolk District Medical Society could, would and might do.

Dr. Jeffries, the president of the new society, is an excellent presiding officer. He is patient, courteous, candid and strictly just. When the society is fairly organized, and its order of duty and business defined, we have no doubt it will be found a useful one. May it live a thousand years.—*Medical Journal*, October 10, 1849.

Medical communications and questions soon began to be presented to the society by others than its members.

The Suffolk District Medical Society held its second meeting for medical communications, Saturday, November 24, 1849. Dr. John Ware read two letters, addressed to him by Dr. Webber, of Charlestown, N. H., one containing some observations in vegetable physiology, and broaching the theory that the potato is sometimes viviparous.

Dr. Webber was a college classmate of the president, H. U., 1815; I have the letter, and Professor Goodale's reply to me on reading it.

It should be mentioned that a donation was made by Dr. Jeffries, the president, which was duly "deposited." A cup of coffee and a suitable accompaniment of cake added to the well being of the physical as did the other exercises to that of the intellectual man.—*Boston Medical and Surgical Journal*, December 5, 1849.

Such donations were followed by some subsequent presidents, till probably the increase in numbers of fellows naturally prevented.

The medical communications meetings continued through the winter of 1849 and 1850. In the *Boston Medical and Surgical Journal* of April 24, 1850, there is a notice as follows:

SUFFOLK DISTRICT MEDICAL SOCIETY. — The annual address before the society will be delivered by the president, Dr. Jeffries, at the Masonic Temple, on Saturday evening, April 27th, at half-past seven. The profession generally are cordially invited to be present.

May 8th, the JOURNAL says :

The anniversary address before the Suffolk District Medical Society was delivered by the president, Dr. John Jeffries, on Saturday, April 27th, at the Masonic Temple in this city. The public generally were invited to be present on the occasion, and the profound attention which was given to the eloquence of the lecturer bespoke their admiration and appreciation. The learned doctor's theme was "The Relation of Medical Men to the Public."

Am I perhaps the only one here who was present on that occasion, peculiar in its being the first anniversary, and still more so, in that the public at large were invited, and appreciated what they heard? If so, may I indulge in a few moments of remembrance, as I hope some fellows now present will do of this evening when our *centennial* celebration occurs.

Fifty years ago last evening a Latin School boy could have been seen crossing the Common from Beacon Hill to the Masonic Temple, now raised up as Stearns's store on the corner of Tremont Street and Temple Place. He was led by curiosity, to hear what the "doctor" had to say. The lad found the hall filled with the ladies and gentlemen of Boston, and much too shy to seat himself amongst them, stood in the rear and peered over the high backs of the seats. The impression of the scene is as clear today as then, and vividly recalled by reading the printed address half a century afterwards.

Now, why our society was formed, and its aims and success will perhaps be best understood by reading a few sentences from a copy, which substantiates the committee's report. The lecturer said :

Once more has this principle of association been brought into action by the formation of the Suffolk District Medical Society, whose commencement we are assembled to celebrate. The parent society's members were too widely spread to avail themselves of frequent meetings for medical improvement or social intercourse. Feeling its weakness in this respect, it now *requires*, by its new code of by-laws, what it formerly permitted or advised: the formation of subordinate societies in every part of the State, which should reach, in their action, everything which has relation to medical character. The other societies, of which mention has been made, although right in kind, are all limited in extent, not embracing the whole body of physicians in this locality; besides, as they do not owe allegiance to the general society, they are not so well calculated in their isolated operation to influence so powerfully the general medical interest.

Again, there is among the junior members of the profession an amount of intelligence and activity which should, by no means, be permitted to lie dormant. There has been nothing more remarkable, in the few monthly meetings of this society, than the talent and information evinced by the younger members. It is not only just and proper that an opportunity should be afforded them to present their claims for distinguished abilities, but also that the way should be open for them to contribute their proportion to the general fund of knowledge, and to receive the fruits of experience which it is the duty of the older to distribute.

The frequent interchange of friendly feelings is as essential to the comfort of the physician as is the interchange of professional opinion for his improvement. In this way, this society is calculated to do much good. It cannot be but that some asperities will arise between those who are aspirants for the same objects, and where much is heard, and little seen, of rivals in the pursuit of alluence or fame,

these asperities may ripen into animosities. But where frequent and free intercourse is enjoyed, especially under circumstances which bring out the kindly affections, the rough points are rubbed off, and a smooth and more polished surface appears beneath.

Again, it is desirable that there should be something before the public eye which portrays the doings of so important a part of the community as the medical profession; some point at which they should occasionally meet for mutual observation. May it not well be in the operations and public meetings of this society, whose transactions are published, and whose doors are annually opened, as on this occasion, to the observation of an enlightened and a scrutinizing public? The more closely the attention of the community is turned towards the medical profession, the better for the interests of that body.

It is very evident that there was no chance for every young medical man to show what he had done and could do. Joining the Massachusetts Medical Society did not help him in this *in our city*. The Suffolk District Society gave him the opportunity, and it was availed of at once, as it has always been since. It was an enforced recognition of the younger generation of medical men.

The brightest boy and man I ever knew was Col. Charles Russell Lowell, my Latin schoolmate and first scholar in our Harvard Class of '54. Only four years after the time we are now recalling tonight, on Commencement Day, was given to him as orator, this theme: "The Respect of the Old Due to the Young." I have never forgotten the scene and the talk and feeling which followed. It was the commencement of a new era in Harvard College, to be remembered. I recall it here and now, as Kipling says, "lest we forget."

It can be well understood what an amount of committee work was required to carry out the formation of the society under the then conditions of natural opposition from the existing medical organizations, namely, the Boston Medical Association, the Medical Improvement Society and the Society for Medical Observation.

A large part of the various committees' work was done in the same office where our present committee met once to arrange this evening's programme. The Latin School boy did not properly appreciate those meetings, as they generally came at a time of the day when he was likely to be helped in his lessons, so that now he remembers the meetings better than the lessons. There was, however, an impression made upon his mind, never to be effaced, and which, perhaps unconsciously, contributed in no small degree in determining his choice of his father's and grandfather's profession. It was the very cordial and pleasant way in which the doctors greeted each other when coming together; a friendly *camaraderie* which he met with when he later entered the profession, and which he trusts will always exist, as it does amongst us met here tonight.

DR. A. T. CABOT: This society was founded fifty years ago by men desirous to promote the advancement of medical learning. There were other medical clubs then existing whose membership was limited and somewhat narrowed, perhaps, by social lines, but the Suffolk District Society was open to any man, and later to any woman, in this community, who was able to pass the examinations for the State society. It was started as a thoroughly democratic institution, and

its success has vindicated the judgment of its founders, and is another triumph for the American spirit which inscribes "free to all" over its temples of learning. With open doors we have gone on through the first half century of our existence, growing and expanding until finally the interests represented among us became too wide to be held confined in one body, and by a sort of fissiparous process the society divided into the special sections in which its scientific work is now done.

Our growth has followed natural lines of evolution. The sections which really filled a need have gone on and prospered, while those which were established in subjects that did not awaken great interest or that were adequately provided for elsewhere, have fallen into disuse. At present, general surgery, general medicine, obstetrics and gynecological surgery are provided for in sections of this society. Medical subjects of a purely scientific interest are more properly presented to the Society for the Medical Sciences, and, thanks to Dr. Ernst, that society has become wide in scope and opens its doors to all earnest workers.

There are other societies, of which the Medical Improvement and the Obstetrical will at once occur to you all, and also smaller clubs, in which opportunity is given for the discussion of medical questions of all sorts. Boston is thus richly provided with opportunity for the fullest interchange of medical ideas.

Not the least of the benefits that this society owes to its founders is that they chose the middle of the nineteenth century for its birth. These fifty years that it has lived have seen no halting in the onward progress of scientific medicine. Discovery has followed discovery so closely that the medical horizon has been kept bright by the constant rise of new and ever more wonderful luminaries. The free interchange of thought at our meetings has helped to keep us all in step with these advances and to open our eyes to the ways pointed out by distant investigators. It has been a happy time for all who love their art. Expansion may be a dangerous policy for a nation. There are those who think it so. But I never heard it doubted that constant widening growth was the best evidence of health in a human mind, or in a science which is the product of the aggregate human mind.

It is a great and constantly growing branch on the tree of knowledge which represents medical thought. In order that this branch may be healthy it must be supported by roots that are fast in the solid ground of fact. The growth of medicine has of late been largely at the root. The scientific laboratory investigation, which has been going on the world over, has been deepening and strengthening our hold in the substantial strata of observed facts which underlie and hold up our medical speculations and beliefs. No theory is allowed to stand which cannot show the ground in which it is firmly rooted. It is in just such societies as this that by free discussion the unsupported theories are lopped off, and the strength which was being wasted in them is turned into more promising channels.

In order that a society like this shall do its best work, it is important that a habit of discussion shall be cultivated. It happens too often, I think, in our medical gatherings that a man reads a carefully prepared paper which is listened to with interest perhaps, but which excites little or no comment. This is a depressing condition of things for the writer, who has usually many interesting side lights to throw on his

subject which he could not bring within the limits of his paper, but which might well be brought out in the discussion.

The specialization which has led the Suffolk District Society to divide into sections has done much to promote freedom of discussion; for in these section meetings the members are all interested in the subjects that are brought forward, and, therefore, capable of judging ideas that are advanced.

The most modern methods of medical teaching educate our young men into habits of analysis and criticism, and thus greatly add to their after usefulness in the medical community. Men so educated bring an interest and an aptitude for discussion to our medical meetings.

If the signs are rightly read, we are entering our second half century with brighter prospects than those surrounding the birth of the society. Medical activity is everywhere at high pressure. Frequent discoveries reward patient investigation and work. In large centres like Boston the number of competent practitioners and scientific workers increases in a constantly accelerating progression. Let us see to it that the amount and importance of our medical work grows in like proportion.

DR. WHITE: It has been suggested that I say something to you about the part played by former members of this society in the advancement of natural science in this community and country. It was a very important part. Fifty years ago I was a student at Harvard College, where Agassiz was just beginning to attract students of natural history to the Lawrence Scientific School, and to popularize its study by lectures delivered at the Lowell Institute and in other parts of the country. But before his day there were two most accomplished masters and teachers there, who had received their early training in the study of medicine: Drs. Jeffries, Wyman and Asa Gray. The fascinating instruction given by the former, especially, had without doubt a powerful influence upon many students, then and subsequently in the selection of medicine and the natural sciences for their future professions.

Before the date above given and for some time afterwards the study of natural history in all its branches in the United States was almost exclusively confined to physicians, who mostly in the busy life of the practitioner found time to make independent investigations, and without the aid of existing books on the subject, to collect material for and publish books of great merit in all departments of natural science. They were the principal founders, too, of the Boston Society of Natural History, now established in the building adjoining this hall, which has done so much for the development of and instruction in this field of study amongst us.

Permit me to mention briefly some of our deceased members who have rendered such great service to American science.

Dr. John C. Warren, senior, 1803,¹ was one of the earliest students of natural history in this community, and a generous patron. He established an extensive museum, then one of the most valuable collections in the country, and became president of the Boston Society of Natural History.

¹ The date annexed to the names is that of their membership in the Massachusetts Medical Society.

That all-accomplished man and skilled practitioner, Jacob Bigelow, 1813, was one of the earliest students of the botany of the northern portions of this continent. His "Flora Bostoniensis" was a most interesting treatise on the plants of this region, and his large illustrated work on "Medical Botany" was a great storehouse of information concerning the therapeutical properties of our native flora.

Thaddeus W. Harris, M.D., 1820, subsequently librarian of Harvard College, was an enthusiastic student of entomology. His treatise on "Insects Injurious to Vegetation" was the standard authority for half a century.

David Humphreys Storer, 1829, was one of the most conspicuous members of this band of naturalist-physicians. He was an active ichthyologist for thirty years, and his State report on the fishes of Massachusetts in 1839, with the subsequent more extensive publications on the subject, bear witness to his zeal and labors for science in addition to those demanded by an extensive practice and his duties as teacher.

Augustus A. Gould, 1832, was another physician of the same type. His reputation as a conchologist was world wide, and his publications in this field were numerous.

Amos Binney, M.D., 1826, was also a well-known student of *Mollusca*.

Charles Pickering, M.D., 1826, became a cyclopedia of knowledge connected with unexplored nooks in natural history in all parts of the globe.

Charles T. Jackson, 1833, was not only a chemist, but one of the pioneer students of the mineralogy and geology of North America.

Thomas M. Brewer, 1838, was an excellent field ornithologist, and an extensive contributor to the literature of oölogy.

Samuel Cabot, 1843, was also an ardent student of birds throughout his life and made valuable observations and collections in Central America.

Dr. Henry Bryant, 1847, was an active and critical ornithologist, and a most generous benefactor of our Natural History Society, having bought for it one of the largest collections of birds in Europe. Although not an active practitioner, he rendered valuable professional services to our armies during the Civil War.

This bare list of our deceased brothers, who played so distinguished a part in the development of our early knowledge in the many branches of natural science, recalls how devoted students they were both of nature and disease. In these days the same earnest class of physicians, leaving such studies to the professional naturalists who have succeeded them find ample scope for this spirit of research in directions more intimately connected with scientific medicine, as pathological histology, bacteriology, hygiene, and the like, and here, too, their labors bear a rich reward to mankind.

I listened lately with interest to a discussion in a medical society upon new methods of teaching medicine. Wonder was expressed by a distinguished master in education that physicians taught under former methods, those who have passed away within our memory, and the living of the passing generation, could have learned so much as they knew and know. Consider the men whose lives as successful practitioners, as unsurpassed teachers, as renowned students of natural science, I have recalled to your recollection.

They found their early inspiration for research, their trained powers of observation, their methods of investigation in their medical studies under the old system thus slightly characterized. They had not the advantages of prolonged terms of school instruction, of laboratories, or concentration of drill in systematic succession, but they learned medicine under the more personal direction of the experienced practitioner either in the city school and hospital, or under the direct guidance of the shrewd country doctor in the office and by the bedside of the private patient. That schooling and its fruits have been tried. It made the great physicians, teachers, naturalists of the passing century. The results of the education of the future have not yet been proved. Let us trust that it may make as admirable practitioners and as accomplished men.

DR. CHEEVER: Of the fifty years of the Suffolk District Medical Society I have passed forty-two years, in practice, in Boston. During this period 136 members of this society whom I have known personally have died.

The electric car and the telephone have replaced largely the doctor's chaise, and the need of a central office, easily seen and passed by all men. The division of our society into working sections has been one of our greatest advances. Sulphuric ether, the clinical thermometer, the germ theory of disease and anti-sepsis have revolutionized surgery and remodelled medicine. Increasing numbers and higher education have rendered competition keener, while specialties have largely broken up family practice.

The age of professional advancement has increased. When I was a medical student, of seven professors two were 50 years old, two were 40 years old and three were 38 years. In the Harvard School today two are over 60 years of age, thirteen are over 50 years, thirteen are over 40 years and three below 40 years. A similar change has taken place in the two large hospitals. At the Massachusetts General Hospital then, 45, 43, 40, 34 years were the ages; now, 60, 54 and over 45 years. At the City Hospital then, 59, 42, 38 and 33 years; now, 66, 50, and over 40 years. This increasing age prevails in all the minor positions and appointments.

Among the greater changes are the following: A registration law has been in force several years; and, even more important, the medical examiner has replaced the coroner; a State Board of Health has established a sanitary reputation, envied throughout our country. We have now in Massachusetts one doctor to between 500 and 750 inhabitants. Formerly it was considered that 1,000 persons were needed to secure a living for one doctor.

It is hard, perhaps impossible, for any generation to realize the changed status of the young physician of today. He must learn it for himself. The enthusiasm of youth will lead him, and its elasticity will enable him to adapt himself to his changed surroundings. His scientific training is far higher; may his professional sincerity and purity and honor keep pace with it! And I believe they will.

DR. WARREN: I have very little to say in a formal way. I thought over a few incidents and names during the past century which possibly may be interesting to the members of the society, and what remarks

I have to make are of very desultory character, not quite on the plane of those who have preceded me.

I have been in the habit of looking at this past century as composed of three periods from the point of view of the generations of medical men who made up the century. They each occupy a period of about one-third of a century overlapping into the succeeding period. At the beginning of the century there was a group of men who had obtained their education in this part of the world. They form the first faculty of the Medical Department of Harvard University, one of the first teaching bodies, second, I think, in the United States, following the University of Pennsylvania, which was the first. The pupils of these men were young men just about graduating when the century opened and they were not satisfied with the modest education they received at that time, and I think we might say it was about that period that the fashion was set which has been maintained throughout the century, of having men go to the other side of the water to finish their medical education. The place where they went at that time was Great Britain, just as in the middle of the century it was France, and later in the century it was Germany, and, as I hope, in the coming century the current will turn in this direction. Dr. John C. Warren, my grandfather, was one of the pioneers in going to Europe to obtain his education. He was there probably at the time, certainly very soon after, the Royal College of Surgeons of London, whose centenary is to be celebrated in July, was founded. He studied not only in London, but in Edinburgh under Bell and under Cline, and under Sir Astley Cooper in London. That set of men were about closing their career at the time we are referring to this evening. They were retiring and a second set of men were beginning to come forward. Dr. Jeffries, the president, might have represented some of the younger ones of the first set and Dr. Cabot, the vice president, the second set, an active body of men, giving an impetus to medicine which was distinctly felt at this period of the century and which was emphasized perhaps by the great discovery of anesthesia and also by a tendency to organization and to improvements in the methods of instruction. These men were succeeded by the older men present this evening, who wind up the century.

There are some little points in connection with the period in which this society was founded which I thought possibly might be interesting. I was able to gather some data from the life of Dr. Warren, and therefore I speak about him more than others, because it was more accessible to me. Dr. John C. Warren was retiring from active practice at about that time. He resigned his professorship in 1847. I notice in his biography allusion to a subject which is the forerunner of the modern study of cerebral localization — phrenology. Spurzheim came over to this country in the early part of the century. He was associated with Gall, and he gave lectures here on the subject of phrenology or craniognomy, as it was called at that time. He died in 1832, and at this period of which I speak, 1847, his collection was purchased by Dr. Warren and placed in the museum of the Medical College. It was a collection of some five or six hundred specimens of casts of heads and crania intended to illustrate the development of the brain and it was thought of interest and worthy of preservation as calling attention to the finer points in its anatomy.

Spurzheim endeavored of course to locate the functions of the brain with more accuracy than the data of that time justified, but it gave an impetus to scientific study which finally blossomed out into the modern science of cerebral localization.

There was a great deal of progress about the middle of the century. Cochituate water was introduced in 1848 into Boston, and largely through the influence of the physicians. It was also about this time, if I am not mistaken, that the cemetery at Mt. Auburn was founded, perhaps a little later than this, by Dr. Jacob Bigelow, and the sanitary condition of the city thus further improved. It was an interesting fact that the last visitation of epidemic cholera was the year following the introduction of water, that is, before the water probably had been generally brought into use, in June, 1849, and since then there has hardly been a case of cholera in this city. Gas was first introduced into Boston at about this period, and I base my knowledge of that fact upon the circumstance that the old house numbered 6 Park Street in which I lived, into which my father moved in 1845, was the first private dwelling into which gas was introduced, and there was a notice at the time in the papers of the fact.

The American Medical Association was founded in 1845, and it was in 1850 that the meeting was held in Boston. Dr. Warren was elected president of the association that year, and the following year the association met in Cincinnati, and as president he gave his address in that year. It was on the "Progress of Surgery," and the three principal facts that he thought important to dwell upon were the reintroduction of the microscope, lithotripsy and tenotomy. He alluded to the microscope of the old observers, and intimated that it had gone out of use for a long period, and was about being introduced again, more particularly for the study of medicine. Some of the old microscopes that Professor Ernst has shown in his interesting lecture on "The Development of the Microscope" were made about that period. I gave to Dr. Ernst an old microscope of Chevallier's make, which was evidently made in the forties, and was the first of a series which I had in my possession which have been imported from time to time since. I think the earlier observers with the microscope in medicine did their work shortly previous to this time in Europe. The second point to which he alluded was lithotripsy. The only way, of course, previous to the introduction of lithotripsy by Civiale was by cutting for the stone. I remember seeing Civiale when, a boy about ten, I was taken by my father to his country place in Paris, and recall a very benevolent and courteous old gentleman, who was looked upon then, throughout the world, as a great authority on the subject of calculi, and his method was considered justly as a great advance in surgery at that time. The only other topic the president had to mention in his address worthy of note was tenotomy. Tenotomy was really the pioneer of anti-septic surgery. Its great merit in that day was the possibility of using the knife without causing suppuration.

I myself personally am able to recall only little of that period. I do have a few dim recollections of those early times. More particularly there comes back to me the meeting of the American Medical Association in New York in 1853, when I went on there with my father. The meeting was graven deeply on my memory owing to the frightful accident that oc-

curred to the party returning. The bridge at Norwalk was open and the train, going at full speed, went into the space and was wrecked in the river, and some sixty lives lost. A number of physicians of this vicinity were in the train. Dr. Pierson, the grandfather of the present Dr. Pierson, of Salem, was killed. Dr. Lamb, of Lowell, was severely injured. Dr. J. Mason Warren, my father, I think was injured, though there was no recognizable trauma, in a way from which he never fully recovered.

These are some of the points which I have hastily gathered together which I thought would possibly be of some interest to the society. I think the true meaning of the foundation of this society lies in the fact that there was at the middle of this century a period of restlessness which found vent in organization, and which was worked out afterwards by the great development of the profession in this country. As Dr. Cabot has said, we have the great advantage over many other countries in being familiar with what they are doing besides with what we are doing ourselves, and I fully believe that this half century of active work will bring about its reward, and that we are now probably on the eve of having the world turn to us for study and for instruction.

DR. GEORGE B. SHATTUCK: After what you have already heard I feel more inclined to give you a little account of the trials of one who has been asked to address you tonight upon the aims, objects, aspirations and duties of the Suffolk District Medical Society than to attempt to give you any further history of that society itself. Your representative, Dr. Jeffries, when he came to see me some little time ago and suggested that I should be one of those who should attempt to say something to you this evening, observed, I think, that I was somewhat distraught between the appreciation of the honor and the consciousness of personal inability, and he proceeded to encourage me somewhat thus: "You will naturally of course be one of the last speakers [laughter], and it is a very desirable position to occupy, because, if you don't know anything yourself, you will have the advantage of being able to pick up something from what you have heard from the preceding speakers." (Laughter.) In fact, he led me to believe that my position would be somewhat that of the bee let loose in a garden just after the flowers have blossomed. (Laughter.) At the present moment, gentlemen, I feel more like the flowers which have been visited by the bee. (Laughter.) However, allow me to continue a little with the history of your speaker's efforts: having undertaken to say something to you, I thought it my duty to equip myself in some manner and I naturally, with my knowledge of its worth, turned to that present help in time of trouble, that repository of everything that a well-regulated medical man ought to know — you immediately see that I mean the *Boston Medical and Surgical Journal* (laughter) — and I thought I would look over its pages and see what the aims, objects and duties of the Suffolk District Society had been, or it had been proposed that they should be. In order to do that more advantageously I abstracted from the Boston Medical Library the volumes containing the history of that society during the first two or three years, hoping I should thus have this history all to myself, but in this justifiably selfish scheme already suspected, I had been frustrated before this evening came. Although

not being fully conscious of the extent of my failure to engineer a corner on the past records of this society, I was still prepared to give you an account of the *jeunesse orange* of this society, one incident of which our friend Dr. Jeffries has described — I have it all written down in my pocket — where this society in its extremely lusty youth attempted to do away entirely with another society, the Boston Medical Society, but was restrained happily in time, a time that preceded by only a few months another melancholy event in Boston's medical circles. After that the society got into some trouble by attempting to try its members for doing things which it did not approve of, but just as it found out that the Boston Medical Society was prepared to arrange the question of fees, it also found out then, I think, that the parent society, the Massachusetts Medical Society, had the function of trying the members, so it gave this up also and then evidently settled down to its genuine duties of discussing medical subjects and drinking coffee and eating cake, which it did regularly.

In looking over those first two or three years, I remember some of the subjects which are interesting which came up for discussion. Among other things I remember coming across the report of two different cases of ovarian cyst by two different distinguished surgeons of the time. One of them we may speak of as a natural operation for ovarian cyst. The lady fell down and the cyst was ruptured; a large amount of fluid was discharged from the bowels and the patient recovered. The other case we may speak of as an artificial ovariectomy. The patient, a young woman, had a very large ovarian cyst, as it is called; the operation was performed, and I noted the subsequent remarks that "owing to a broken constitution and the unfavorable character of the weather the patient died." (Laughter.) I notice among other subjects that were discussed in those first two or three years, one was the discoloration of the skin after the internal use of nitrate of silver in epilepsy; another was an account of the methods for preparing cod-liver oil and for selecting the best livers; another was a discussion of the best preparations of opium, and I notice that McMunn's elixir was spoken of as one of the very best and most recent and the methods for preparing it were specified; and then there was a paper, and I should judge a very good one, on the necessity not only for vaccination, but revaccination. And then I noticed, I think it was December 4, 1850, a few paragraphs to this effect: Dr. Bowditch related the case of a child who had a large amount of water in the right chest and who suffered from successive paroxysms of dyspnea, during one of which he died, and Dr. Bowditch added: "I then made up my mind if I ever had another such case I would open the chest."

There were various committees appointed. They seemed rather fond of appointing committees. They appointed fully as many as we do now, and I should judge that fully as much was effected. I dare say their committees would accomplish as much today as ours with reference to dust and asphalt and adjustable furniture for schools. One committee was appointed to report upon doing away with Latin nomenclature for written prescriptions, and to suggest a simpler method for written prescriptions. There was a committee appointed to report on the subject of criminal abortions and another to report upon cholera, and there were a variety of other subjects which they

took up. I also notice that there were a number of rather apologetic statements with reference to the want of a large attendance at the meetings (laughter) and speculations as to what would be the best methods to pursue in order to foment a more earnest attendance at the meetings, and that reminded me singularly of what I have happened to see going on within the last year or two with reference to other societies at the present time. At least human nature does not change; we may know more or we may know less, but men are the same and whether it is a new society that wants to become active or an old society that has become inactive and is in danger of dissolution, these same processes are going on among us. And still, whether the new society is active or the old society less so, I believe unquestionably that there is a very large amount of extremely good medical work done in our societies all through the year; and, year in and year out, and at the present time, certainly there is a sufficiently large number of medical societies. Nobody can complain, as they seemed disposed to complain at the time this society was founded, — nobody can complain that there is not a whereabouts for him to go where he may discuss with his confrères subjects of medical interest, or that he may not be able to take his choice between societies more or less aristocratic or democratic, more or less ascetic or otherwise. We have societies that have no meretricious adjuvants in the way of cake, coffee, beer and cigars, and others that offer those facilities for improved medical thought. (Laughter.)

Mr. President, I feel the truth of what your representative said to me when he encouraged me to come and say a few words to you. I think the position of those who speak last is an extremely honorable one. In fact, I cannot help comparing it to the position of the Old Guard at Waterloo, or the Black Watch or the Gordon Highlanders; those are the men who are always called in to disperse the meeting at the critical moment, and give a *coup de grace* to the proceedings. I shall rely upon you, Mr. President, to give the *coup de grace*, with full confidence it will be well done. But I regret that I am unable to make that comparison between the first president of this society and the last, with reference to their both being always courteous, always candid, always patient, and above all, always just. I had intended to make such a comparison, but I cannot. (Laughter.) I had also expected to close my remarks by wishing this society, in the language of my predecessor, Dr. Jerome Van Crowninshield Smith, editor of the *Medical Journal*, and Mayor of Boston, that it might live one thousand years, fifty of which have already passed, my wish being by just so much less audacious than his, but that wish I am unable to indulge in on account of our friend Dr. Jeffries, who has rifled the sweets of the flower garden. (Applause.)

DR. BURRELL: The Suffolk District Medical Society is indebted to the gentlemen who have addressed us this evening for presenting to us so vividly the beginnings of this society and the state of the medical profession in this community half a century ago. The progress that has been made is great and its contemplation should serve as an inspiration to us all. It is a proud heritage that has been given us by the Warrens, the Bowditches, the Bigelows, the Jacksons, the Shattucks and others.

Many of us are apt to think that a golden age has passed, but to me the future is full of suggestive possibilities. The great advance that has occurred in surgery, and which is coming in medicine, from the application of scientific methods has made many of us forget the history of medicine. The pressure of modern life makes the immediate present oppressive and does not give us an opportunity for contemplation and for a close analysis of the past which is so instructive. Youth is ever impatient with the conservatism of old age, and old age of necessity clings closely to that which is known and which is proven. As a profession we are passing through a volcanic period of activity in which traditions are swept away by iconoclasts who do not replace that which is known by absolute facts.

A healthy scepticism is needful in any body of men, but great and abrupt changes, while often attended by ultimate benefit, are, like war, destructive of peace and harmony. In surgery we are in danger of believing that asepsis can solve all and that the teachings of the past are no longer of value. In medicine an intelligent empiricism is being swept away by seductive laboratory exactness.

It hardly seems possible, gentlemen, that we should make the same advance in the next half century that has been made in the past, but one has only to look a bit into the future and read the signs of the times, to see here and there suggestive possibilities springing up of, for example, municipal sanitation, rational therapeutics, causation of cancer, advances from physiological chemistry, which suggest great and broad advance for the future.

One other word: It has been said, and with some truth, that there is danger of medicine becoming a trade. There have been and always will be members in the profession who have adopted and will adopt commercial methods, but we should look well to the future and protect most zealously the profession of medicine. The great questions of medical charity, of the establishment of hospitals, the relations of specialties to general medicine, the relation of laboratory men to the profession of medicine and medical education, should all excite our interest and engage our attention. And, gentlemen, in honor of the founders of this society, who zealously worked for suffering humanity, may I ask you to stand fast to the high standard which they established.

Recent Literature.

Laboratory Directions for Beginners in Bacteriology.

An Introduction to Practical Bacteriology for Students and Practitioners of Comparative and of Human Medicine. By VERANUS A. MOORE, B.S., M.D., Professor of Comparative Pathology and Bacteriology, New York State Veterinary College, and of Bacteriology, Cornell University Medical College, Ithaca, N. Y. Second edition, enlarged and revised. Boston: Ginn & Co. 1900.

The title of this book sufficiently indicates its contents. It is designed to be used as an aid in class work in elementary bacteriology. To the independent worker in the laboratory it will be of little value.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, NOVEMBER 22, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS.

NEWSPAPER MEDICINE.

RENEWED attention has of late been directed to the ever-present evil of exploiting medical matters in the daily press for the edification of ignorant readers. It goes without saying that not all papers descend to this method of exciting a morbid interest, but that some persistently continue in the practice is quite reason enough for calling out a general protest.

Reference to the *Philadelphia Medical Journal* for November 10th will show how futile Dr. W. W. Keen's efforts have been to prevent the garbled publication of his public operative work. Dr. Keen has published in full the correspondence between himself and a Philadelphia daily paper, which he does not mention by name. The circumstances were briefly as follows: Reports of one of his clinics had appeared in several of the papers entirely without his knowledge. He immediately wrote letters of protest to the editors of the principal papers, stating his position in the matter, that inasmuch as no pains are taken to exclude persons from such clinics, who come under the guise of medical students, it is quite impossible to be protected against designing reporters. He therefore requested that the editors should comply with his wish that no more such reports should appear. The result of this letter was satisfactory in all but one instance. In this one case Dr. Keen received an evasive letter, stating their desire to publish news accurately, and that to further this end they would be pleased to send a good reporter for a personal interview. To this Dr. Keen replied that his position had been entirely misinterpreted, that it was not the fact that the newspaper account was inaccurate, but that he objected to *any* report whatever bearing on professional matters. This letter was sent to the city editor with the urgent request that his wishes therein expressed be respected. Five days later a flagrant report of the old material appeared in the paper, rendered attractive to readers by illustrations, which, however, did not represent Dr. Keen's clinic. Dr. Keen now appealed to the proprietor of the paper, briefly stating the facts in the case.

The matter has temporarily ended with the following extraordinary statement, again from the city editor, that "future stories with which your (Dr. Keen's) name is connected will not appear until you have had the opportunity to make such statement in reference thereto as you may desire." To this Dr. Keen again replied: "You still misunderstand my objection. I do not wish any 'future stories with which my name is connected' to appear in the —."

We quote this experience merely as an example of what is continually happening in some form. Not long since, for example, an outrageous and wholly inaccurate report appeared in one of the Boston Sunday papers describing one of our best known hospitals for the insane, with the introduction of various photographic reproductions which further misrepresented the wholly erroneous statements in the text. The reputation of this particular hospital renders it quite able to ignore such attempts to pry into its management, a fact which naturally in no way alters the principle involved. The publication from time to time of the details of surgical operations done by eminent men is another instance in point, as, for example, in Dr. Keen's case. It is often said that certain men at least connive at this practice, an opinion which Dr. Keen's candid communication does much to controvert. It is clear that if a reporter be sufficiently unscrupulous and pertinacious he can always accomplish his end, of which the least important attribute is accuracy. That a physician is in fact wholly helpless in the matter is again shown by the fact that often when an interview is entirely declined, an account is subsequently published as coming from the physician. In a recent discussion on this subject a physician of high standing, whose work keeps him much in the public eye, asserted that he had on several occasions been represented in the daily press as expressing opinions in a given case which he had absolutely declined to discuss with the reporter. There is, however, a word to be said in justification, or at least in explanation, of the reporter's position in the matter. It must be remembered that a reporter is merely a servant of his paper, that the continuance of his connection with it depends upon his obedience, that if he be told to do some impossible or unreasonable piece of work, he is expected to do it, or at least to draw upon his imagination when his facts fail. Dr. Keen's correspondence brings out the true inwardness of the matter, showing, as it does, that the ultimate responsibility in every case must lie with the management of the paper concerned. This brings us to the vital question of the possibility of redress for this perfectly apparent evil. There is, to our mind, no immediate redress possible. The law has no jurisdiction in the matter and the attempt at greater secrecy in the performance, for example, of surgical operations would unquestionably increase rather than diminish the ardor of the enterprising disseminators of news. If the editorial staff and the management of a paper have reached such a depth of degradation that they are quite willing to publish bare-

faced lies to increase its circulation, it is clear that argument and moral suasion will be of small avail. We must go deeper, and if possible influence public opinion to such an extent that it will no longer tolerate such publications, and above all, as a profession, we must refrain from every suspicion of the desire for publicity in the conduct of our professional affairs. Were this completely done it is probable that the people at large would so far discount sensational newspaper reports that they would forthwith lose their interest. The more firmly established the ethics of the profession becomes in this particular the less probable will be its exposure to the caprice even of the most unscrupulous editor.

THE UNITED STATES TAX ON LEGACIES TO EDUCATIONAL, CHARITABLE AND RELIGIOUS ORGANIZATIONS.

MANY of our readers are probably aware that certain provisions of the War Revenue Act of 1898 lay a United States tax on legacies to educational, charitable and religious organizations. This tax rate was on a sliding scale, increasing up to 15 per cent. on estates of \$1,000,000 and upwards. When first collected the tax on legacies was levied at the rate fixed for the entire estate. The Supreme Court, however, has ruled that this was an improper interpretation of the provisions of the act, and that the legacy tax should be in a ratio to the amount of the legacy and not to the total amount of the estate. This mitigates in a measure the hardships imposed by an unfortunate and, it may safely be said, unwise provision. The country does not need the money, and the educational, charitable and religious organizations from which it is filched do. It is a most undemocratic form of taxation. It is our boast in this country that the individual citizen provides, and provides most generously, for the foundation and support of such organizations, whereas elsewhere they are, as a rule, dependent on the State. It indeed seems monstrous that under such conditions the State should prey upon the thoughtful testamentary dispositions made by its prosperous and enlightened citizens for their less fortunate fellows, and all the more monstrous when it is plain that the State does not require the money thus taken.

The next session of Congress will be devoted in part to the reduction of taxation under the War Revenue Act of 1898. The provisions to which we here refer should be repealed.

At the last meeting of the Congress of American Physicians and Surgeons in May at Washington, a committee, consisting of Drs. Frederick C. Shattuck, Abraham Jacobi and William H. Welch, was appointed with full powers to urge upon Congress such a repeal. A petition has been introduced in the Senate by Senator Lodge, and a copy is in the hands of the Hon. Sereno Payne, Chairman of the Committee on Ways and Means of the House. The Committee

of the Congress of American Physicians and Surgeons has issued a circular urging all their fellow members of that congress to exert their utmost influence with any members of the Congress of the United States to promote such a repeal. We desire to avail ourselves of this opportunity to make the same request of all members of the medical profession whom we can reach.

The only argument against such a repeal which has come to our attention proceeded from a venerable senator, now deceased, from a border Southern State, who stated with a somewhat brutal frankness that as there were practically no such legacies made to such organizations in his State, he considered this method of raising money for the expenses of the General Government a good one. About that same time the representative of at least one most deserving and useful institution in this senator's own State was seeking to raise funds in New England.

We should hope that this matter only requires that general attention should be directed to it to secure prompt and satisfactory action.

MEDICAL NOTES.

THE RECENT GALVESTON STORM.—The *Texas Medical Journal* devotes a considerable space in its October number to a consideration of the great storm of September which destroyed a large part of Galveston, Texas. The article is embellished with a number of photographic reproductions, which give the reader a vivid idea of the general devastation effected by the storm. It is a matter of interest that no physician was killed, in spite of the fact that the loss of life is estimated at 6,000.

REGISTRATION OF TUBERCULOSIS IN PHILADELPHIA.—A resolution recommending to the Bureau of Health the compulsory registration of tuberculosis has been adopted by the Philadelphia County Medical Society. This action is said to be the result of a paper advocating the registration of tuberculosis read by Dr. Hermann M. Biggs, of the Department of Health of New York.

PRECAUTIONS AGAINST DISEASE IN GREECE.—It is reported that the Greek health officers are requiring that the personal baggage of travellers, when unaccompanied by their owners, must, on arrival at any port in Greece, be accompanied by a certificate of origin, or a certificate from the health authorities of the port from which the baggage was shipped to Greece.

INCREASE OF CARCINOMA.—According to the *Philadelphia Medical Journal*, increase of carcinoma is engaging attention in Hamburg. In 1872 there was 1 case in 1,396; in 1898, in 1,022. An interesting point is that the mortality of males is increasing and bids fair to soon equal that of females.

BUBONIC PLAGUE IN CAPE COLONY, SOUTH AFRICA.—An outbreak of bubonic plague is reported

among the natives of Szinyoka, near King William's Town. Precautions are being taken to prevent the spread of the disease among the whites.

GLASGOW FREE OF PLAGUE. — A cablegram from U. S. Surgeon Thomas, at Glasgow, announces that the city is now declared free from plague.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, November 21, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 169, scarlatina 29, measles 24, typhoid fever 16.

BOSTON MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending November 17th was 190, as against 201 the corresponding week last year, showing a decrease of 11 deaths, and making the death rate for the week 17.67. The deaths from consumption were 26, pneumonia 19, whooping cough none, heart disease 10, bronchitis 3, marasmus 11. There were 15 deaths from violent causes. The number of children who died under one year was 35, under five years 60, persons more than sixty 33; deaths in public institutions 73.

ADDITION TO VINCENT MEMORIAL HOSPITAL. — A new building adjoining the one which has now been in use for about ten years is to be opened this week for the reception of patients. This extension of the work of the hospital will necessitate increased resources for its proper maintenance, which, it is hoped, may be forthcoming. It may not be generally known that Mrs. Vincent did not herself leave money to start the hospital. It was started by a friend, who gave \$1,000 as a memorial to Mrs. Vincent.

A CENTENARIAN. — Mr. John Knights, of Concord, N. H., died November 14th, at the reputed age of one hundred years and ten months. He was born in England, and became a United States citizen in 1835. He is said to have voted seventeen times for President, his latest choice being McKinley.

NEW YORK.

RELATION OF TUBERCULOSIS TO THE TENEMENT HOUSE PROBLEM. — The first public hearing by the State Tenement House Commission created by the last legislature was held in New York on November 16th, when the subject under discussion was "The Relation of Tuberculosis to the Tenement House Problem." Among those who spoke were Dr. Pryor, of Buffalo, and Drs. H. M. Biggs and S. A. Knopf, of New York. Dr. Pryor said that the two distinctive tenement house diseases were tuberculosis and rickets, and that in almost every tenement house in large cities there was at least 1 case of consumption. In speaking of remedies for the present conditions he said that at least 600 cubic feet of air should be allowed for each adult and that no rooms without sunlight should be occupied. Dr. Biggs stated that in one block on the East Side 144 out of 1,000 persons, and

in another 318 out of 2,000 persons, had died from consumption in the last four years. In regard to remedies, he thought it an error to make landlords build very expensive houses for poor people. The cost was ultimately borne by the tenants and that meant overcrowding. The chances of death from fire in a tenement house were infinitely less than the chances of death from consumption. He had no doubt that tuberculosis could be stamped out, for the reason that the disease was transmitted only by germs contained in sputa. Carpets and wall paper should therefore be prohibited in tenement houses. Dr. Knopf urged the desirability of having breathing places for the inhabitants on the roofs of tenement houses.

IMPROVEMENT OF MILK SUPPLY. — In response to the call of a special committee of the Medical Society of the County of New York, consisting of Drs. H. D. Chapin, A. Jacobi, J. E. Winters and W. Lester Carr, a meeting was held on November 16th, at the Academy of Medicine, to discuss informally the improvement of the milk supply of New York. The plan proposed by Dr. Chapin, the chairman, included the services of a competent bacteriologist, who should examine the milk furnished by such dealers as desired such examination, and on finding it up to the required standard issue a certificate to that effect. Such milk would always command a good price. The trouble often met with in the milk, he said, did not rest with the city dealers, but with the dairy farms, and it was the idea of the committee that when milk was found of inferior quality the dealer should insist on the managers of the farms correcting the difficulty. The proposed plan was now being followed in Buffalo and in Newark, N. J., and was working well. He also read a set of rules proposed for the guidance of dairymen in the care of cows, with precautions to be observed in milking. The meeting was attended by most of the prominent milk dealers of the city, and a number of them took part in the discussion. One of them made the statement that quantities of "embalmed" milk were sold in New York every day, and another exhibited circulars advertising "freezine" and "iceine," formaldehyde compounds which it was claimed would preserve milk for several days and which would "defy detection."

MORTALITY STATISTICS. — The Board of Health's reports show a slight reduction in the death rate of October (17.54) over that of September (18.46). This mortality indicates a satisfactory condition of the public health and about the same number of deaths as in October, 1899, when the death rate was 17.28. In the last week of the month the death rate declined to 16.39, the lowest figure reached since the first week in June last. The weekly average of deaths from scarlet fever and measles was only 2.5 and 2 respectively, and in the last week of the month, for the first time in the history of the Greater New York, not a single death was reported from the former disease. The weekly average of

deaths from diarrheal diseases declined from 149.75 in September to 51 in October, and of deaths from this class in children under five, from 135.25 to 44.5. The weekly average of deaths from whooping cough declined from 7.75 to 5.25, while that from typhoid fever remained the same, 24. On the other hand, the weekly average of deaths from diphtheria increased from 19.25 to 30.7; that from phthisis, from 129.75 to 169.25; that from pneumonia, from 82.75 to 122.5, and that from bronchitis, from 16 to 26.35. During the four weeks ending November 3rd, there were 172 deaths from cancer, a weekly average of 43.

ACUTE TRAUMATIC MALIGNANCY. — At the last meeting of the Medical Association of the Greater City of New York, Dr. Wm. B. Coley, in a paper on "Acute Traumatic Malignancy," reported a case of sarcoma ensuing upon trauma which ran its course in a remarkably brief period of time. In January, 1900, the patient, who was twenty-eight years old, received an injury to the right testicle, which was followed by a large swelling. When Dr. Coley first saw him, in February, he had already been tapped twice for supposed hydrocele. He made the diagnosis of hematocele, with possible sarcoma, and operated, when the growth was found to be a round-celled sarcoma. Later the patient was admitted to Dr. B. Farquhar Curtis's service at Bellevue Hospital, suffering from an abdominal tumor as large as a man's head and connected with the kidney, and he died on April 18th, only about three months after the injury to the testicle was received.

PARTIAL LOSS BY FIRE OF BUILDING OF CORNELL VETERINARY SCHOOL. — The main building of the Veterinary School of Cornell University, at Ithaca, was partially destroyed by fire on November 13th. The laboratory apparatus destroyed was valued at \$10,000 and the total loss by the fire was \$30,000, which is reported to be fully covered by insurance. At a special meeting of the Executive Committee of the Board of Trustees, held the same day, it was determined to construct a temporary roof over what remained of the Veterinary College, and, after some other hasty repairs, it was expected that the classes could be resumed on November 19th. It is stated that Prof. S. H. Gage and Assistant Prof. B. F. Kingsbury are heavy individual losers by the fire, the latter having lost the entire manuscript of a new textbook.

RECOVERY OF DAMAGES AGAINST A HOTEL KEEPER. — On November 13th the Court of Appeals affirmed the judgment of the lower court in the action of Sarah Lawson against William Eggleston, a hotel keeper in Dayton, Cattaraugus County. Mrs. Lawson recovered \$1,000 damages for injuries sustained by a gunshot wound inflicted by her husband and for the loss of means of support by reason of her husband having shot and killed himself. She alleged that the damages were caused while he was in an intoxicated and delirious condition which was brought about through the use of liquor sold to her husband by the defendant.

PASTEUR PREVENTIVE TREATMENT TO BE FURNISHED GRATIS. — It is announced that the Board of Health is to furnish gratis the Pasteur preventive treatment to victims of dogs believed to have rabies; and a special laboratory for the purpose will be established at the Willard Parker Hospital. According to Dr. H. M. Biggs, chief of the Bureau of Bacteriology, there have been 8 or 9 deaths from hydrophobia during the past year, a number greatly exceeding the mortality of previous years. Usually there have been only 2 or 3 deaths annually from the disease.

Miscellany.

SUICIDE AND HOMICIDE, U. S. ARMY, 1888-1897, 1898 AND 1899.

THE tabulations of the cases of suicide and homicide which occurred in the army during the years 1898 and 1899 are compared in the annual report of Surgeon-General Sternberg, now in press, with the cases which occurred during the ten years 1888-1897. Contrary to the general anticipation, it is found that there were among the troops during the past two years relatively fewer homicides than during the years of the previous decade, and that the mean annual ratio of suicides per thousand men was about two and one-half times greater during the decade of peaceful garrison life than during the recent period of active military service. The following figures show the rates for these years:

Year.	Mean strength.	Suicides.		Homicides.	
		Number.	Ratio per thousand.	Number.	Ratio per thousand.
1888	26,739	8	.30	5	.19
1889	27,206	21	.77	5	.18
1890	26,684	16	.60	7	.26
1891	26,460	22	.83	8	.30
1892	26,861	22	.82	5	.19
1893	27,659	22	.80	5	.18
1894	27,674	18	.65	10	.36
1895	27,326	19	.70	1	.04
1896	27,183	12	.44	4	.15
1897	27,374	10	.37	5	.18
Mean of decade.	27,116	17	.63	5.5	.20
1898	147,795	38	.26	19	.13
1899	105,546	30	.28	23	.22

RESOLUTIONS OF NEW YORK PATHOLOGICAL SOCIETY ON THE DEATH OF LEWIS ALBERT SAYRE, M.D.

IN the death of Dr. Lewis Albert Sayre the New York Pathological Society loses the last of the members who brought it into existence. The first meeting of the society was held in Dr. Sayre's office on June 14, 1844, Drs. George A. Peters and Middleton Goldsmith participating in the formation of the new society. Dr. Sayre kept his interest in the society alive, occasionally attending its meetings, until the end of his professional activity. It is with a special sense of loss that the society sees fade from its list of

active members this illustrious name, enrolled at its first meeting, when "the oldest pathological society in the world," as he was fond of saying, was created.

The New York Pathological Society now records upon its minutes the death of Dr. Lewis Albert Sayre, and adopts the following resolution:

Resolved, That the sympathy of the New York Pathological Society be extended to the family of Dr. Sayre in their bereavement, and that the above testimony be published in the current medical periodicals.

(Signed) W. P. NORTHROP, M.D.,
 JAMES EWING, M.D.,
 E. K. DUNHAM, M.D., } *Committee.*

Obituary.

DR. HENRY D. NOYES.

DR. HENRY DRURY NOYES, one of the most eminent oculists of New York, died at Mount Washington, Mass., on November 12th. He had been in failing health for some time, and had not returned to the city after the summer vacation. He was born in New York in 1832, and was graduated from the College of Physicians and Surgeons in 1855. He early devoted himself to the specialty in which he achieved such marked distinction. At the time of his death he was surgeon to the New York Eye and Ear Infirmary, and was professor of ophthalmology in the University and Bellevue Hospital Medical College, a position which he had previously held in the Bellevue College for many years before the consolidation of the two schools. He was also an ex-president of the New York Ophthalmological Society. Aside from his professional attainments, Dr. Noyes was widely known and very highly esteemed in the community.

Correspondence.

KIRKES' PHYSIOLOGY: A REPLY.

NEW YORK, November 16, 1900.

MR. EDITOR:—My attention has been called to the review of "Kirkes' Physiology" in your issue of November 8, 1900, and the reviewer's note which accompanies it. As certain charges have been brought which are not in accord with facts which the reviewer himself could have verified by referring to earlier editions, I ask that in simple justice you will grant me space for reply.

For errors of proof reading or failure in any instance to bring the text up to date, I have no excuses. But I must deny the implication that the present American edition is a compilation from a recent English edition, and the definite charges that figures have been "lifted bodily" from the English edition, and that I have pirated any portions of the text.

The reviewer will find the figures of blood crystals, which he charges me with "lifting," in the thirteenth edition, (1892), page 145 (published by Wm. Wood & Co.), which edition bears only the names of Mr. Harris and Dr. Baker on the title page. Moreover, he will find the similarities of text, of which he complains, between the present American and English editions to obtain also between the thirteenth American and the latest English editions.

It would have been fairer if the reviewer had confined himself to the field of legitimate criticism, or, transgressing that, at least had made sure of his facts before bringing such offensive charges.

Respectfully yours,
 WARREN COLEMAN, M.D.

METEOROLOGICAL RECORD

For the week ending November 10th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, NOVEMBER 10, 1900.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Diarrheal diseases.	Typhoid fever.	Diphtheria and croup

Deaths reported 2,281; under five years of age 699; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 554, consumption 291, acute lung diseases 274, diphtheria and croup 88, diarrheal diseases 72, typhoid fever 62, whooping cough 14, scarlet fever 14, cerebrospinal meningitis 9, erysipelas 2, measles 2.

From whooping cough New York 7, Philadelphia and Pittsburg 3 each, Boston 1. From scarlet fever Boston 5, New York 4, Philadelphia, Worcester, Somerville, Lawrence and North Adams 1 each. From cerebrospinal meningitis New York 6.

New Bedford 2, Boston 1. From erysipelas New York and Baltimore 1 each. From measles Boston and Worcester 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending November 3d, the death rate was 17.6. Deaths reported 3,908; acute diseases of the respiratory organs (London) 268, diarrhea 121, diphtheria 94, fever 81, measles 49, whooping cough 44, scarlet fever 36.

The death rates ranged from 9.1 in Norwich to 25.5 in Salford: Birmingham 20.9, Bradford 15.0, Cardiff 15.4, Gateshead 22.4, Huddersfield 15.0, Leeds 16.6, Liverpool 23.4, London 16.7, Manchester 22.4, Newcastle-on-Tyne 20.7, Nottingham 18.0, Portsmouth 15.5, Sheffield 21.2, Swansea 15.3, West Ham 15.3.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 17, 1900.

C. H. WHITE, medical director, placed on the retired list of the navy from November 19, 1900, having reached the age of sixty-two years.

R. S. BLAKEMAN, passed assistant surgeon, detached from the "Pensacola" and ordered to Naval Hospital, Mare Island, Cal., for treatment.

C. S. BUTLER, assistant surgeon, ordered to the "Independence."

W. A. MCCLURG, surgeon, ordered to additional duty on the "Yankee."

W. M. GARTON, assistant surgeon, detached from the "Indiana" and ordered home to wait orders.

A. R. ALFRED, passed assistant surgeon, detached from the "Castine" and ordered to the "Culgoa."

M. K. JOHNSON, passed assistant surgeon, detached from the "Celtic" and ordered to the "Brutus."

H. C. CURL, assistant surgeon, detached from the "Culgoa" and ordered to the "Castine."

E. DAVIS, assistant surgeon, detached from the Cavite Naval Station and ordered to the "Brutus."

W. L. BELL, assistant surgeon, detached from duty at Guam and ordered to the "Celtic."

B. L. WRIGHT, assistant surgeon, detached from the Naval Hospital, Cavite, and ordered to the Naval Hospital, Yokohama, for treatment.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOVEMBER 15, 1900.

CARTER, H. R., surgeon. Granted leave of absence for fifteen days from November 16th, on account of sickness. November 10, 1900.

STONER, J. B., passed assistant surgeon. To report at Washington, D. C., for special temporary duty. November 13, 1900.

GREENE, J. B., passed assistant surgeon. To proceed to Bremen, Germany, for special temporary duty. November 13, 1900.

MONCURE, J. A., acting assistant surgeon. Granted leave of absence for thirty days from December 15th. November 14, 1900.

SCHLAAR, W. F., hospital steward. To report to acting director of hygienic laboratory for duty. November 9, 1900.

SCOTT, E. B., hospital steward. Granted one day's extension of leave of absence. November 12, 1900.

MASON, M. R., hospital steward. To proceed to San Francisco, Cal., and report to medical officer in command for duty and assignment to quarters. November 12, 1900.

RYDER, L. W., hospital steward. Relieved from duty in the hygienic laboratory and directed to report to medical officer in command at Washington, D. C., for duty. November 9, 1900.

BOARD CONVENED.

Board convened to meet at Washington, D. C., Tuesday, November 13, 1900, for the examination of Assistant Surgeon L. E. COFER, to determine his fitness for promotion to the grade of passed assistant surgeon. Detail for the board: Surgeon PRESTON H. BAILHACHE, chairman; Surgeon G. T. VAUGHAN and Surgeon H. D. GEDDINGS, recorder.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.—The regular meeting of the society will be held at the Medical Library, 19 Boylston Place, on Monday, November 26th, at 8.15 P. M.

Papers: Dr. F. B. Lund will read a paper entitled "Acute Hemorrhagic Pancreatitis; Its Surgical Treatment, with a Report of Six Cases."

Dr. H. G. Beyer, U. S. Navy, will present a paper entitled "Experiment and Experience with the Rifle." This paper will be illustrated with lantern slides.

ARTHUR K. STONE, M.D., Secretary, 657 Boylston Street.

ST. LOUIS ACADEMY OF MEDICAL AND SURGICAL SCIENCES.—At the last meeting of the St. Louis Academy of Medical and

Surgical Sciences, Dr. Emery Lanphear was elected president, and Dr. O. L. Suggett, secretary, for 1901.

BOOKS AND PAMPHLETS RECEIVED.

Clinique Chirurgicale, Hôpital Necker. Par M. Mauclair.

The Digestive Power of Pepsin. By Benjamin T. Fairchild, New York. Reprint.

Biennial Report of the Department of Health of the City of Chicago for the Years 1897-1898.

The Materia Medica of Pichi. By Noah E. Aronstan, M.D., Ph.G., Detroit, Mich. Reprint. 1900.

Methods in the Diagnosis of Diseases of the Stomach. By Charles D. Aaron, M.D., Detroit. Reprint. 1900.

Two Unusual Cases of Surgery of the Trachea. By W. S. Jones, M.D., and W. W. Keen, M.D., Philadelphia. Reprint. 1899.

Report of the Surgeon-General of U. S. Navy, Chief of the Bureau of Medicine and Surgery, to the Secretary of the Navy. 1900.

The Surgical Use of Celluloid Thread. By W. W. Keen, M.D., LL.D., Philadelphia, and Randle C. Rosenberger, M.D. Reprint. 1900.

The Need of Hospitals and Training Schools for Colored People of the South. By Daniel H. Williams, M.D., Chicago, Ill. Reprint.

A Manual of Hygiene and Sanitation. By Seneca Egbert, A.M., M.D. Second edition, enlarged and thoroughly revised. Illustrated. Philadelphia: Lea Brothers & Co. 1900.

Diseases of the Tongue. By Henry T. Butlin, F.R.C.S., D.C.L., and Walter G. Spencer, M.S., M.B. (Lond.), F.R.C.S. Illustrated. London, New York, etc.: Cassell & Co., Ltd. 1900.

Cancer of the Stomach: A Clinical Study. By William Osler, M.D., and Thomas McCrae, M.B. (Tor.), of the Johns Hopkins Hospital, Baltimore. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

A Manual of Syphilis and the Venereal Diseases. By James Nevins Hyde, A.M., M.D., and Frank Hugh Montgomery, M.D. Second edition, revised and enlarged. Illustrated. Philadelphia: W. B. Saunders & Co. 1900.

The Surgical Treatment of Congenital and Pathological Disfigurements of the Face. Abstract of the Mütter Lectures of the College of Physicians of Philadelphia for 1900. By John B. Roberts, A.M., M.D. Philadelphia. 1900.

Rhinology, Laryngology and Otolary and their Significance in General Medicine. By E. P. Friedrich, M.D. (Leipzig). Authorized translation from German edited by H. Holbrook Curtis, M.D. Philadelphia: W. B. Saunders & Co. 1900.

The Care of the Consumptive: A Consideration of the Scientific Use of Natural Therapeutic Agencies in the Prevention and Cure of Consumption; Together with a Chapter on Colorado as a Resort for Invalids. By Charles Fox Gardner, M.D. New York and London: G. P. Putnam's Sons. The Knickerbocker Press. 1900.

Acute Yellow Atrophy of the Liver. Seven Brief Medical Papers: Floating Spleen. Fatty Cirrhosis of the Liver. Amyloid Degeneration of the Kidney. Typhoid Fever with Complications. Diagnosis in the Light of a Necropsy. Empyema. Infectious Diseases. By Stephen Smith Burt, A.M., M.D. Reprints. 1900.

A Manual of Chemistry, Inorganic and Organic, with an Introduction to the Study of Chemistry. By Arthur P. Luff, M.D., B.Sc. (Lond.), F.R.C.P., F.I.C., and Frederic James M. Page, B.Sc. (Lond.), F.I.C., Associate of the Royal School of Mines. Illustrated. London, Paris, New York and Melbourne: Cassell & Co., Ltd. 1900.

A Textbook of Histology, including Microscopic Technic. By A. A. Böhm, M.D., and M. von Davidoff, M.D., of the Anatomical Institute in Munich. Edited with extensive additions by G. Carl Huber, M.D., Junior Professor of Anatomy and Director of Histological Laboratory, University of Michigan. Authorized translation from second revised German edition by Herbert H. Cushing, M.D. Illustrated. Philadelphia: W. B. Saunders & Co. 1900.

A Case of Appendicitis in which the Appendix became Permanently Soldered to the Bladder, like a Third Ureter, Producing a Urinary Fecal Fistula. Report of a Case of Resection of the Liver for the Removal of a Neoplasm, with a Table of Seventy-six Cases of Resection of the Liver for Hepatic Tumors. Surgical Treatment of Perforation of the Bowel in Typhoid Fever, with a Table of 158 Cases. I. A Bullet in the Popliteal Space. II. A Case of Dilated Esophagus; Two Cases Showing the Value of the X-rays and at the Same Time that in the First Case they were Misleading. The President's Address delivered at the Fifty-first Annual Meeting of the American Medical Association, held at Atlantic City, N. J., June 5-8, 1900. The Ideal Physician. By W. W. Keen, M.D., LL.D., Philadelphia. Reprints. 1898, 1899, 1900.

ACUTE HEMORRHAGIC PANCREATITIS, ITS SURGICAL TREATMENT, WITH REPORT OF SIX CASES.

BY F. B. LUND, M.D., BOSTON.

During the little more than a decade which has elapsed since Fitz, in his classical monograph on "Pancreatitis" (Middleton-Goldsmith Lecture for 1889),¹ first adequately described the disease and classified its various manifestations into three forms, the hemorrhagic, the suppurative, and the gangrenous types, considerable attention has been devoted to it, both by clinicians and pathologists. Many interesting results have been attained by their assiduous labors, which will be but briefly noticed here, as it is the surgical aspects of the disease which the writer desires especially to consider. The deep situation of the pancreas in the abdomen, and its close anatomical relations to important organs of digestion and assimilation, and the main trunks of their arterial, venous and nervous supply, render its acute inflammatory affections of especial interest and proportionate difficulty, both from the point of view of medicine and surgery. From a medical standpoint the treatment of its acute inflammatory conditions can only be supportive and symptomatic. The possibilities and limitations of the surgical treatment of these affections it is the object of this paper to attempt to illustrate, as far as possible, by 6 cases taken from the personal experience of the writer, and of Drs. John C. Munro and W. P. Bolles, who have kindly placed 4 cases at the writer's disposal.

Case I, of Dr. J. C. Munro, was successfully operated upon in his private practice. As but 4 previous cases of recovery after operation have been recorded this case is of particular interest and value.

Case II, operated upon by the writer, in which the operation was performed as an emergency in the presence of signs of pneumonia, at the base of the left lung, and in which the patient lived eight weeks, coming successfully through a pneumonia, and finally succumbing to hemorrhage from an intestinal ulcer, also presents many points of interest concerning the surgical treatment of this disease.

Ten years ago Dr. Fitz saw the surgeon's opportunity in these cases in the drainage of the parapancreatic abscess which follows the hemorrhagic process, and is often associated with necrosis of the pancreas. A review of Cases I and II, which were both operated upon in the presence of a tumor consisting of blood clot and necrotic fat, on account of the progressive increase in the severity of the symptoms, would indicate that if lives are to be saved in the more severe forms of the disease, it will be too late to wait for necrosis and sequestration of the pancreas with abscess before operating.

Case IV is here in point. In this case, two weeks after the onset of the disease, the entire pancreas was necrotic, and areas of fat necrosis extended throughout the abdomen. Another argument in favor of early operation is the impossibility of absolute diagnosis. The surgeon is confronted with an acute epigastric peritonitis. It is not impossible in more or less typical cases to make a diagnosis, but in other cases it will be impossible, absolutely, to exclude perforating gastric ulcer, perforation of a gall duct, or duodenal ul-

cer. The presence of tumor some time after either of these conditions may be explained by the formation of a localized abscess in the lesser peritoneal cavity. It is impossible to exclude perforating gastric ulcer on account of the absence of a history of hematemesis, as was suggested by Dr. Fitz in his paper, for we now know that many cases of gastric ulcer have gone on to perforation without ever presenting the symptom of hematemesis, local tenderness, or any other symptom on which an absolute diagnosis could be made. These conditions present emergencies requiring immediate operation, delay involving spreading of peritonitis, burrowing of pus in the retroperitoneal space and other grave accidents, so that unless they can be excluded, exploration is imperative. If, therefore, we can show that in the alternative of acute pancreatitis with hemorrhage and fat necrosis, operation is also imperative, we have established the advisability of operating upon all cases of acute epigastric peritonitis not attended by such marked shock as to render the operation dangerous to life. In Case II the patient's general condition and the presence of a beginning pneumonia in the left lung rendered the question of operation a very serious one, and indicated the employment of local anesthesia, if possible. Yet in this case a rapid clearing out and packing of the cavity with gauze gave the patient immediate comfort, and distinctly benefited her condition for four days. Then she successfully went through a pneumonia, lived eight weeks after the operation, and in case the abscess had pointed, as it commonly does, in the lumbar region, and not perforated the diaphragm, would probably have been successfully drained and cured.

It must not be lost sight of that probably many mild cases of pancreatitis or peripancreatitis attended by less degrees of hemorrhage and by fat necrosis recover spontaneously by absorption and perhaps cicatrization. In the cases which have been reported as successfully operated upon by Osler² and Manges,³ the operation consisted in simply opening the abdomen, making a diagnosis of the presence of hemorrhage and fat necrosis and sewing the abdomen up tight.

If either of these cases, as did the case of Thayer and Finney or Cases I and II of this paper, had gone on to necrosis and sequestration of portions of the pancreas, and abscess formation, it is fair to assume that the history would have been different, and that further operation for evacuation and drainage of the abscesses would have been necessary to save life.

It seems probable that the cases that go on to gangrene of the whole or part of the pancreas and parapancreatic abscess are those which may be classed as of the second grade of severity: the most severe cases proving immediately fatal from hemorrhage and shock, those of the second grade, marked by severe symptoms at first, but going on to parapancreatic abscess and gangrene of the pancreas, and the milder cases recovering.

The symptoms of pancreatitis are described by Fitz as consisting of "sudden, severe, often intense, epigastric pain without obvious cause, in most instances followed by nausea, vomiting, sensitiveness and tympanitic swelling of the epigastrium. There are prostration, often extreme, frequent collapse, low fever, and a feeble pulse. Obstinate constipation

is the rule, but diarrhea sometimes occurs. If the case does not end fatally in a few days, recovery is possible, or the recurrence of the symptoms in a milder form takes place, and the characteristics of subacute peritonitis are developed." The presence of the tumor in the epigastrium was noted in 4 of the cases reported in this paper, though in most of them the presence of the stomach or intestine in front of the tumor rendered it tympanitic on percussion. In Case II the tumor, consisting of blood clot and necrotic tissue, presented against the anterior abdominal wall.

Etiology and pathology.—Acute pancreatitis has been considered rare in women, and of 41 cases collected by Körte⁵ in 1898, only 4 were women. Of the 6 cases reported in this paper, 5 were women. Three of the 5 women were extremely fat. In none was a history of alcoholic excess obtained. The ages ranged from thirty to fifty years. The presence of gall stones in the gall bladder and ducts was noted in 4 of the cases. In these cases it is impossible to say whether the previous attacks of epigastric pain and vomiting were due to milder attacks of pancreatitis or to gall stones. The presence of gall stones in a considerable number of cases of pancreatitis points to obstruction of the duct of Wirsung or abrasion of the walls of the ductus communis choledochus, with possible infection of the head of the pancreas, by which the duct is practically surrounded during the latter part of its course, as possible causes of the disease.

The presence of fat necrosis was noted in all the cases. The relation of fat necrosis to pancreatic hemorrhage and inflammation have been the subject of a great deal of study of late years. The most notable recent contributions to our knowledge of this process are those published by Flexner⁶ and Williams.⁷ Flexner regards the fat necrosis as the effect of the fat-splitting ferment of the pancreatic fluid, which in some way escapes from the duct into the surrounding tissues. The fat tissues immediately surrounding the pancreas are at first affected, but in acute or long-continued cases the process may extend all over the abdomen, or even to the pericardial fat. Fat necroses are not found in all cases of acute pancreatic disease, and have been noted during laparotomies for various abdominal conditions where no evidence of pancreatitis was found, but they are present in the vast majority of cases of acute pancreatic disease, and their presence is generally considered pathognomonic. They accompany especially the hemorrhagic form, and Flexner, in his experimental work, found disintegration of pancreatic tissue to be one of the results of free hemorrhage. He regards the necrosis of the fat tissue, as well as of the pancreatic tissue, as results of the escape of pancreatic secretion, due in its turn to the degeneration resulting from hemorrhage. Hemorrhage is to be regarded as one of the effects of inflammation of the gland, and when excessive, both in clinical and experimental cases, dominates the picture. The necrosis of fat and pancreatic tissue resulting from the hemorrhage may in time form foci for the action of micro-organisms and still further spread the process. The entrance of the micro-organisms responsible for the primary inflammation and hemorrhage probably takes place through the ducts.

It cannot be regarded as definitely settled that the

escape of pancreatic fluid is always the cause of pancreatitis in the human subject. In Case II of this paper, the autopsy showed a practically normal pancreas, having areas of fat necrosis extending in among the acini from the periphery, and no distention, inflammation, or other abnormality of the pancreatic duct or its branches. The pancreas removed after death in Case III also showed a process apparently extending inward from the periphery, and no discoverable abnormality of the ducts.

CLINICAL HISTORIES.

A brief account of the 6 cases upon which this paper is based, and résumé of the points which they illustrate, may well precede the deductions on the surgery of the pancreas, with which the paper will conclude.

CASE I. Summary.—Acute pancreatitis with fat necrosis. History of previous attacks. Operation one month after onset. Median laparotomy and lumbar incision for drainage. Immediate improvement. Second operation for drainage of pus pockets through lumbar incision five weeks later. Recovery.

Clinical History.

[From Notes of Drs. J. C. Munro and Henry Jackson.]

Mrs. S., age thirty-six, was seen by Dr. Henry Jackson, in consultation with Dr. Flanders, on March 4, 1899. As a girl, she had various symptoms suggestive of hysteria or a highly neurotic condition. Two years previously she had had three attacks of pain in the epigastrium, running through to the back; this pain she described as boring in character; accompanied by vomiting, but not by jaundice. Three weeks before she was seen by Dr. Jackson she had had an attack of severe pain in the epigastrium and left hypochondrium, relieved only by morphine, and accompanied by vomiting. No interference with the action of the bowels. The vomiting persisted for one week. She had

FIG. 1.

had moderate fever since the beginning of the attack, and a pulse 90 to 100.

On March 7th the woman was seen by Dr. J. C. Munro, from whose notes the following account is abstracted:

Physical examination showed a very corpulent woman suffering from pain, general abdominal tenderness and spasm, especially marked in both hypochondria and epigastrium. Tumor, as in shaded portion of Fig. 1, especially in left renal region and hypochondrium and over gall bladder. Leucocytosis. Pulse 120. Urine negative.

Diagnosis.—Probable rupture of gall duct with retroperitoneal abscess. Pancreatitis, and possibly abscess or tumor of kidney complicating gall stones, were considered.

Operation, March 8th. A long median incision was

made through the very thick abdominal walls in the epigastrium. The omentum, which was lightly adherent to the abdominal parietes, contained nodules of fat necrosis, which were also noted on the parietal peritoneum. On freeing the omentum, the pancreas was found swollen in the median line, and on the left enlarged so as to form a tumor, which felt hard and nodular. The finger was pushed into the tumor in various directions, in the hope of finding pus. The patient's condition at this time became alarming; the pulse rose to 180, and she became cyanotic. There was moderate bleeding from the fresh adhesions about the pancreas. An opening was made in the left lumbar region, using the finger as a guide, and the anterior wound closed with deep sutures of silkworm gut. Through the lumbar opening the tumor was broken up by pushing the finger in various directions, and a nodule removed, together with some omentum and fat necrosis. The wound was packed with iodoform gauze around a glass drainage tube, and a baked gauze dressing applied. The patient was in very poor condition at the close of the operation and was stimulated freely. During the night she rallied somewhat, though vomiting continually. At 10 A. M. on March 9th, the vomiting ceased, and the bowels moved. During the next few days her condition steadily improved. On March 12th, on removal of the gauze drains, there was a free greenish discharge, with fine fat globules.

On March 20th there was still considerable greenish discharge from the lumbar wound; the anterior wound had healed by first intention. There was no albumin nor sugar in the urine. The patient continued to improve, the wound discharging freely until April 8th, one month after the operation, when a rise of temperature to 103° took place, with vomiting and prostration. On the next four days the temperature ran between 101° and 105°, and the patient was nervous, restless and discouraged. On April 11th tenderness and a tumor were noted in the left renal region. While probing the sinus the probe passed through a thin wall into a cavity, with evacuation of several ounces of sweet, greenish pus of molasses odor, containing particles of broken-down pancreas and fat necrosis.

On April 15th, under ether, the sinus was enlarged and its posterior wall broken through, admitting the finger into several pockets containing greenish, sweet-smelling pus. These pockets reached to the median line, downwards along the posterior abdominal wall for 2½ inches, and upwards along the latter for 5½ inches, passing behind the stomach towards the epigastrium. A counter opening on a level with the floor of the pockets was made posteriorly in the left lumbar region and drainage with rubber tubes and gauze wicks was provided.

Following this operation there was a very free discharge from the sinuses. Subsequently this discharge became fecal, and was noted to contain certain particles of food eaten the day before it appeared in the discharge. This discharge ceased in about ten days and the patient steadily improved and went on to complete recovery, leaving the house for a ride on July 10, 1899. Her health ever since has been excellent.

Remarks.—This case is notable for the absence of pancreatic hemorrhage found at the operation. The location of the tumor and the presence of the fat necrosis, however, establish the diagnosis of pancreatitis. The serious condition of the patient at the primary operation emphasizes the necessity of rapid operating and simple procedures in these cases. The provision for lumbar drainage undoubtedly played a most important part in bringing about ultimate recovery, for the retroperitoneal pus pockets at the second operation were successfully drained through the lumbar incision, and it is difficult to see how this could have been accomplished otherwise, though Thayer's case recovered after drainage of the abscess through a median epigastric incision. It is probable in the lat-

ter case that the pus was confined to the lesser peritoneal cavity, and had not burrowed to any extent in the retroperitoneal space. Körte¹ in 1899 called attention to the importance of lumbar incision in retroperitoneal pocketing of the pus in necrosis of the pancreas with abscess formation, and describes 3 cases operated upon through a lumbar incision, with 2 recoveries. In this case lumbar drainage was provided at the primary operation, owing to the fact that the tumor extended into the left lumbar region, and this provision was later undoubtedly the means of saving the patient after abscess formation. The continued good health of the patient after the operation would show that there had not been sufficient destruction of pancreatic tissue to permanently interfere with its functions.

CASE II. Summary.—Acute hemorrhagic pancreatitis. Operation one week after onset. Evacuation through median and right lateral incision of blood and necrotic fat. Relief of symptoms followed by rise of pulse, temperature and respiration, with cyanosis. Dulness and râles over bases of both lungs. Exploratory incision in left lumbar region. Death eight weeks after operation from hemorrhage from erosion of an artery in wall of splenic flexure. Autopsy. Abscess in lesser peritoneal cavity, perforating diaphragm above spleen. No retroperitoneal or lumbar pockets. Perforating ulcer of splenic flexure of colon, with hemorrhage from an eroded artery. Perforating ulcer of jejunum.

Clinical History.

[Abstract from Hospital Record.]

N. G., thirty, single, dressmaker. Entered the City Hospital July 26, 1900. Service of Dr. H. W. Cushing. Three years ago had "indigestion" for about a year, followed by attack like present, but less severe; associated with abdominal pain, running into left shoulder; fever; vomiting. No jaundice; bowels regular; sick in bed two weeks. Has been well since. Gaining in weight. One week ago woke up with abdominal pain and vomiting. Says she was not feverish. No chill then or since. Pain

FIG. 2.

was crampy, and not localized. Vomitus bitter; no blood. Bowels moved with enemata and laxatives; dejecta just after onset were very light colored; since then dark; no blood noted. Vomited day after onset, but not since. Two days after onset, abdomen was distended and tender. Urine has been high-colored, never bloody. Since onset there has been shortness of breath, and deep breath has been painful. No cough or expectoration. Pain has remained about the same since onset; some pain in left shoulder.

Physical Examination.—Corpulent. Pupils equal and

react. Scleræ yellow. Tongue fairly clean. Temperature 100.8°; pulse 128; respiration 40. Heart's action somewhat irregular. Aortic second sound occasionally reduplicates. The first pulmonic is replaced by a soft murmur; pulmonic second not accented.

Lungs.—Fine moist râles in right back and axilla. On left back, near angle of scapula, there is dulness, diminished bronchovesicular respiration; increased voice sounds; fine crackling râles.

Liver.—Dulness begins at fifth space.

Abdomen.—There is muscular spasm and tenderness in the upper abdomen, especially on left. A firm, smooth, resistant mass is felt occupying the epigastrium, mostly to the right of the median line and extending down to level of umbilicus, where edge of mass is apparently felt. (Fig. 2.) Percussion note is tympanitic over this mass. There is slight distention. No free fluid could be demonstrated. No tenderness in lower abdomen. There is slight pitting of the ankles.

July 27th. Seen in consultation by Drs. Post and Jackson, who advised operation at once. The diagnosis was an abscess or inflammatory tumor in epigastrium, due to pancreatitis or localized abscess from perforating gastric ulcer.

Operation., by the writer, under local anesthesia with 1-1000 cocaine solution. Incision 5 inches long, median line above umbilicus. On entering the abdomen a tumor was felt just to the right of the median line, adherent by light fresh adhesions to the abdominal wall. Tumor could be felt to fluctuate. The patient was then etherized to the primary stage, and a second incision made just outside the outer border of the right rectus muscle. Finger was passed into the centre of the tumor, which was found to consist of necrotic tissue and blood clot. A considerable amount of blood clot was scooped out, and the cavity freely irrigated from one incision to the other. The finger reached the region of the pancreas. Gauze packing was attempted, but profuse hemorrhage required immediate removal, and repacking of the cavity, which controlled the bleeding. Incisions partially closed with silkworm gut. Patient stood operation very well.

July 28th. Fairly comfortable night. No vomiting. No cough. Bowels moved this morning. Pulse 148, respiration 52. In the evening was slightly distended, and complained of pain in lower abdomen. Analysis of urine. Albumin, slightest possible trace. Few blood globules. Hyaline and fine granular casts.

July 29th. General condition improved. Pulse 124. Respiration 40. Bowels moved freely. First dressing done; gauze soaked with bloody discharge, odorless; no evidence of suppuration.

Pathological report: Probably hemorrhagic pancreatitis or peripancreatitis, with fat necrosis.

July 31st. All wicks removed, except one in each incision. Considerable dark liquid blood followed removal of packing from lateral incision; quickly stopped. Wounds irrigated with salt solution. New wicks inserted.

August 1st. Remaining wicks removed. Irrigated from one incision through to other. Rubber drainage tubes applied. Discharge less. Continues to improve.

August 4th. Pulse 124, temperature 101°, respiration 35. There is a free discharge of brownish, thick turbid fluid, with numerous shreds from both incisions; odorless. Wound irrigated and dressed twice daily. Patient complains of some pain in left hypochondrium. Takes nourishment well and is receiving free stimulation. Oxygen when required for cyanosis.

August 6th. Twice since last date has had periods of delirium and unconsciousness with rapid pulse and respiration. This morning respiration is labored; patient cyanotic; tracheal râles. Temperature 101°, pulse 140, respiration 50. Signs of consolidation remain in the left lower lobe, coarse râles in both chests. In left lumbar region there is tenderness, slight bulging and dulness. On account of these signs an exploratory incision was made under cocaine in the left lumbar region. No pus was found in the retroperitoneal space; incision was packed.

August 13th. Condition rather better. Color good.

Temperature 99.8°, pulse 124, respiration 36. Discharge from abdominal incision is more free, and consists of a thick brownish material with numerous sloughs. Lumbar incisions clean and healing.

August 20th. Several large masses of sloughing tissue were washed out today.

Pathologist's report: Necrotic fat tissue with considerable hemorrhage.

August 24th. Pulse and respirations continue elevated; no cyanosis. No expectoration. Signs continue in left lower lobe. Today there is biliary fluid on the dressing. A piece of bowel in the lower angle of the right incision has perforated, allowing the escape of intestinal contents. Closed with Lembert sutures.

August 28th. Attempt to close fistulous opening unsuccessful and a second one has appeared just above the first. Discharge from incisions is diminishing in amount.

September 3rd. Tube omitted from median incision. Lumbar incision healed. Third incision presents deep sinus above, and two openings in exposed knuckle of gut below. Discharge is less in amount, stained with bile, and mixed with intestinal contents which escape from the fistulæ. General condition slightly improved.

September 5th. There is some digestion of the skin about the intestinal fistulæ.

September 10th. Patient appeared as well as usual this morning. Temperature 99°, pulse 120, respiration 44. Binder had just been unpinned preparatory to dressing, when blood was noted gushing from incision in right side. Patient was quickly blanched. Active bleeding stopped quickly. As soon as preparation could be made light ether was given; incision enlarged, and cavity packed with gauze. Foot of bed elevated. Salt infusion and stimulants were given subcutaneously. Patient reacted somewhat, but pulse gradually failed, and patient died at 1.45 P.M., eight weeks and three days after the operation.

Autopsy.—Dr. Steensland, three hours post mortem.

Body of a well-developed, very well-nourished woman, thirty years old. Healed operation incision in epigastric region in median line, and one in left lumbar region. Longitudinal incision 12 centimetres long in epigastric region to right of median line.

Peritoneal cavity: Extensive, firm, fibrous adhesions about the two epigastric incisions, involving chiefly the omentum between the transverse colon and the pyloric end of the stomach. From the skin incision a passage leads into the lesser peritoneal cavity. The walls of this passage and of the lesser peritoneal cavity have a dirty blackish appearance. The lower lobe of the left lung is firmly adherent to the parietal and diaphragmatic pleura. When these are separate, a hole in the diaphragm 6 centimetres in diameter, surrounded by blackish necrotic borders, is revealed. Through this is projecting a perfectly free blackish mass, about the size and shape of a normal pancreas. It probably passed up into the pleural cavity after the adhesions of the lung to the diaphragm were separated. On section it is blackish in color, and shows a few grayish markings, suggesting the lobulation of pancreatic tissue. The mass is soft, and of a somewhat pasty consistence. The cavity contains no fresh blood clot. The spleen is completely concealed by firm adhesions. When the splenic flexure of the colon is separated from its relation with the lesser peritoneal cavity its external surface appears blackish necrotic, and a hole in the wall 1 centimetre in diameter with blackish necrotic borders is found.

In the region of the operation incision over an area 4 centimetres in diameter the same blackish appearance of the external surface is seen. The wall is here much thinned, leaving practically nothing but mucosa. The pancreas is concealed by the same blackish discoloration. The left border of the liver is bound to the anterior wall of the stomach by firm fibrous adhesions. The general peritoneal surface is smooth and glistening, presenting no evidence of inflammation. Numerous fat necroses in the tissue surrounding the lesser peritoneal cavity, the largest 6 centimetres in diameter. Some are considerably harder than the surrounding fat.

Pleural cavities.—Upper lobe of left lung free. Few fairly firm fibrous adhesions over lateral and posterior surfaces of middle and lower lobes of right lung.

Lungs.—On section lower part of left lung darker in color than surrounding tissue, lax and apparently collapsed. Upper portion of left lung and all of right lung, pink and downy. No nodules at apices. On section some color presented. Mucosa of bronchi pale. Bronchial lymph nodes not enlarged.

Spleen.—On section, pale red, soft. Lymph nodules distinct, trabeculae indistinct. Considerable increase of pulp.

Gastro-intestinal tract.—Mucosa, except as described above, pale. Small intestine contains little bile-stained fluid material, with no evidence of blood. Transverse colon contains 50 grammes of fresh blood clot. Perforating ulcer of splenic flexure and another of upper part of jejunum.

Pancreas.—Probe readily introduced into pancreatic duct, which passes through the centre of practically the whole length of the pancreatic tissue. Mucosa of duct smooth and pale. Its orifice is in common with the bile duct. Pancreas extends from the duodenum to spleen and adrenal. It is apparently slightly smaller than normal. Pancreatic tissue is lax. On section color is more yellowish than normal, and the lobular markings are somewhat indistinct. In the intestinal tissue are a few fat necroses, the largest 5 millimetres in diameter.

Liver.—Weight, 1 280 grammes. Very pale, smooth and of normal consistency. On section very pale, lobular markings distinct. Gall-bladder filled with small gall stones and a small amount of normal appearing bile. Mucosa normal. Mucosa of common bile duct pale. No gall stones present.

Microscopic.—Subsequent careful examination by Drs. F. B. Mallory and H. C. Lowe of the mass so closely resembling necrotic pancreas projecting through the diaphragm showed that it consisted of nothing more than necrotic fat tissue.

Anatomical diagnosis.—Hemorrhagic peripancreatitis; fat necroses of pancreas; general subperitoneal fat necroses; necrotic mass in lesser peritoneal cavity (fat necrosis); aperture connecting left pleura and lesser peritoneal cavity; atelectasis of left lung; hemorrhage into colon; localized chronic adhesive peritonitis; cholelithiasis; perforating ulcer of splenic flexure of colon; perforating ulcer of upper part of jejunum.

Remarks.—This case presents many points of interest, and though resulting fatally, there can be no doubt that life was prolonged by the operation, and might have been saved had the abscess extended into the left lumbar region instead of perforating the diaphragm into the pleura.

The patient's condition on entering the hospital was so bad that a very grave prognosis was given, and, on account of the condition at the base of the left lung, it was decided to dispense with general anesthesia. When, owing to the necessity for a second incision and extensive manipulation, ether had to be given, the operation was performed as rapidly as possible, and on account of a really alarming hemorrhage the cavity had to be rapidly stuffed with gauze. A fatal prognosis was given immediately after the operation. The course of the abscess upward through the diaphragm points to an early infection extending probably to the left pleura, and perhaps accounting for the signs which were noted at entrance over the lower left back. The walling off of this process may have accounted for the process thought to be a pneumonia which followed the operation. If the lower left pleura had been drained by resecting a rib it is possible that the result might have been different. Pock-eting was expected, and looked for in the left lum-

bar region, but naturally not found. The abscess cavity lay well up under the diaphragm, and the mass of necrotic tissue extended through the hole in the diaphragm above the spleen.

The fact that enough nearly normal pancreas was left at the time of the autopsy to raise a doubt whether the disease was not almost entirely a peripancreatitis, with no permanent injury to the pancreas other than an extension inward from its periphery of a few areas of fat necrosis, would indicate that in case of recovery there would have been no permanent interference with the functions of the pancreas. The presence of gall stones in the case is noteworthy. The fact that the mass found at autopsy projecting through the diaphragm, and thought at first to be sloughing pancreatic tissue, proved on careful microscopic examination to be nothing more than necrotic fat tissue, points to the case having been one of peripancreatitis rather than pancreatitis. The normal condition of the ducts renders it difficult to account for the disease by the escape of pancreatic fluid. The discovery that this mass so closely resembling necrotic pancreas was really necrotic fat tissue casts a doubt on the reported cases in which patients have recovered after passing a necrotic pancreas by rectum. (Trafoyer, quoted by Chiari.) May not the so-called necrotic pancreas have been merely a mass of necrotic fat?

CASE III. Summary.—Acute hemorrhagic peripancreatitis. On fourth day, operation, in spite of severe prostration, on account of symptoms of epigastric peritonitis. Pancreas dark in color and surrounded by areas of fat necrosis. Incision and gauze drainage. Gall bladder and ducts noted to be full of stones. Death three and one-half hours after operation. Pancreas removed after death. Duct of Wirsung and central portion of pancreas normal. The connective tissue surrounding the pancreas infiltrated with blood. Areas of fat necrosis numerous over the surface of the pancreas, and diminishing rapidly toward the central portion, which was normal in appearance.

Clinical History.

[Abstract from Hospital Record.]

M. W., age thirty-one, housewife. Entered July 11, 1900, at 11 P. M.; service of Dr. H. W. Cushing. Has had three attacks which patient says were "similar to present," the first five years ago, the second eight months ago, the third three months ago. No one of these attacks ever so severe as present. Previous attacks were associated with abdominal pain, vomiting and fever; in one attack at least patient was jaundiced. (Patient too sick to give an accurate account of symptoms.) In interval, since last attack, has been well; able to eat anything; bowels regular; no pain.

The present attack began on July 6th, in the afternoon, with sudden, sharp pain, which started in the back, between the shoulders, and ran round to the epigastrium. Feverish, but no chill. No vomiting. Bowels moved naturally. The next two days was more comfortable; slept fairly well; went to a dispensary for treatment. On July 9th pain became much more severe. Fever continued. No chill. Vomited twice. Bowels moved a number of times following castor oil. Vomitus yellow and bitter. Dejecta loose, brownish, not particularly offensive; not bloody. Unable to sleep on account of pain. No cough; no pain in chest. Yesterday pain continued. Vomited once. Bowels moved once. Abdomen began to distend. Motions of breathing became painful. Obligated to lie on back, as every motion aggravated the pain. Today symptoms have continued. Distention has increased, but there has been no nausea or vomiting. Bowels have not moved

today, but patient has passed gas. Frequent eructations also of gas. Pain is a dull ache in back and abdomen. Not localized in any particular spot at any time, but in upper rather than in lower abdomen. Very restless; unable to sleep; mouth dry. Urine has been darker than normal, but not bloody; passed normally. Has noted no yellowness as in previous attack.

Corpulent; face dusky; eyes bright; pupils equally contracted. Tongue dry, with white coat. Whole surface of body covered with cold sweat. Hands and feet cold. Pulse 128, weak; temperature 101.4°, respiration 38, shallow. Slight yellowness of conjunctivæ. Heart sounds weak; no murmurs. Lungs negative. No edema of ankles. Abdomen markedly distended; generally tender, especially in epigastrium and left hypochondrium. Marked spasm in these regions. Slight tenderness and spasm over rest of abdomen. Distinct resistance in epigastrium as of a prominent tumor, which was tympanitic, as was the rest of the abdomen. Operation under cocaine proposed, but refused. Ether was therefore given at 3.30 A. M., July 12th. Operation by the writer. Incision 5 inches long, median line, above umbilicus. General peritoneal cavity normal. Transverse colon greatly distended. On tearing through transverse mesocolon, at the bottom of the lesser peritoneal cavity, there was felt the much thickened pancreas. Seen to be dark in color, and studded with areas of fat necrosis. A small amount of turbid fluid lay in the bottom of the cavity. Gall bladder and ducts contained a large number of small gall stones. On account of the serious condition of the patient nothing further was done than to insert rubber tube and three strips of gauze down to necrotic pancreas. Incision partly closed with silk. Patient left table in great shock. Duration of operation fifteen to twenty minutes. During and after operation, free stimulation by brandy, strychnia, atropine, digitalis and salt solution. Patient rallied slightly, but the pulse gradually failed, and she died three and one-half hours after the operation.

Remarks.—This case was operated upon for the reason that the symptoms suggested a general peritonitis, beginning in the epigastrium, and incision, irrigation and drainage in this event were thought to give a possible chance to the patient.

The operation showed that the prostration of the patient was not due, as thought probable, to a general peritonitis, but to a pancreatitis. This marked tendency to collapse and shock in this disease has been explained by various writers as due to the close relation of the organ to the solar plexus.

The result of the examination of the pancreas agreed with that of the autopsy on Case II, as showing that the case was a peripancreatitis rather than a pancreatitis, so to speak, and indicating that if recovery had taken place the pancreas would not have been sufficiently damaged to interfere seriously with its functions.

CASE IV. *Summary.*—Acute hemorrhagic pancreatitis in a male thirty-seven years of age, who had had previous attacks of epigastric pain. Seen by surgeon, Dr. W. P. Bolles, two weeks after onset of attack. Operation contraindicated by poor condition of patient. Death on third day after admission to hospital.

Autopsy.—Hemorrhagic pancreatitis with necrosis of pancreas and abscess in lesser peritoneal cavity. Extensive disseminated necrosis of subperitoneal fat. Cholelithiasis.

Clinical History.

[From Hospital Record.]

G. L. S., age thirty-seven, married, book-keeper, was admitted to the service of Dr. W. P. Bolles, on January 11, 1899. Four months before entrance had an attack of

gastric pain, vomiting and jaundice, lasting five days. Two months later a similar attack, lasting one week. Two weeks before entrance the present attack began with a dull ache in the right hypochondrium and vomiting, with prostration. After a week the pain and vomiting ceased, but retching continued. During the five days preceding his entrance he had two chills.

Physical examination.—Well developed, rather than thin. Abdomen somewhat distended and tympanitic, except for slight dullness in the flanks. Temperature 103.2°, pulse 124, weak. Slight tenderness to pressure in the right hypochondrium. The upper border of the liver was slightly higher than normal, and the lower border, though somewhat masked by tympany, was apparently somewhat lower than normal. The facial expression was dull and apathetic, and the patient looked very sick. On January 12th the bowels moved freely without cathartics. The patient was dull and slightly delirious at times. Movements semi-solid in consistency. He was seen by Drs. Jackson, Thorndike and the writer in consultation, and operation advised against, owing to the weakness of the patient. After a fairly comfortable night with slight fall in temperature the patient had a severe chill, followed by collapse, requiring free stimulation, on January 13th, the second day after entrance. He did not rally under stimulation, sank into coma, and died at 11 P. M. The diagnosis in this case lay between abscess of the liver and pancreatitis, inclining to the former. At no time during the patient's stay in the hospital was his condition good enough to permit of operation.

At the autopsy by Dr. F. B. Mallory, on making the first incision there were found small, yellow, opaque areas in the fat tissue of the abdominal wall just beneath the peritoneum. Similar spots from 1 to 4 or 5 centimetres in diameter were found all over the surface of the great omentum. They were slightly raised above the surrounding fat tissue, more or less circular in outline, with edges usually irregular. Similar areas were found in enormous numbers in the fat tissue beneath the lining peritoneum, everywhere in the abdominal cavity, being especially numerous in the mesentery. The lesser peritoneal cavity was found to be much distended, and filled with clotted blood and hemorrhagic fluid, almost a litre in quantity. At the bottom of the lesser peritoneal cavity was a dark, reddish-brown, friable mass, all that remained of the pancreas. The cavity had extended beyond the ordinary limits of the lesser peritoneal cavity on the left side over the kidney and apparently ruptured into the general peritoneal cavity, a reddish-gray fluid oozing up on carefully drawing up the coils of small intestine on the right side. In the general peritoneal cavity was a small amount of reddish-yellow exudate, most abundant in the pelvis. On opening the duodenum there was a thin place in the wall below the pylorus, at which point the contents of the lesser peritoneal cavity seemed just on the point of breaking into the duodenum.

The papilla of the common bile duct appeared normal, and no obstruction of any sort could be found in or near it. The gall bladder contained numerous small gall stones. The pancreas seemed to be destroyed right up to the wall of the duodenum. The fat capsule of the left kidney formed a part of the wall of the lesser peritoneal cavity. Yellowish areas, similar to those already described, were found throughout this fat tissue, both in front of and behind the kidneys. In the fat tissue on the left side below the kidney, along the outer border of the psoas muscle, was a great mass of necrotic fat. At the middle of the seventh rib on the right side and along the lower border of the tenth rib beneath the costal pleura were areas of necrosis.

Anatomical diagnosis.—Necrosis of pancreas with hemorrhage; acute peritonitis; cholelithiasis.

Remarks.—In this case the only one in the series in a male patient, we have the presence of gall stones and a history of previous attacks. In the two weeks which elapsed before the patient entered the hospital, necrosis of the entire pancreas with diffusion of

patches of fat necrosis over the entire peritoneal cavity and extensive suppuration in and about the lesser peritoneal cavity had occurred.

It does not seem impossible that if operation had been performed early, after the primary shock of the beginning of the attack, perhaps, but before the process had become so extensive, and if adequate drainage had been provided and maintained, a fatal issue might have been averted. Certainly if operation is to be of avail in these cases it must be performed before the process has become as extensive as it had in this case when he first came under observation.

CASE V. Summary. — Localized necrosis of pancreas with fat necrosis. Exploratory laparotomy on third day of disease. Diagnosis of appendicitis or epigastric peritonitis of unknown origin. Evacuation and drainage of small abscess of the pancreas. Death on third day after operation. No autopsy.

Clinical History.

[Abstract from Hospital Record.]

K. T., age forty-five, a widow, was admitted to the service of Dr. H. W. Cushing on April 20, 1899. Her previous history showed that she had had eight normal deliveries and suffered from a hernia. During the last six years she had had repeated attacks of abdominal pain, constipation and vomiting, lasting several days. Two days before entrance she was seized with severe abdominal pain and vomiting. The second day of the attack the pain had become more on the right side, and the vomiting was severe and continuous; the abdomen became tender and she had a chill.

On entrance she was found to be fairly well nourished, sick and apathetic in appearance. The temperature was 99° and pulse 100. Tongue slightly coated. Constant vomiting of greenish material. Abdomen distended and generally tender, though this symptom was most marked in the region of the gall bladder and the left iliac fossa. There was muscular spasm on deep pressure. No tumor was made out. Vaginal and rectal examinations were negative. The following night the bowels were moved by an enema, and considerable gas was passed. On April 21st, the third day of the attack, there was slight tenderness over the entire right side of the abdomen, most marked over the region of the appendix. There was also marked tenderness in the epigastrium, and percussion in this region showed a tympanitic area suggesting a dilated stomach. The patient was seen in consultation by Dr. C. F. Withington, and operation advised. Exploratory laparotomy was performed by Dr. J. C. Munro. Through a short median incision below the umbilicus the appendix was found apparently somewhat thickened, lying high, under the border of the liver, slightly adherent. It was ligated and removed. Then a careful examination of all the intestines was made for constriction, during which a smooth tumor, pulsating with the aorta, was found in the position of the head of the pancreas. An incision was then made in the epigastrium, by which the adherent colon was accidentally opened, and closed at once with silk. Then the omentum and intestines were packed off to allow a view of the posterior peritoneum and a gray diphtheritic patch found on the peritoneum over the tumor, which was punctured with a director, allowing the escape of a little sero-purulent material and fat necrosis. A cavity in the pancreas the size of an English walnut, which lay beneath this patch, was curetted and drained with a glass tube. The epigastric wound was packed with gauze around the tube and the other wounds sutured. The operation was well borne. Free stimulation and cathartics were the line of treatment after the operation, and the following day the patient's condition made marked improvement, and the bowels moved. The second day after operation vomiting began, and the general condition grew worse. Death occurred at noon of the third day following the operation.

Cultures from the abdomen at the time of the operation were sterile. Examination of the material removed from the cavity in the pancreas showed fat necrosis.

Remarks. — This case is interesting as presenting grave symptoms depending on a localized necrosis rather than a general inflammation of the pancreas. It is unfortunate that no autopsy was obtained, as much light might have been thrown on the condition of the pancreas and surrounding organs.

CASE VI. Summary. — Pancreatitis. Severe attack with marked prostration. Prodromal symptoms for three days. Operation on fifth day, for symptoms suggesting a general peritonitis. Death on the operating table. Imperfect autopsy showed peritoneum studded with areas of fat necrosis.

W. N. M., fifty, married, housewife, was admitted to the City Hospital, service of Dr. H. W. Cushing, May 4, 1898. Eight days before entrance she began to suffer from indigestion and heartburn. Five days before entrance was suddenly seized with intense pain in the region of the gall bladder, which lasted several hours, and required three-quarters of a grain of morphia. She vomited several times. After the subsidence of the pain tenderness remained, but gradual improvement took place till the day before entrance, when the pain returned, attended by vomiting and prostration. Today the prostration has increased and fecal vomiting begun.

Physical examination. — General distention of abdomen, and slight general tenderness, without marked spasm. The face is anxious, pulse rapid, but of fair strength. Slight edema of legs. Urine normal. Dr. Munro operated under ether. The patient took ether badly; became cyanotic, with constant fecal vomiting. An incision 4 inches long was made through the anterior abdominal wall, and exploration begun, when the patient suddenly collapsed and died, in spite of energetic stimulation, etc.

A hasty examination after death showed a mild general peritonitis, and the parietal peritoneum and mesentery were found studded with fine white dots. Fresh adhesions were found everywhere. Several of the white dots were removed, and on microscopic examination reported by Dr. F. B. Mallory to show fat necrosis.

GENERAL SUMMARY.

Six cases of pancreatitis in patients between thirty and fifty years of age, 5 of them women and 4 having also gall stones.

Definite diagnosis was made in no case, the diagnosis being approximated three times (Cases I, II and IV). Operation in 5 cases. One recovery. One death two months after operation from inadequate drainage. Two deaths from shock. Operation declined by surgeon in the single non-operated case owing to poor condition of patient.

VARIETIES OF THE DISEASE.

Cases II and III should be properly classified as peripancreatitis; Case IV, as necrosis of the entire pancreas, which followed undoubtedly upon a hemorrhagic pancreatitis. Case V was a localized necrosis of the pancreas resulting in abscess.

REMARKS ON DIAGNOSIS,

as illustrated by the 3 cases seen by the writer, Cases II, III and V:

(1) In differentiating from perforating gastric ulcer we find the pain not quite so sharp, and the tenderness on light pressure not so acute. Moderate tenderness on deep pressure has characterized the cases of pancreatitis; acute pain on light pressure, the cases of perforating gastric ulcer.

(2) The sensation of fulness, as of a tumor in the epigastrium overlain by the stomach, has been noted in all the cases observed by the writer, and in Case I observed by Dr. Munro. In Cases I and II a tumor could be definitely delimited.

(3) Muscular spasm was not so marked in these cases as in perforating gastric ulcer or acute appendicitis. In both perforating gastric ulcer and pancreatitis we have localized epigastric tenderness and spasm, but both more marked in the former than the latter condition. This comparison is based on the personal observation of 4 cases of perforating gastric ulcer verified by operation, which have been observed by the writer in the last eighteen months.

An absolute diagnosis is generally impossible. The diagnosis narrows down to an acute peritonitis originating in the epigastrium, which, from whatever cause, demands exploration of the abdomen.

CONCLUSION AS TO THE SURGERY OF PANCREATITIS.

Milder cases of acute pancreatitis or peripancreatitis recover both with and without operative intervention. Severe cases require operation, which should be performed early, for the following reasons: (1) Because the primary hemorrhage in itself (Flexner) leads to necrosis and disintegration of gland tissue, and the hemorrhage may be stopped and further necrosis both of fat and gland tissue prevented by gauze packing and adequate drainage. (Cases I and II.) (2) Because the patient is in far better condition to withstand an operation early in the disease than later when weakened by suppuration in the lesser peritoneal cavity, and necrosis of much fat and gland tissue.

A certain class of cases in which the primary shock is so severe as to render operation out of the question must be excepted from the operative cases.

The mortality from pancreatitis will undoubtedly be high, but there is reason to hope that with early operation and adequate provision for lumbar drainage it may be considerably diminished.

REMARKS ON TECHNIQUE.

As the diagnosis must, in a large percentage, be tentative, the first or exploratory incision should be made in the median line above the umbilicus. This incision may, in severe cases, be made with advantage under local anesthesia. On account of the weak condition of most of the patients rapid operating is essential. The great omentum must be traversed to reach the lesser peritoneal cavity. Masses of blood clot and necrotic fat should be rapidly evacuated. Further hemorrhages may be stopped by gauze packing. It will be generally impracticable to search for bleeding points.

Where the mass of blood clot or the abscess cavity has extended into the left lumbar region, adequate drainage must be provided by a lumbar incision made on the finger passed into the cavity. This dependent lumbar drainage is probably the most important step of the operation, since in the majority of cases it will probably not be possible to drain successfully through a median incision, as was done by Finney in Thayer's case. In case symptoms at the base of the left pleural cavity point to pocketing of pus above the spleen, the subphrenic space should be drained by resecting the tenth or eleventh rib in the posterior axillary line. The pleural cavity will be opened, but will be probably walled off by adhesions. At any

rate, drainage of this pocket is essential, in order to avoid perforation of the diaphragm by the abscess, which happened in Case II. Drainage of the sub-diaphragmatic space above the spleen would probably have saved this patient, as the upper part of the pleural cavity was walled off. Careful diagnosis, rapid operating and careful nursing will be necessary to save these cases, as the proximity of the inflammatory process to the solar plexus, the diaphragm, heart, lungs, stomach and duodenum, together with the deep situation of the pancreas, all contribute to make its inflammation so dangerous and difficult as to tax to the utmost the art and skill of the surgeon.

OBSERVATIONS UPON THE SYMPTOMS AND TREATMENT OF HYPERACIDITY OF THE STOMACH.¹

BY HENRY F. HEWES, M.D., BOSTON,

Physician to Out Patients at the Massachusetts General Hospital;
Instructor in Clinical Chemistry, Harvard Medical School.

THE study of the diseases of the stomach has convinced practically all observers that a common cause of disturbance of function and of symptoms in these maladies is a disorder in the secretions of the organ.

Variation from the normal in the secretions, usually an excess or diminution in the quantity of the secreted hydrochloric acid, is a common associate of these disorders. Thus of 300 cases of gastric disorder in my clinic, 159, or 53%, had an abnormality in this respect.

This abnormality may be in some cases an associate, perhaps a result, of distinguishable organic lesions of the stomach, as ulcer, cancer, chronic gastritis, motor insufficiency. It may be the only abnormality among the physical signs discoverable by our methods of examination, existing as the evident and only apparent first cause for symptoms. In both sets of cases it may be a secondary condition and may have no influence in the production of symptoms. Thus we see individuals with marked diminution in the hydrochloric acid secretion leading healthy lives without symptoms of gastric disturbance, the digestive function being sufficiently performed by the intestines. In a considerable number of cases, however, these abnormalities in acidity, whether primary or secondary, have apparently a distinct influence upon the functions of the organ and upon the production of symptoms.

Evidence of this connection between chemical ab-

¹ Read before the Boston Society for Medical Improvement, October 29, 1900.

normalities and symptoms is seen in all varieties of disorder of secretion, but is most marked in that class of cases in which the acid secretion is increased, the cases of hyperacidity, or hyperchlorhydria. Here, especially in the cases in which the excessive acidity is the only abnormal physical sign discoverable, the cases of uncomplicated hyperacidity, this influence of the acid excess upon function and upon the production of symptoms can readily be studied.

During the last two years I have had the opportunity to study 58 cases of this uncomplicated hyperchlorhydria. The symptoms and symptomatologies in these cases were as follows: The most constant symptom was distress. If we include pain, burning sensation, nausea and a sense of unrest under this heading, we may say that distress was present in practically all cases. A large majority of cases described the distress as a sense of uneasiness in the stomach as if the food did not sit comfortably, or as a sense of emptiness. In the more severe cases the distress was spoken of as cramp-like pain or a burning sensation spreading over the whole epigastric and sternal regions. The distress appeared within thirty minutes of ingestion in 21 cases. In several it occurred immediately upon ingestion. In 37 cases it occurred from one to three hours after food, in most of these in the third or fourth hour. The next symptom in point of frequency was the raising of gas or the desire to raise gas. This occurred in 50 cases. As a rule it came with the distress. Heartburn occurred in 25 cases. Pyrosis, or raising of acid contents or fluid into the mouth, occurred in 20 cases. As a rule this occurred one to three hours after ingestion of food. Vomiting occurred as a regular or occasional symptom in 17 cases. In some the vomiting occurred with the other symptoms, soon or late after food. In some it occurred in the morning before food. Regurgitation was often described as vomiting and the diagnosis of this symptom necessitated careful questioning. Relief of symptoms by food was a characteristic of 30 cases, practically all cases in which the symptoms appeared long after ingestion of food.

In addition to these symptoms, which were drawn from the experience of the patient, it was possible to obtain a further most important characteristic of these cases by experiment, the characteristic of relief of symptoms by ingestion of an alkali. This characteristic was present in a large majority of the cases. Of 48 cases in which the experiment was tried, this symptom was present in 45. It was constant in all the cases in which symptoms occurred as late as one hour after food.

In addition to the above local symptoms, several of a general nature were frequent associates of the cases. Of these, two, headache and nervousness, were such frequent associates and disappeared so regularly with the relief of the gastric condition that it seemed probable that they, like the local symptoms, might be resultants of the hyperacidity. The headache was as a rule frontal, occurring during the forenoon, often disappearing as the day wore on.

The combinations of symptoms or symptomatologies in the cases varied as much as the symptoms. The most striking symptomatology which occurred in any number of cases was the following: Distress, pain or a sense of unrest coming on two hours or so after eating, associated with some eructation of gas and heartburn and occasional raising of acid contents

into the mouth; relief of symptoms by ingestion of food or an alkali. This is the so-called typical symptomatology of hyperacidity of the stomach. It occurred in 16 of my cases.

The combination of distress, eructation of gas, heartburn, occurring within a half hour after food, and relief of symptoms by alkali, occurred in 5 cases. Pyrosis occurred in 4 of these.

In the 33 remaining cases the symptomatology consisted of distress plus eructation of gas or desire to raise gas, with relief of symptoms by soda. In 14 of these cases the symptoms were within one hour, in 19 later. Relief of symptoms by food occurred in all these latter cases.

This review of the symptoms of these cases of hyperacidity brings out some interesting facts in connection with the diagnosis and understanding of this condition. It shows, in the first place, that the combinations of subjective symptoms or symptomatologies which are associated with this single cause in these cases of hyperacidity are far from uniform, and that they are in a majority of the cases not diagnostic or even suggestive of the underlying condition. That is, they are not such as would help us to determine in our case whether we were dealing with hyperacidity or with one of several other affections of the stomach. For the combined symptoms of distress and eructations of gas which formed the whole symptomatology of over half the cases are, as a careful study of other gastric disorders has proven to me, the symptoms of a majority of all affections of the stomach from whatever cause.² As to whether the symptomatology in these cases of hyperacidity is ever diagnostic, I should say that it was so in about one-fourth of the cases. The combination of symptoms, distress occurring from one to three hours after meals, associated with heartburn and pyrosis, relief of symptoms by ingestion of food and by alkalies, is when found in its entirety very suggestive if not absolutely diagnostic.

This is the typical symptomatology of hyperacidity given in most textbooks. It is, as you see, but an occasional associate of the disorder, occurring in but 16 of my cases. Where it is proved to be present by experience with the case, not merely by the history of the patient in reply to your questions, it may be taken as diagnostic of hyperacidity (not of course necessarily of uncomplicated hyperacidity) to the extent of warranting treatment upon the lines of this diagnosis. The occurrence of such a symptomatology in any other affection is certainly extremely rare. The combination of symptoms which occurred in the cases remaining after the exclusion of these 16 typical cases and the 33 cases with the symptomatology common to a majority of all cases of gastric disorder, distress, heartburn, pyrosis, occurring soon after food, relief by soda, is strongly suggestive of hyperacidity, but not as much so as the first group. It is more common in hyperacidity than in other conditions, but does occur fairly often in hypoacidity and hypomotility cases.

Certain of the separate symptoms have some diagnostic importance, but less than that of these symptomatologies or combinations of them. Distress is of course a symptom common to all stomach disorders. In a majority of cases of gastric disease it occurs soon after ingestion of food. Distress occurring long after

² Howes: A Study of the Nature and Significance of Symptoms in Disorders of the Stomach, Boston Medical Journal, May 17, 1900.

food is, however, found in cases of hypoaclidity and hypomotility as well as in hyperacidity. The distress of hyperacidity is more apt to be described as a distinct pain or a gnawing sensation than is that of other affections. Eructation of gas is common to all gastric affections. Heartburn is more common in hyperacidity than in other conditions, but may occur in some people with normal or low acidity. Pyrosis is uncommon save in hyperacidity and is a very suggestive sign. It was, however, described as a symptom in several cases of normal and low acidity which did not yield to treatment for hyperacidity. Vomiting is not more common in this than in other affections.

Relief of symptoms by alkalis is a practically constant symptom of hyperacidity—the only one. It does occur, however, in other conditions, as, for example, nervous conditions and hypoaclidity, and is not diagnostic. Its absence would be evidence against hyperacidity. Relief of symptoms by food is by no means a uniform symptom of hyperacidity. It is very rare in other conditions, but does occur. When found it is very suggestive of hyperacidity, and shares with pyrosis the property of being the most suggestive of all symptoms of this condition.

In regard to the diagnosis of our condition, then we may say that it can be diagnosed with fair accuracy from the symptomatology in from one-fourth to three-eighths of the cases. In the remaining five-eighths the symptoms give us no assistance. Here we must depend upon symptoms plus chemical findings. And the condition can be absolutely diagnosed in any case only by a study of both symptoms and chemical findings.

The treatment of this clinical condition of hyperacidity of the stomach is based upon this knowledge of the cause and its effects which we gain by such an experimental study of the condition. In these cases the exciting cause, the excess of acid, acts to produce disturbance and symptoms, to my mind, in several ways. In the first place, it may irritate the membrane of the organ, causing pain or distress, peristaltic unrest, regurgitation, heartburn, pyrosis. It inhibits the digestion of starches by the ptyalin of the saliva, and may then tend to the accumulation of starch in the stomach. It acts upon the motor processes of the stomach, often diminishing the activity, even causing spasmodic contraction of the pylorus, so that retarded emptying or stasis of the contents may result. All these effects, the irritation of the acid, the affection of the motility, the retardation of starch digestion, may have results in causing symptoms, the distress, eructations, heartburn, vomiting. The affection of motility may cause stasis of contents, when dilatation or fermentation by yeast or sarcinae may occur.

In addition to and through those specific disturbances of function, the disorder has detrimental results to the body generally. As a result of the distress accompanying the act of digestion the patient eats less food than necessary. This, with the nervous influence resulting from the irritation and disturbance, affects the nutrition of the body. As a result the health is impaired, the nerve tone affected and the stomach made even less able to gain upon its disease. The irritation of the acidity also has disturbing effects upon the nervous system which doubtless tend to perpetuate the increased secretion of the stomach and the intolerance of food.

In addition to the above specific source or sources

of disturbance or symptoms in these cases, we have to consider still another element which may be present as a pathological condition influencing the disorder, namely, the relative hyperesthesia of the patient. A close study of our cases reveals the fact that the severity of the disturbance of function or symptoms is not proportional to the quantity of acid present. Cases with great excess may have symptoms milder than those with very slight excess. We not uncommonly see cases of clinical hyperacidity yielding to treatment of this affection in which the quantity of acid is normal for the average individual. Furthermore, in treating certain cases of hyperacidity we find that after cure of all disorders the quantity of acid remains the same or above the normal limits.

These facts suggest that in certain cases increased or abnormal susceptibility of the patient to the secreted acid is a causative element in the case. This is, perhaps, the case with those individuals who suffer with normal amounts of acid, and probably with those who, when cured, still retain the excess of acid. These cases might better be termed gastric hyperesthesia. In treating them, by building them up, or by neutralizing the acid which tends to maintain the sensitiveness, we relieve the hyperesthesia and stop the symptoms. It is probable that this element of hyperesthesia enters to some extent together with the acid excess as a factor in the disturbance of many of the cases. And thus in developing our method of treatment we must bear in mind these two causal conditions, the excess of acid with its irritation, and its influence upon the motor and digestive functions of the stomach, and the possible hyperesthesia of the patient having its origin in the nutritional or nervous condition of the patient. In this treatment we attack our case along both lines. We aim (1) to reduce the acidity of the contents, and (2) to increase the resistance of the patient to the acid, that is, improve the nutrition and nerve tone. Practically we find that an attack along either line is beneficial for both purposes.

To reduce the acidity of the contents, our first aim in the treatment, we may, as a first resort, administer substances which combine with or neutralize the acid. Such substances are, first, proteid food substances which combine with large quantities of acid, and, second, alkalis which neutralize the acid present. This is a simple method and works in a large majority of cases very satisfactorily. The excess of acid can be perfectly controlled by the food with small quantities of alkalis provided these substances are administered in the proper manner and at the proper time. In some cases this regular control of the acidity leads finally to a lessened secretion. In almost all cases it does away with irritation and disposes of the disturbances due to the acid excess and the symptoms of these. With the improved function which follows this treatment, and the full diet which is part of it, the system tends to regain its normal tone and the hyperesthesia of poor condition is controlled.

The system of treatment which I have used in most cases is built up upon these lines: The patient is given a diet of a caloric worth sufficient for the weight and conditions containing as high proportion of proteid foods as comfortable for the patient. (In my experience the average patient with stomach trouble is eating less than half of a sufficient diet.) This diet is separated into six daily meals, the constituents of each meal, with some alternative choice, being prescribed.

The treatment tends to use up the acid secreted and facilitates the motor function. Starches should be limited, and of carbohydrate foods sugars or predigested starches, dextrinized flours, as Avenacia flour or Horlick's food, used as much as possible, since starch digestion in the stomach is impeded in these cases. For all symptoms of disorder, as distress or eructations, some proteid, as a raw egg, is to be taken. An alkali, bicarbonate of soda in half-teaspoonful doses, or 15 grains of magnesian hydrate, may be taken in addition to food or in place of it for the relief of symptoms. In some cases large amounts of alkali, 3 drachms bicarbonate of soda, must be used in the twenty-four hours. Three pints of water are prescribed to be taken in small amounts at a time throughout the day. In addition, general rules in regard to baths, exercise, the bowels, the work, and general manner of living are laid down in writing. Debility must be treated by tonics. *Nux vomica* is a most useful agent here to improve the tone of the system and thus also perhaps the motor capacity of the stomach. Where anemia is present by blood tests iron should be given. Chlorosis is not infrequently associated with hyperacidity. After an administration of iron with the regular régime for a few weeks these cases as a rule lose all symptoms of hyperacidity even with cessation of treatment. There is little doubt that it is a similar improvement in nutrition which accompanies the increased diet, and good régime and freedom from nerve disturbance which ensure the cure in a majority of all the cases.

The exact details of treatment of course vary with the cases. Many cases of hyperacidity are intermittent or paroxysmal. These cases it is necessary to treat locally only during the period of attack, while a general method of régime should be employed constantly to prevent recurrence. In some cases the acidity is only after one meal, as, for example, dinner. This must be borne in mind in the determining of the diagnosis as well as in the treatment. We must get the contents at the period of symptoms.

This treatment gives excellent results in the great majority of cases. In some, relief is immediate, and with the return of normal tone it is possible after a month or two to drop special treatment. In a majority of these cases the acidity is found in time to be normal, in others the acidity remains as at first, though the symptoms disappear. In a certain proportion of cases the treatment must be followed in a general way permanently. It is impossible to collect accurate statistics of cure from an out-patient clinic. But it is certainly a rare exception to see a case of hyperacidity which does not yield to this treatment when properly applied. In my records I find less than 10% of cases returned as not relieved after trial of this simple treatment of régime, diet and alkalies. In these obstinate cases lavage is often a useful adjunct to treatment. After a few weeks of lavage combined with a very special diet worked out by experience with the case, the patient is raised to the regular régime. In these cases it is often necessary to feed small amounts frequently and to use concentrated food substances, as the Leuke-Rosenthal meat solution, Mosquera beef meal, somatose, which have a high capacity for combination with hydrochloric acid. Such cases are, however, exceptional. As a rule the diet of easily digested or liquid foods is the least useful one that can be chosen. In some obstinate cases I have used

nitrate of silver for internal treatment and for lavage with success.

It is well known that our cases of hyperacidity are of two types: One in which a neurosis or functional hyperactivity appears to be the fundamental element in the case, and one in which a marked increase in the gland tubules and oxyntic cells of the gastric membrane is present as an underlying pathological condition. This latter condition, a form of chronic gastritis, the gastritis acida of Cohnheim, is diagnosed by the presence of fragments of the pathological membrane in the stomach washings. It is said by some observers (Hemmeter) that 50% of the cases of hyperchlorhydria have some such hyperplasia of the tubular structures. Typical cases of this condition are, however, much less common, and such fragments are, in my experience, found in a much less per cent. of cases by ordinary methods of examination. When our condition is obstinate, and does not tolerate the regular treatment, it is well to investigate specially as to whether our case is one of this gastritis acida. For such cases, and indeed for all cases proving obstinate to the proteid treatment, the method of continuous treatment upon low proteid diet should be tried.

It has been urged that the method of treatment of hyperacidity by the utilization of the acid by food simply aims to offset the acidity of the contents, not to control the secretion, and that a more fundamental method of treatment would consist in aiming to lessen this secretion. Also it is claimed by certain observers that the secretion of acid in the stomach is proportionate to the amount of food requiring acid for digestion, that is, the proteid food. And that therefore the proteid diet, while relieving symptoms, tends to increase the disorder, while a low proteid diet will tend to decrease the actual cause of disturbance, and thus give permanent cure. Hemmeter reports some observations upon dogs which tend to support this theory.

In the few cases in which I have tried this latter method I have found it difficult to keep up. It does not give the immediate relief of symptoms obtained by the proteid method and the patients do not keep to the diet as well as in the proteid method.

The proteid treatment, whatever its aim, certainly ends in reducing the secretion of acid in many cases. It controls symptoms at the time in almost all cases. Since it acts so effectually I have used it regularly as a first resort in all cases where it is tolerated. Where it fails the other method should be given a trial.

SUBPERIOSTEAL FRACTURES.¹

BY FREDERICK J. COTTON, M.D., BOSTON.

ABOUT a year ago a somewhat peculiar case of subperiosteal fracture called my attention to this class of cases; the cases here presented are such as have come under my notice since that time. They are presented not with the idea that they show anything actually new, but because subperiosteal fractures are very common in children and a proportion of them seem on closer examination to have little in common with the type known as green-stick fractures, with which they are usually classed.

The usual type of green-stick fractures is of course

¹ Read before the Boston Society for Medical Improvement, October 29, 1900.

subperiosteal, but beyond this the correspondence between the types is not close. The usual type of green-stick fractures is familiar enough. There is a giving way of the bone on the convex side—a tearing apart, while the concave side shows simply a bending of the cortical layer. There is deformity on account of the difficulty of returning the torn bone surfaces on the convex side back to exact position, while the lack of mobility is ensured by the intact layer of bone on the inner concave side, even apart from a locking of the torn bone surfaces and from the strength of the untormented periosteum.

In the cases to be shown the conditions are different. Here there is no deformity because there are no torn surfaces, but a clean-cut crack or cross fracture, and no bent or half-broken layer of bone to prevent the motion necessary to readjustment of the surfaces. The lack of crepitus and mobility seems to be largely or entirely dependent on the strength of the thick intact periosteal layer.

CASE I. A boy of thirteen, whose right arm had been caught between the knee of another boy and the ground in the course of a football scrimmage. He came to the hospital next day complaining of slight pain and weakness of the arm and hand. There was no swelling or ecchymosis, and the disability was comparatively slight. There was localized tenderness at the middle of the right radius, but no suspicion of deformity or mobility even on the application of considerable force. The arm was put up in splints and examined at intervals, but not until ten days after the accident was there anything to be felt. At this time there was a small callus at the point of injury, and an x-ray was taken which showed a transverse fracture line apparently traversing the full thickness of the bone. There was a callus, seemingly entirely subperiosteal. There was no deformity. Within three weeks from the time of injury repair seemed complete and the arm could be freely used.

CASE II. A fracture running obliquely across the radius just above the lower epiphyseal line, showing no deformity or mobility. The x-ray showed a clean fracture line with practically no displacement. This again is evidently in no strict sense a green-stick fracture, but corresponds to the relatively not infrequent Colles's fracture without displacement seen in adults.²

CASE III. A fracture of the olecranon in a boy of seven, resulting from a fall on the elbow. The fracture line as made out under ether ran somewhat obliquely up and outward. There was a little mobility to be made out by the use of considerable force, but only through the slightest range; there was no separation of fragments, and no deformity, and it seemed evident that the fragment was held in place by the intact periosteum alone. The skiagraph shows the lateral view, in which the fracture line appears only as a crack.

CASE IV. A girl of five years fell and struck her elbow against a plank. Next day she came to the hospital. There was some effusion into the joint, some pain and tenderness. A careful examination, however, showed no sign of fracture, no deformity, mobility or crepitus. The skiagraph, however, showed a distinct crack across the humerus above the epiphyseal line, without displacement. Later there was more swelling, and some ecchymosis came to the surface. The recovery was, as in the previous cases, entirely uneventful.

CASE V. A fracture of the right radius from a fall, showing no signs of fracture at the time of injury. A callus was palpable later, and the x-ray taken after two weeks, though not good, showed the fact and location of the fracture, the presence of the callus, and the absence of displacement.

CASE VI. A fracture of the right arm three days old, in a child of five years. The middle third of the right radius showed beginning callus. The deformity in this case was trifling, but a very slight bowing could be made out; no attempt was made to reduce it. This case may have been a green-stick fracture in the stricter sense. No x-ray was taken.

CASE VII. A fracture of the right clavicle in a girl of five years, untreated for five days. Disability very little. No mobility, little pain. The only tangible sign of fracture was the beginning callus, which continued to increase in size later. The case differed from the more familiar green-stick fracture of the clavicle in that there was literally and absolutely no deformity, not even the least bowing.

CASE VIII. An almost exactly similar case of fracture of the clavicle just outside the middle in a small boy of four. Like the other case, it had gone untreated for a week, owing to the slightness of the symptoms.

CASE IX. A girl of four fell and injured her leg. There was no crepitus to be made out in an examination without ether, but a slight abnormal mobility in the lower third of the tibia. The x-ray showed a complete fracture of the tibia. The limitation of the mobility was evidently due to the periosteum. There was a slight displacement in the way of shortening—a small fraction of an inch only.

CASE X. A boy of three and one-half years was brought in on account of lameness, persisting six days after a fall on some steps. On examination there was localized tenderness at the middle of the right tibia, and a distinct callus surrounding the bone on all sides so far as could be palpated. The leg was put up in plaster, and after three weeks more was apparently well, but the callus still present, though smaller. No x-ray was taken in this case.

During this same period I have of course had opportunity to observe various typical green-stick fractures of the arm, clavicle, etc. These are not here recorded.

The cases presented do not show a fixed type in direction or character of the fracture lines, but they do show that fractures of various sorts may, even in the child, show an apparent immobility, due not to intact bone so much as to intact periosteum, and that the long bones even in children may be broken in clean lines without any resulting displacement.

Some experiments were carried out on the cadavers of new-born, presumably normal, infants to see how readily clean fractures could be produced and how much the periosteum hindered displacement at the time of breaking and on subsequent manipulation. Fractures were produced first by slow forcible bending in the hands. There resulted: (1) in a femur; green-stick fracture, periosteum intact; (2) tibia; green-stick fracture with a Y-shaped fracture line, periosteum intact; (3) tibia; exactly the same result, typical green-stick fracture; (4) clavicle; the bone could be bent double and back again, with some breaking of bony substance, but no definite fracture line. In none of these experiments was there any difficulty in forcibly reducing the fracture and bringing the bone back to the straight line, nor any necessity of completing the fracture to get good position—a much-mentioned measure which has seemed to me unnecessary clinically, as it proved to be experimentally.

Next the effect of direct blows on the shaft of the bones was tried, both with dissected and undissected limbs. (1) A right tibia so struck showed square transverse fracture; (2) femur; slightly oblique but clean-cut fracture, not extending through the full thickness of the bone, but mobile with a hinge motion, perfect reduction possible.

² Cases I and II were seen at the City Hospital while the writer was acting out-patient surgeon; the others seen at the Children's Hospital and reported by permission of Drs. Lovett and Brackett.

A humerus was stood on end, and struck on the upper end; it buckled and broke in the middle; there was some displacement of the ends and free hinge motion, but the periosteum remained unbroken.

Obviously, these experiments are too few to warrant any sweeping conclusions, but it would seem that blows are less likely than a slower acting strain to produce typical green-stick fractures, and it is at least obvious that even the soft bones of the new-born may be broken or cracked in clean-cut approximately transverse fracture lines by forces moderate enough to leave the periosteum intact.

In conclusion, it seems that fractures in children showing no deformity and no appreciable mobility are not uncommon; that they might readily be overlooked; that they often need no reduction, having no deformity; that they repair with callus and quickly.

IRRITABLE BREASTS, OR CHRONIC LOBULAR MASTITIS.¹

BY R. C. CABOT, M.D., BOSTON.

I HAVE no paper. I bring up this subject because I want to find out something more about it, and because it seems to me from talking with my friends that other physicians in the community are almost as ignorant as I.

I will begin by giving a short account of two cases that first brought the subject to my interest. About eight months ago I saw for the first time two young women between twenty and twenty-five, unmarried, both of them strikingly neurotic in temperament, of thin build and pale, but not anemic by blood test, both of whom came to me to know the nature of a lump in the breast. That lump in both cases was in the outer upper quadrant; it was distinctly tender to the touch, and it was for the pain as well as for the presence of the lump that the patients came. The lump was in one case about the size of a large horse chestnut, in the other a little larger. It was flattened from before backwards and it was notable when you pressed the breast against the thorax it was much more difficult to feel the lump than when you took it in the fingers from side to side. In one case there was no enlargement of the axillary glands, in the other they were slightly enlarged and somewhat tender. There was no retraction of the nipple, and the tumor was freely movable beneath the skin, not accurately circumscribed in either case, but faded out into the tissues of the breast, so that it was difficult to say exactly how large it was in either case. In each case under observation the tumor originally seen diminished in size and another appeared in the other breast.

These cases have been under observation now seven or eight months and have improved a good deal under general treatment. One was a girl obviously lacking in occupation, and when an occupation was secured the lump nearly disappeared, and the symptoms entirely disappeared. Neither had any symptoms except the symptoms of general debility.

This description corresponds fairly accurately with the description of "irritable breast," that given in the old textbooks on surgery, for example, in Ashhurst's "Surgery" and in one of the newer books, Shields

¹ Read before the Boston Society for Medical Improvement, October 29, 1900.

on "Tumors of the Breast," and it seemed to me the diagnosis was justified. But when I came to read over the literature I found many points indefinitely touched upon, and many which I should like to know more about. It is a subject which seems to be on the border line between surgery and medicine (since most writers recommend the treatment should be expectant and not operative) and hence of special interest.

First, as to the pathology of these tumors. The majority of writers describe them as *inflammatory*, that is, as chronic lobular mastitis, and the microscopic changes as an increase of fibrous tissue with the formation of very small cysts, the changes fading out at the periphery of the lobule and being in no sense sharply circumscribed. But, on the other hand, every writer I have seen on the subject states that these tumors frequently disappear. Herbert Snow speaks of them as the "dispersible" tumors of adolescence, as the familiar "adenoid of adolescence," but it seems curious that these thickenings should entirely disappear if their pathology is that of a fibrous hyperplasia. If the breast were very fat, it would be easy to see how a fibrous nodule might escape notice. In my cases, however, the breasts were flabby and thin, so that a small accumulation or thickening of this kind would be felt, if present. I have asked myself the question whether there is any possibility that in some of these cases the accumulation may be a galactoecele. Several cases of galactoecele are on record in unmarried women, — an accumulation either of milk or cheesy substance in the breast. That is a question I want to bring up and have answered, if possible.

I also want to ask the question whether it is possible or likely that these lumps are physiological, that a considerable number of women have them and do not find them out. It struck me very much that all the writers emphasize the neurotic constitution of the patient, describing the type of patient who would easily get stirred up about such things, feel of the breasts a great deal, handle them and be led to lay great stress on the symptoms, whereas the same might exist in less neurotic patients and not be noticed at all. One of my patients was a nurse and the other the sister of a medical student. I want to bring up the question whether it is possible that a considerable number of these tumors exist and are not discovered, and if so, whether it is fair to call them *mastitis*.

Then, as to the *prognosis* of these tumors, the question as to whether they do or do not become cancerous. In the literature the majority of writers seem to think they do not, but a respectable minority believe that out of these tumors a cancerous process may develop. The bearing of this question upon treatment is obvious.

As to the *treatment*, should these cases be operated upon? The great majority of writers say no, and recommend the treatment of iodide of potash internally, acetate of lead ointment externally, and attention to the general condition of the patient. I should like to know if it is the opinion of those competent to speak whether these measures have any effect on the process itself or act entirely as placebos.

I think I will take no more of the time of the meeting. What I want is to find out as far as possible what is the pathology of these tumors, what is their course, and what is the proper treatment.

CYST OF THE VOCAL CORD.¹

BY J. PAYSON CLARK, M.D., BOSTON.

This case is reported because it differs from the usual description of cysts of the larynx and in its general characteristics, before operation, rather suggested a fibroma.

B. K., male, age twenty-five, a clerk by occupation, came to the Throat Clinic of the Massachusetts General Hospital in July, 1899, complaining of hoarseness and difficulty in speaking, the voice getting easily tired. He began to be hoarse twelve years before and had gradually become worse. Two years ago he began to notice the sensation of something in the larynx. His general health is fair. He has never had any serious illness, but has never been robust. He

FIG. 1.

has no cough. Family history is good, with no record of any laryngeal or pulmonary troubles.

Examination of the larynx reveals considerable reddening of the vocal cords except at the middle of the right cord, above the surface of which projects an oval, smooth, grayish-white, pearly swelling, occupying a quarter to a third of the length and the whole width of the cord and causing a bulging of the free border (Fig. 1).

On introducing Schroetter forceps and attempting to grasp the growth (having first thoroughly cocain-

FIG. 2.

ized the larynx), it was found so firm and resistant that the forceps slipped off without grasping it. At the suggestion of a colleague that it might be a cyst I introduced a concealed laryngeal knife and incised the tumor near the free border of the cord. On removing the knife it was seen to be covered by a milky looking fluid, and, on again looking at the larynx, the tumor or cyst, as it proved to be, had entirely disappeared. A microscopical examination of the contents of the cyst showed a mass of degenerated epithelial cells and a few leucocytes.

The patient was seen again about nine months after the operation. The redness of the vocal cords

had almost disappeared. There were two minute knobs of mucous membrane projecting from the free edge of the vocal cord (Fig. 2). The patient has no difficulty in talking and his voice is fairly clear.

Speaking of cysts of the larynx, Bosworth says: "A cystoma is a small, soft, compressible growth, usually pedunculated. . . . The character of the growth is easily determined by the probe, or by its collapsing on seizure with the forceps." Lennox Browne says they are "generally red in color with surrounding hyperemia." McBride mentions only one case which he has seen. He speaks of the tense look, peculiar opaque translucency and globular shape of the cyst in his case. The growth collapsed on grasping with Mackenzie forceps. This description more nearly approaches the appearance of the cyst in my case. The sessile character and great firmness of the cyst in this case was, no doubt, due to its being rather deeply situated in the substance of the cord.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, Monday, October 29, 1900, DR. E. H. BRADFORD in the chair.

DR. H. F. HEWES read a paper entitled

OBSERVATIONS UPON THE SYMPTOMS AND TREATMENT OF HYPERACIDITY OF THE STOMACH.¹

DR. C. P. PUTNAM: In establishing the diagnosis of hyperacidity is it necessary to make the examinations at several different times of the digestion, or can you be satisfied with taking the acidity at any one time?

DR. HEWES: If you find it the first time you can be satisfied it is there, but if you fail you may have to go further, because it may be present at other times of the day or upon other days.

DR. C. P. PUTNAM: If you find excess of HCl at the beginning of digestion you may be sure there is not a lack of it at any other time of the day?

DR. HEWES: I should say you could be sure of that. If you find an excess you have a right to go on the basis that that is the cause of the symptoms.

DR. C. P. PUTNAM: You say, however, that when you do not find it you look again, so that sometimes it is a case of acidity where during digestion there is not at all times an excess of it?

DR. HEWES: Yes; and you must get your contents at the time when there are symptoms. Some people have symptoms only at one meal; at other meals they do not have them. The average case has hyperacidity at all times. You notice in the case passed around there were two different meals, one large and one small, and the hyperacidity was present with each meal, larger in the second meal, but present in both cases.

¹ Read before the American Laryngological Association at its Twenty-second Annual Congress, Washington, D. C., May, 1900.

¹ See page 550 of the Journal.

DR. C. P. PUTNAM: Do you take the usual methods recommended in books, test meals, in making observations on this point?

DR. HEWES: I use the Ewald meal first because I have a table of experiments on the normal individual with this meal to use for comparison, and then I use in doubtful cases the large meal or the Leube meal, which is equivalent to the ordinary dinner, and record tests with both.

DR. R. C. CABOT presented the subject of

IRRITABLE BREASTS, OR CHRONIC LOBULAR MASTITIS.²

DR. C. B. PORTER: I should not pretend to give the pathology, and should hope somebody more competent than I might speak of that subject. As Dr. Cabot described his cases they seemed to me to be typical of what I have been accustomed to call chronic mammary tumors, and in the majority of instances the advice was given to let them alone. I do not know of any benefit from any external treatment but to cease to handle the tumors, pay as little attention as possible to them. I have no statistics with regard to how many have disappeared and how many have come to further operative treatment. I think the feel which Dr. Cabot described corresponds very much to the cystic growths that come in the breast, and where I have felt pretty positive they were cysts I have advised removal.

DR. ARTHUR TRACY CABOT said that he had taken much interest in this subject of irritable breasts, and had had many opportunities of following patients so afflicted for considerable periods of time. He said that, to begin at the beginning of the subject, these conditions of the breast occurred notably at two periods of life—in adolescence, as Dr. Richard Cabot has said, and also at the time of the menopause. These breasts may be occupied by several more or less distinct lumps or may contain but one such swelling. This condition often entirely disappears under treatment, and the treatment recommended by the speaker was the internal administration of iodide of potash, combined with bromide of potash. The irritation of the breast seems to have very close connection with the condition of the pelvic organs. It is very common to find in these cases that there is some disturbance of the uterus, usually with irregularities of menstruation. Not uncommonly the condition of the breast is very much aggravated, with increase of swelling and of pain at the time of or just before menstruation, and this condition of pain and swelling (tumefaction) is relieved by the completion of menstruation. The pathological condition of these breasts in their early stages is difficult to demonstrate, because it is not a fatal disease, and it is a disease which we rarely operate for. If medicine is given, and the tumor disappears entirely, operation is not advisable. When, however, the swelling persists, or reappears, and an operation is finally done, the condition found is usually a diffuse fibrous condition of the greater part of the breast, which by its pressure upon the ducts gives rise to the formation of retention cysts. These cysts are sometimes single good-sized cavities, with little fibrous tissue about them; but usually they are small, and are scattered pretty thickly through the fibrous tissue of which the breast is largely made up. The changes in the size of the swellings, and

the rapidity of these changes, especially at the time of menstruation, make it appear probable that a tumefaction, that is, an increased determination of blood to the parts, is largely responsible for the increase of size which causes a tumor. It is plain, however, that when the condition persists for a considerable time, new cells are thrown out which become organized into the fibrous tissues described.

In illustration of the occasional development of a cancer in connection with this condition, Dr. Cabot cited the case of a nurse, who had for many years had an irritable and lumpy breast. This patient had had a sister operated upon for cancer of the breast, which fact had led her to watch her own breasts with unusual care. She persistently, as she was approaching the menopause, noticed close to the nipple a little adhesion of the skin to one of the little lumps. This was so slight that it was difficult to demonstrate it, and it could only be made apparent by pinching up the skin and seeing that there was a slight dimple over the little lump.

Upon operating, it was found that at the suspected point there was a little nodule of commencing carcinoma, not larger than half a pea.

This case was typical of a considerable number in Dr. Cabot's experience in which carcinoma finally appeared in breasts which had for years presented all the appearances of chronic mastitis. This not very infrequent sequence of events would make it seem wise to place such a case under the observation of a surgeon, in order that it might be investigated by operation if it did not get well under appropriate treatment. The operation is a slight one if the lump does not prove to be a cancerous nodule, and a very important one if it does, so that a case of this sort, particularly a case occurring at about the menopause, which is a favorable time for the development of cancer, should be kept under observation, put under treatment, and, if it does not entirely disappear, should be operated upon.

In regard to the pathology Dr. Cabot said that he regarded the commencement of the process as a simple tumefaction. When this has persisted for some time it leads to the formation of fibrous tissue. Oftentimes a breast may be quite extensively occupied by this fibrous tissue and still feel soft and pliable.

Usually in consequence of the pressure of the fibrous tissue around the gland ducts, retention cysts form sooner or later.

DR. BAKER: In my experience the majority of these cases, and I have seen not a few, have suffered from some menstrual irregularity, coming into their lives either at twenty-five or thirty years of age, or at the menopause. In those cases occurring early in life this irregularity is due to some chronic congestion of the uterus and ovaries, unrelieved by the flow, for it is almost universally the case that there is a very scant flow. When this trouble comes about the menopause it is usually the case that they have gone two or three months without any flow, and the patient is very likely suffering from chronic metritis or areolar hyperplasia in the secondary stage. Both are favorably affected by the abstraction from the uterus of two or three ounces of blood, which treatment followed up once a month for two or three successive months, has in my experience made a very decided effect on the tumor of the breast.

In the matter of the pathology I am sorry I cannot

² See page 555 of the Journal.

add any especial light on that part of the subject, but from the fact of the treatment which has been in my hands the most successful, second to the abstraction of blood from the uterus already referred to, I should think that the suggestion which Dr. R. C. Cabot has made of the galactoele was a very reasonable one, because under the influence of the galvanic current, which I have been accustomed to use in these cases twice a week, at the strength of 15 to 20 milliamperes for ten to fifteen minutes at each sitting, I do not see what effect that current is likely to have on fibrous tissue, but, if we consider it a galactoele, it would seem to me it would have a very decided effect, and as these tumors have disappeared in my experience the most rapidly by its use I should think it more likely to be the latter than the former. The fact that the patient has a lump in her breast which may be cancer is a matter of too great importance in her mind to be cast aside and altogether forgotten. Its importance to her physically as well as mentally demands our close observation. At all events, its speedy disappearance is greatly to be desired, failure of which by treatment would necessitate an operation for its removal.

DR. BRIGGS: One point in regard to treatment has not been brought out. The cases I have happened to see have been in large, pendulous breasts. I have found that supporting the breast and light pressure on the breast have been very beneficial, apparently causing disappearance of the swelling.

DR. MUMFORD: I feel very much as does Dr. A. T. Cabot in regard to the causes and conditions in these processes, but I understood Dr. R. C. Cabot to refer only to those masses we see in the breasts of neurotic young women, and not to the lumps or tumors we see in women at the time of the menopause. In the latter class of cases one must watch carefully, bearing in mind that there may be a malignant termination of the condition.

In the former class, that of neurotic young women, I have always assumed these processes to be of an inflammatory nature. I feel that this assumption is borne out by the result of competent massage. A competent massense, a *rara avis* in the town, can usually in two or three treatments greatly diminish, or cause to disappear, these masses.

Dr. Briggs suggested the support of a breast bandage, and this, as it relieves tension and congestion when the breast happens to be heavy, carries out the same idea as massage.

DR. PUTNAM: It seems to me very questionable to recommend any treatment of tumors which apparently have a habit of going away themselves. It seems to me those tumors mentioned by Dr. A. T. Cabot are different from those spoken of by Dr. R. C. Cabot, which are of a pretty distinct type, tumors which are deep in the breast and not easily felt unless the breast falls forward, and which have a peculiar feeling. When Dr. Cabot speaks of tumors that adhere to the surface it seems to me he is speaking about a different class. I have seen a good many such breasts as Dr. R. C. Cabot speaks of, and not by any means always at the adolescent age, or at the menopause. Some of these I have taken to surgeons and some I have left alone, and as far as I know none have been operated on, and the surgeons in the particular cases mentioned recommended no treatment, recommended leaving them alone. One, for instance,

I remember in a lady who is rather thin and has rather pendulous breasts, but not large ones. She was not at either of the ages mentioned, but about forty at the time that occurred; another one I recall very distinctly was about forty-five. In both those cases the tumors went away without treatment more than a placebo, such as bathing gently with alcohol and water, and being careful not to press them at all. I believe cases such as Dr. Cabot described do not require treatment; internal medication or any such application as electricity can hardly have the effect attributed to them. The tumors go away themselves.

DR. HEWES: In regard to the question of these tumors being accumulations of blood or milk I have one interesting fact to report. I have a case in a young girl which has been in the wards of the hospital for observation, and came to me to the Out Patient several times with mastitis and a tumor. She said the tumor occasionally went away. After other methods of treatment, without improvement, I tried hypnotism for the relief of the pain and tenderness, and of the fixed idea of the patient, and under hypnotism this tumor disappeared for the time being absolutely. It came back again somewhat after the hypnotism, but there was no doubt as to its disappearing at the time. That is suggestive of the tumor being a matter of congestion in this particular case.

DR. R. C. CABOT: One question I have not quite got answered to my satisfaction, the question raised by Shields, whether these lumps are not physiological to a certain extent, whether it is a fact that a large proportion of women have them at some time and do not find it out. I wish I could get an expression of opinion from the surgeons present on that point; is it not a matter of accident that we find them in a neurotic sensitive, and is it not a possibility that they are more common than we know? As to their commonness, every one I have spoken to says he has seen a good many, and yet there is astonishingly little about them in literature. I do not understand exactly what Dr. A. T. Cabot means by a tumefaction. I do not know much of anything about the structure of the breast, but perhaps he can explain a little more in detail just what he means by a "tumefaction" such that without the presence of anything more than blood in addition to the ordinary constituents of the breast, a hard, more or less circumscribed lump would be produced.

DR. FREDERICK J. COTTON read a paper on

SUBPERIOSTEAL FRACTURES.³

AMERICAN PUBLIC HEALTH ASSOCIATION.

TWENTY-EIGHTH ANNUAL MEETING, HELD AT INDIANAPOLIS, IND., OCTOBER 22, 23, 24, 25 AND 26, 1900.

THE Section on Bacteriology and Chemistry met at the Pathological Laboratory of the Central Hospital for the Insane, with the chairman of the section, DR. THEOBALD SMITH, of Boston, presiding.

Several papers were read and discussed. Among them was one by DR. H. L. RUSSELL, of Madison, Wis., in which he showed the degree of heat which is necessary to destroy the tubercle bacillus in milk without injuring commercially the value of the milk. He also read the report of the Committee on the Bac-

³ See page 553 of the Journal.

teriology of Milk in its Sanitary Relations. As illustrating the peculiar way by which such germs find their way into milk, an incident occurring in a hospital at Leeds, England, was related. The nurses in that institution were in the habit of taking glasses of milk from the pantry up into the sick wards several hours before the milk was drunk. An outbreak of typhoid fever occurred among the nurses. Investigation disclosed the practice to which they had been resorting, and when it was ordered discontinued, the epidemic subsided.

DR. V. A. MOORE, of Ithaca, N. Y., related a diphtheria epidemic which was started in that city from milk delivered by a dairyman whose family had suffered from acute tonsillitis. The eldest son, who attended to the milking of the cows, had been pronounced well and resumed his regular work, but scientific investigation demonstrated that he still had germs of the disease in his system.

The meeting of the association was presided over by DR. PETER H. BRYCE, of Toronto, Canada. The sessions were held in the amphitheatre of the German House. Addresses of welcome were delivered by EX-PRESIDENT BENJAMIN HARRISON, GOV. JAMES A. MOUNT, and HON. ADDISON C. HARRIS, Minister to Austria. The response to these addresses was made by DR. CHARLES A. LINDSLEY, of New Haven, Conn.

The first paper presented at the general meeting was by PROF. S. H. WOODBRIDGE, of Boston, which was the report of the Committee on Car Sanitation.

CAR SANITATION.

The following recommendations were reported in the paper:

(1) When a passenger is known to be contagiously ill, he should be isolated in a compartment appropriately equipped and ventilated in such a manner as to separate it from the rest of the car. Through trains should be provided with rooms for the sick as well as state-rooms.

(2) The interior of passenger cars should be plain, finished with hard, smooth and polished surfaces.

(3) All furnishings should be as non-absorbent as possible.

(4) Coaches should be furnished with effective means for continuously supplying not less than 1,000 cubic feet of warm air an hour for each single seat, and for distributing and removing the air without troublesome draught.

(5) The temperature should be regulated.

(6) The cleaning of cars should be frequent and thorough.

(7) Floors and sanitary and lavatory fixtures should be frequently treated with a disinfecting wash.

(8) All fabrics in cars should receive sterilizing treatment. All bed and lavatory linen should be thoroughly sterilized in the process of laundering.

(9) Sewage tanks and earth closets should be provided under the cars. The practice of disposing of excreta by scattering it over road beds is dangerous.

(10) Water and ice should be obtained from the purest available sources. The use of tongs in handling ice should be insisted upon.

(11) The water tank should be frequently cleansed and periodically sterilized with boiling water or otherwise.

(12) The public should be educated to use individ-

ual cups. Paper paraffine cups might be provided by a cent-in-the-slot device.

(13) The use of canned goods in buffet car service makes careful inspection of such goods imperative. Fruits and all eatables before and after purchase should be stored with care, to avoid all unnecessary exposure to street and car dust.

(14) The filthy habit of spitting on car floors should be dealt with in a manner to cause its prompt discontinuance. It should be punished as one of the most flagrant of the thoughtless offences against the public right to health.

(15) Station premises should receive attention directed to general cleanliness of floors, furnishings, air, sanitariums, lavatories, platforms and approaches, and should be plentifully supplied with approved disinfecting material.

The recommendations of the committee were concurred in by the association.

DR. J. N. HURTY, of Indianapolis, said that if the association would make a vigorous demand for white blankets for sleeping cars, instead of colored ones, it would be a great reform. The white blanket would tell its own story. Colored blankets are frequently saturated with filth.

DR. H. M. BRACKEN, of Minneapolis, said that inasmuch as the travelling public pay a good price for Pullman cars, it is only right that the cars should be kept clean and in good condition. The beds are made up, people sleep in them, the next morning the linen is removed, while the mattresses and blankets are thrown into the upper berths and remain there until the next night, then used again. It is not uncommon for people, on entering Pullman cars, to complain of the odor of stale bedding, etc.

DR. C. H. JONES, of Baltimore, referred to tuberculous patients who travel long distances. When the greatest care and caution are observed, the blankets used on Pullman cars are now and then spat upon by them. The attendants cannot always be with such patients to cover their mouths with handkerchiefs. Railway managers should be notified of the great danger to the public from this source. When the public are educated in this matter, a great reform will have been inaugurated.

DR. C. P. WILKINSON, of New Orleans, stated that the chief objection to the equipment and furnishings of railway cars is that they are upholstered in absorbable material. In the extreme South rattan and steel springs were now used instead of plush and woollen furnishings.

DR. U. O. B. WINGATE, of Milwaukee, referred to the work that is being done in this direction by the International Association of Railway Surgeons, and suggested that it might be well to appoint a committee to co-operate with a similar committee of that association to do further work in car sanitation.

DR. HURTY spoke of one railroad which is now constructing seven cars with perfectly plain interiors. The bottoms and backs of the seats can be taken out and thoroughly sterilized at the end of every run.

DR. DOMINGO ORVANANOS, of Mexico City, Mexico, read a supplementary report on car sanitation. Boards of health in the territories covered by the association ought to try and obtain support from the different legislatures so as to make certain provisions obligatory on railway companies, as, for instance:

(1) The isolation in special cars of any persons suf-

fering from transmissible diseases; (2) to supply guaranteed filters in the tanks of drinking water; (3) the disinfection of bedclothes, hangings, curtains and towels; (4) all sleeping cars should be provided with small disinfectant stoves for small toilet articles; (5) the absolute prohibition under severe penalty of expectoration on pavements; (6) all railroad cars should be provided with a sufficient number of cuspidors containing a strong disinfecting solution.

NEW QUARANTINE METHODS AND CHANGES WHICH ARE CALLED FOR IN MARINE SANITATION.

This paper was contributed by DR. ALVAN H. DOTY, of New York City. Contrary to the popular belief, the most careful investigation, both from a scientific and practical standpoint, has demonstrated that the clothing actually worn by well persons is not a medium of infection. This is also true of the cargoes of ships. In making this statement, the author does not mean to imply that infection from these sources is not within the realms of possibility. Evidence was adduced that the cargo of a ship does not act as a medium of infection. If exceptions exist, they have not been revealed to practical sanitarians. Outbreaks of bubonic plague in European and other ports have brought prominently before our notice the question of the transmission of this disease by rats and other vermin. Information on this subject at present is incomplete, although Kitasato and Yersin have demonstrated the presence of the disease in rats during the epidemic of bubonic plague in Hong Kong in 1894. Beyond this, sanitarians have but little authentic information on the subject. It is reasonable to believe, however, that in such communities as are found in India and China, where filth, overcrowding and bad sanitary regulations exist to an extent which is almost beyond belief, that the dissemination of infection is so general that even vermin are involved. In civilized communities, however, where the ordinary sanitary regulations are carried out, the danger from this source would seem to be very limited. No authentic reports exist which show that cargoes of vessels have transmitted bubonic plague through the medium of infected rats or other sources.

In the inspection of persons coming from infected ports, the ordinary examination, which includes a statement from the person concerned, is not sufficient at all times to detect mild or ambulant cases. The most practical and important addition to the ordinary method of inspection is the use of the clinical thermometer. This has been in operation for the past two years in New York, and the most satisfactory results have been obtained in detecting mild or ambulant cases. While the essayist is convinced that the maximum period of incubation of yellow fever is five days, there is no doubt but that during the first day or so of the disease persons affected may present themselves and pass the ordinary inspection. The use of the thermometer at this time, however, will almost always show an elevation of temperature sufficiently high to justify the physician or health officer in causing a longer detention.

The author closed with a reference to the value of modern sanitary regulations.

PROF. F. C. ROBINSON, of Maine, said that formerly a great deal of paper was made from rags, and he was surprised to hear that there was no danger from infectious diseases from cargoes of rags. He believes

outbreaks of smallpox and other contagious diseases have been traced to rags.

DR. H. M. BRACKEN vigorously controverted the statement of the essayist that healthy persons are not liable to carry disease in their clothing. Every physician of experience could cite instances of physicians who have carried contagion to healthy people.

This paper was further discussed by DRs. WILSON, MONTIZAMBERT, the PRESIDENT, LEE, DURGIN, JONES, most of whom protested against the idea that physicians could not carry infection in their clothing.

DR. A. WALTER SUTER, of Herkimer, N. Y., read the

REPORT OF THE COMMITTEE ON CAUSE AND PREVENTION OF INFECTIOUS DISEASES.

Reference was made to smallpox, which he said was on the increase, and he cited copious statistics to prove his assertion. He added the pleasing assurance that the death rate from this malady is decreasing. The latter fact must not be viewed too optimistically, because smallpox is certain, if an epidemic of it continues long enough, to develop its greatest degree of virulence. He showed the value of sanitary precautions and of vaccination by citing the fact that Puerto Rico, since the United States had dominated its government, has rid itself of the disease, which, before the war, was very prevalent in that island.

He also discussed malaria, scarlet fever, typhoid fever, and declared himself a believer in the theory that the germs of malaria are transmitted by mosquitoes in many instances.

In discussing typhoid fever he referred to the declaration of Dr. Vaughan, that more than 80% of deaths among American soldiers in the Spanish War were caused by typhoid fever, and emphasized the necessity of cleanliness about military camps. He touched upon bubonic plague, and said he did not anticipate a scourge of this disease here, but urged great sanitary precautions.

ETIOLOGY OF YELLOW FEVER.

DR. WALTER REED, of Washington, D. C., read a paper on this subject, it being the joint production of himself, DR. JAMES CARROLL, DR. A. AGRAMONTE and DR. JESSE W. LAZEAR. A series of clinical, bacteriological and pathological observations was narrated, comprising 18 cases of yellow fever. Of this number 11 were designated as severe cases of the disease, with 4 deaths; 3 as well-marked cases, with no deaths, and 4 as mild cases, with no deaths. Blood cultures were made of 18 cases during life, and of 48 separate cultures made from the blood on various days of the disease and representing 115 bouillon inoculations, and 18 agar plates, they failed to find the bacillus icteroides in any of the tubes or plates. They failed to isolate the bacillus icteroides in 11 autopsies of yellow-fever patients. Having failed to isolate this bacillus, either from the blood during life, or from the blood and organs of cadavers, two courses of procedure appeared to be worthy of attention, namely: (1) A careful study of the intestinal flora in yellow fever in comparison with the bacteria that might be isolated from the intestinal canal of healthy individuals in this vicinity, or of those sick with other diseases; or (2) to give attention to the theory of the propagation of yellow fever by means of the mosquito. The essayists pursued the second line of investigation by reason of

the well-known facts connected with the epidemiology of this disease, and by the brilliant work of Ross and the Italian observers in connection with the theory of the propagation of malaria by the mosquito. Their observations point to the presence of an intermediate host, such as the mosquito, which having taken the parasite into its stomach soon after the entrance of the patient into the non-infected house was able, after a certain interval, to reconvey the infecting agent to other individuals, thereby converting the non-infected house into an infected house. This interval would appear to be from nine to sixteen days, allowing for the period of incubation, which agrees fairly closely with the time required for the passage of the malarial parasite from the stomach of the mosquito to its salivary glands.

In view of the foregoing observations they tested the theory of Finley on human beings. Experiments were made on 11 non-immune individuals. The mosquito used in all cases was *Culex fasciatus Fabr.* Results were 9 negatives, and 2 positives. The 2 cases reported as positives the authors detailed at great length.

Since they record 1 case in which a typical attack of yellow fever followed the bite of an infected mosquito within the usual period of incubation of the disease, and in which other sources of infection could be excluded, they feel confident that the publication of their detailed observations will excite renewed interest in the mosquito theory of the propagation of yellow fever, as first proposed by Finley. From their studies thus far of the disease, they conclude that the bacillus icteroides stands in no causative relation to yellow fever, but, when present, should be considered as a secondary invader in this malady. The mosquito serves as an intermediate host for the parasite of yellow fever.

DR. HENRY B. HORLBECK, of Charleston, S. C., read the

REPORT OF THE COMMITTEE ON THE ETIOLOGY OF YELLOW FEVER.

Reference was made to previous contributions on this subject by the committee, and a digest given of the labors of bacteriologists who have during the past twelve months devoted themselves to the study of the bacillus icteroides. The report closed with the following conclusions from an article by Proust and Wurtz, published September 7th, 1900:

"(1) The bacillus icteroides of Sanarelli seems to be the specific agent of yellow fever. That micro-organism injected into certain animals, especially dogs, reproduces symptoms and lesions strikingly analogous to those observed in man. The toxin of this bacillus produces in animals the same effect as the microbe. The injection of this toxin into 5 individuals reproduced in man typical yellow fever, accompanied by its symptoms and anatomical lesions. The serum of individuals attacked with yellow fever agglutinates cultures of the bacillus icteroides.

"(2) The bacillus has a prolonged vitality both in air and water (fresh and sea). It is certain that it is the same in the soil. Moulds favor its development. These facts confirm conditions that have been known a long time. They explain the reawakening of yellow fever a long time after the extinction of an epidemic, and the longevity of the disease aboard vessels in bad hygienic conditions.

"No new prophylactic measures have come out in this knowledge of the etiology of the disease. As formerly, the prevention of yellow fever consists in applying the measures of isolation and of disinfection, and of improving the hygienic conditions."

While the numerous contributions to the cause of yellow fever are far from being conclusive, the researches made during the last few years furnish matters of information which will be guiding stars in future investigations.

DR. J. P. BERNALDEZ, of Mexico, spoke of

HUMAN VACCINE AS A PROPHYLACTIC OF SMALL-POX,

and discussed its advantages and disadvantages.

DR. M. S. IGLESIAS, of Vera Cruz, Mexico, spoke of the

ELEMENTS OF DEFENCE AGAINST INFECTIOCONTAGIOUS DISEASES AT THE PORT OF VERA CRUZ.

DR. F. W. ELGIN, of Philadelphia, read a paper entitled

INFLUENCE OF TEMPERATURE ON VACCINE VIRUS.

After detailing a series of experiments, he drew attention briefly to some of the lessons suggested by the experiments: (1) Vaccine points are unreliable when stored for any length of time at any temperature; (2) virus on points may be inert, yet germs charged along with the virus remain active, causing a form of irritation somewhat resembling vaccine vesicles, and known as spurious vaccination; (3) that glycerin will not destroy the extraneous bacteria in lymph when stored at or below the freezing point; (4) that continued exposure of germs to low temperature, when constant, does not destroy their activity and but slightly decreases their number; (5) hot, and especially variable, temperatures speedily injure vaccine; (6) hot temperatures increase enormously the number of germs in fluid lymph other than that stored in glycerin.

DR. H. C. H. HEROLD, of Newark, N. J., read a paper on

NEWARK'S DIPHTHERIA ANTITOXIN PLANT.

Early in 1895, a laboratory for bacteriological research, with an attendant plant for the application of antitoxin for diphtheria, was established under the jurisdiction of the Board of Health in Newark. This department has been in practical operation for more than five years. The author presented the results of the experiment of establishing such a plant, and showed by statistics of greatly reduced mortality from diphtheria by the use of antitoxin that it is one of the best things the city officials and medical profession of that city have ever undertaken.

PRESIDENTIAL ADDRESS.

This was delivered by DR. PETER H. BRYCE, of Toronto, who sketched at great length the progress of sanitary science from its birth in the period of the Renaissance down to the present time, and declared that scientific workers ought to take courage from what they have seen accomplished in this century. The address was scholarly, and an admirable, compact sanitary digest.

REPORT OF THE COMMITTEE ON POLLUTION OF WATER SUPPLY.

This was presented by the chairman, MR. GEORGE W. FULLER, of New York City. The report took the form of records and summaries showing recent progress in the more important branches of the subject. With regard to quality, the water supply of the future should meet the following requirements: It shall be free, or substantially free, from disease-producing germs; it shall be clear and colorless, containing no noticeable turbidity or vegetable stain; it shall be free from objectionable tastes and odors, as supplied to the consumer; it shall be free from noticeable amounts of dissolved iron, such as unfit for household use; it shall be free from excessive amounts of lime and magnesia, such as make water too hard for ordinary use; it shall be carefully examined with regard to constituents capable of dissolving metals used in distributing pipes.

Of the various branches of public works connected with the pollution of water supply, there is none in which such substantial progress has recently been made as in water purification. Ten years ago information upon this subject was very meagre, and comparatively few plants were in operation. During this period English sand filter plants have been increased from about 1.5 to 19 acres, with respective normal capacities of about 4,000,000 and 57,000,000 gallons daily; and the American or mechanical filter plants have been increased from about 12,000 to 90,000 square feet, with respective nominal capacities of about 36,000,000 and 270,000,000 gallons daily. Projected plants for some of the largest cities in the country show that in the next few years there will be very rapid development in the application of both of the leading methods of purification. Of the various processes for the purification of water supplies, there are two general methods which have shown distinctly their practicability, namely, the English method of slow sand filtration, and the American method, employing rapid mechanical filters. For those waters which never possess more than a slight or moderate amount of turbidity or dissolved vegetable color, the English method is somewhat more efficient, and, as a rule, it is slightly the cheaper for such waters. For those waters which for long periods at a time contain excessive quantities of either finely divided clay or of dissolved vegetable matter, there is now no practicable method of purification without the use of coagulants and subsiding basins. While coagulants can be successfully used in connection with the English method of sand filtration, the American method, in which coagulants are imperative, yields somewhat more efficient and economical results, as a rule.

TEACHING OF HYGIENE AND GRANTING OF DEGREES OF DOCTOR OF PUBLIC HEALTH.

DR. WYATT JOHNSTON, of Montreal, compared methods of hygienic instruction in vogue in the United States and in foreign countries, with the result that the showing was decidedly favorable to the foreign countries. He inveighed strongly against the looseness of methods in this country by which men are able to secure positions as health officers or as members of boards of health without having the necessary qualifications. He urged the association to con-

sider this matter, and endeavor to arrive at some standard for a purely hygienic education.

DR. L. P. JONES, of Greenwich, Conn., followed Dr. Johnston, and outlined the following scheme for preventive medicine: (1) The endowment of a chair of preventive medicine in each of the leading medical colleges of the country; (2) the establishment of an institute the members of which should be the incumbents of these chairs; (3) an award of prizes by this institute for essays and discoveries of special merit in sanitary science; (4) establishment of fellowships for a limited number of advanced students.

DISPOSAL OF REFUSE MATERIAL.

This subject was dwelt upon by MR. RUDOLPH HERRING, of New York City, who presented a report in which he mentioned the methods for disposing of garbage in the great cities of the world. He referred to the progress made by European cities in this direction, and said that the present status of disposing of garbage and refuse has resolved itself largely into a question of engineering.

(To be continued.)

Recent Literature.

Surgical Anatomy. A Treatise on Human Anatomy in its Application to the Practice of Medicine and Surgery. By JOHN B. DEEVER, M.D., Surgeon in Chief to the German Hospital, Philadelphia. In three volumes. Illustrated by about 400 plates, nearly all drawn for this work from original dissections. Vol. II, Neck; Mouth; Pharynx; Larynx; Nose; Orbit; Eyeball; Organ of Hearing; Brain; Male Perineum; Female Perineum. Philadelphia: P. Blakiston's Son & Co. 1900.

The second volume of this *edition de luxe* on surgical anatomy fully equals in the excellence of its plates the high standard set by the first. Among the plates on the neck especial attention may be called to the section at the line of the sixth cervical vertebra, and the diagram of the deep cervical fascia, which give an excellent idea of this difficult and surgically important structure. Another very clear and accurate plate illustrates the collateral circulation after ligation of the subclavian and common carotid arteries. The plates illustrating the distribution of the lymphatic vessels and glands of the head and neck are also to be commended.

On the subject of ligation of the innominate artery the author quotes Ashurst's statement (the date is not given) that this artery had been ligatured 24 times with 2 recoveries, whereas Burrell in 1895 collected 29 authentic cases.¹ The important and sometimes indispensable procedure of resection of the sternum in this operation, described by Burrell, is not mentioned by the author.

In the description of the frontal and maxillary sinuses the close relation of the infundibulum with the orifice of the latter and the consequent frequent drainage of pus from the former into the latter are not mentioned by the author.

In general the plates and descriptions of the nose, orbit and eyeball are clear and sufficient.

¹ International Textbook of Surgery, vol. i, p. 313.

The illustrations of the brain and craniocerebral topography are good. Reid's method for locating the fissure of Rolando, which, requiring no special apparatus, is perhaps the best and simplest, is wisely chosen by the author for description. The sections of the brain are well chosen and beautifully executed.

In criticism of the description of surgical procedures throughout the work it may be justly said that they are insufficient for the guidance of the surgeon, and that many of them might have been omitted with advantage, as not relevant to a work on surgical anatomy, and as disfiguring by their incompleteness an otherwise excellent work. For instance, the statement with regard to imperforate anus that the operation consists of searching for the rectum through an incision anterior to the coccyx, and that if the rectum cannot be found the only alternative is colotomy, leaves out of account the extremely valuable procedures of resection of the coccyx and part of the sacrum.

The plates on the male and female perineum are clear and valuable.

A Textbook of Pathology. By ALFRED STENDEL, M.D., Professor of Clinical Medicine in the University of Pennsylvania; Physician to the Philadelphia Hospital; Physician to the Children's Hospital, Philadelphia, etc. Third edition, revised. With 372 illustrations. Philadelphia and London: W. B. Saunders & Co. 1900.

This work is popular, for already it appears in its third edition. The author states that his primary purpose is to supply a moderate sized book on clinical pathology, but why the term "clinical" should be introduced here is not apparent, for it is not clear to the reviewer that the subject matter is any more clinical than that of other well-known works on general and special pathology.

The author has succeeded remarkably well in condensing a large quantity of facts into a comparatively small space. The use of the heavy-faced type for headings of subdivisions of chapters attracts the eye. The book is evidently written for young medical students and in general seems to be well up to date.

Several criticisms seem to be called for. The author's classification of carcinomata is objectionable. We can see no good reason for using the term "cylindrical epithelioma" for carcinomata arising from columnar or cylindrical epithelium, and then classifying other carcinomata of identical histological structure under "glandular carcinomata." Such a multiplication of terms must prove to be as confusing to the student as it has been to the reviewer. Thus we find, in the description of carcinomata of the stomach, adenocarcinoma discussed in a separate paragraph from "cylindrical epithelioma," as if these were different forms of tumor and with an apparent effort to make a distinction between them. If there is such a distinction the author's description does not make it plain. Moreover, we think that the application of the term "epithelioma" to certain forms of carcinomata tends to a useless multiplicity of terms and to the confusion of the student, for the forms of tumor grouped under this term by the author are all carcinomata. We agree with Ziegler that the term "epithelioma" should be preserved for certain benign epithelial growths.

The description of the histology of acute nephritis is also unsatisfactory. Thus, there is no mention or description of the commonest form of glomerular

nephritis, the intracapillary form, while acute interstitial nephritis is described as characterized by the formation of purulent foci in the kidney and is apparently considered to be identical with suppurative nephritis. Acute interstitial nephritis, non-suppurative, is said not to exist as an independent affection. The author apparently does not accept the results contained in the literature on the histology of acute and subacute nephritis and especially in the published work of Councilman upon the subject. The section on mycetoma indicates that the author apparently rejects the results of the work by Boyce and Surveyor and others on this disease.

Considered as a whole, we think that the book shows good reasons for the extensive sale it has evidently enjoyed among medical students.

A Textbook upon the Pathogenic Bacteria. For Students of Medicine and Physicians. By JOSEPH MCFARLAND, M.D., Professor of Pathology in the Medico-Chirurgical College, Philadelphia; Pathologist to the Medico-Chirurgical Hospital, Philadelphia; Fellow of the College of Physicians of Philadelphia, etc. Third edition, revised and enlarged. With 142 illustrations. Philadelphia: W. B. Saunders & Co. 1900.

This book aims to be not only a manual for the bacteriological laboratory, but also to present a readable account of the properties and peculiarities of all of the important pathogenic bacteria. The present edition of the book represents an improvement over the last edition. The author has evidently considerably enlarged his acquaintance with the literature of bacteriology and the pages abound in useful references as footnotes. In this connection it is gratifying to note the number of references to American workers.

The reviewer does not find much to object to, but yet he does object to the crediting to Canon of a part in the discovery of the influenza bacillus and to the presentation of the subject of mycetoma.

Canon's alleged discovery of the bacillus of influenza will not bear examination, for it has never been shown that the bacillus that he claimed to have discovered in the circulating blood of influenza cases was identical with, or had any resemblance to, the now accepted bacillus of influenza, described by Pfeiffer in the bronchial secretions. Canon's claim rests upon little more than an assertion.

The chapter on mycetoma is objected to, chiefly because no adequate explanation is given of what the photographs which accompany the chapter are meant to illustrate. The author apparently does not accept the views concerning the dual nature of this disease expressed in the paper from which these photographs were taken.

Manual of Pathology, including Bacteriology. The Technique of Post-mortems, and Methods of Pathologic Research. By W. M. LATE COPLIN, M.D., Professor of Pathology and Bacteriology, Jefferson Medical College, Philadelphia; Pathologist to Jefferson Medical College Hospital and to the Philadelphia (Blockley) Hospital; Bacteriologist to the Pennsylvania State Board of Health. Third edition, revised and enlarged. Pp. 846, with 330 illustrations and 7 colored plates. Philadelphia: P. Blakiston's Son & Co. 1900.

Although it is stated in the preface of this work that it is not intended to be a treatise or book of ref-

erence, but a manual for use in the laboratory and post-mortem room, and in clinical diagnosis by microscopical methods, the size and makeup of the work show that the book has a more ambitious scope than this. Thus, not only does it treat of "bacteriologic," "histologic," post-mortem, and other kinds of laboratory technique useful in medicine, including the microscopical examination of the urine, but it also attempts to present the subjects of general and special pathology.

The book is evidently written to satisfy the demand of medical students for a large amount of information on various subjects in a concentrated form. That it meets this demand to the satisfaction of a large number of medical students is shown by the fact that this, the third edition, has been published. Of course, the present edition is much larger than the first edition.

From the reviewer's point of view the book is unsatisfactory because it covers too much ground. It is neither a good work on laboratory technique, nor is its presentation of the subject of general and special pathology adequate. We note that the author defines the term hypertrophy as "increased functional power having a tendency to persist, and that is beyond the normal for a given tissue under its existing conditions." For the definition of inflammation he adopts that of Park: "Inflammation is an expression of the effort made by a given organism to rid itself of, or to render inert, noxious irritants arising from within or introduced from without." In the next edition these definitions should be improved.

Experiments on Animals. By STEPHEN PAGET. With an introduction by LORD LISTER. Pp. 274. London: T. Fisher Unwin. 1900.

This volume on animal experimentation comes with peculiar grace from Mr. Paget, who although not himself engaged in experimental work, was for twelve years secretary to the Association for the Advancement of Medicine by Research. In this official capacity, and without the enthusiasm engendered by personal experiment, which is supposed to warp judgment, Mr. Paget must be regarded as a fair critic of the questions at issue. The book is a concise, scholarly and, to unprejudiced persons, convincing presentation of facts relating to experiments on animals. It is replete with literature references and statistics, and throughout shows a judicial attitude, which should commend it to all readers, however widely their opinions may differ. The book is conveniently divided into three general parts, under which there are a number of chapters. The first part deals with experiments in physiology and narrates the classical experiments, which have formed the foundation of much of our later knowledge. The second part concerns itself with experiments in pathology, bacteriology and therapeutics, constituting the bulk of the book. The various diseases due to bacteria are treated in considerable detail, with the experiments which have so materially added to our knowledge of their etiology and prophylaxis. Parasitic diseases, myxedema, the action of drugs, and snake venom are also each given a chapter. The third part discusses the "Act Relating to Experiments on Animals," and is naturally of particular interest to English scientists.

It is hard to commend such a book too highly, containing, as it does, an admirable presentation of facts, carefully collected and concisely presented to the

reader. The final decision in this whole question of animal experimentation must clearly be reached by a painstaking collection and proper interpretation of facts and by nothing else. The book is well printed and sufficiently well bound, and has three full-page illustrations.

Disinfection and Disinfectants. By H. M. BRACKEN, M.D., Secretary of the Minnesota State Board of Health. Chicago: The Trade Periodical Co. 1900.

This handy volume contains a condensed statement of the subject of disinfection and its practical application, and will be found a valuable handbook for the use of health officers, who are constantly engaged in the campaign against infectious diseases.

The short and terse distinctions between the terms, "germicide," "disinfectant," "antiseptic" and "deodorizer" in the introduction are clearly stated. The chapter, concerning Certain Infectious Diseases, contains many useful hints and instructions, and shows very clearly the different uses of the various disinfectants in their applications to the different kinds of communicable disease to which man is liable. Undue importance, however, appears to be given to the necessity of embalming the bodies of persons dying of such diseases, the frequent allusions to this process conveying the impression that such bodies constitute a menace to the public health almost as serious as the presence of the living who are suffering from similar diseases, a theory which is not borne out by everyday experience.

The book is fully illustrated with excellent illustrations showing various forms of apparatus used in disinfection, the methods employed for disinfecting interior apartments, etc.

The Theory and Practice of Hygiene. By J. LANE NOTTER, M.A., M.D., and W. H. HORROCKS, M.B., B.Sc. Second edition. Philadelphia: P. Blakiston's Son & Co. 1900.

This work constitutes one of the best treatises yet published in English upon this subject, and may be regarded as nearly up to date as the extremely progressive character of the subject will admit. Several of the former chapters have been rewritten and important additions have been made to those which relate to water supply, sewage disposal, immunity, disinfection and infectious diseases. The material relating to the bacteriological examination of water is very fully presented. The chapters relating to water, food and beverages, sewage disposal, infectious diseases and sanitary law are very thoroughly treated. Each chapter is followed by a bibliographical list of the works employed in its preparation.

The work is illustrated with 15 inserted plates, and many wood cuts. Due credit is given to the State Board of Health of Massachusetts for the use of Plate VII in the chapter relating to food. Plate XV, illustrating Dr. Manson's observations upon the malarial parasite, together with the review of the modern researches as to the part played by the mosquito, and the methods employed for its destruction illustrate the progressive character of the work. Very much material has been brought together in this comprehensive volume which will make it a useful work of reference for students, but more especially for all persons who are interested as practical workers in sanitary science.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, NOVEMBER 29, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

"THANKSGIVING DAY."

NOTWITHSTANDING the reflection that the physician, as such, is more apt to be practically and professionally concerned with the days immediately following Thanksgiving Day, with the sequelæ of its present celebration, than with the day itself or the observances thereof, it is perhaps not amiss that we should devote a brief space in a number of a Boston medical periodical issuing on an anniversary of this old New England function to its consideration, without yielding to the temptation to produce, after the fashion of the modern magazine, a Thanksgiving number.

Thanksgiving Day is generally recognized all through the country as pre-eminently a New England function. It is only since 1863 that the proclamation appointing a general day for all the States of the Union has proceeded from the President.

Previously, as those in middle life can well remember, the governors of those States which held the day in honor issued each his own proclamation, naming his own day, which might or might not be that of other States.

The first "Thanksgiving" celebration is said to have been held by the Plymouth Colony in 1621, but the first regularly appointed Thanksgiving Day in Massachusetts was apparently held on February 22d, a date of good omen, 1632. "These days seem to have originated in the public acknowledgment of some immediate causes of gratitude to God, and not as mere formal anniversary observances." The conditions leading up to and surrounding this Thanksgiving Day of February, 1632, are in such a dramatic contrast to those now obtaining in this neighborhood, or in fact almost anywhere in this country, as to merit being again described for our chastening and correction. On the 29th of November, 1631, Governor Winthrop writes from Boston to his wife in England: "We are here in a paradise. Though we have not beef and mutton, etc., yet (God be praised) we want them not; our Indian corn answers for all. Yet here is fowl and fish in great plenty. . . . We here enjoy

God and Jesus Christ. Is not this enough? What would we have more?" Before the winter was far advanced, however, the people "were necessitated to live on clams, and muscles, and ground nuts and acorns." The governor himself had the last batch of bread in the oven, and was seen giving the last handful of meal in the barrel into a poor man distressed by the wolf at the door. A ship had been sent to England six months before for provisions, but had not been heard from. A day had been appointed for a general humiliation, to seek the Lord by fasting and prayer; for this form of observance the facilities were ample. At the last moment, in the very hour of despair, the ship was seen entering Boston Harbor, laden with provisions for them all.¹

It is not to be inferred that the fast became a feast from this early period, but a great differentiation has certainly been slowly evolved, and the observances of today — the devotion to pastimes and the generous consumption of sustenance — would doubtless scandalize the early worthies of the colonies. After the Revolution the custom of appointing a Thanksgiving Day gradually extended to the Middle States, later to the West, and more slowly to the South.

There are few years in which the inhabitants of this country have not much to be thankful for, and certainly there have been very few in which there were more, or more general, causes for keeping a day than this year — even those who voted for Mr. Bryan need not exclude themselves.

Although we have ceased to fast and humiliate ourselves, and there may be some even who do not pray, the day still has its uses, and we believe of no small value morally, socially, and even physically, to the citizens of so widely expanding a country. It gives another holiday, and as yet our people have none too many; its tribute is paid to the family; it brings the old and the young together; reknits periodically the dropped stitches in the old home life; brings those who are crowding more and more into the whirl of the cities back now and then to the calm of the country, where they were reared and where they may take new bearings as to relative values. In all these respects we hold that Thanksgiving Day is good and should be pleasant medicine for the American of today, of whatsoever descent he may be.

THE ETIOLOGY OF BERI-BERI.

THE time is clearly approaching when the various infectious diseases will so far have yielded to investigation that we shall know their causative agents and the means by which infection is produced. The extraordinary interest recently manifested in the study of tropical disease has done much to broaden our horizon and to supply problems and material for research which are quite out of reach in our temperate and highly civilized home communities. To study the subtle questions of etiology, it is clearly essential to

¹ Memorial History of Boston, pp. 117, 118.

go where the disease under investigation is endemic, and this, it is gratifying to note, is being done more and more by men well equipped with the training necessary to successful research. The recent brilliant investigations on malaria are a case in point. Admirable work had been already done in the study of individual cases, but the fundamental problem underlying the spread of the disease was practically untouched, until the very haunts and breeding places of the disorder were invaded. The conception which led to the opening of the London School of Tropical Medicine has already demonstrated the wisdom of its founders, and we look forward with confidence to a constantly increasing number of enthusiastic workers who will go out from its instruction to add to our knowledge of preventive medicine.

Beri-beri has long been a disease of which we have heard, and of which the textbooks write; to actually see it has been an opportunity which few have enjoyed. Sporadic cases, often doubtful of diagnosis, appear from time to time, as has recently happened at the Boston City Hospital, but never in sufficient numbers to permit of more than a superficial study. The condition, no doubt, derives its chief interest from the difficulties which have beset our efforts to get at its etiology. In this connection, a letter written to Dr. Patrick Manson by Dr. Van der Scheer, of the Hague, formerly of Java, and published in the November number of the *Journal of Tropical Medicine*, is of more than passing interest. Dr. Van der Scheer has had unusual opportunities for study, and has already published some of his results in the *Indian Medical Gazette*. The present letter is called out by the fact that various journal references to his work have been insufficient to attract attention to his hypothesis. Dr. Van der Scheer does not believe that beri-beri is a disease due to the influence of an exogenous toxin from the soil or from food. Regarding the influence of food, he says that many examples are known of people partaking of the same food, but living in different houses, among whom one group develops beri-beri while another remains exempt. He believes, further, that the disease is not contagious and not miasmatic, though he does not explain as fully as we should wish precisely what he means by "miasmatic."

Regarding this he writes: "I wish to point out that I have become convinced of the truth of this theory during my residence at the hospital in Batavia. It is a collection of large, spacious buildings, separated from each other at a distance of several yards and occupied by no more than 50 to 70 patients in each. The floors of the 'pavilions' are cemented. The water is furnished by artesian wells, the food is excellent, and real miasmatic diseases, as cholera, typhoid, dysentery, never occur in it, although patients suffering from these are often treated within its walls. Beri-beri occurs there in a severe fashion. And so we see it everywhere. It appears in hospitals, barracks, etc., which are apparently under the best hy-

gienic conditions; it disappears when the patients attacked (natives) leave the spot and are dwelling in their private houses under conditions much worse than the former."

The following interesting facts are also noted: That whereas cholera, typhoid and allied disorders are apt to increase when troops, for example, are collected in camps, beri-beri disappears; that persons are usually not attacked when much in the open air and that hospitals and vessels at sea are notorious centres for the development of the disease. The fact that beri-beri often breaks out on board ship long after leaving port militates against the idea that this is due to a long incubation period, since the incubation period is known, at times, to be very short and it is unlikely that this period would vary within such wide limits. Dr. Van der Scheer has reached the definite conclusion that the spread of the disease must take place through an intermediate host, either an insect or some other form of animal life. His suspicions have rested on the *blatta orientalis* (black beetle, cockroach) or of some member of that family as the probable carrier of the infection. This beetle is found in all parts of the tropics where beri-beri exists, and is frequently found on shipboard.

The general conclusions are as follows: "According to my idea beri-beri must be caused by a parasite (ameba or something else) that lives in the intestinal tube and forms a toxin which causes degeneration of nerves. A part of the life cycle of the parasite may take place in the body of a *blatta* species (in its intestines, kidneys, or lymph glands), and the spread of the disease to them would be possible when: (1) There are patients suffering from beri-beri; (2) when the *blatta* species is present; (3) when it is possible that the *blatta* eats human feces; (4) when man is infected by *blatta* excrement.

In view of the vogue which the theory of the conveyance of the exciting cause of disease by means of animal hosts is now having, this conception is certainly one demanding close inspection and further study. The matter must be taken absolutely out of the realm of speculation or possible coincidence and demonstrated as a fact before it can be accepted by scientific men. It is to be hoped that more attention will be given Dr. Van der Scheer's theory in the future than appears to have been accorded it up to this time.

MEDICAL NOTES.

SECTION ON MEDICINE OF PAN-AMERICAN MEDICAL CONGRESS.—The next meeting of the Pan-American Medical Congress, to be held at Havana, from December 26 to 29, 1900, promises to be a successful one and a large attendance is expected. It is sincerely hoped that the United States will be well represented and that the programme of the Section on Medicine will be a creditable one. The titles of papers intended for this section, together with the name and address of the author, should be sent as soon as pos-

sible to the secretary of the congress, Dr. Tomas V. Coronado, Prado 105, Havana, Cuba, and it is especially desired that a short abstract of the paper should also be prepared and mailed at the same time. For further particulars address Dr. Judson Daland, 317 South 18th Street, Philadelphia, Secretary of the Section on Medicine.

TWO CENTENARIANS.—Mrs. Thomas Flournoy, said to be in her one hundred and first year, died in Philadelphia last week. She was the widow of General Flournoy, an officer in the War of 1812, and her father served in the Revolution. Mr. George Kendall, of Fairfield, Me., also died last week, at the reputed age of one hundred years and some months. His father was the first settler in the village.

PLAGUE ON EAST COAST OF AFRICA.—It is announced that Sir Alfred Milner has proclaimed that all the East Coast ports of South Africa between the tenth and fortieth parallels are infected with plague.

DR. ABRAHAM JACOBI, VICE PRESIDENT OF THE PAN-AMERICAN MEDICAL CONGRESS.—Dr. Abraham Jacobi has been appointed vice president for the United States of the coming Pan-American Medical Congress.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the six days ending at noon, November 27, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 158, scarlatina 39, measles 12, typhoid fever 15.

BOSTON MORTALITY REPORT.—The number of deaths reported to the Board of Health for the week ending November 24 was 200, as against 225 the corresponding week last year, showing a decrease of 25 deaths, and making the death rate for the week 18.6. The deaths from tuberculosis of the lungs were 23, pneumonia 14, whooping cough 1, heart disease 23, bronchitis 4, marasmus 6. There were 9 deaths from violent causes. The number of children who died under one year was 24, under five years 41, persons more than sixty years 52; deaths in public institutions 61.

COMMITMENT OF WOMEN TO INSANE HOSPITALS.—In the recent test case regarding the claims of a certain Mrs. White that she was illegally detained in an insane asylum, Judge Morton, of the Supreme Court, in remanding her to the hospital, made the following statement: "I still think that it is a crying injustice that, although a man may be brought before the court and have every careful safeguard put around him before being committed to an insane asylum, a woman can have none of this, but may be committed without notice of hearing."

DIPHTHERIA IN A SOMERVILLE, MASS., SCHOOL.—The Jackson Primary School has been closed by the Board of Health until after the Thanksgiving vacation. The schoolhouse consists of four rooms and accommodates about 150 pupils. The janitor lives in

the basement of the building, and recently two of his children were taken ill with diphtheria. None of the pupils are ill with the disease; the building is closed merely as a precautionary measure.

SANITARIUM IN SALEM, MASS., HARBOR.—Arrangements have been completed for tearing down the main building at Lowell Island in Salem Harbor, used for a children's sanitarium, and erecting a smaller and more convenient building on the same site. It is hoped that it will be possible to have the new building in readiness for use by next summer.

ABOLITION OF CANE RUSHES.—As the indirect result of the death of a student at the Massachusetts Institute of Technology, while engaged in a cane rush, the custom has been discontinued at that institution. The student body at Tufts College has likewise voted to substitute a less dangerous test of superiority for the so-called flag rush.

CHANGES AT LONG ISLAND HOSPITAL, BOSTON HARBOR.—Dr. A. J. Ranney, who will assume the superintendency of the Long Island Institution, has announced his intention of appointing Dr. A. S. Hartwell assistant superintendent. Dr. Hartwell's position heretofore has been first medical officer.

DIPHTHERIA IN CAMBRIDGE, MASS.—A death from diphtheria was recorded at the Cambridge Board of Health November 26th, together with 5 hitherto unreported cases.

NEW YORK.

APPROPRIATIONS FOR CHARITABLE PURPOSES.—The annual meeting of the Charity Organization Society of New York was held on November 16th. The report of the council showed that the appropriations for private hospitals and other institutions in the city budget for 1901 is \$2,786,011, or \$71,730 less than for 1900. The most urgent needs of the city in the line of charity were given as additional day nurseries, more diet kitchens, increased provision for aged people, hospitals for consumptives, and active volunteer workers. Among the speakers were Dr. John H. Pryor, of Buffalo, Commissioner of Charities Keller, and Controller Coler. Mr. Keller spoke of the urgent need of a new city hospital for Harlem, and said that he had applied to the Board of Estimate and Apportionment for an appropriation to erect the proposed buildings in a more central location than the present inadequate structure. Mr. Coler said that he could promise the commissioner at least one vote both for the Harlem Hospital and for a hospital for consumptives.

STATE CHARITIES AND CORRECTION.—The first New York State Conference of Charities and Correction was held at Albany on November 20th, 21st and 22d. The number of dependents under institutional care in the State, including the insane, was stated by the president, William P. Letchworth, to be 86,893. In a paper contributed by Controller Coler, the latter said he could not but feel that the city authorities

ought to have fuller information about the quality, work, needs and merits of the large number of private institutions appealing to the city for annual subsidies. The report of the Committee on the Mentally Defective was presented by Dr. William P. Spratling, Medical Superintendent of the Craig Colony for Epileptics.

BROOKLYN WATER SYSTEM.—The Court of Appeals has just rendered a decision which may seriously cripple the water system of the Borough of Brooklyn. While the decision only awards \$6,000 damages to Benjamin Forbell, a farmer, and grants a perpetual injunction restraining the city from operating the driven wells at the Spring Creek pumping station, it involves the entire water supply system of Brooklyn, and it seems probable that the city will be called upon to make good damages aggregating \$1,500,000. More than a hundred similar suits are now pending, but they have been held back until the Court of Appeals decided the Forbell case, which was regarded as a test case.

A GOLDEN WEDDING.—Dr. Thomas M. Markoe, emeritus professor of surgery in the College of Physicians and Surgeons, and Mrs. Markoe celebrated their golden wedding on November 20th.

Miscellany.

VITAL STATISTICS OF HAVANA.

W. C. GORGAS, Major and Surgeon, U. S. Army, and chief sanitary officer, makes the following statements in his report to the Adjutant General, Division of Cuba:

The general death rate for this month makes a very favorable showing as compared with the past four months, being less by eleven deaths than the smallest figure shown in these months. The report shows that we had 507 deaths, which gives a death-rate of 25.08. This rate compares very favorably with the rate for October for the ten preceding years, being smaller than the lowest, that of 1899. We had 74 deaths from yellow fever this October. While this is large for October, it is not, as has been reported in many of the papers of the United States, as large as that for October in many of the preceding years. The years 1895 and 1896 showed considerably larger numbers. Of the cases of yellow fever occurring during this month, 62 were Americans and 225 were Spaniards; 8 Americans died and 51 Spaniards, giving a rate respectively of 12.90 for the Americans and 22.66 for the Spaniards. The immigration continues to increase, and is the great cause of our comparatively large number of yellow-fever cases. We have had so far the largest number of immigrants that has come into Havana in any one year up to November the first, and, for October, very much the largest immigration that has occurred in any October within ten years. We hope a great deal from the recently established Immigration Bureau, but so far it has not had time to have any perceptible effect. Of 308 cases this month, 167 have been on the island less than a year and 215 less than two years, which goes to prove that our yellow fever is made up almost entirely from the recently arrived Spanish immigrants. During the past month many exaggerated reports of the yellow-fever situation have been published in the United States. Out of a population of 242,000 there have been since the first of

January 968 cases. Mr. Dobson, the correspondent of the Associated Press, published very widely the statement that every block in Havana had from 1 to 17 cases. We have 857 occupied blocks. Out of these 397 have had cases of yellow fever. Of the blocks which have had cases, 224 had only 1 case, and only one or two blocks in the city approximated the numbers given by Mr. Dobson. In Havana there are 16,480 houses, of which 709 have had cases of yellow fever. In the *Boston Transcript* of October 20th, Gen. Fitzhugh Lee is quoted as stating that a yellow-fever epidemic exists in Havana at present, which epidemic is the worst in his experience. It will be seen in the body of the report that for the past ten years there have been few years in which the deaths from yellow fever are as few in number as they have been this year. General Lee, I think, spent 1896 and 1897 in Havana. In 1896 there were 1,282 deaths from yellow fever and in 1897 there were 858; this year, so far, there have been 236. The *New York Evening Post* of October 29th, in an article commenting upon the extent of yellow fever in Havana, among other things says: "Certainly, the army itself did not have so many or such serious losses to deplore as this year." The records of this office show that during the year 1899, among the soldiers within the present city limits of the city of Havana, officers and enlisted men, we had 26 cases of yellow fever with 7 deaths. Up to the first of November for the year 1900, in the same class and over the same area, we have had 20 cases and 6 deaths.

I call attention to these facts to emphasize the statement that I have frequently made, that yellow fever is not very general in its distribution in Havana, as is reported, and not by any means as universal as is generally believed. I would like in this connection to call attention to the apparently good results that we have obtained from our system of disinfection and isolation. In these 553 houses in which we have had 1 case of yellow fever, the disinfection has apparently been successful and has prevented a recurrence of the disease. I also wish to call attention to the large amount of cleaning and disinfecting that has been done during the past month. This is considerably more than this department has before accomplished in any one month during my administration. I think the money and labor we are spending in this direction is well spent, but I desire again to call the attention of the adjutant general to the need of a general system of sewerage. I do not believe that our present system of isolation and disinfection will answer in itself to eradicate yellow fever from Havana, but must be supplemented by a general sewerage system, and I earnestly urge that this be commenced at the earliest possible date.

MESSAGE IN JAPAN.

DR. H. C. WOOD, of Philadelphia, sends an interesting letter to the *Philadelphia Medical Journal* on his observations on massage in Japan:

"As every one knows, massage has been largely practised in Japan almost from time immemorial. In a recent tour through that country one of the most interesting and curious sights that I witnessed was a little 'tot' between five and seven years old, with the utmost seriousness and earnestness, and with a marked degree of skill, standing and massaging the age-stiffened trapezius and other muscles of the shoulders of an old grandfather or grandmother squatting before him. The common belief that the blind have in Japan a monopoly of the practice of massage appears to be only so far correct that probably 90% of the practitioners of the art are blind persons, who wander about the streets blowing a peculiar double whistle whose two weird notes may be heard at almost any hour of the day or night, pleading for work and sustenance.

"In order to make out the differences between the art as practised by the Japanese and the Europeans, I ordered a masseur in Yokohama, Tokyo, Kyoto, Mianoshita, Nikko, and one or two other places. As was perchance naturally to be expected, Yokohama being simply a foreign excrescence on the Japanese body corporate, the masseur in that city was not blind and seemed simply to be badly trained in the European methods. I could not make out any difference between him and a second-class American masseur.

"Kyoto is the centre of all that pertains to Japanese religion, art or customs, having been the capital of old Japan, and being still the culture capital of the country. The masseur I saw there possessed great skill; his methods, however, did not differ very greatly from those to which we are accustomed, except in one motion, which seems to me the most efficient I had ever had practised on me, for the purpose of deep kneading between groups of muscles or of muscles situated much below the surface. The motions were so quick that in the absence of ability to talk with the practitioner it was a little difficult to perceive exactly how they were made, but I finally made out that the procedure might be termed a rolling use of the different joints of the fingers; first, the tip; then the distal intraphalangeal articulation; then the next joint; and then the knuckles applied one after another with great rapidity and force; the maximum of the force sometimes being reached with the second intraphalangeal joint, the knuckles only pressing lightly; in other cases the knuckles themselves giving the main blow. It was apparently when it was desired to penetrate deeply between two closely placed muscle groups that the maximum force was applied with the second intraphalangeal joint.

"One or two somewhat curious differences between the Japanese customs and our own were noticeable. In one of the places a woman, old, blind and ugly, was sent to do the work. The length of the séances seemed to be arranged according to the desire or the ability of the person operated upon to pay, and were remarkably cheap, even when the foreign price was demanded. Thus, asking the charge at one of the hotels, before engaging an operator, I was told 'Thirty sen,' that is, fifteen cents an hour. On expressing surprise, saying I had always paid forty sen, the man replied, 'Oh, yes, that is the price for the foreigner.' Not considering myself seriously cheated I paid the forty sen, or twenty cents for an hour of labor sufficiently hard to make the operator sweat freely."

THE USE OF TOBACCO ON ACTIVE SERVICE.

THE war in South Africa has taught many things of greater and of less importance. Perhaps nothing that it has demonstrated has been more marked than the important part which tobacco plays in the soldier's existence. Whether this is to be reckoned as a great fact or a small one there can be no doubt about the truth of it. Yet the Duke of Wellington's armies had no tobacco worth speaking of. If they did not forbid its use, at any rate the Iron Duke's officers were directed to advise their men strongly against it. What a curious contrast with the campaigning in South Africa, where marches and privations as long and as stern as any suffered by our great-grandfathers were borne by the volunteers and soldiers of today with a

grumble only when their "smoke" failed them. We have it from many who took part in the forced marches leading to Paardeberg, to Bloemfontein, to Pretoria, and beyond, that when rations were but two or three biscuits a day the only real physical content of each twenty-four hours came with the pipe smoked by the smouldering embers of a camp fire. This pipe eased the way to sleep that might otherwise have lingered, delayed by the sheer bodily fatigue and mental restlessness caused by prolonged and monotonous exertion. It is difficult, then, to believe that tobacco is anything but a real help to men who are suffering long labors and receiving little food, and probably the way in which it helps is by quieting cerebration — for no one doubts its sedative qualities — and thus allowing more easily sleep, which is so all-important when semi-starvation has to be endured. The cases of acute mental derangement in the course of campaigns such as the present are many. There have indeed been many in South Africa. It would be most profitable and interesting could medical officers have taken special note of the capacity for sleep previously evidenced by those who broke down, and also of their indulgence or non-indulgence in tobacco. We are inclined to believe that, used with due moderation, tobacco is of value second only to food itself when long privations and exertions are to be endured. Two features are to be noted with regard to the smoking practised on active service. It is almost entirely in the open air, and it is largely on an empty stomach. The former is always an advantage; the latter we generally reckon a most unfavorable condition. Shall we see in the near future patients with tobacco amblyopia or smoker's heart acquired while the trusting friend of tobacco thought that he was enjoying unharmed the well-earned solace of a hard day's march? We believe not, and that the open air will have saved what might have been the untoward results of smoking when unfed. — *Lancet*.

A NEW SCOTTISH TEMPERANCE SOCIETY.

A new temperance society has been formed in Scotland with the Duke of Sutherland as president. It is to be known as the Scottish Self-Control Society, or, briefly, the "S. S. S." Its members undertake three things: (1) Not to drink intoxicants before noon or at any time except at a regular meal; (2) not to treat, that is, not to offer or accept alcoholic drinks except with a regular meal; (3) not to give or to accept drink in return for services rendered.

The standard of temperance is not so rigorous but that a strenuous effort might enable a member to live up to it.

Correspondence.

KIRKES' PHYSIOLOGY: A REPLY.

BOSTON, November 29, 1900.

MR. EDITOR:—The letter entitled "Kirk's Physiology: A Reply" appearing in your issue of November 22d over the signature of Warren Coleman, M.D., calls for an additional statement from your reviewer.

If Dr. Coleman will carefully reread the reviews and the "reviewer's note" he will find that he is not personally ac-

cused of *lifting bodily* cuts and text from the English edition. These similarities, however, exist, and if Dr. Coleman investigates, he will find that the reviewer's statement is correct, although he may personally have had nothing to do with the actual *lifting*. That the American edition (Wm. Wood & Co.) is revised from the English editions is practically acknowledged by the fact that the names of Baker and Harris, the former English editors, appear on the title page. It is useless, therefore, for Dr. Coleman to deny that the book under discussion was compiled from an English edition. The similarities in text between the recent American and English editions will be evident to any one who has both the fifteenth and the thirteenth American and English editions (before Dr. Coleman or Dr. Halliburton edited these respectively) at hand.

Dr. Coleman should surely know that no charges have been made which are not in accord with facts, and such charges as were made were not made for the first time in the reviews under discussion. Since the publication of the reviews, the reviewer has obtained a copy of the *Philadelphia Medical Journal* dated February 24, 1900, containing a letter from Mr. Murray—the owner of Kirkes' Physiology in England—protesting against "*this glaring and persistent case of literary piracy.*" I have searched for some reply to this letter from either the American editors or publishers, but can find none. Does Dr. Coleman recollect the old saw about silence and consent? Dr. Coleman insinuates that the reviewer did not confine himself to the field of "legitimate criticism." This reviewer considers it legitimate criticism to point out any questionable proceeding in connection with a book he has to review.

Dr. Coleman speaks of offensive charges. It was not the intention of the reviewer to make any accusations of an offensive nature, but the statements of which Dr. Coleman complains being true, it was the duty of the reviewer to call the attention of the public to them. Under the circumstances, the reviewer does not consider the reviews "offensive," but it must be extremely unpleasant to lend one's name to a proceeding thinking it to be honest, and then to have it shown that it is not so.

Very truly yours,
THE REVIEWER.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 24, 1900.

A. W. DUNBAR, passed assistant surgeon, detached from the "Monongahela" and ordered to the "Vermont" for temporary duty with the crew of the "Wisconsin," and then to Naval Hospital, Mare Island, Cal.

R. B. WILLIAMS, assistant surgeon, appointed assistant surgeon from November 17, 1900.

J. T. KENNEDY, assistant surgeon, detached from the "Monocacy" and ordered to the Cavite Naval Station.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOVEMBER 22, 1900.

STONER, J. B., passed assistant surgeon. Relieved from duty at Quebec, Can., and directed to proceed to Norfolk, Va., and assume temporary command of the service during the absence of the medical officer. November 20, 1900.

THOMAS, A. R., passed assistant surgeon. Granted leave of absence for four days. November 3, 1900. Granted leave of absence for one month. November 19, 1900.

WICKES, H. W., passed assistant surgeon. Granted leave of absence for seven days from November 28th. November 19, 1900.

COFER, L. E., assistant surgeon. Directed to rejoin station at Los Angeles, Cal. November 17, 1900.

HOBDDY, W. C., assistant surgeon. Granted extension of leave of absence for two weeks from November 3d. November 2, 1900.

BAHRENBURG, L. P. H., assistant surgeon. Relieved from duty at Liverpool, Eng., and directed to proceed to New York, N. Y., and report to Surgeon L. L. WILLIAMS at immigration depot for duty. November 16, 1900.

LAVINDER, C. H., assistant surgeon. Granted leave of absence for two months from November 20th. November 22, 1900.

GIBSON, L. P., acting assistant surgeon. Granted leave of absence for ten days from November 13th. November 15, 1900.

GOODMAN, F. S., hospital steward. Granted leave of absence for thirty days from December 19th. November 21, 1900.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — The Surgical Section will meet at the Medical Library, 19 Boylston Place, on Wednesday evening, December 5, 1900, at 8.15 o'clock.

Paper: "Enlargements of the Prostate; the Results of Personal Investigations into the Surgical Anatomy of the Enlarged Prostate, with Special Reference to Operative Treatment," by Dr. Samuel Alexander. Drs. A. T. Cabot, Abner Post and Paul Thorndike will take part in the discussion.

F. G. BALCH, M.D., Secretary, 279 Clarendon Street.

CHANGES IN STAFF OF CARNEY HOSPITAL.

The following changes have taken place in the staff of the Carney Hospital:

Resigned: DR. MUMFORD, visiting surgeon; DR. GREENOUGH, surgeon to out patients; DR. THOMPSON, physician to out patients.

Appointed: DR. PEASE, visiting surgeon; DR. J. S. STONE, assistant visiting surgeon; DRs. A. L. CHUTE, R. O'NEIL, surgeons to out patients; DR. T. J. O'BRIEN, physician to out patients; DR. F. L. D. RUST, assistant ophthalmic surgeon to out patients; DRs. E. S. HATCH, R. B. OSGOOD, H. S. WARREN, assistants in orthopedic out-patient department.

RECENT DEATHS.

HORACE TRACY HANKS, M.D., one of the best known gynecologists in New York, died on November 18th, at the age of sixty-four. He was a native of Vermont and was graduated from the Albany Medical College in 1861. During a portion of the Civil War he served as assistant surgeon of the 30th Regiment, New York Volunteers. He resigned in 1863, and after practising a year at Royalston, Mass., removed to New York. From 1872 to 1882 he was gynecologist to the DeMilt Dispensary, and in 1889, after having served for fourteen years as assistant surgeon, was appointed surgeon to the Woman's Hospital. Since 1885 he had been professor of diseases of women in the New York Post-Graduate Medical School and Hospital.

ROBERT ACTON, JR., M.D., visiting physician to the House of Correction, Blackwell's Island, died at the Presbyterian Hospital, New York, on November 22d. He was thirty-two years old and a native of Kinsale, Ire. He came to this country in 1891, and later was graduated from the Harvard Medical School. Dr. Acton had a magnificent physique, being six feet one inch tall, and in 1893 he was a member of the Harvard University football team. *

FREDERICK CORNELL DEMUND, M.D., of Bensonhurst, Brooklyn, N. Y., died on November 20th, in his seventy-first year. He was born at Millstown, N. J. He was graduated from the College of Physicians and Surgeons, New York, in 1855, and from 1857 to 1895 practised in the New Utrecht section of Kings County.

BOOKS AND PAMPHLETS RECEIVED.

Treatment of Typhoid Fever. By Stephen Smith Burt, A.M., M.D., New York. Reprint. 1900.

Transactions of the Obstetrical Society of London for Year 1900. Vol. XLII. Parts I, II and III for January to July. Edited by Herbert R. Spencer, M.D., and Percy Boulton, M.D. 1900.

Les Maladies qu'on soigne à Berck: Abcès froids, Adénites, Ostéites, Tumeurs blanches, Coxalgie, Mal de Pott, Scoliose, Luxation congénitale de la Hanche, Pied Bot, etc. Par F. Calot. Paris. 1900.

Sexual Debility in Man. By F. R. Sturgis, M.D., formerly Clinical Professor of Venereal Diseases in Medical Department of the University of the City of New York, etc. New York: E. B. Treat & Co. 1900.

Arzneiverordnungen in der Kinderpraxis, für Studierende und Ärzte bearbeitet. Von Dr. H. Guttmann. Dritte, gemass dem Arzneibuche für das deutsche Reich von 1901. Berlin: Verlag von S. Karger. 1901.

The Prevention of Valvular Disease of the Heart: A Proposal to Check Rheumatic Endocarditis in its Early Stage and thus Prevent the Development of Permanent Organic Disease of the Valves. By Richard Caton, M.D., F.R.C.P. Illustrated. London: C. J. Clay & Sons. 1900.

An American Textbook of Physiology. By Henry P. Bowditch, M.D., John G. Curtis, M.D., Henry H. Donaldson, Ph.D., W. H. Howell, Ph.D., M.D., Frederic S. Lee, Ph.D., Warren P. Lombard, M.D., Graham Lusk, Ph.D., F.R.S. (Edin.), W. T. Porter, M.D., Edward T. Reichert, M.D., Henry Sewell, Ph.D., M.D. Edited by William H. Howell, Ph.D., M.D. Second edition, revised. Vol. I. Blood, Lymph and Circulation; Secretion, Digestion and Nutrition; Respiration and Animal Heat; Chemistry of the Body. Philadelphia: W. B. Saunders & Co. 1900.

Original Articles.

THE TREATMENT OF PLACENTA PREVIA BY CÆSAREAN SECTION, WITH REPORT OF A SUCCESSFUL CASE.*

BY FRANCIS D. DONOHUE, M.D., BOSTON,

Assistant in Operative Surgery, Tufts College Medical School; Assistant Surgeon, Boston Dispensary.

The condition known as placenta previa is today the most fatal condition with which the obstetrician has to deal, and even in the hands of the most expert obstetricians and under the most favorable conditions, shows a death rate, fetal and maternal, higher than almost any other obstetrical condition. That the published statistics do not fairly represent the high mortality in this condition is the opinion of nearly all observers; for they consider that the reported cases give simply the lowest mortality obtainable, because, as a rule, selected cases only are reported. Lawson Tait,¹ voicing this sentiment, says that more than half the cases die of hemorrhage or sepsis, and advised the removal of the uterus as the only safe method of treatment.

Definition.—A placenta is usually denominated previa when it occupies the lower uterine segment, or that part of the uterus which dilates during labor. Clinically, however, a placenta is previa when it has an attachment in the lower uterine zone and partially or entirely covers the os.⁶⁰

Varieties.—The varieties have been denominated as complete, incomplete, lateral, central, marginal, partial and deep implantation; but that which one observer calls partial another will term complete, while lateral, partial and marginal are terms which are used with an interchangeable signification in literature. Practically no two men adopt the same classification.

It would be better² if the varieties were divided into two classes,³ complete and lateral; complete meaning that condition in which the os uteri is entirely covered by the placental tissue; lateral meaning all other insertions in the lower uterine zone in which the os uteri is not covered. Lateral previa under this definition is much more frequent than complete, but the ratio is hard to estimate owing to the confusion of terms in reported cases.

Frequency.—Authorities vary as to the frequency of placenta previa, but from an average of reported cases it would appear that it occurs about once in 800 deliveries. Late statistics, however, would lead us to infer that it is becoming more frequent, but this, I think, may be attributed to more careful diagnosis. There is a marked difference between its occurrence in primiparæ and multiparæ,⁶⁷ its occurrence being about seven times more frequent in the latter class.⁶⁸ It is also liable to occur twice with the same patient. Out of 51 cases reported by Jardine,⁴ 2 had had placenta previa in former pregnancies. The age at which it occurs is also of interest. In 239 cases Read⁵ found that 54% of the patients were over thirty years old, and Mueller,⁶ in 248 cases, found that 50% had passed the thirtieth year. If we consider that three times the number of women give birth to children before their thirtieth year, we find that it is relatively three times as frequent in persons who have passed thirty years as in those who have not attained that age.⁶⁸

* Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, October 24, 1900.

One very important fact in its occurrence is the number of abnormal presentations, due, perhaps, to the abnormal shape of the uterus, various observers giving from 21% to 32% of abnormal presentation.^{23 24}

Diagnosis.—The diagnosis is not usually made until hemorrhage occurs, and it is the occurrence of this symptom which directs the attention of the physician to the possibility of a previa.

Hemorrhage occurring without appreciable cause after the third month of pregnancy, that is, after the formation of the placenta, should give rise to suspicion of placenta previa.⁷ On examination, the lower uterine segment will be found to be soft and boggy,²² and in case of lateral placenta one side will be found thicker than the other. The presence of unusually large blood vessels in vaginal or uterine wall may aid in confirming diagnosis.¹² Ballotement is usually absent.⁷⁷ Absence of morning sickness in multiparæ who have been previously troubled may be considered a diagnostic sign.⁸ For the purpose of confirming the diagnosis of such a serious condition it is held justifiable (if case is seen during last three months of pregnancy and hemorrhage is profuse), to pass the finger through os to determine the presence or absence of placenta. If the examining finger encounters a rough, granular and spongy mass, differing in constitution from a blood clot, the diagnosis may be considered as confirmed.

Treatment.—The treatment of placenta previa in the past has not taken sufficiently into consideration the fact that two lives are involved, and while craniotomy has become a thing of the past, and its performance on a living child, by many men, not justified today,⁴⁷ there is not the same feeling about the induction of premature labor, or the resort to severe operative delivery, which no less surely than craniotomy takes away the chance of life from the child. Lusk,⁹ in 1887, speaking of craniotomy, said: "If it were proposed to a physician to beat out the brains of a newborn child with a view to diminish the perils of the puerperal period, the proposition would certainly be rejected as too horrible for consideration, even though the physician were convinced that the theoretical ground for the recommendation were correct. Yet there seems to be a prevailing disposition to treat any hesitancy to destroy the unborn child, in the interests of the mother, as pure sentimentality."⁷

A list of the various methods generally employed would include tampons of vagina³⁹ or cervix,⁷³ colpeurynter, partial or circular detachment of placenta, perforation of the placenta,⁸³ incision of cervix,⁵³ rupture of membranes,²¹ forceps, induction of premature labor, version followed by immediate delivery, version not followed by immediate delivery, and Cæsarean section. These methods and others have each had, and still have, vigorous supporters and defenders, but all the treatments have been directed to arresting the flow of blood, emptying the uterus, combating anemia.¹¹

For the purposes of this paper a consideration of the following will be sufficient: (1) Induction of premature labor;^{69 71} (2) rupture of membranes followed by natural delivery or delivery by forceps;^{27 91} (3) manual dilatation of os with delivery by version;⁴ (4) Cæsarean section.

Induction of premature labor is advised as soon as diagnosis is made.¹² This treatment is based solely

on the desire for the safety of the mother without regard to the child's life. After the seventh month it might be logical treatment if no better offered, but before the seventh month it should not be justified. In the early days of pregnancy the classical treatment for threatened abortion should be given, namely, rest in bed, patient not being allowed to rise for any purpose during continuation of symptoms; all mechanical irritation of cervix should be avoided and the bowels kept open. In cases of contracted pelvis, maternal mortality of section at term is no higher than after induced labor, while the fetal mortality is practically nothing. On the other hand, the cases of induced labor show an immediate fetal mortality of 33.3% with an ultimate mortality of from 50% to 75%.¹³ This fetal mortality can never be much diminished, for it depends upon conditions over which we have no control, namely, the delicacy of the premature infant and its consequent liability to suffer from the effects of labor; the frequent necessity for interference during labor, due to malpositions and deficient uterine action; the liability of the child to perish from malnutrition within the first weeks of extra-uterine life;¹⁴ and the impossibility of knowing that we are dealing with a viable child.¹⁵

The second method is useful in cases of lateral or marginal placenta, where good pains are present and os dilated or dilating. Under favorable conditions this treatment shows extremely low mortality, but it is useful only in cases which do well naturally and is not recommended where immediate delivery is indicated, or in cases of complete previa.

The third method, the treatment of placenta previa by manual dilatation followed by version, is the method almost universally used today by English and American obstetricians, and has shown in the hands of experts a steadily decreasing maternal mortality; but it can hardly be called an ideal treatment, since while it has reduced the maternal mortality to probably the lowest point obtainable (about 12%), it has done so at the expense of the fetus.¹⁶

Blackmer, whose results with version show the lowest mortality of reported cases, says: "The safety of the mother is, of course, of paramount importance, but a mode of treatment which does not in any way tend to lessen the already numerous dangers to the child's life cannot be called an ideal one. We are justified, then," he continues, "in considering any method which may diminish the risk to the child while at the same time it does not increase the risk to the mother."¹⁶

The difficulties and dangers of version are not shown in the published statistics, even of experts, as they all agree that the results obtained in private practice are entirely different from those obtained in hospital service. The chief objection to version must ever be the high fetal mortality obtained even in the most skilled hands. Other objections are: (1) That it is not always easy to do and does not arrest hemorrhage;¹⁷ (2) with multiparae the difficulties of version increase, owing to continued increase in size of fetus with successive pregnancies, and also there is lessened intensity of contractions of the uterine and abdominal walls;¹⁸ (3) the fetus is already shocked by placental hemorrhage, and there is additional shock to the fetal heart from the manipulation of the cord necessary in version;¹⁹ (4) owing to a disproportion in size of head, or for other reasons, it is sometimes necessary to perforate aftercoming head.¹⁹

Cæsarean section for this condition was recommended as long ago as 1892 by Dr. W. Huston Ford,¹⁰ of St. Louis, who advocated section in certain cases on purely theoretical ground. At that time, however, the mortality from Cæsarean section, even in selected cases, was a high one, due principally to errors in technique, and abdominal surgery in general had not reached that perfection which we know today. Dr. Bernay,²⁰ of St. Louis, reported in 1894 that he had performed the operation upon a patient with central previa who was much exhausted from loss of blood. He saved the mother, but the child died in ten hours of asphyxia. He also reported 2 other instances in which the operation had been done under extremely unfavorable circumstances by other men, both cases resulting unfavorably. Dr. Wenning,²¹ of Cincinnati, in 1898 mentioned Cæsarean section as a treatment but gave no details as to the indications.

At the meeting of the Maine Medical Society in June of this year, Dr. Dudley,²² of New York, read a paper advocating Cæsarean section also on theoretical grounds.*

The resort to Cæsarean section in these cases must, therefore, in the absence of statistics, be based more or less upon theoretical ground, but the justification for this radical treatment is found today in the hundreds of successful Cæsarean sections for causes other than placenta previa, which have resulted in an extremely low maternal mortality and practically no fetal.

Dr. Reynolds,¹³ in an article on the causes of failure after Cæsarean section according to the Sanger method, in cases of contracted pelvis, defends the following proposition: "That when the mother is in good condition, that is, when she is generally sound, uninfected, and not exhausted by long labor, or by prolonged efforts at delivery by the forceps, the Cæsarean section is so safe an operation that it may be used unhesitatingly in cases at term whenever an intrapelvic delivery will be fatal to the child, and may often be preferred even to the induction of premature labor, on account of its superiority in the saving of fetal life. [Italics are mine.] How low the fetal death rate of the Cæsarean section will prove it is difficult to say; but if we consider the favorable cases only, it is certainly the lowest infant death rate obtainable." In support of this proposition, Dr. Reynolds reported 15 cases of Cæsarean section without a death, maternal or fetal. Since the publication of the above paper he has operated on 4 more cases, which I have his permission to quote, with the same successful results. He also reports 50 operations of Leopold when these conditions were observed, and also 24 of Evarkes; a total of 93 sections without a maternal or fetal death. In spite of these extremely favorable results, it is too radical to advise section in all cases of placenta previa, as there are certain cases which do well under conservative treatment. There are, however, certain cases which do not do well under any of the classical treatments, and in which section seems indicated.

Very few groups of cases are so reported as to be capable of analysis on the basis of surgical intervention or not, but examination of the reported cases of placenta previa show: (1) That the greatest mortal-

* I have carefully looked for the reports of other cases but have found none, and in communications, Drs. Ford, Bernay, Wenning and Dudley say they know of none except those already mentioned. So that the case I am reporting appears to be the first entirely successful one in this country.

ity, both fetal and maternal, is obtained in cases of complete previa. Depaul²³ reports 25 central with a maternal mortality of 56%, Jardine⁴ reports 12 complete with a maternal mortality of 16 $\frac{2}{3}$ % and a fetal mortality of 66 $\frac{2}{3}$ %. (2) The second deduction from reported cases shows that in primipare the firmness and resistance of the tissues render quick operative interference difficult. (3) A source of great danger is found in a rigid os uteri. Read⁶ reports 39 cases where the condition of the os was given as rigid. These showed a maternal mortality of 33% and a fetal mortality of 70%. (4) In cases of contracted pelvis the greatest death rate is not obtained in the major degrees of contraction, but where there is disproportion between the size of the fetus and the size of the pelvis.¹⁹ (5) Malpositions of fetus requiring operative interference, and cases where the cord is prolapsed, show high mortalities.²⁴

If we accept the foregoing deductions as correct it would seem that section, in preference to other operative interference, is indicated in: (1) Cases of complete previa; (2) cases of previa in primipare when signs of fetal or maternal exhaustion are evident; (3) when the condition of rigid os is present; (4) where there is a history of previous operative delivery; (5) in transverse positions and in cases of prolapsed cord, if the cord is not easily returnable.

That Casarean section is the easiest of celiotomies all who have performed it admit, and in nearly every large community it is possible to obtain an operator capable of performing it under strict aseptic and antiseptic precautions. It is also an extremely safe operation not only for mother but for child, and this latter fact leads Dr. Reynolds¹⁸ to say in the paper already quoted: "Is not the life of the child as good a reason for the performance of a simple abdominal operation as the chronic backache for which such operations are done daily?"

For the successful performance of version an obstetrician having the necessary experience (performance of at least fifty versions, for instance, being considered sufficient experience) is not so readily obtainable. The place of operation is generally considered of great importance,^{28 92} but it seems to me that section may be safely done where the performance of any clean obstetrical operation is possible.

A second Casarean section on the same woman is easier and less dangerous than the first.⁶⁰ Pollak²⁵ reports 120 Casarean sections performed on 58 women with 1 death, a woman dying of embolism after the fifth operation. After the operation the uterine wall becomes thoroughly healed without thinning, if it has been properly sutured. The abdominal wall, when closed by terraced sutures, shows no tendency to rupture, and in cases where the uterine scar has adhered to the abdominal at the time of the first operation, subsequent operations are really extraperitoneal.²⁶

This paper, while it does not aim at completeness, is designed to emphasize the fact that modern surgery has not reached its limitations, and the successful outcome of section in the appended case, when another mode of delivery would have been fatal to at least one of the lives involved, offers hope of success to others when confronted by the same grave emergency.

The report of the case is as follows:

Ruth W., age forty years, born in Plymouth, Mass., married nine years. One previous pregnancy six years and six months ago; delivered at that time by forceps.

Last catamenia, November 5, 1899. Expected confinement August 12, 1900. Quickening began last March. No unusual symptoms until Monday, August 6, 1900. Flow suddenly commenced, lasting two hours. It was profuse and unaccompanied by pains. It was not sufficient, however, to cause alarm. On August 12th she began to flow in the morning, and Dr. E. D. Hill was called from Plymouth about nine o'clock that night. He made a diagnosis of placenta previa. Mother's temperature 99°, pulse 80, fetal heart 120. Position O. L. A. Dr. Hill remained with patient until 11.30 p. m., when, symptoms not being urgent, he returned to Plymouth.

In the morning, being detained by an operative case, Dr. Churchill was sent at 9 a. m. to look after the case twelve miles away at Long Pond, and report to Dr. Hill, who was with Dr. Mixer at Manomet, seven miles away on the other leg of a triangle. Dr. Churchill reported to Dr. Hill at one o'clock that the pulse of the mother was 110, the temperature 99°, and the fetal heart 130. Hemorrhage not profuse. As the case seemed to be doing well, Dr. Mixer, to whom I had suggested Ciesarean section if it was a case of complete previa, returned to Boston, leaving me behind to look after the case and to operate if I thought necessary. About 5 p. m., Dr. Hill, Dr. Churchill and myself drove down from Plymouth to see patient; found her in a state of collapse. The hemorrhage had recurred and a messenger had been sent to Plymouth, but we had missed him on the road. Hemorrhage had been so profuse that the mattress on the bed had been soaked through completely.

On examination, vagina was found full of clots. Clots were removed and douche of corrosive sublimate solution, 1-3,000 given, but during examination active hemorrhage persisted and clots continued to form. The os was high up in pelvis and not reachable until the whole hand had been passed into the vagina. Os was then found to be dilated so that it would admit two fingers, covered by placental tissue, and extremely rigid. The whole lower segment of the uterus was boggy and no ballottement could be obtained. Patient's temperature 99.4°, pulse 140. Labor pains present. Operation advised, and consented to at once by husband and by patient.

The house was an ordinary one-story country house, with three or four rooms on the ground floor. Patient was in charge of ordinary country nurse, who afterwards took care of patient during convalescence. Operating table was made by extending the kitchen table with a light stand, and the whole covered with a folding blanket and sheet. A washstand served as a table for sponges and instruments. Light was furnished by two kerosene lamps. A wash boiler of hot water was soon ready in which the instruments were boiled. In a washbowl was mixed 2 quarts of corrosive-sublimate solution, 1-500, in which six towels were put to soak. Hands were washed at sink, water being supplied from purp. After scrubbing hands with green soap, crystals of permanganate of potassium were emptied into the palms of hands and with a little water pumped onto them made a saturated solution, which although small in amount was effective. The excess of permanganate of potassium was washed off by more well water, and the hands and arms bleached in a solution of oxalic acid. Dr. Hill, who assisted me, went through the same process. Ether in the meantime was being administered patient by Dr. Churchill. Dr. Henry R. Hitchcock, of Hyde Park, Mass., who was at his summer place about one mile away, had been sent for to help with baby, and arrived soon after woman had been placed on table. Preparation of woman consisted of shaving, scrubbing with green soap, corrosive-sublimate solution, and finished up by a dash of peroxide of hydrogen. Field of operation was surrounded by wet corrosive towels. Incision was made at a point corresponding to middle of rectus, beginning opposite umbilicus and extending well down to pubes. Abdominal wall was extremely thin and first incision opened peritoneal cavity for about one inch. Incision enlarged with a scissors until uterus could be pulled through it. Gauze then packed into abdominal cavity to hold back

intestines. Rubber tube was passed round broad ligaments, tight enough only to control hemorrhage. Uterus opened by vertical incision in median line, and membrane bulged into incision, which was enlarged upward and downward. Pail of hot and one of cold water had been provided for resuscitation of child. Membranes were then ruptured, and child's head presenting, was delivered in that way. Eyes sponged out, throat cleared with finger. Baby gasped a little, but as cord was pulsating feebly it was clamped and cut. Under treatment of Dr. Hitchcock child was soon crying vigorously. Rubber tube was then relaxed and contraction of the uterus followed. As patient was in good condition and no hemorrhage going on, the placenta was allowed to separate in the normal way, and after ten minutes was delivered through incision in uterus. There was no hemorrhage except a very slight oozing from the placental side which was directly over the os. Hemorrhage was so slight it did not wet one gauze sponge. Mucosa closed by a continuous suture of No. 1 half chromicized catgut (St. John Leavens). The uterine muscle was brought together by eight interrupted sutures, and a continuous suture of catgut closed the peritoneal wound. Gauze packing then removed. Peritoneum closed by continuous catgut suture, rectus muscle caught together by the same material, and fascia of rectus closed by continuous suture. Continuous silk-worm-gut suture closed skin incision. Sterilized dressing applied, patient returned to bed. Whole operation consuming forty-five minutes. After treatment consisted of corrosive douches with pad until tenth day, when a slight odor of lochia caused a change to sulphonaphthol douches. Patient sat up in bed on twelfth day and left bed on twenty-first day.

On September 12th, house and outbuildings were completely destroyed by forest fires, and patient was driven to Plymouth after walking one and one-half miles through woods with baby in her arms. Patient suffered no ill effects from this, and she and baby are alive and well today.

THE DUTIES OF THE MEDICAL EXAMINER IN MASSACHUSETTS.¹

BY JULIAN A. MEAD, M.D., WATERTOWN, MASS.

IN these days when the subject of medicine is divided into so many specialties, the medical examiner may be considered very properly a specialist in the detection of the causes that result in unnatural deaths.

He should be familiar with the appearances that wounds on the live body present after death, and be able to decide the nature of the instrument that inflicted them; he should be able to recognize the post-

¹ Read before the Middlesex South District Medical Society, October 10, 1900.

mortem appearances that are caused by drowning, and to decide whether a body entered the water before death, or was thrown in after death; he should be conversant with the action of poisons, and able to differentiate between the symptom of food poisoning, generally called ptomaine poisoning, and metallic irritants. Continued experience in these and many other questions that are continually confronting the medical examiner should qualify him to assign to any suspicious circumstance its proper weight, and thereby enable him to disclose a hidden crime, or to prevent an unjust suspicion from clouding the life of an innocent person.

The medical examiner will find that it is just as true in his specialty as in all others that the value of his services depends mainly on the extent and thoroughness of the foundation that he has laid in his study of general medicine. The statute that abolished the coroner and created the medical examiner recognized this fact when it provided that the medical examiner "should be learned in the science of medicine." He is indebted for this qualification to the medical profession, which becomes, therefore, in this respect responsible for him. He can reasonably expect that he has been thoroughly grounded in his student days in the many causes that change physiological processes in the body into pathological ones, and that he has been taught to read aright in the lifeless organ the story of destruction that an insidious disease has written there.

If the teachers of medicine have done their duty, and have made the medical examiner, as the law prescribes, learned in the science of medicine, then the responsibility for success or failure in the many important duties that he is called upon to perform is shifted from the profession to the individual, and should he prove unequal to them, the profession should insist that they be entrusted to more competent hands.

The medical examiner, in addition to being learned in the science of medicine, must know something of the legal side of the question, and, if he is well versed in medical jurisprudence, he will be in a position to render valuable service to the Commonwealth, and to reflect credit on his corps. He should not encroach, however, on what pertains to the law, but confine himself to the solution of the question, What caused this death? leaving the question, Who did it? to be answered by the legal profession.

The medical examiner stands between the two professions, and at the same time unites them. He does this by reason of a knowledge of the legal side of a question that the medical profession in general has little means of acquiring, and by a knowledge of the medical aspect that is beyond the scope of a legal education.

Perhaps the best way to give you an idea of the duties of the medical examiner will be to show him at work in a particular case: with this view in mind, I will briefly relate a case that came under my care about a year ago.

In the forenoon of October 12, 1899, I was summoned to the city of Newton to view the bodies of two persons who were said to have been murdered. I immediately went to the place indicated, and learned the following story from the policeman in charge. The family living in the house had moved to Boston for the winter, but had left their coachman and horses

in the stable. Two days before my view, the coachman had driven his mistress about Boston, and had returned to Newton in the evening. Nothing was heard or seen of him the next day. On the day that his body was discovered, his mistress expected him to drive to her house in Boston at nine o'clock in the forenoon. After waiting an hour or more, she decided to go to Newton, and learn why he had not driven to Boston. She found the stable door locked, and two days' supply of milk at the door. She then sought the assistance of a policeman, who entered the stable through the window and found the coachman dead in his room. At this point, I wish to call your attention to the correct method of procedure followed by the policeman. He locked the room, notified the medical examiner, disturbed nothing, and remained on guard until I arrived. As a consequence, I found everything to the slightest detail just as it was left by these two persons, the cause of whose death it was my duty to determine if possible. The members of the medical profession should thoroughly appreciate the great importance of leaving everything undisturbed, for they are often the first to see these cases; in many instances, by an entirely unnecessary examination of the body, they have either destroyed or befogged important evidence, and thereby increased the difficulty of unravelling the puzzling questions that such cases often present.

After hearing the history of the case I went upstairs, and entered a small, unplastered room, in which up against the board partition was a single bed, on which were lying two dead bodies. Before making an examination of the bodies, it was my duty to note and record every fact in connection with the contents of the room, so that I might be able to reproduce a picture of the room for the prosecuting attorney and the jury when the case should be tried. In such cases the medical examiner cannot exercise too much care in gleaning every trifling detail, which should be jotted down in a methodical manner for future use.

This is not the time or place to give such a detailed description of the room and surroundings as I have just indicated; a few of the important facts will suffice to give you a proper understanding of the case.

There was an earthen pitcher and a cup half filled with a fluid on a chair close to the bed; on the floor near the bed was a spittoon also partly filled with fluid. The contents of these receptacles were put into clean bottles, and given to a chemist, who reported that the cup and jug contained water, and the spittoon a mixture of water and urine, in the sediment of which was vaginal epithelium. On a narrow single bed standing against the wall were the bodies of a man and a woman, covered with three comforters. The woman was lying on her back on the outer side of the bed; her hands were clenched, her arms were crossed on her breast, her mouth was partly open, and her lips were slightly discolored with a dark stain. She was undressed and wore only a thin chemise and a light undervest. The man was lying partly on his side over against the wall. In addition to his accustomed everyday clothes, he had on a thick overcoat, and a carriage robe around his shoulders.

There was no indication of any struggle, and everything was suggestive of a peaceful sleep; neither were there any marks of violence on either body. Rigor mortis was present.

As it was impossible to decide the cause of the death

of this man and woman from the view alone, I proceeded to act under authority of Section 8 of the act concerning medical examiners, which reads as follows: "If on view thereof, and personal inquiry into the cause and manner of death, he deems a further examination necessary, he shall, upon being thereto authorized in writing by the district attorney, mayor, or selectmen of the district, city, or town where such body lies, in the presence of two or more discreet persons, make an autopsy." Having obtained permission to make the autopsy, I decided to employ a chemist, as empowered to do under Section 16, which provides that "the medical examiner may, if he deems it necessary, call a chemist to aid in the examination of the body or of substances supposed to have caused or contributed to the death."

Dr. Harrington, of the Harvard Medical School, the chemist, was present at the autopsies. He sealed up in separate jars and took away with him such portions of the different organs as he required for his examination.

It is always desirable to have the chemist present at the autopsy, and have him take charge of the specimens, so that the opposing attorney at the trial cannot say that the specimens have been tampered with in passing through several hands.

In making an autopsy, the law provides that the medical examiner shall then and there carefully reduce or cause to be reduced to writing every fact and circumstance tending to show the condition of the body, and the cause and manner of death, together with the names and addresses of said witnesses, which record he shall subscribe. Before making such autopsy, he shall call the attention of said witnesses to the position and appearance of the body. The evidence in both these autopsies was negative, except that a large ante-mortem clot was found in the heart of the woman. After an autopsy the law requires the medical examiner to notify the district attorney and a justice of the district court, and to file a duly attested copy of the record of his autopsy in such court, and a like copy with such district attorney. The case then goes into the hands of the legal profession, and further action is left to the prosecuting attorney. Although the case that I have cited briefly is only of secondary importance, and designed to illustrate some of the duties of the medical examiner, still you may be interested to hear the report of the chemist, and the findings of the judge.

Dr. Harrington reported as follows:

HARVARD MEDICAL SCHOOL,
Laboratory of Hygiene.
BOSTON, December 5, 1899.

DR. JULIAN A. MEAD, *Medical Examiner*,
Watertown, Mass.

DEAR SIR:—I have the honor to report on the examination of the organs of William McCauley and Alma Y. Peterson. The condition of the bodies when found, the absence of evidence of diarrhea and vomiting, the non-occurrence of convulsions evidenced by the undisturbed condition of the bedclothes, and the negative evidence of the autopsies were of themselves sufficient to rule out of the list of possible causes of death most of the poisons with which we are acquainted; but, notwithstanding, I made a careful examination for the presence of irritants, cyanides, chloral and alkaloidal poisons. In both cases the result has been wholly negative excepting that with Fröhde's reagent I obtained a faint, somewhat doubtful reaction for the only poison which is compatible with all

the circumstances, namely, morphine. I have characterized the reaction obtained as "somewhat doubtful," that is to say, it was so slight that I should feel a decided reluctance to report it positively if thereby one's life or liberty were placed in jeopardy.

Yours very truly,
(Signed) CHARLES HARRINGTON.

(COPY.)

At the inquest, the judge asked me who I thought caused the death. I replied that, in my opinion, one or both had committed suicide. He told me some weeks later that he came to the conclusion that the woman poisoned the man and then took the poison herself. The police learned later that the man had a wife and several children in Canada, that a woman in Boston claimed him as the father of her child, and that he was engaged to the woman who was found in bed with him. It is possible that the deceased woman may have anticipated the police in acquiring the above information.

The method of procedure, as prescribed by law, is much the same in every case, but the line of inquiry followed by the medical examiner varies very materially with the nature of the violence he is called upon to investigate.

It is apparent that the prosecuting attorney will not care to know anything about poisons in a case of homicide by shooting; but he will want to know how the pistol was held, how far the muzzle was from the person when the pistol was discharged, if the deceased could have inflicted the wound by his own act, and if the bullet entered at right angles or obliquely to the surface of the body. The experienced medical examiner will be prepared as far as possible to answer these questions, and to give his reasons for his opinions in such language as the average man in the jury can comprehend; if there is a common name in use for a particular bone, muscle or any part of the body he will use that word instead of the technical term, and he will bear in mind that he can only instruct the members of the jury by using language that they can understand.

The medical examiner law went into effect twenty odd years ago, a time sufficiently long to determine the wisdom of its creators; it was a new and conspicuous departure in that vast system of protection which it has been found necessary to establish for the community; other States have expressed their opinion of it by that sincerest mark of approval, imitation. The medical examiners during this period of twenty years have done good work for the State, and have reflected credit on the medical profession, but perhaps it would be better on this point to call as a witness one who represents the legal profession, and therefore I will close this paper by quoting from an address by Attorney-General Knowlton, delivered some two years ago at a meeting of the Medico-Legal Society.

"My experience," he says, "is that success grows and results much more from men than from machinery in any department of human activity, whether in business or in the working of laws. It is the men who are entrusted with the work, rather than the machinery that is devised, that make or mar results. I am glad to say this, gentlemen; it is the first opportunity that I have had of putting in formal shape my testimony to the very commendable exertions of the members of this body, and of the medical examiners throughout the State, to enforce the provisions of this

law in the interest of justice in the Commonwealth. It may be that my experience has been larger than that of living men. I have had to do directly and indirectly with the trial of thirteen indictments for murder, and the investigations of many more cases, and I have uniformly found the medical examiners with whom I have been brought in contact to have that understanding, that intelligent understanding, of the duties imposed upon them by the Medical Examiner Act that was necessary for its success. As you know, the medical examiner system succeeded a system that had fallen into disrepute, and which had become worse than obsolete. This act was an immense advance in the business of detecting and punishing crime, and yet this act would not have been a success, had it not been for the character of the men who enforced it."

A CASE OF ALEXIA, MIND BLINDNESS, ETC., WITH AUTOPSY.¹

BY EDWIN E. JACK, M.D., BOSTON.

THE patient was a rather spare man, aged sixty-three, whose general health, with the exception of chronic indigestion, had always been good. There had been some sickness, but it had no apparent bearing on his later condition. Up to a year ago he had been at work at his trade, wood-carving. It became necessary from lack of employment, etc., to turn to other things, and the change and the worry incident to it had a bad effect on him generally.

He consulted me first the 23d of last December, giving a history of failing vision for about one month, first noticed in reading the labels on boxes. V. O. D. = 5-20, V. O. S. = 5-27, the letters being slowly picked out. A correction of his hypermetropia did not seem to improve him. There was nothing in the test or in anything he or his wife said which led me to believe he could really see better. Fundi, both discs slightly red and hazy but not abnormal; small spot of chorioretinitis in the right eye a short distance upward and to nasal side of macula. Fields normal, pupils normal. Inability to name colors. This latter fact, though the apparent color scotoma was not confined to the central region, suggested retrolbulbar trouble, and in the absence of any tobacco or alcohol history, the possibility of diabetes came to mind and an examination for sugar was made later with negative result. I did not at this first visit suspect the real trouble, no hint except that of a negative examination being got from either patient or his wife. At the second visit, three days later, correcting the hypermetropia, I found that by pointing out letters at the first of the examination he could name a letter or two of much smaller type, and that when after a moment or two he could not do this, he could roughly draw their shape. The power to do this also was quickly exhausted. These observations led to questions which showed the nature of his trouble.

He was unable to come to my office alone; he had no idea of the signs on the cars; former familiar streets were only partially or not at all recognized. There was evidently no difficulty in merely seeing letters, words or objects. Later investigation of the case brought out the following symptoms, which

varied from time to time. With these I will give other negative ones, the two together making a more complete picture of the defects in question.

The patient could hear sounds of all kinds and recognize them, with one odd exception. He certainly on one occasion failed to interpret musical sounds. I asked him once if he knew the tune "Annie Rooney"; he did not. I then whistled it; still he did not know it. Immediately afterward I played on a small parlor organ a hymn of which he was particularly fond, and on asking what it was he slowly shook his head and said interrogatingly, "Annie Rooney?" A day or so later the same tune was recognized and awakened the sad memory of former failure. He understood spoken words. He could see letters, numbers and words, printed and written, but he could not, except to a slight and variable extent, comprehend them. There was at all times an ability to recognize a few letters and figures and even words, and this not confined to any particular ones, but limited apparently by the exhaustion of his power. He could see objects, but there was an inability to a considerable extent to recognize them. Such objects as matches, a key, comb, napkin, photographs, etc., brought up no remembrance of similar previous ocular images. Other objects he evidently recognized, but could not find words to express the name, or the idea vanished before he could put it into words. This inability to interpret objects was not limited to those seen. When asked, he could not describe the schoolhouse across the way nor the arrangement of the streets, and this not due to lack of aural perception apparently. There was a variable inability to tell the use of objects, very often an absolute ignorance. For example, one day a key was held up; he could not tell what it was or its use, and when put into his hands he was helpless; an attempt to draw it on paper was also a failure. He once named a watch correctly and immediately afterward called a knife a watch; he could not tell its use, but could use it. A later examination showed less of this particular power even. In showing me the use of a small hand mirror he took out a pencil and began to write on it. I think he had just been using a pencil. The use of a chair, stove, trousers and money were unknown. His wife said that at times he did not recognize her and that he made odd mistakes, trying to drink out of the sugar bowl and salt cellar, dipping his toast into the jelly tumbler instead of his coffee and then eating without apparently noticing his mistake, and once mistaking his hat for his coat and trying to put it on over his arm. Hearing usually set him on the right track; touch sometimes failed. Salt was readily recognized when tasted, though wholly unknown by sight.

He could speak voluntarily, for the most part well, but often forgetting words or stopping short, having the whole mental picture of what he wished to say vanish. He had spells of wandering off in his talk to the scenes of his past life, applying them to the present. He could not speak words read, that is, he could not read aloud. Here again some modification of statement must be made, though a few letters or figures and a word or two were all he was at any time able to recognize. He could write voluntarily a little. The best example of this is shown on the paper dated January 23d, when he wrote his own name and recognized it afterward. The power of writing to dictation was limited in about the same way; the ex-

¹ Read before the American Ophthalmological Society at Washington, May 3, 1900.

tent of his success is also shown on the papers. He could not do transfer copying, that is, he could not turn writing into printing, and vice versa. He could not give the names to the more ordinary colors, but there was not true color blindness, though matching the worsteds was done very slowly.

After the second visit to my office the patient was too weak to make the rather long journey to the city. The only symptoms developed other than those mentioned were a lack of appetite, frontal headache spreading over the parietal region to the occiput, not severe and variable, and some vomiting. The importance of this last symptom was doubtful because of its following closely the taking of potassium iodide, and because of its cessation soon after stopping the drug, the same process being repeated on taking up the iodide again. In about three or four weeks the patient took to his bed and did not again, except for a few days, leave it. At this time there was an increase in the localizing symptoms. He was uncomplaining, but the presence of pain was made evident by his putting his hands to the forehead. There was, too, some soreness or pain on dragging the head on the pillow, in the left parieto-occipital region, but in all probability it was not at any time severe. In the latter days there was more vomiting, and this without relation to any medicine. I made no observations the last ten days of the patient's life, but up to that time there was no optic neuritis, and up to within two weeks of death no well-defined hemianopsia. An examination by Dr. J. P. Conroy, of Everett, who referred the case to me, showed a mitral regurgitant murmur and moderate arterial sclerosis.

The clinical diagnosis made was alexia and mind blindness, both partial and of the cortical variety, and amnesic color blindness. The lesion was placed on the left side (the patient being right-handed) at the region of the angular gyrus and in the occipital lobe, probably sparing the cuneus and calcarine fissure. The cortical situation of the lesion was inferred from the inability to write spontaneously or to dictate, for in pure word blindness, with a subcortical lesion between the visual word centre and optic centres (or, as some put it, between the visual word centre and the centre for speech-sound memory), the ability to do both these things is present. The mind blindness, too, was regarded as cortical, because, beside the difficulty in recognizing by sight objects placed before him, there was a like difficulty in picturing them to himself voluntarily or on questioning.

The autopsy and pathological investigation and report were made by Dr. George Burgess Magrath, of the Harvard Medical School, to whom I wish to express my indebtedness.

Cranium.— Upon removal of the calvarium the dura presents a condition of somewhat increased tension; it is adherent to the under surface of the left temporal lobe within an area 5 by 4 centimetres, situated a little posterior to the middle third of the lobe.

Dura mater.— Presents conditions above mentioned.

Sinuses.— Natural.

Pia mater.— Over the convexity of the brain presents a somewhat cloudy appearance, most marked over the sulci, along the course of the blood vessels. The subarachnoid tissues are slightly edematous.

Brain.— Weight, 1,350 grammes; arteries of the

base natural. The inferior aspect of the left temporal lobe presents an area of softening occupying its middle third; posterior to this, the dura mater is adherent to the brain within an area 4 by 5 centimetres. The lateral aspect of this lobe opposite the region of the adhesion presents, within an area 3 centimetres in diameter, a somewhat gelatinous appearance, differing markedly from the surrounding brain substance. Upon section through the area of adhesion, there presents a spherical mass 4 centimetres in diameter, adherent to the dura mater, which at the site of adherence is 3 centimetres in thickness; distinct from the surrounding brain substance, from which it is defined by a thin zone of gray pulsatous material. The surface of section presents a nearly homogeneous appearance, yellow, mottled with minute translucent areas. The extent of the mass is backward to the anterior boundary of the left occipital lobe; forward from this posterior limit for a distance of 6 centimetres; upward to the level of the first temporal convolution; inward to the collateral fissure. It involves the third temporal convolution in its most posterior part and the gyrus fusiformis. Anterior to the mass and extending somewhat deeper into the substance of the left occipital lobe, there is a region of softening apparent only on the under surface of the brain. Upon section this region extends forward, externally to the descending horn of the left lateral ventricle, into the substance of the temporal lobe, and backward from the mass into the substance of the occipital lobe. The latter presents upon the surface of section an irregularly outlined area occupying for the most part the white matter, at one point extending into the gray matter (base of occipital lobe), the central part of which is yellow, soft, and similar to the surface of section of the mass, the outer part reddish gray, continuous anteriorly with the circumscribed mass, extending upward to within 1 centimetre of the surface of the first occipital convolution, downward and backward to the posterior border of the occipital lobe, and inward to within 3 centimetres of the mesial surface of the occipital lobe.

The floor of the left lateral ventricle presents a grayish appearance, and is softened in places to the point of disappearance. The roof of this ventricle presents extensive softening, being represented by more or less gelatinous, pulsatous material. This softening involves the under surface of the hemisphere as far as the hippocambal gyrus.

Microscopic examination.— For the purpose of microscopic study, pieces were taken from (1) the main mass of the tumor; (2) the white matter of the occipital lobe (softened); (3) the white matter of the anterior part of the temporal lobe (softened). These pieces were prepared for staining neuroglia by Mallory's method, cut in celloidin and stained with phosphotungstic acid hematoxylin. Upon microscopic examination:

(1) The main mass of the tumor presents along one side the dura very much thickened. The histological components of the mass are blood vessels and abundant cells; the blood vessels are fairly numerous, and many of them are of the capillary type, with thin walls and surrounded by a moderate amount of fibrous connective tissue. The cells are for the most part placed very closely together; in places they are less numerous than elsewhere. The cells are medium sized and

small, round, with deeply staining nuclei; between these cells there is a rich network of fine threads; in places this constitutes an open meshwork, elsewhere it contains large numbers of cells. Some of the cells are apparently fatty degenerated. There are some areas of necrosis.

(2) The white matter of the occipital tube presents an appearance very similar to that above described; in this region, between the cells, in addition to the neuroglia fibres, there is a certain amount of granular material; there is little or no evidence of normal brain structure present.

(3) The white matter (softened) of the anterior portion of the temporal lobe presents the same appearances, the blood vessels constituting the only surviving elements of the normal structure.

Anatomical diagnosis.—Glioma of the brain. Localized softening of the brain.

It will be seen by referring to the pathological report and to the sections which I have made (plates are in the original article) that the angular gyrus is apparently not directly involved, though the greatest development of the tumor is in the same vertical lateral plane. It is to be supposed then, that either the effect was produced by pressure, inhibition, etc., of the tumor, or that an involvement of the fibres to and from this centre would give the group of symptoms present, or, further, that the area in question is not the only one that has to do with the visual memory of words. To me, unaccustomed to deal with such brain problems and therefore accepting the more readily the easier solution which the involvement of definite centres gives, the first of the suppositions seems the most probable. This seems to agree well also with the partial and variable nature of the symptoms. The connecting fibres must have been affected, however, and possibly a partial isolation of the visual word centre from the optic, auditory perceptive, and graphic centres would account for the symptoms, but such is purely hypothetical and has no basis of fact. It would be simpler and very likely nearer the truth, as Dr. J. J. Putnam has suggested to me, to abandon trying to make certain symptoms or groups of symptoms correspond with defects in definite areas, but to regard this whole region as having to do with visual and sound perception and interpretation, all parts being intimately connected together and interdependent, on them resting the power of speech and writing, a break in any part of the mechanism throwing the whole machinery out.

A more careful investigation of the fields, especially in the later days, would probably have shown defects, not necessarily hemianopsia. I regret that this was not done, but it would have been very difficult under the circumstances. The sections show that the cuneus and calcarine fissure were probably not involved, but the course of the fibres forward around the horn of the ventricle, especially the upper ones, could hardly have escaped interruption, though I suppose considerable pressure might not be destructive of function. The absence of optic neuritis is not surprising. The mind blindness and amnesic color blindness I should say were easily accounted for by changes in the occipital lobe.

The absence of hemianopsia with amnesic color blindness is, I believe, unrecorded. It unfortunately cannot be definitely stated that this case is an exception to the rule.

Clinical Department.

NOTE ON THE X-RAYS AS A CURATIVE AGENT IN CERTAIN DISEASES OF THE SKIN.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

It is now recognized that the Röntgen rays assist both the physician and the surgeon in the diagnosis of disease, but there is comparatively little appreciation in this country of their usefulness as a therapeutic agent. My own use of the x-rays has been chiefly limited to their employment as an aid in the diagnosis of diseases of the chest; still it has seemed to me desirable to test their value as a curative agent and to call attention to their usefulness in this direction.

During the past three years, a number of dermatologists, chief among whom are Schiff and Freund, of Vienna, have reported good results in lupus, favus, acne, sycoosis, herpes tonsurans, eczema, folliculitis and hypertrichosis by means of the x-rays. In lupus especially this method has proved more satisfactory than any other when large areas are present, and the skin is left in a better condition; for small patches other methods of treatment are, as a rule, sufficient. In the removal of patches of superfluous hair the x-rays have also shown their superiority over other methods of treatment, but if only a few hairs are in question, electrolysis is to be preferred. In the treatment of certain skin diseases it is essential to temporarily remove the hair of the beard, for example, from the diseased area, and the x-rays have been serviceable in accomplishing this purpose.

My own experience with the x-rays as a curative agent in lupus has demonstrated to me: (1) That excellent results can be obtained by exposing the diseased portion of the skin near a Crookes tube which is giving off x-rays, and that the treatment causes no pain and that it is not necessary to repeat it so frequently as to produce an inflammatory reaction; (2) it is essential that the treatment should only be undertaken by one who has learned how to manage an x-ray apparatus and has provided himself with special appliances for carrying out this method.

I wish here to thank Dr. James S. Howe for sending me at my request, two cases of lupus for treatment with the x-rays. I shall hope later to give a detailed account of the method of procedure in this field. It is certainly wonderful to see the excellent results that follow this treatment in lupus.

Medical Progress.

REPORT ON PROGRESS IN MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D., BOSTON.

MELANCHOLIA.

KRAEPELIN¹ attempts to draw the distinction between conditions of depression in other diseases and the independent disease—melancholia. The conditions of depression appearing before the age of thirty are never simple forms ending in recovery, but are either cases of dementia precox or the beginning of circular insanity. The latter may also begin

¹ Mounats, f. Psych., November, 1899.

much later in life. He thinks that the development of pronounced inhibitory conditions in the domain of thought and volition is peculiar to the circular form. A large number of cases of depression end in dementia, and it is often possible to predict this termination comparatively early. The chief indications of a termination in dementia are the lack of any profound emotional excitement, the occurrence of negativism and automatism and stereotyped movements. In advanced life conditions of depression also arise, which do not recover like the ordinary forms of retrogressive melancholia, but end in dementia. These occur usually in more advanced age, and show at the start a certain amount of mental failure. The cases of periodic or circular insanity beginning in more advanced years are also difficult to distinguish from ordinary retrogressive melancholia, except by long-continued observation, and there are finally cases occurring in advanced life which show marked depression with symptoms of katatonia and negativism.

DEMENTIA PRECOX.

Finzi and Vedrani² have studied a series of cases presenting dementia beginning primarily in young persons and associated with katatonic symptoms. In all there was an almost complete absence of emotional disturbance, with a lack of motive for their conduct and pronounced stupor and negativism. The chief factor, the dementia, should give the name to the disease, as it is the most important clinical symptom, the former term hebephrenia being limited to a definite age, and katatonia referring merely to one group of symptoms. All the cases which they report had more or less realization of their disease, unlike a patient with paranoia. Delusions were early and often persistent, but they were not organized into a permanent system. The indications of mental weakness were present from the outset. The patients often seemed confused, but in reality they are never confused, or only for a very short time. The dementia is an early condition and not secondary. It may develop progressively and subacutely, without acute paroxysms, or slowly at first and then rapidly after an acute attack, or very slowly with many acute attacks. The fundamental clinical characteristic is the peculiar acquired mental weakness, which is common only to those cases which have been described as hebephrenia, katatonia, fantastic paranoia, and dementia paranoides, which should now be grouped under the one term of dementia precox. The katatonic symptoms, like hallucinations and delusions, are not characteristic of one form of disease, but they appear with special frequency in dementia precox. Finzi³ has also studied the organic symptoms in cases of dementia precox in 87 cases, and finds that in only about one-quarter were they always absent. The most frequent symptoms were exaggerated reflexes, changes in the pupils, vasomotor symptoms, flushing and pallor, and sialorrhea. In addition, among the common symptoms were a sense of physical exhaustion, headache, sleeplessness, paresthesia, loss of appetite or absolute refusal of food, and various vasomotor symptoms. The organic symptoms are, on the whole, comparatively numerous, but they may vary in the individual cases, and there are not usually many in a single case. They may change in number in the same individual,

and even wholly disappear; but the same symptoms tend to persist or to reappear in the same individual. They are more frequent in the initial stages than in the terminal, and they are more frequent in some conditions than in others, and some are found by preference only in definite conditions. None of them, of course, are essential or necessary either to the disease or to any combination of symptoms. It seems, however, that neurasthenic symptoms and vasomotor disturbances may be of some value to the diagnosis of dementia precox if associated with impulsive acts, meaningless agitation and apathy, a rapid and marked increase or decrease in weight unrelated to any change in the mental symptoms, and sialorrhea, which are more common in dementia precox than in any other mental disease. The organic symptoms, however, are sometimes the direct manifestation of some coexisting disease, which is not associated with the mental trouble.

GENERAL PARALYSIS AND DEGENERATION.

Pilez⁴ quotes the recent opinion of Näcke that hereditary taint and frequent signs of degeneration exist in the majority of cases of general paralysis, contrary to the opinion which has previously prevailed. He, however, believes that heredity is an unimportant feature in general paralysis, and that there is a certain antagonism between paralysis and degeneration, degeneration affording a certain immunity against general paralysis. He, therefore, studies two groups of the insane; one of general paralytics, and the other of degenerates with criminal tendencies. Criminals, prostitutes, and the like, are not very often affected by general paralysis. Thirty-two out of 170 cases of general paralysis showed hereditary taint, and of these 32, 23 had certainly been infected; 28 out of 67 degenerates showed hereditary taint. Out of 117 paralytics 44 had a stretch of the arms greater than the height; out of 65 degenerates, 48; and out of 28 epileptics 24 had a stretch greater than the height. Twelve out of 170 paralytics, and 32 out of 67 degenerates were tattooed. Fifty-one out of 170 paralytics, and 44 out of 67 degenerates had other stigmata of degeneration. Of the 51 paralytics with stigmata of degeneration, 31 had only one; 13 had two; 5, three; 1, four; and 1, five. Out of 44 degenerates 14 had only one stigma; 7 had two; 7, three; 7, four; 5, five; 2, six; and 2, seven. Of the 170 paralytics 74.2% had certainly been infected, but only about 20% of the 67 degenerates. He believes, therefore, that a neuropathic heredity protects the nervous system against the injurious action of syphilitic infection as producing organic disease, at least so far as general paralysis is concerned. The brain of the degenerate is comparatively little disturbed by feeling for others, and therefore the struggle for existence tells less severely upon him. Of the two factors, syphilization and civilization, which, according to Krafft-Ebing, cause general paralysis, the latter has comparatively little effect upon the degenerate.

DIFFERENTIAL DIAGNOSIS OF GENERAL PARALYSIS AND SYPHILITIC PSEUDOPARALYSIS.

Klein,⁵ after a careful study of 7 cases of cerebral syphilis, draws the following conclusions: Diffuse syphilis of the brain and general paralysis may have

² Rev. Sper. di Fren, vol. xxv, pp. 180, 326.

³ Revista di Patologia nerv. e ment., February, 1900.

⁴ Monats. f. Psych., July, 1899.

⁵ Loc. cit., June, July, August, 1899.

very similar symptoms, which renders it difficult to distinguish between them; but the two diseases should be absolutely separated on account of their clinical course, the prognosis, and the results of treatment. The differential diagnosis often cannot be made except by a prolonged observation and study of the history and the results of treatment. The mental state is also a very important factor. In cerebral syphilis we see the violent onset of severe symptoms unlike to those of general paralysis, but with a positive history of infection. There may be bulbar symptoms or symptoms of a tumor, some affection of the ocular apparatus—either neuritis or temporary disturbance of the muscles of the eye—with a predominance of symptoms of a focal lesion. There is usually the absence of hypaesthesia or of disturbances of speech or handwriting. The affection progresses much more slowly, and may last for twenty years or more. Secondary manifestations may appear during the mental trouble. The mental state and the favorable results of treatment also are an important aid. Contrary to what is seen in general paralysis, there is no progressive mental weakness. The mental symptoms often present themselves under the form of psychoses or of functional neuroses, hysteria, melancholia, mania, confusion, paranoia. These mental troubles have a tendency to vary constantly. The patients much more frequently have a full appreciation of their morbid state. Symptoms of paranoia have a certain value in diagnosis in the chronic cases. Among these are hallucinations of hearing, morbid ideas of suspicion, obsessions, hallucinations of muscular sense and abnormal sensations with a deluded interpretation. In many cases the picture may be very similar to that of chronic paranoia. Hallucinations of hearing are rare in general paralysis; they are much more common in diffuse syphilis of the brain. In all doubtful cases it is urgent to put the patient under treatment by iodide of potassium for the purposes of diagnosis as well as of treatment.

ACUTE PSYCHOSES AND KATATONIA.

E. Meyer⁶ has collected 54 cases of acute psychoses observed in the clinic at Tübingen, excluding the cases of pronounced mania and melancholia. In 10 cases occurring in the puerperal state he found that the common feature was an acute dream-like confusion, with many unconnected hallucinations and illusions and a few delusions. The confusion he believed to be brought about through the hallucinations, which came on so acutely that they were not made a part of the life of sensation and ideas, as in the chronic hallucinations. The hallucinations were often vague and indistinct, and everything seemed upset and confused in the patient's mind. In the cases occurring at the period of the climacteric the diseases usually began without any pronounced preliminary stage; the patients became anxious, restless and often excited, at the same time that the hallucinations developed. In these cases, too, the confusion was marked and was usually to be attributed to the hallucinations and the disturbances of perception. A third class of cases similar in nature occur in the period of puberty. The katatonic symptoms were stupor of varying degree, stereotyped positions and movements and the wax-like flexibility. Meyer opposes the theory of Kraepelin and his pupils that

these conditions of stupor are primary. On the contrary he regards the stupor and confusion as the result of the delusions and hallucinations. In the cases which have recovered the patients often have explained their stupor, their resistance to treatment, and their stereotyped movements as due to the influence of such delusions. Katatonic symptoms may be seen after various psychoses, confusional insanity, chronic paranoia, degenerative insanity, etc. Where these symptoms are pronounced the patients may recover, but the course is relatively more unfavorable. Meyer thinks the majority of acute cases may be spoken of as confusional, although the distinctions between the various acute forms of insanity are somewhat vague. The hallucinations and delusions are less marked in mania than in confusion and also in melancholia, excepting in the so-called melancholia attonita. The so-called acute paranoia seems to him to be closely allied to confusion, if not the same thing. Chronic paranoia may be distinguished from this by the existence of a slow beginning, permanent systematized delusions and preservation of the logical order of thought.

ACUTE DELIRIUM.

Ceni⁷ reports 2 cases of severe psychomotor attacks with simple sensory delirium. These attacks ran their course without fever; the patients recovered and returned to their normal conditions. In later attacks in the same patients there was a marked rise of temperature; the symptoms were more severe and the patients soon died with symptoms of a true acute infection and genuine delirium. In the first attacks it was never possible to find any micro-organisms in the blood; in the last attacks they found in the first case staphylococcus pyogenes and just before death the bacterium coli, and in the second case the streptococcus pyogenes and the micrococcus tetragenus. The presence of these germs in the blood was not regarded as the direct cause of the morbid symptoms, but the pre-existing mental conditions were exaggerated by the infection and were, therefore, changed in character; the infection of the blood was probably due to the various functional and organic alterations which formed the basis of the mental trouble.

DELIRIUM OF NEGATION.

Obici⁸ has studied certain chronic delusional conditions, especially those intermediate between the acute and chronic psychoses. He concludes that the delirium of negation is not a disease by itself, but that the ideas may arise in various forms of psychoses, even in acute psychoses, from exogenous causes, although they predominate in the chronic forms with disorganization of the personality. The ideas of negation assume the degree of complexity and systematization indicated by Cotard, especially in the graver forms of melancholia; but they are also frequent in patients who have had repeated attacks of periodical melancholia. In these last cases the delirium of negation appears only at the period when the process of involution of the organism begins, and it seems to be a direct expression of this. It seems, therefore, to be rather a condition secondary to an antecedent periodical psychosis, and is to be considered as an associated affection which may modify or change the character-

⁶ Arch. f. Psych., xxxii, 780.

⁷ Rev. Sper. di Fren., xxvi, 70.

⁸ Loc. cit., 291.

istics of the first form. In other chronic forms the ideas of negation do not modify the fundamental course or change the primary characteristics. The melancholia of senility seems rather the initial expression of the same process which leads to profound dementia. In such cases, although the melancholia may seem to be cured, there is never a complete restoration, but always some diminution of the mental powers with an acceleration of the senile processes. This form of melancholia is merely a phase of transition to senile dementia, except where it results fatally. Secondary paranoia also is merely a symptom of acquired mental weakness. In true paranoia there is an original mental weakness indicated by the profound alteration of the personality and an insufficiency of the intellectual functions. This weakness may be congenital, in which case the trouble may be regarded as due to an original defect in the brain, which does not progress, or it may be acquired as the result of some injury to the developed brain, in which case the trouble is apt to be progressive and to lead to dementia.

EARLY DISCHARGE OF THE INSANE.

Tonoli⁹ calls attention to the fact that, although the asylum in Brescia has an extremely large number of admissions each year, it has not a corresponding increase in the total number of inmates each year. This is due to the practice of discharging patients to their homes before they are fully recovered, which has been carried out particularly in that asylum. He cites the old views of the advantages of asylum treatment for the insane, and the modern reaction from those views, criticising asylum treatment, and believes that the practice of early discharge helps to reconcile the two views. The system followed at Brescia was applied to the insane who were recovering very slowly, and to others who had scarcely passed the most acute stage of the disease, but who were evidently convalescing. Such patients were entrusted to the care and treatment of their own families. Tonoli's figures refer only to the female patients. In the year 1898, 223 women were admitted to the asylum, and 173 discharged. Of the discharges, 77 were cured, 64 were improving, 25 were stationary cases, and in 7 cases the insanity was not established. Many of the cases had an inheritance of pellagra or alcohol, which did not admit a complete development of the intelligence, and favored the development of vague delusions, so that it was often difficult to draw the line between insanity and their habitual state. Such patients often had a torpid mental organization, so that it would often be useless to expect a complete cure in the asylum, and they improved more rapidly at home. They were frequently confused, excited, and victims of hallucinations. From such a condition, Tonoli believes that they can be rescued only by putting them back into a familiar and sympathetic environment which does not require any new perceptions and adjustments. In this way he believes that secondary dementia may often be prevented, the removal from their friends and the association with other insane tending to keep up the mental disturbance. The position of the asylum at Brescia favors frequent visiting by the friends of the patients and consequent familiarity on the part of the physicians with the family conditions. This naturally enables the physi-

cian to determine more readily the suitability of the family conditions for an early discharge. The director of the asylum also has a small fund at his disposal each year of 3,000 francs, with which he can aid the patients who have been dismissed from the asylum, especially the cases of pellagra. The results of this early discharge have been extremely good; the patients often showed a marked improvement, and of 173 patients thus discharged in 1898, only 14 were returned up to June, 1899. These were chiefly cases of periodic excitement and pellagra.

(To be continued.)

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARE, M.D., SECRETARY.

REGULAR meeting, Wednesday, October 24, 1900,
DR. R. A. KINGMAN in the chair.

DR. SARAH E. PALMER gave a

REPORT OF A CÆSAREAN SECTION.¹

DR. FRANCIS D. DONOGHUE read a paper entitled

TREATMENT OF PLACENTA PREVIA BY CÆSAREAN
SECTION, WITH REPORT OF A SUCCESSFUL CASE.²

DR. REYNOLDS: I think if we are going to deal with the subject of placenta previa in the rather crude way of having one rule it would probably be safer to adopt the rule that the Cæsarean section should be done. I think the mortality, maternal and fetal, would probably be lower. But I think there are comparatively few previas that cannot be dealt with with very great safety to mother and child by the ordinary methods. Previa complicated by any mechanical difficulty in delivery would certainly show an exceedingly high mortality for mother and child. Central previa would show, I should suppose, at least 10% to 12%, and the Cæsarean section in anything like favorable circumstances can certainly show a far lower maternal mortality than that.

I think that we ought to realize for placenta previa, as for all obstetric cases in which the Cæsarean is raised, that the choice should properly be made at the beginning of labor. If the section is going to be done it ought to be done with all the chances in its favor. In the case quoted it certainly would have been far better if the operator had been on hand at the beginning of labor and operated before the mother was exhausted. A large proportion of babies are lost in the detachment of the placenta during labor, and cannot be saved after the placenta has been detached, and the great maternal mortality, in fact I should suppose three-fourths of the maternal mortality from placenta previa is from post-partum hemorrhage, owing to the fact that the uterus is so weakened by ante-partum hemorrhage that it cannot contract; all this should be saved. Of course in cases such as this one just read, where the operator first sees the case when the woman is exhausted, he has got to deal with the problem on

⁹ Rev. Sper. di Fren, xxv, 614.

¹ To be published later.

² See page 571 of the Journal.

that basis and I should fancy that, as a rule, section would even then be safer than forcible extraction.

The only portion of the paper with which I feel strongly at issue is that in which it was stated that craniotomy is to be reprobated and never performed on the living child. Probably nobody in this country is a stronger advocate for Caesarean section than I, but my study of the subject has led me to the conclusion that, while section under favorable circumstances is an exceedingly safe operation, yet when the woman is exhausted by labor it is an operation with so enormous a mortality—a mortality of 40% or 50% maternal—as to be utterly unjustified, and I think that the man who finds an insuperable mechanical obstacle, that is, too great even for symphysectomy, to the delivery of a child in a woman exhausted with labor is, setting the religious question aside, simply a coward if he fails to face the most disagreeable operation I have ever performed or seen—that of craniotomy on the living child. I think it is his duty. But I hope the day will come when we shall not be forced to this, because women will not be allowed to reach this point without operation.

Dr. HIGGINS: I think Dr. Donoghue is to be congratulated on his very successful case, but I have come to believe pretty strongly that Caesarean section is not indicated except when the mother is in pretty good condition. Most cases of placenta previa at the hospital come in as emergency cases after a good deal of hemorrhage, and in such circumstances we believe Caesarean section contra-indicated. I think for a long time we have recognized that Caesarean section would be indicated in favorable cases where the placenta is complete. I believe in those cases that are somewhat exhausted if we could pack the vagina tightly to control the hemorrhage and wait a certain length of time until the mother has recuperated, all the time under careful observation, the fetal mortality as well as maternal would be considerably reduced and Caesarean section could then be more safely performed.

Dr. WORCESTER: I have been delighted to hear both the papers and I think among the many auspicious signs for the coming century none is more auspicious in its import than the advent of the surgeon in the domain of obstetrics. I go back with dismay to the time when I was confronted with the necessity of doing Caesarean section, for the operation had not been done hereabouts for many a long year, moreover the patient was thoroughly exhausted in labor. But the delight I have taken in her joyous motherhood, for she had lost the five preceding children and longed to have a living child, and the delight I have taken since in that eight-year-old youngster named for me has amply repaid my anxiety.

With regard to the operation for placenta previa, I have come to the conclusion that it is the right operation. After a most disastrous series of cases of placenta previa some two or three years ago I tried to obtain the support of my colleagues of the Obstetrical Society to this procedure, but at that time I could not find one who would assent to it. One surgeon told me of a successful case of ligaturing the uterine arteries through the vagina and so controlling a hemorrhage that otherwise would have been fatal. A few weeks after that meeting I ran up against another case of placenta previa. I confess my absolute inability to distinguish the different forms. When you go through the os and find the placenta I don't know how to de-

cide whether it is marginal, lateral, central or anything else. It is there in front of you. I thought perhaps the best way to do was to get ready to ligature the uterine arteries. I got ready and then went in the usual old murderous way, boring through the placenta, and delivered the child. I have forgotten now whether the child was alive or not. I know the mother was dead in a pretty short time and in spite of my too late and perhaps too bungling ligaturing of the uterine arteries. I never shall try that again. To ligature the uterine arteries by the vagina may be a very easy job for some men, but with a rush of blood as if poured out of a pitcher, it is no easy task. It must be done by the sense of touch and you have not many minutes to lose in such hemorrhages as I have seen. In another such case I shall do a Caesarean section if allowed to do it and I think I shall back out of the case if not allowed. I admit having reached that time when perhaps timidity overcomes a man and he is more willing than he should be to believe that others confronted by the same difficulty might do better.

But I have had such frightfully bad fortune in following the regular obstetrical methods in handling these cases that I have in my own mind come to the conclusion that there is nothing so bungling, so unsurgical, so unscientific and so barbarous as the treatment advised for placenta previa. I understand that treatment to be in the face of a hemorrhage to dilate manually, bore through the placenta with the hand, do podalic version, get the child out as best you can, and the remains of the placenta afterwards, and then to use the ordinary, unscientific measures advocated for the treatment of post-partum hemorrhage. There is but one real way to stop hemorrhage. That is to compress the vessels. And the use of styptics, and hot douches to shock the inside of the uterus, all such measures are unreliable. The only right way to stop a post-partum hemorrhage is to compress the vessels from which the blood is coming. I believe in cases where it is decided best to bore through the placenta and deliver the child by podalic version, that it would be only a decent life-saving provision to have somebody ready to open the abdomen and compress the uterine arteries in case the hemorrhage proved to be tremendous. In such a crisis, with the thin belly wall between the surgeon and the vessels through which the life blood is flowing, a man who has even a pen knife and hesitates to go through that belly and get at those vessels where he can properly compress them is a coward. It is the only right way of treating such cases, and hesitancy to apply surgical principles is merely our evil inheritance from presterile times. When we remember that the natural closure of the vessels which supply the placental site during pregnancy depends upon the contraction of the uterus when the placenta separates, when we remember also the fact that the lower segment of the uterus has no power of contraction after the cervix has been forcibly dilated, and when we think of the operation of tearing the placenta free from the lower segment of the uterus, leaving those sinuses open, hoping blood will coagulate in them and knowing that they will not be subject to pressure; when we remember, too, that the forcible delivery in these cases is almost sure to rupture the cervix badly, keeping these things in mind could we imagine an operation more unscientific and unsurgical than the forcible dilatation of the cervix in such cases? It is ab-

solutely wrong. I am now purposely confining my attention to the danger of the mother without ignoring the greater danger to the child. It may be that we have not sufficient statistics to arrive at a final judgment, but certainly among the general practitioners who have had experience in everyday obstetrics there is a greater dread of placenta previa than of any other condition that has to be faced. I can think of no other exigency where the surgeon's advent into the obstetrician's domain will bring greater relief. In these cases it is always possible for the general practitioner to control ante-partum hemorrhage. The vagina can be plugged and even if the cervix is considerably dilated it is possible to drive in tampons against the gravid uterus in such a way as to prevent further hemorrhage. Of course the tampons may leak in a little while, but the general practitioner knows enough to take them out and put others in, thus giving time for the proper preparation of the patient for operation and for summoning a surgeon capable of doing the Cesarean section.

In the case of a woman who is exhausted by ineffectual labor, whose pelvis presents mechanical obstacles to her safe delivery, I feel that we must not forget or ignore the old-time practice, which was safer than we perhaps admit, of letting such a woman have a good long rest. If we let her alone her pains become more and more infrequent and she naturally sinks into restful sleep. I believe, in the case of a woman who has thus exhausted herself by ineffectual labor, that, by making the vagina antiseptic and resting her even under slight anesthesia during her pains, it would be possible, with the arts of reviving the patient that we have at command, to get her ready where she would stand the shock of a Cesarean section a great deal better than she would the shock of a craniotomy and the tearing through of a child whose head has been jammed to pieces; to say nothing of the mental and moral shock to all concerned.

DR. M. H. RICHARDSON: I have been very much interested in what I have heard. I am interested in this subject because, as a general surgeon, I may be called upon at any moment to decide the question of Cesarean section when I cannot have the advice of skilled obstetricians. Certain questions of technique have seemed to me especially important. An abdominal surgeon, and especially one who has operated many times upon the uterus, ought to be able to perform a Cesarean section, and to perform it well; it is the indication for operation that it is difficult to recognize. The general surgeon is not often called upon to intervene in recognized cases of pregnancy. He is called upon once in a while to operate upon uterine neoplasms in which careful study has shown the tumor to be a pregnant uterus. Unless he is constantly on his guard, the surgeon will find himself opening the abdomen for normal pregnancy. He ought therefore to know most intimately the signs and symptoms of pregnancy, not only in the early, but also in the advanced months. It is amazing to see how frequently pregnancy is overlooked, even by the experienced. On the other hand, it is extraordinary to see how often the diagnosis of pregnancy is made when there is only a fibroid, or other tumor of the uterus. A familiarity with the pregnant uterus is therefore essential for the abdominal surgeon, and he should be as prepared to perform a Cesarean section or a Porro as to remove the uterus for a fibroma.

He is not likely perhaps to be asked often to operate in the emergencies of well recognized and advanced pregnancy; yet Cesarean section lies well within the province of the abdominal surgeon. Indeed, no other but the surgeon experienced in abdominal work should be called upon to perform this most formidable intra-abdominal operation.

Taking the evidence that has been presented here tonight, the verdict must be, I think, in favor of Cesarean section in some cases at least of placenta previa. Perhaps the evidence is not as yet wholly conclusive, and the question may be regarded as still *sub judice*.

I am convinced of the safety of most operations upon the uterus. The safety of a complete removal of the uterus by experienced operators is great. Perhaps I am not justified in saying that hysterectomy is as safe as a difficult labor; but if not quite, it is very nearly as safe. In uncomplicated hysterectomy, skilfully performed with the most approved aseptic technique, the mortality is not over 5%. I am not sure that it is not less than 5% in experienced hands. Just what the mortality in labor is I do not know; but, taking all the cases together, normal labor, placenta previa, faulty positions of the fetus, albuminurias and eclampsias, prolonged labors — taking, as I say, all the cases of obstetrics together — I am inclined to think that in a hysterectomy skilfully performed upon a strong patient the dangers are not much greater than the general dangers of obstetrics.

Every speaker tonight has referred to the enormous mortality of placenta previa. I am surprised to learn that the best results show a mortality of 12%, and in some cases of 50%. The mortality in Dr. Reynolds's collection of 93 cases of Cesarean section — his own, Dr. Washburn's, and others — has been practically nothing. So far as I know there has been in this community practically no mortality in Cesarean section. I cannot see, then, how the verdict can fail to be in favor of a scientific operation, an aseptic operation, and an anatomical operation, — one which permits exact dissection, which cannot fail to stop the hemorrhage, which cannot fail to save the child, and in which the mortality — wholly in the cases of the mothers — is vastly less than by the older methods.

Very little can be said against Dr. Worcester's radical views on this subject; very little could now be said against the radical position in other surgical subjects which years ago he defended in this room. The course of events in the last ten years has shown that no matter how advanced views a man may take in surgery, it is difficult for him to make them too advanced.

DR. WASHBURN: I did not come in time to hear the papers and I ought not to say anything except that it has not been my misfortune to see a case of placenta previa that was not distinctly marginal, but I have some time since made up my mind that in case I did see one that was not absolutely and distinctly marginal I should do a Cesarean section on it. And I should like to say one word also on another thing that has developed in the discussion of the evening, and that is the great danger of doing Cesarean section on a patient somewhat exhausted by labor. I think that in most cases the danger of any other interference except of the simplest kind is fully as great as the danger from a rapidly and carefully performed Cesarean section. I think the dangers of Cesarean

section performed with absolute attention to asepsis and with tolerable rapidity in the hands of a careful person are not very great and the chances of saving not only the mother but the child also are very well worth working for.

Dr. H. R. HIRENCOCK: I have not anything to add to the paper except that I was the first doctor to see the case. At that time, 5 P. M., I examined her and thought it was placenta previa and wrote Dr. Hill to that effect and I did not see her again until she was under ether. It was a very quick and clean, neat operation; very instructive.

Dr. RICHARDSON: I should like to ask Dr. Worcester why separation of the placenta by Cesarean section should any more effectually check hemorrhage than separation after version.

Dr. WORCESTER: It seems to me the difference is this: By separating the placenta after Cesarean section you do not disturb the cervix, do not lacerate it, do not even tire it out. When you dilate the cervix by drawing the child through, you tire out the muscles of the cervix so it cannot contract at all.

Dr. DONOGHUE: In regard to the question just asked by Dr. Richardson, when you take the child out above you should allow the uterus to contract, and the contraction and retraction of the uterine fibres would separate the placenta. That was the method I followed in this case. Instead of attempting to separate the placenta immediately I waited ten minutes for the placenta to separate in the normal way and close the sinuses at the same time.

The idea of the operation in exhausted cases was suggested first to my mind by the operative results in cases of extra-uterine pregnancy with hemorrhage. One of Dr. Mixer's cases made a deep impression on my mind. The patient was pulseless. Dr. Mixer opened a vein in the arm and after infusing a quart to three pints of salt solution the pulse returned, laparotomy was done, the bleeding tube tied off, abdominal cavity filled with salt solution and the woman made a perfect recovery. Looking up the statistics of the surgical treatment of intra-abdominal hemorrhage, the mortalities are found to be surprisingly low, and if those things are possible in an extra-uterine hemorrhage the same surgical treatment applied to any kind of hemorrhage ought to meet with the same results. If the woman, in a case of placenta previa, was exhausted from ante-partum hemorrhage, it seems to me it would be logical to open a vein, infuse salt solution, do Cesarean section, fill the abdominal cavity (if necessary) with salt solution and give it the ordinary surgical treatment of shock.

Dr. REYNOLDS: I am very heartily in accord with what Dr. Donoghue said as to the section being the quickest and probably the best way to control hemorrhage. I should not think hemorrhage pure and simple was a contraindication to the section. I am now making observation on this subject which I intend to publish later, but I may say that at present it seems to me that there is a pathological basis for my opinion that prolonged labor pains and the section form a particularly fatal combination.

Dr. RICHARDSON: I should like to say one thing suggested by Dr. Donoghue. Six or eight years ago I published a list of extra-uterine pregnancies, and stated then that if the patients were on the verge of the grave from hemorrhage, it would be better to let them alone, in the hope that they would react from

the collapse and grow strong enough for operation. Since that time my experience has been such that my opinion is decidedly different. I believe that if you wait for the pulse and strength to return when the patient is collapsed and pulseless, you generally wait in vain. Under such circumstances the intravenous injection of salt solution is a very valuable life-saving procedure — a procedure by which the pulse may be brought up and the patient enabled to rally enough to withstand a rapid operation. We have tried it a number of times. In a case of post-operative hemorrhage in which the patient had practically no pulse, two quarts of salt solution brought the pulse up so that by an extremely rapid operation the bleeding vessel was tied, and the patient was saved. I never shall wait again in a case of extra-uterine pregnancy or of abdominal hemorrhage in the hope that the patient may, by elevation of the feet, stimulation, and so on, be restored enough to endure the operation. I recall several fatal cases in which I did not operate for the reason that I felt sure the shock of the etherization would be sufficient to turn the scale. I shall never wait again, even in such a case; I shall infuse and stop the hemorrhage — no matter how desperate the circumstances — and I am sure that I shall save many a patient who would succumb under any less immediate and heroic measures.

AMERICAN PUBLIC HEALTH ASSOCIATION.

TWENTY-EIGHTH ANNUAL MEETING, HELD AT INDIANAPOLIS, IND., OCTOBER 22, 23, 24, 25 AND 26, 1900.

(Concluded from No. 22, p. 562.)

Dr. JUAN BRENA, of Zacatecas, Mexico, dealt with the

VICE OF SMOKING AMONG YOUTHS,

and offered suggestions as to the means of overcoming it.

REPORT OF THE COMMITTEE ON DISINFECTION.

This was presented by Prof. F. C. ROBINSON, of Brunswick, Me. From what has been accomplished in this work, the following conclusions seem warrantable:

(1) Household disinfection after infectious diseases should combine the use of formaldehyde with other means. It can be safely relied upon for all exposed surfaces, and these only.

(2) Formaldehyde requires moisture enough in the air to nearly saturate it for its most efficient working.

(3) There is much disagreement among experimenters as to the disinfection of tuberculous matter. One says a 2% solution of formaldehyde disinfects it; another, that even a 10% solution does not. Several say that formaldehyde gas applied as above destroys it; others deny this. Further experiments are needed.

(4) Soap is a poor disinfectant, but 1% caustic alkali, or 20% carbonate of alkali is efficient.

(5) Carbolic acid, less than a 5% solution, has little scientific value.

(6) The creosotes, as used in creolin, lysol and solutol, are safe disinfectants.

(7) Alcohol at from 50% to 75% has considerable disinfecting power, but not at other strengths.

(8) Most metallic salts, except those of mercury, have little disinfecting action.

(9) Bichloride of mercury, or corrosive sublimate, should be used in strength of at least 5-1,000 if tuberculous matter is to be disinfected. A fresh solution is more active than one which has stood for some weeks. The addition of salts does not increase the strength of a fresh solution, but prevents it from losing its strength as rapidly.

(10) Bright sunlight kills the tubercle bacillus in a few hours, and, as a rule, pathogenic bacteria keep their greatest virulence only when kept in the dark.

Dr. JESUS CHICO, of Guanajuato, Mexico, gave some

HINTS ON MALARIA FROM PERSONAL OBSERVATIONS,

in which he did not think the mosquito was as important a causative factor as had been generally supposed, but in Mexico he thought the injudicious use of tropical fruits played an important rôle.

Miss HESTER McCLUNG, of Indianapolis, recounted the

SANITARY WORK OF WOMEN IN THAT CITY.

REPORT OF THE COMMITTEE TO DEFINE WHAT CONSTITUTES AN EPIDEMIC.

This was read by the chairman, Dr. BENJAMIN LEE, of Philadelphia. In the minds of the public at large, and of many of the profession, the word "epidemic" still conveys an idea of universal atmospheric contamination. This is to be deplored, because, while on the one hand its use inspires an indefinable horror and creates panic, on the other hand it leads to the disregard of the very precautions which are of essential use in restricting the spread of the contagion, namely, those which should be taken in regard to the person and the excreta of the patient, his effects and his immediate environment.

In view of changed views as to the propagation of communicable diseases, the word "epidemic" has outgrown its usefulness. It has become the means of perpetuating false conceptions, and its official use may be misleading and mischievous. Without attempting any stricter, more comprehensive, or more lucid definition of this word, the committee recommended that, as opportunity occurs, in all laws and regulations in which certain executive action is made contingent on the declaration by health authorities of the existence of an epidemic, the phraseology shall be altered by omitting the word "epidemic," and in place thereof inserting a brief statement of the condition calling for such action, as, for example, "whenever a communicable disease prevails to such an extent, or is spreading with such rapidity as in the opinion of the board to make it its duty to notify either the general public or the authorities of neighboring towns of the fact that such and such action shall be taken." The report of the committee was adopted, and the committee discharged.

REPORT OF THE COMMITTEE ON NATIONAL LEPER HOME.

Dr. H. H. BRACKEN, of Minneapolis, chairman, presented this report. The committee dealt with the desirability of establishing national leprosaria in the United States. The records of Dr. Bracken for cer-

tain States, compared with those of Dr. Hyde, are as follows:

State.	Dr. Hyde.	Dr. Bracken.
North Dakota	2	2
South Dakota		1
Iowa	20	3
Minnesota	120	61
New Jersey	1	1
Ohio		1
Pennsylvania	6	6
Wisconsin	20	7

He presumes that Dr. Hyde's figures for Iowa and Wisconsin are estimated. Probably they are not too high. He has taken only those cases of which a history could be given. It is probable that the 120 cases credited to Minnesota are taken from Dr. Hansen's report. It seems to him that this, too, must be an estimate. If there were 120 cases in Minnesota, the speaker cannot understand why they are not on his records. If there were that number of cases in 1888, the number for Minnesota is much higher than he has given, for many of the cases in the official list cannot have possibly belonged to Dr. Hansen's 120.

It might appear from the report of cases in the Northwest that leprosy was far more common in Minnesota than in the neighboring State. He can see no reason for this belief, for the lepers in this district are among the immigrants from Norway, Sweden, Iceland and China. These people have quite a representation in all this group of States. He can only attribute the more complete returns for Minnesota to the fact (1) that there has been less agitation against leprosy in this than in some of the neighboring States; (2) that with this lack of agitation against leprosy, physicians report their cases more willingly to the State Board of Health, which has endeavored during the last twenty years to palliate the sufferings of this unfortunate class; (3) that Minnesota is fortunate in having among its physicians men who are familiar with leprosy, and who are interested in philanthropic work, and these physicians have given material aid to the State authorities engaged in securing a list of all lepers in Minnesota. Several lepers in the Minnesota list give the history of a previous residence in Wisconsin, but their names in not a single instance appear upon the Wisconsin records. Of the 37 living lepers known to be resident in the Northwest, 17 only are in Minnesota, and there is a strong possibility of 2 of these being dead, but he has no positive knowledge of the fact. He does not dwell upon these facts as an alarmist, but simply reminds the association that leprosy has existed, does exist, and will continue to exist for years to come in all three countries represented in the association.

ESTABLISHMENT OF LEPROSARIA.

A leprosarium should afford a comfortable home for lepers. This means, not only good buildings, but extensive grounds comprising many acres, where the lepers may have liberties and still be in seclusion. The buildings connected with the leprosarium must combine the privileges of a home and of a hospital. Those who have the disease in mild form may need little if any medical care. They need comfortable clothing and good food. With those in whom the disease is more advanced, the care should be that of a hospital patient, with medicines to lessen their suffering, and dressings that would commend themselves to any surgeon. A leprosarium should resemble modern colonies for epileptics. It should furnish employment

for those who are able to work, and amusement of various kinds for all.

Two of the strongest medical societies in Minnesota have placed themselves on record as favoring the establishment of national leprosaria, also the American Dermatological Association has appointed a committee to determine the best methods to be used in the care of lepers.

By resolutions the association placed itself on record as favorable to the establishment of national leprosaria.

DR. JOHN H. S. FULTON, of Baltimore, described

A SUITABLE DRESS FOR DEFENCE AGAINST INFECTIOUS DISEASES.

MR. F. H. NEWELL, government hydrographer, contributed a paper showing

SOME RESULTS OF THE INVESTIGATION OF STREAM POLLUTION

which has been made by the United States Geological Survey. The government, realizing the importance of public water supplies, and their conservation and protection against pollution, has established a special division under the title of Board of Hydrography.

REPORT OF THE COMMITTEE ON ANIMAL DISEASES AND ANIMAL FOOD.

This was read by DR. D. E. SALMON, of Washington, D. C., chairman. He urged the importance of careful observations being made of glanders, in view of the fact that serum for use in the treatment of many human ailments is obtained from horses. Army horses are peculiarly liable to contract the disease in time of war, on account of the extra exertion and frequent lack of full rations during such periods. He roundly condemned the carelessness of the U. S. Government in the matter of providing skilled and trained veterinarians in the army. He discussed the subject of hydrophobia, and emphasized the importance of active measures looking to the extermination of this disease. He cited statistics of many outbreaks of rabies, and showed the disease to be peculiarly virulent and almost invariably fatal to human beings. Misguided people who declare there is no such thing as hydrophobia communicated to man from animals were sternly rebuked. Dr. Salmon declares that their obstructive tactics have wrought incalculable harm in the way of deceiving people into a careless attitude towards this malevolent disease. The Pasteur treatment was highly commended by the committee, which also recommended that the association take steps to enlighten the public on the disease and its treatment, as well as means for its prevention.

TUBERCULOSIS.

The committee made strong recommendations on the subject of tuberculosis, asserting its belief in the theory that the disease can be and is communicated from infected cows through their milk. Here also the committee encountered learned men who controvert the theory, asserting that the difference in appearance of the bacillus of human tuberculosis and that of bovine indicates that the latter cannot communicate the disease to human beings. Bovine tuberculosis is undoubtedly communicable. He inveighed against loose methods prevailing in many creameries by which the milk received from an infected herd is

mixed with the general supply of milk on hand; and further, the practice of distributing, without previous sterilization, the waste milk and cream to be used as food for swine was condemned.

PRESIDENT BRYCE added a few terse, vigorous utterances on the care which ought to be employed in dairies to guard against the distribution of milk infected with tubercle bacilli.

DR. R. M. WOODWARD, of Washington, D. C., gave a résumé of the recent foreign work of the Marine-Hospital Service.

DR. F. F. WESBROOK, of Minneapolis, reported on behalf of the Committee on Transportation of Diseased Tissue by Mail, recommending that nose and throat specimens be included in one package.

DR. CRESSY L. WILBUR, of Lansing, Mich., presented the report of the Committee on Demography and Statistics in their Sanitary Relations. He mentioned the progress that has been made in matters relating to vital statistics concerning which the association had acted in the past. He urged the association to stand for united and determined action in elevating the standard of registration laws in this country, and in ensuring the practical success of new laws when enacted.

The following resolutions were introduced, discussed and adopted:

(1) *Resolved*, That the association, recognizing the benefits of medical school inspection, heartily approves the efforts of boards of health and of education directed towards the establishment of systems of inspection. (Offered by Dr. Adolph Gehrmann.)

(2) *Resolved*, That the association approves of and encourages all efforts made by governments, whether national, state or municipal, for the limitation of pollution of streams. (Offered by Mr. C. Monjeau.)

(3) *Resolved*, That a committee of three be appointed, to be known as the Committee on Uniform Municipal Statistics, to take such steps as may seem practicable towards securing greater uniformity in all branches of municipal accounts, reports and statistics, and particularly those branches relating to vital and sanitary statistics; said committee to have power to confer with similar committees from other societies already or hereafter appointed to the same general end, and to report at the next meeting of the association. (Offered by Dr. Leal, of Paterson, N. J.)

ELECTION OF OFFICERS.

The following officers were selected for the ensuing year: President, Dr. Benjamin Lee, of Philadelphia, Pa.; First Vice President, Mr. Rudolph Hering, of New York City; Second Vice President, Dr. J. N. Hurty, of Indianapolis, Ind.; Secretary, Dr. Charles O. Probst, of Columbus, O.; Treasurer, Dr. Henry D. Holton, of Brattleboro, Vt.

Buffalo was selected as the place for holding the next annual meeting. The Executive Committee recommended that the time be fixed during the third week in September, 1901.

DIPHTHERIA AND MEASLES IN INDIANA. — There are, according to the *Medical News*, 1,000 cases of diphtheria and measles in Muncie and physicians are powerless to stamp out the contagion. One-fifth of the school children are afflicted and the schools are depopulated.

Recent Literature.

A Textbook of Practical Medicine. By WILLIAM GILMAN THOMPSON, M.D., Professor of Medicine in Cornell University Medical College, New York City; Physician to the Presbyterian and Bellevue Hospitals, New York. New York and Philadelphia: Lea Brothers & Co. 1900.

This "Textbook of Practical Medicine" has 1,000 pages and is illustrated by 79 engravings. The author is professor of medicine in one of the large New York medical schools. One cannot reasonably write a textbook of medicine without being a professor in a medical school, and conversely it may be regarded as true that one can hardly be a professor of medicine or clinical medicine without writing a book. In this case the author considers that "the advent of a new century makes appropriate a comprehensive review of the present status of medical practice," and it is "the aim of this book to offer such a presentation to students and practitioners."

The contents of Professor Thompson's work are divided into nine parts and seventy-nine chapters. The first part, with thirty-four chapters and 355 pages, more than one-third of the whole book, is devoted to the important subject of infectious diseases; the second part, with 160 pages, to diseases of the digestive system; the third part, of 32 pages, to diseases of the spleen, lymphatic system, and ductless glands; the fourth part, of 83 pages, to diseases of the blood and vascular system; the fifth part, of 63 pages, to diseases of the respiratory system; the sixth part, of 35 pages, to diseases of the urinary system; the seventh part, of 137 pages, to diseases of the nervous system; the eighth part, of 2 pages, to diseases of the muscular system, and the ninth part, of 82 pages, to miscellaneous diseases, poisons and drug habits and diseases due to parasites.

Professor Thompson has added another very good textbook to those which have preceded his, and the work of the publishers has been well done.

The Student's Medical Dictionary. Including all the Words and Phrases generally used in Medicine, with Their Proper Pronunciation and Definitions, Based on Recent Medical Literature. By GEORGE M. GOULD, A.M., M.D. Eleventh edition, enlarged. Illustrated. Philadelphia: P. Blakiston's Son & Co. 1900.

Gould's Student's Medical Dictionary has reached its eleventh edition in somewhat enlarged form. It still remains, however, a comparatively small and portable volume, a size which we hope future editions will not greatly exceed. The book has stood the test of time and criticism, and remains one of the best dictionaries we have; it retains the cardinal merit of being inexpensive.

Saunders' Pocket Medical Formulary. By WILLIAM M. POWELL, M.D. Sixth edition, thoroughly revised. Philadelphia: W. B. Saunders & Co. 1900.

This small volume is essentially a collection of prescriptions gathered together from many sources. In addition it contains considerable information on various medical matters. The book is attractively bound in flexible leather and the fact that it has reached its sixth edition bears ample testimony to its popularity.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, DECEMBER 6, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS

OYSTERS AND DISEASE.

WITH the advance in our knowledge of the subtle and unexpected ways in which disease may be transmitted, suspicion has from time to time, and not unjustifiably, fallen upon the oyster. It has been easy for a somewhat vivid imagination to picture the contamination to which oyster beds may be exposed, and to conceive of the possible multiplication of pathogenic bacteria or other agents inimical to health within their shells. Admitting these facts, it is a short step to imagine the effect upon man of eating such oysters and to add another terror to the constantly increasing number with which we are surrounded. Fortunately in this, as in many other matters, an appeal to experiment does much to clear the way for a calmer and more rational interpretation of the facts. This service has lately been rendered by an exhaustive and painstaking study on the general subject of oysters and disease undertaken by Prof. W. A. Herdman, of Liverpool, and Prof. Rubert Boyce, also of Liverpool, and both of University College. Their work is published in full, with plates, in the second volume of the Thompson Yates Laboratories Report, and well repays a careful perusal. The conclusions of these investigators are of moment, and should be generally known both by the raisers and consumers of shellfish. In general their experiments, in common with those of others, go to show that oysters and other shellfish used as food must from their nature and the circumstances of their cultivation and sale be regarded as liable to contamination from pathogenic and other organisms or their products. Recognizing this fact, the following statement made by the writers is sufficiently self-evident: "Shellfish must not be taken as food from grounds where there is any possibility of sewage contamination; after removal from the sea, while in transit, in store, or in market, they should be carefully protected from any possibility of insanitary environment; they should not be kept longer than is absolutely necessary in shops, cellars, etc., in towns where, even if not running the risk of fresh contamination, they are under conditions favorable to the reduction of

their vitality, and the growth of their bacterial contents — the fresher they are from the sea the more healthy they are likely to be; finally, only absolutely fresh shellfish should be eaten uncooked, and those that are cooked must be *sufficiently cooked*, raised to boiling point and kept there at least ten minutes."

Among the details of their experiments several matters of great interest were brought out. The vexed question of "greening" in oysters was one. The investigation showed that there are several perfectly distinct varieties of greenness, some being entirely healthy, and others indicating an excess of copper; in certain American oysters, for example, it was distinctly proved that their green color was due to copper, and also that the copper is situated in the blood cells, or leucocytes, which are much increased in number. This condition they call a green leucocytosis. On the other hand experiments in feeding oysters with weak solutions of copper and iron salts gave no clear evidence of any absorption of the metals accompanied by greening.

The investigations on the presence of typhoid bacilli in oysters is also of much importance. They did not find the bacillus in any oysters obtained from the sea or from markets, but were able experimentally to inoculate oysters with typhoid and recover the organism from their bodies up to the tenth day. It appears, however, that the bacilli do not increase in the body or tissues, and probably die in the intestine. Sea water was found inimical to the growth of the bacilli and the washing of infected oysters in a stream of clear sea water led to a great diminution or, in some cases, a total disappearance of the bacilli in from one to seven days. The colon group of bacilli is frequently found in shellfish, but probably not in those living in pure sea water. It is unsafe, however, to infer from this that the presence of colon bacilli invariably indicates sewage contamination. Further investigation on this point is desirable. The writers inform us with reference to their negative results regarding typhoid that their samples of oysters were in no case, so far as they were aware, derived from a bed known or suspected of contamination with typhoid.

As a result of their investigations they feel amply justified in sounding a warning note regarding the raising and selling of oysters. They urge the greatest possible care in the prevention of contamination, and for the regular inspection of the grounds by qualified persons. Foreign oysters should be as carefully inspected as those raised at home, and a systematic quarantine established.

The report is, in a general way, reassuring, and yet, throughout, it recognizes a real danger, provided the utmost precaution be not taken to guard the oyster beds as we would any other source of food supply. It is well that we should be fully aware of all the facts and insist upon the legal enforcement of close inspection. When this is done we may, no doubt, still enjoy our oysters, with the practical assurance of their harmlessness.

REVISION OF CHARTER OF CITY OF NEW YORK.

IN the report of the commission appointed by Governor Roosevelt to revise the charter of the city of New York, which has just been made public, the opinion is expressed that the present Board of Health is unnecessarily expensive and complicated, and that the mayor should not be prohibited, as at present, from appointing a physician president of the board. It is therefore recommended that the board be composed of one commissioner (to be selected by the mayor, without restriction upon his choice), the head of the Police Department, and the health officer of the port. The powers and duties of the Health Department are not materially changed. The substitution is recommended of a single commissioner of Public Charities for the present board, consisting of three commissioners. The most important change, however, in the matter of public charities is that Bellevue and its allied hospitals, namely, Fordham, Gouverneur and the Emergency Hospital, be placed under the administration of a board of seven trustees to be appointed by the mayor. Provision is made that certain societies have a recognized opportunity to make nominations for those appointments, but the power of the mayor in the matter is to be in no degree abridged by such recommendations or nominations. It is the belief of those favoring this change that the executive efficiency of the Department of Public Charities will be in no wise impaired thereby, as the experiment of conducting city hospitals by boards of trustees, rather than by the executive officers of the city government, has been successfully tried in Boston, Baltimore, Cincinnati and other large cities. The commissioner of charities will be *ex officio* a member of the board, and his existing powers of visitation will be fully preserved. In regard to the water supply, the commission strongly recommends that the excessive powers granted under what is known as the Ramapo Charter, being Chapter 985 of the laws of 1895, should be repealed. It furthermore recommends the adoption of the Massachusetts plan, under which cities and towns are furnished by the State itself; water so furnished to be sold to the various municipalities using it, and the State to issue bonds for needed appropriations.

THE THIRD PAN-AMERICAN MEDICAL CONGRESS.

THOSE who contemplate attending the third Pan-American Medical Congress, which meets in Havana from December 26th to 28th, inclusive, will be interested in the following details which we have received from Dr. Ramon Guiteras, the associate secretary of the congress.

One can go either by the land routes, which are all *via* Florida and are much more expensive for those going from our Northeastern States, or by steamer from New York. The new Ward Line steamer *Morro*

Castle, with capacity of 136 cabin passengers, leaves New York December 22d, arrives in Cuba on the 25th, remains there until the close of the congress, leaving Cuba late on the 29th, and reaches New York on January 1st. The round trip by steamer, everything included, is \$60. Any one going *via* the Ward Line will be absent from New York ten days.

English-speaking members of the Cuban Reception Committee will meet all steamers on their arrival in Havana, and escort all delegates to the hotels assigned to them. The best hotels in Havana are the *Telegrapho*, *Mascotte*, *Inglaterra*, *Pasaje* and *Roma*. Rates are from \$3.00 to \$5.00 a day, everything included.

Excursions have been planned by the committee to various points of interest on the island, among which are the caves of *Bella Mar* in *Matanzas*, the large sugar plantations, *Morro Castle* and other points of interest. A number of receptions and entertainments will be given in honor of the delegates from foreign countries. All details of entertainments are as yet in the hands of the Cuban Committee.

Quarantine was raised on November 15th. Before that time New York passengers were detained long enough to cover five days from their departure from Havana. There will be no danger from yellow fever at the time of the congress.

In another column may be found the names of the presidents and English-speaking secretaries of sections. Particulars regarding sections and other information as received from Havana will be given from time to time. All literature pertaining to the congress will be in Spanish.

MEDICAL NOTES.

PAN-AMERICAN RED PEPPERS AT THE PAN-AMERICAN EXPOSITION.—We quote the following from a circular recently received from the Division of Foods, Pan-American Exposition: "It is intended to make this the finest and most extensive collection of red peppers ever made, with the object of demonstrating by special exhibit connected with 'accessories to foods' that Pan-America can produce all the red peppers consumed in Pan-America. It is, perhaps, only known to experts that vast quantities of red peppers are imported from Europe, Asia and Africa every year because Pan-Americans are not actively alive to their own interest in this important matter. To whom this greeting comes, we ask for co-operation in making this demonstration, and we promise that recognition shall be given all who take an interest in the affair."

ENGLISH CAPITALISTS NEGOTIATING FOR BADEN SULPHUR BATHS.—It is reported from Vienna that certain English capitalists are negotiating for a lease of the hot sulphur baths at Baden, a few miles southwest of Vienna. They are said to have offered a rent of \$28,000 and pledge themselves to expend \$1,000,000 in improvements of the property, besides adding a theatre, casino and other attractions.

PASSING OF THE FIJI ISLANDERS.—Dr. Morgan I. Fiumcane, medical inspector of the colony, is authority for the statement that the black tribe of Fiji Islanders is dying out. This is due not to a small birth rate, but to an enormous infant mortality, caused by sanitary neglect, filthy houses, and the absence of skilled physicians. It is not expected that much can be done in the way of improving the conditions while the native character remains as it is.

ESTIMATED COST OF PROFESSIONAL EDUCATIONS.—A writer in the *London Daily Mail* has figured it out that, averaging the poor and frugal with the rich and extravagant, it costs a young Englishman about \$2,000 to fit himself for the navy, \$3,000 for the army, \$3,875 for the church, \$4,000 for the bar, and \$4,720 for the practice of medicine.

JOHN HOPKINS UNIVERSITY.—According to the *Philadelphia Medical Journal*, Dr. William H. Welch and Dr. William Osler, of the Johns Hopkins Medical School, have been named as possible candidates for the presidency of the university in place of President Gilman, resigned.

A CENTENARIAN.—Nathaniel Wells, a chemist by profession, died in Washington, November 29th, at the reputed age of one hundred and seven. He was a friend of Darwin, Spencer and Huxley. He is said to have been around the world twenty-five times.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the eight days ending at noon, December 5, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 171, scarlatina 23, measles 19, typhoid fever 14.

BOSTON MORTALITY REPORT.—The number of deaths reported to the Board of Health for the week ending December 1st is 186, as against 206 the corresponding week last year, showing a decrease of 20 deaths, and making the death rate for the week 17.3. The deaths from consumption were 19, pneumonia 14, whooping cough 1, heart disease 18, bronchitis 2, marasmus 7. There were 9 deaths from violent causes. The number of children who died under one year was 31, under five years 58, persons more than sixty years 43; deaths in public institutions 64.

FAULKNER HOSPITAL CORPORATION.—The organization of the hospital under the will of the late Mrs. Abbey L. A. Faulkner, of Jamaica Plain, has been perfected. As far as possible the proposed hospital will be modelled after the Massachusetts General Hospital, to be managed by a board of five trustees, according to the express wish of the donor, but as the privilege was allowed the executors of the will to increase the number, the Board of Trustees as now constituted consists of Charles P. Bowditch and Alfred Bowditch, whom Mrs. Faulkner had nominated herself; Ellen C. Morse, Cornelia Bowditch, Charles H. Souther, Henry B. Chapin, all of Jamaica Plain, and Emily G. Denny, of Brookline. The work of the hospital will have to be decided later by the trus-

tees, but it is probable that it will contain a medical and a surgical ward, as well as out-patient and convalescent departments. It is hoped that the work of construction may begin in the spring.

A NEW ENGLAND CENTENARIAN. — Mrs. Anna Weed, said to be one hundred and two years old, died recently at Merrimac, Mass. Both her maternal and paternal ancestors were remarkable for their longevity.

NEW YORK.

NEWARK'S ENTERPRISING BOARD OF HEALTH. — If any one desires to avoid the ills of life and attain a serene and undisturbed old age he should at once decide to make his home in Newark, N. J. At a recent meeting of the Board of Health of that city it was determined to add to its Sanitary Code twelve new ordinances, among which are included measures to compel barbers to sterilize their razors and use a separate towel for each customer, to stop obnoxious noises, such as the screeching of factory and locomotive whistles, to prevent the early morning crowing of roosters by prohibiting the keeping of chickens within the city limits, to regulate the habits of dogs by enforcing certain rules for their owners, to prevent cats from running at large at night, to close wells in which typhoid bacilli may disport themselves, to secure the removal of dead trees, decayed telegraph and telephone poles, and unsafe pulley lines, to regulate the exposure of food stuffs, to restrict the manufacture of water gas, and to prohibit the operation of open trolley cars during unseasonable parts of the year. As Newark has recently secured for itself a permanent supply of excellent water, there would seem to be little left to make residence there a truly Utopian existence.

COMMENDATION OF WORK OF STATE TENEMENT HOUSE COMMISSION. — In the annual report of the Charity Organization Society, just issued, the work of the State Tenement House Commission is highly commended. Special attention is directed to the dark, narrow and unventilated airshaft and the dark hallways of the tenements as usually constructed, as a menace to health and morals; and the hope is expressed that the legislature, with the knowledge which will be placed at its disposal in the report of the present commission, will not fail to take some effective step, through the erection of a new city or State department, or otherwise, to remedy these and other evils. The report gives the result of the new law authorizing the payment of city subsidies to private institutions, and then goes on to say: "The question arises whether the amount disbursed prior to the adoption of the present rules should not have been regarded as a maximum to be distributed on some basis for services rendered by the institutions approved by the Board of Estimate and Apportionment. Otherwise it will be only a few years until public subsidies have entirely supplanted private charity in the field of medical relief."

OUTBREAK OF SMALLPOX IN NEW YORK. — There has been during the past week quite an unusual outbreak of smallpox in the city. On November 27th 6 cases were reported in Manhattan, this being the first appearance of the disease in New York, with the exception of an isolated case in the Borough of Brooklyn a few days previously, since the third week in August, when 1 death was caused by it. On the following day 4 additional cases were reported, and on November 29th 14 new cases. On November 30th, however, only 2 new cases were discovered. Nearly all the cases were in one tenement house block, and 11 of them were in one house. A large proportion of the patients were young children, some of whom attended a kindergarten maintained by the Riverside Association in West 69th Street. The disease is supposed to have originated from a negro who is an actor belonging to a Southern troupe and who recently arrived in the city and took lodgings in the neighborhood where it broke out.

MEETING OF THE CHILDREN'S AID SOCIETY. — The forty-eighth annual meeting of the Children's Aid Society was held on November 27th. The report of the secretary showed that during the past year 581 children have been placed in homes in the country. Homeless and destitute families numbering 1,013 persons, mostly children, have been assisted to reach friends or employment in the country, making a total of 1,594 persons sent away from the overcrowded city. The farm school in Westchester County proved important in turning the attention of many city boys to the advantages of country employment. During the summer the Sick Children's Mission aided with medical advice, food, medicine, etc., 1,157 children, and 6,508 children enjoyed the benefits of the Summer Home, at Bath Beach. At the Health Home and Coney Island there were 7,385 mothers and sick infants, 3,122 of whom remained for a week or longer.

NO "EMBALMED" MILK. — The president of the Board of Health has just made public a report by Chief Milk Inspector Herman Betz, which shows that no "embalmed" milk is being sold in the city, as was recently charged. The report is in part as follows: "Every sample of milk taken by our inspectors during 1898, 1899 and 1900, up to today, to the number of 2,846, has been examined in the laboratory, as part of the analysis, for antiseptics such as formaldehyde and boracic acid; but not a single case has been found which would have justified legal proceedings. Suspicious samples were found on several occasions, but when an attempt was made at verification the result was always negative.

CITY AND SUBURBAN HOME COMPANY. — The Directors of the City and Suburban Home Company, of which Dr. Gould is president, have issued notices that its dividend rate has been raised from 4 to 5 per cent. per annum. They have also sent out a circular inviting subscriptions to an issue of \$500,000 additional stock, the money raised by the sale of which is to be

used to erect model tenement houses on land adjoining the company's present property on First Avenue. The experience with those previously constructed in this location has demonstrated beyond question that the plan to build model tenements on a paying basis in New York is a perfectly feasible one.

NEW WARD FOR DISEASES OF WOMEN AT BELLEVUE. — There was recently opened, with a service conducted by the Rev. Dr. Huntington, of Grace Church, an annex to the Marquand Pavilion, for diseases of women, at Bellevue Hospital. It contains a very finely equipped operating room and twelve beds, and is the gift of Mrs. Louisa Dehon and her daughter. The latter is a patient of Dr. Wm. M. Polk, and it was at his suggestion that the building, which cost about \$10,000, was erected.

A COURAGEOUS POLICEMAN. — On Thanksgiving night a policeman named William Baumeister, while arresting a desperado who was engaged in a fight, was shot in the abdomen by the latter; but, although mortally wounded, he pluckily held on to his prisoner until some other officers came to his assistance. The poor fellow was taken to the Harlem Hospital, where he died on the following day.

CROTON WATER SYSTEM. — Some complaints have recently been made about the condition of the Croton water, but there is apparently no reason whatever for a scare in regard to it. Mr. Birdsall is authority for the statement that there is absolutely no contamination from outside sources, and that the slight discoloration and at times unpleasant taste are due simply to unusual weather conditions.

AN AQUARIUM RATHER THAN A MORGUE. — Apropos of this subject, Judge Howland, at the recent dinner of the Society of Mayflower Descendants at Delmonico's, told of a lady who when asked if she did not boil the Croton water nowadays to kill the microbes, replied, "No; I would rather be an aquarium than a morgue."

Miscellany.

OFFICERS OF THE THIRD PAN-AMERICAN MEDICAL CONGRESS.

THE following are the presidents and American secretaries of the more important sections of the coming Pan-American Medical Congress: General Medicine: President, Dr. Carlos Finaly; Secretary, Dr. Judson Daland. General Surgery: President, Dr. Tomas Plasencia; Secretaries, Drs. W. P. Nicholson, John Ridlon, Duncan Eve. Military Medicine and Surgery: President, Dr. E. S. Agramonte; Secretary, Surgeon Major Jefferson Kean, U. S. Army. Obstetrics: President, Dr. Eusebio Hernandez; Secretary, Dr. Gustave Zink. Gynecology and Abdominal Surgery: President, Dr. Gabriel Casuso; Secretary, Dr. H. P. Newman. Pathology and Therapeutics: President, Dr. Raimundo Castro; Secretaries, Dr. D. Hunter McAlpine and Dr. Hobart A. Hare. Anatomy: President, Dr. Federico Horsman; Secretary,

Dr. A. D. Bevan. Physiology: President, Dr. M. Sanchez; Secretary, Dr. A. P. Brubaker. Pediatrics: President, Dr. Joaquin L. Duenas; Secretary, Dr. I. N. Love. Ophthalmology: President, Dr. Enrique Lopez; Secretary, Dr. John E. Weeks. Laryngology, Rhinology and Otology: President, Dr. Carlos Desvernine; Secretaries, Dr. G. Hudson Makuen and Dr. James F. McKernon. Dermatology and Syphilography: President, Dr. Henry Robelin; Secretary, Dr. A. Ravogli. General Hygiene and Demography: President, Dr. Vincente de la Guardia; Secretary, Dr. Alvah H. Dotey. Marine Hygiene and Quarantine: President, Dr. Luis Cowley; Secretary, Dr. R. M. Woodward. Mental and Nervous Diseases: President, Dr. Gustavo Lopez; Secretary, Dr. Chas. P. Hughes. Bacteriology: President, Dr. Juan N. Davalos; Secretary, Dr. G. Garcia Rijo.

SPASMODIC WRY NECK AND ITS TREATMENT.

DR. W. M. LESZYNSKY reports in the *New York Medical Journal*, November 24, 1900, two cases with recovery. Both patients were young married women, aged respectively twenty-four and thirty-six years, in whom the condition had existed for seven months. The sternomastoid, trapezius, and splenius capitis muscles were involved. The treatment that led to a successful result was daily massage of the neck muscles, passive movements of the head and neck, and systematic voluntary exercises with and without resistance.

He had resorted to the subcutaneous injection of atropine in twelve cases of clonic wry neck, and believes that while atropine may prove exceedingly beneficial in some cases, it is unsatisfactory in many others, and should only be utilized as an adjunct to absolute rest and general management. In his opinion, the principal therapeutic feature in every case should be the rational use of massage and the methodical education of the muscles and their co-ordinating centres. Such measures, in conjunction with rest in bed and general tonic treatment, should be thorough, and persistently carried out before surgical intervention is considered.

Obituary.

RUFUS P. LINCOLN, M.D.

DEATH has of late been busy among the prominent medical men of New York. Dr. Rufus Pratt Lincoln, the eminent laryngologist, died on November 27th. His case was one of unusual interest from an anatomical, as well as a surgical, standpoint, on account of the peculiarities of intestinal formation disclosed at the autopsy. On October 18th Dr. Lincoln had an acute attack of appendicitis, and a peculiar feature of the latter was the excessive vomiting attending the onset of the trouble. He convalesced within a week, and in ten days resumed his work. On the advice of his physician, Dr. Henry F. Walker, and of Dr. Charles McBurney, he decided to have an operation for the removal of the appendix, and the operation was performed on Sunday, November 18th. The appendix could not be found, while the caput coli was undeveloped and the ascending mesocolon entirely absent. A thick band of inflammatory exudation bound down the small intestines near the usual site of the caput coli. Finding it impossi-

ble to discover the appendix without a hazardous operation, Dr. McBurney, recognizing the abnormalities of structure present, determined to close the wound. The wound healed perfectly, without sign of fever or tenderness. The vomiting following the ether was very severe, and afterwards vomiting became persistent, but was never stercoraceous. Gas passed from the anus, at times very freely, but no full action of the bowels was obtained. Dr. Lincoln died of exhaustion on November 27th, nine days after the operation.

The autopsy was made the same day, Drs. McBurney, Walker, McCosh, Collins and Swift being present. The external and internal wounds were entirely aseptic throughout. It was found that the cecal extremity of the colon was undeveloped, and that its lower end was at the level of the umbilicus. The small intestine passed behind, and entered the colon on its right side, as in fetal life, before rotation of the intestine. The appendix lay behind the colon and upon the kidney, and could be discovered only after complete evisceration. It was tightly strictured at its proximal third, and contained mucopus. Externally it showed signs of inflammation. The mesenteries were everywhere imperfectly developed, and in some parts were entirely wanting. The last twelve inches of small intestine had no mesentery whatever. Two parts of a loop of the ileum were bound together and held down by organized lymph, and the lumen of the gut was almost completely closed. This inflammatory exudation had been distinctly felt and seen at the time of the operation, but its degree and amount could not then be determined. That the vomiting was never stercoraceous was due to the section of intestine stricture.

Dr. Lincoln was born at Belchertown, Mass., on April 17, 1841. He was graduated at Phillips, Exeter, in 1858, and from Amherst in 1862. After leaving college he was commissioned as second lieutenant in the Thirty-seventh Regiment, Massachusetts Volunteers. He served with distinction throughout the Civil War, being wounded both in the battle of the Wilderness and at Spottsylvania, and eventually rose to be colonel of his regiment. During the latter part of the war he was inspector general on the staff of General Wheaton, of the Sixth Corps, Army of the Potomac, and his last promotion was made for conspicuous gallantry before Petersburg. He studied medicine for one year at the College of Physicians and Surgeons, New York, and for two years at the Harvard Medical School, and was graduated from the latter in 1868. After serving as interne at the Massachusetts General Hospital he took up practice in New York, and devoted himself more particularly to diseases of the throat and nose. One of his earliest successes was an extensive operation by means of the galvanocautery upon the late Gen. Judson Kilpatrick, and as this application of electricity was then comparatively rare, the case at once brought him into prominence. From that time on Dr. Lincoln's career was one of uninterrupted success, and for many years he had one of the largest practices among the best class of patients in New York. It is a remarkable fact in connection with this very successful professional attainment that he wrote comparatively little, and that throughout its course he never held a hospital appointment or a teaching position in any of the colleges. He was very highly esteemed by his medical brethren, and his services as a consultant were frequently called for. In this connection it is interesting to recall that his opinion was asked by the late Sir Morell MacKenzie, with whom he was long on terms of close friendship, in the case of Emperor Frederick, of Germany. Early in his professional life Dr. Lincoln rented the house presented to Gen. George B. McClellan by the city of New York, and he had occupied it for thirty-two years at the time of his death. He was an ex-president of the American Laryngological Society and of the Harvard Medical Society of New York. In 1859 he married a niece of the late Professor Tyler, of Amherst College, who, with one daughter, survives him. His only son, Rufus Tyler Lincoln, died about ten years ago, also of appendicitis, while on a pleasure trip in the far West.

METEOROLOGICAL RECORD

For the week ending November 17th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:

Date.	Barometer.		Thermometer.		Relative humidity.		Direction of wind.		Velocity of wind.		Weth'r.		Rainfall in inches.

Deaths reported 1,983; under five years of age 576; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 461, acute lung diseases 230, consumption 244, diphtheria and croup 96, diarrheal diseases 56, typhoid fever 36, cerebrospinal meningitis 8, scarlet fever 8, measles 5, erysipelas 2. From cerebrospinal meningitis New York 5, Baltimore, Worcester and Holyoke 1 each. From scarlet fever Boston 4, New York, Pittsburg, Cambridge and Somerville 1 each. From

measles New York 3, Pittsburg and Boston 1 each. From erysipelas New York 2.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending November 10th, the death rate was 16.9. Deaths reported 3,755; acute diseases of the respiratory organs (London) 307, diphtheria 88, diarrhea 75, fever 70, measles 50, whooping cough 43, scarlet fever 30.

The death rates ranged from 11.8 in Norwich to 26.0 in Salford; Birmingham 18.0, Bradford 13.4, Cardiff 12.1, Gateshead 20.0, Hull 16.2, Leeds 16.9, Liverpool 20.4, London 17.0, Manchester 22.5, Newcastle-on-Tyne 16.9, Nottingham 16.5, Plymouth 12.2, Sheffield 15.5, Sunderland 21.6, Swansea 13.3.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, NOVEMBER 24, 1900.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 1, 1900.

C. R. BURR, assistant surgeon, ordered to the "Monongahela," December 1st.
 R. K. McCLANAHAN, assistant surgeon, detached from the Navy Yard, Washington, and ordered to the "Indiana," December 1st.
 R. SPEAR, passed assistant surgeon, detached from the Naval Hospital, New York, and ordered to the "Buffalo," December 5th.
 R. B. WILLIAMS, assistant surgeon, ordered to duty at the Naval Hospital, New York, December 5th.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — The regular meeting of the society will be held at the Medical Library, 19 Boylston Place, on Monday, December 10th, at 8.15 p. m.
 Papers: Dr. W. B. Lancaster will present a short paper on the "Radical Treatment of Lachrymal Diseases." Cases will be shown.
 Dr. H. Barton Jacobs, of Baltimore, late secretary of the American National Committee, will read "A Short Account of the Recent International Medical Congress at Paris."
 Drs. J. C. Warren, M. H. Richardson, G. B. Shattuck and the president will speak.
 ARTHUR K. STONE, M.D., Secretary, 657 Boylston Street.
 RÖNTGEN SOCIETY OF THE UNITED STATES. — The first regular meeting will be held in New York City, December 13 and 14, 1900, at the Library, Grand Central Palace, Lexington Ave., Corner 43d St.

BOOKS AND PAMPHLETS RECEIVED.

Injuries of the Eyelids and Eyeballs. By L. Webster Fox, A.M., M.D., Philadelphia, Pa. Reprint.
 Röntgen Rays in the Treatment of Skin Diseases and for the Removal of Hair. By William Allen Pusey, A.M., M.D. Reprint. 1900.
 Transactions of the Association of American Physicians, Fifteenth Session, held at Washington, D. C., May 1, 2 and 3, 1900. Philadelphia. 1900.
 Orthopedic Surgery. A Handbook by Charles Bell Keetley, F.R.C.S., Surgeon to the West London Hospital. London: Smith, Elder & Co. 1900.
 Thomas Sydenham. By Joseph Frank Payne, M.D., Fellow and Harveian Librarian of the Royal College of Physicians. New York: Longmans, Green & Co. 1900.
 Impetigo Contagiosa Bullosa; Its Relation to Pemphigus Neonatorum, with the Bacteriology of Eight Cases. By Martin F. Engman, M.D., St. Louis, Mo. Reprint. 1900.
 Progressive Medicine: A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., assisted by H. R. M. Landis, M.D. Vol. IV. December, 1900. PERICARDITIS WITH EFFUSION.¹

BY GEORGE G. SEARS, M.D., BOSTON.

THE present paper supplements one published in the Boston City Hospital Reports of two years ago, which was based on an analysis of 100 cases of pericarditis, by taking up in more detail certain points in the diagnosis and treatment of pericardial effusion which have been especially studied in cases recently under observation. While a number of conditions may simulate a collection of fluid in the pericardium, practically the chief difficulty in diagnosis lies in its differentiation from marked cardiac enlargement, unless the case has come early under observation, and it has been possible either to watch the gradual accumulation of the fluid, or, rarely, to follow its fluctuations from day to day as illustrated by the following case, in which each relapse of the joint symptoms was accompanied by a demonstrable increase in the amount of pericardial effusion, both subsiding under increased doses of the salicylates.

CASE I. A colored boy, twenty-two years old, was admitted April 11, 1900, with a history of acute rheumatism of a month's duration, but without evidence of cardiac involvement. No murmurs were heard, but the second pulmonic sound was quite sharply accentuated. The following day friction sounds developed over the precordia. The area of cardiac dulness increased, until on the 15th it extended nearly 3 inches to the right and 4 inches to the left of the midsternal line, and above to the top of the second rib. The point of cardiac impact farthest down and to the left, which may for convenience be called the apex beat, though probably made by a portion of the heart above the true apex, was situated in the fourth space, $\frac{1}{2}$ inch inside the nipple line. An area of dulness was present in the lower left back and axilla merging anteriorly into that of the pericardium, over which the respiration was somewhat diminished and slightly bronchial, with increased voice. At the right base there was evidence of a small amount of fluid.

April 23d. The area of precordial dulness has decreased half an inch on the right side, but not on the left, and the apex can be faintly felt in the fifth space. The joints are improving.

April 29th. The apex is plainly felt in the fifth space, and apparently considerable of the pericardial fluid has been absorbed. The patient, however, is beginning to complain once more of his joints.

May 2d. Fluid has again increased and some epigastric fulness is noticeable. The cardiac sounds are more feeble and the apex beat is once more in the fourth space. There is evidence of fluid at the bases of both lungs. The joints are quite painful.

May 3d. An attempt at aspiration was made today in the fourth space, 1 inch to the right of the sternal border. Although the needle moved freely in the pericardial sac and the heart could be plainly felt against its point, no fluid was obtained.

May 10th. The width of the cardiac area has again diminished, and the apex beat has moved back to the fifth space.

May 14th. Another relapse with a rise of tem-

perature and pain and swelling in the hands and wrists. The apex beat has returned to the fourth space.

Later he gradually improved and was discharged against advice with some fluid still remaining in the sac.

Where, however, no opportunity has been given for watching the progress of the case, the extreme difficulty, or perhaps impossibility, of diagnosis is acknowledged by all writers, owing to the ambiguous character of most of the physical signs. The extension of the dulness beyond the apex beat points to the presence of pericardial effusion, although it is far from conclusive unless very marked, since it is found in cases of uncomplicated cardiac enlargement, while the lack of correspondence between the comparative strength of the radial pulse and the decided weakness of the impulse and sounds of a heart whose percussion outlines apparently show a great increase in size is also suggestive of the same condition. In spite, however, of the striking character of this increased area of dulness, its shape is still variously described. To quote but three of the numerous authors who have recently written on the subject, Roberts says that it assumes "a more or less triangular, pyramidal, or more strictly speaking, pyriform or pear-shaped outline with its truncated or 'peaked' apex above." Ewart says it resembles a bag of fluid spreading out at the base, while F. C. Shattuck describes it as simply that of "the normal heart equally extended in all directions. Therefore, of course, it is also that of a symmetrically enlarged heart, though the latter can seldom, if ever, produce so large a dull area." Both the latter have apparently given up the idea that it is ever pear shaped, while Shattuck denies the pyramidal form. This may be only a question of definition, or it may be due, as he suggests, to the method of percussion adopted, which must give a different outline according as the outer border of the pericardium or the inner limits of the lungs are sought. My experience would confirm in most details the claims of the last two, but it is more in accord with Ewart than with Shattuck. I have never been able to mark out by percussion a pear-shaped outline, perhaps, because, like Dr. Shattuck, I have always attempted, from greater confidence in the results, to define the outer border of the heart and not the limits of so-called cardiac flatness; nor have I ever obtained any outline which suggested the superposition of a smaller on a larger sphere as was found by Sibson on artificially distending the sac with a moderate amount of fluid, either by percussion or with the skiagraph, but my experience with the latter has been limited to few cases, since most of the patients have been too ill to allow their removal from the ward to the x-ray room. The outlines of these photographs lacked clearness of definition, but nevertheless were very similar to those obtained by percussion and showed a general broadening of the area of precordial dulness, especially at its lower portion, the line on the left being nearly parallel to that which is found with a normal heart, while that on the right of the sternum either flared outward toward the nipple, giving a shape which at times was so symmetrical as to fully justify its comparison to a bag of fluid, or ran parallel to the sternal border as if a part of the right side of the bag had been shaved off vertically. It has seemed to me, as Ewart and others have stated, that in connection with the increased area of cardiac dulness the most important single sign of pericardial effusion in distinction

¹ Read before the Clinical Section of the Suffolk District Medical Society, November 21, 1900.

from cardiac enlargement is the angle made by the line bounding the right side of the precordial dulness with that which marks the upper limit of hepatic flatness. In my experience, no matter how large the heart, its percussion border is always a curved line whose lower end tends to approach the sternum so that the angle made by the outlines of the enlarged heart and the liver on the chest wall is an acute one, or at least never exceeds 90°. In fact, when the cardiohepatic angle is equal to a right one the chances are in favor of pericardial effusion.

Secondary signs resulting from pressure or displacement can only be considered as corroborative evidences. The quadrilateral area of dulness in the lower left back described by Ewart was present in a number of cases, but it may also be found where there is very marked cardiac enlargement. More often it has formed a part of a larger area extending into the axilla and to the front, so that the whole lower portion of the chest has been dull with diminished and somewhat bronchial respiration, or else the presence of secondary or coincident pleural effusions has robbed the sign of its significance.

The pulsus paradoxus, which occurs in pericardial effusions as in several other conditions, was found with considerable frequency, but not always when the quantity of fluid was large, as has been stated; in a few cases it has been well marked where the amount of exudate seemed comparatively small.

An accentuation of the pulmonic second sound has been described by Warthin as the earliest sign of pericarditis and in my cases it has occurred sufficiently often to arouse one's suspicions that such a complication is developing when it is otherwise unexplained and persistent in diseases liable to cardiac accidents. Its presence has allowed me on one or two occasions to make what was a lucky, but correct, guess as to the course of future events.

In the early stages a sedative to quiet the heart and in the later a stimulant were the only medicinal measures used. No attempt to control the effusion was made, but an ice bag or a poultice was applied, if they comforted the patient or reduced the pulse rate. Blisters were never used, as their value seems doubtful and they interfere with the examination of the chest, but tincture of iodine was applied if the patient demanded treatment. The chief interest from the therapeutic standpoint lay in the decision as to when and where to aspirate. The history of my own attempts is largely a record of failure, but no harm has ever resulted and the marked relief to the patient which sometimes follows the withdrawal of a few ounces of fluid fully justifies the procedure. While in pleurisy one expects to get fluid on the introduction of the needle, experience shows that a dry tap is by no means infrequent in pericardial effusion. It was so in Dr. Shattuck's published cases, and it has been even more so in mine. In some instances, even where there was no question that a very considerable amount existed, and where the needle moved freely in all directions after its introduction and could be pushed up against the heart itself, no fluid, or at most a drachm or two, could be drawn through the needle by the aspirator. This has been explained as resulting from the presence of flocculi in the exudate or from its trabeculated or loculated nature. The site selected for puncture undoubtedly has an important bearing on the success of aspiration, but it is ques-

tionable if one position *per se* can be selected as better than another, so much depends on the position of the heart in its relation to the pericardial walls, which is not always constant. The close proximity of a friction rub even in the presence of a considerable amount of fluid has several times prevented me from using the fifth left space, the most frequently recommended, from fear of wounding the heart, and with one exception I have found it inexpedient to adopt the route suggested by Dr. Shattuck, to the left of the apex beat, since the outer limit of the pericardium has been impossible to determine, owing either to the presence of pleural fluid or to the dulness caused by compression or retraction of the left lung. Rotch, some years ago, after some experiments on the cadaver, pointed out the advantages of the fifth right space and recently Damsch has recommended either the fifth or sixth right space near the sternum, since he found in a series of similar experiments that the fluid collected in the lower right-hand portions of the pericardium. Although the fourth and fifth right spaces have been the ones more often selected in my cases, as the danger of wounding the heart seems smallest there, the proportion of productive taps has not been particularly encouraging.

The following cases, with the one reported at the beginning of this paper, comprise my whole experience in paracentesis of the pericardium. Cases IV and V have already been reported elsewhere and are given only in outline.

CASE II. H. R., colored, male, twenty-three years old, entered the Massachusetts Hospital, during my term as house physician, in the service of Dr. W. L. Richardson, to whom I am indebted for the privilege of reporting it, October 11, 1884, suffering from tuberculosis of the lungs and bowels. His chief complaint was of pain near the ensiform cartilage on drawing a long breath. Fluid gradually collected in the pericardium until almost the entire front of the chest, from the second rib downward, was dull on percussion. The abdomen became distended, particularly over its upper portion, which was dull on percussion and gave an indistinct sense of fluctuation. This local distention of the abdomen became so marked a feature of the case that on October 24th a needle was thrust into the right side of the epigastrium, well below the costal border, and 1½ ounces of bloody fluid, slightly tinged with yellow and containing numerous red cells and leucocytes, was obtained. Four days later an attempt at aspiration was made through the upper belly of the right rectus muscle not far from the spot previously selected, but without result. On the left side, however, 3 or 4 ounces of bloody fluid were drawn off. He failed gradually and died November 2d. At the autopsy, which is reported from memory, as the records have unfortunately disappeared, almost the whole front of the chest was occupied by the distended pericardium, which had displaced the diaphragm and with it the liver and other abdominal organs, and was the cause of the tumor noticed in the epigastrium and upper abdomen. Over 2 quarts of bloody fluid were contained in the sac.

CASE III. M. N., male, twenty-four years old, admitted to the City Hospital, December 22, 1896, with acute rheumatism and a well-marked pericardial friction rub. The second sound at the base was very loud. Fluid gradually collected in the pericardium and also in both pleural cavities, so that on January

3d the precordial distress and dyspnea were very marked. An aspirating needle was introduced in the fourth space, a little to the left of the left edge of sternum. It moved freely in all directions, and the heart could be felt beating against it, but no fluid was obtained. Twenty-four ounces of serum were drawn from the right chest with relief. He slowly improved and was discharged "relieved" March 23d.

CASE IV. S. B., male, twenty-three years old, admitted June 19, 1897, with acute rheumatism. He later developed a pneumonia of the left lower lobe and a pleurisy with a small effusion in the right base. Fluid also gradually collected in the pericardial sac. The pulse varied between 110 and 120, and the respirations between 40 and 56. A needle introduced in the fourth right interspace, 1 inch from the sternal border, drew off 10 ounces of bloody fluid containing pneumococci. Improvement slowly followed, and he was discharged September 14th.

CASE V. J. D., male, twenty-five years old, was admitted August 3, 1898, with mediastinal and pulmonary sarcoma. Fluid was present in both pleural cavities and in the pericardium. The following day 16 ounces of bloody serum were withdrawn from the left back, with marked improvement in the physical signs above the angle of the scapula. On the 5th an attempt was made to relieve the pericardium by inserting a needle in the sixth left space a little outside the mamillary line. Thirty-eight ounces of bloody fluid flowed out in vigorous jets synchronous with the heart, while a distinct pulsating movement was imparted to the needle itself. So much relief followed that at the request of the patient a further attempt was made on the following day in the fifth left space just outside the nipple line, but nothing was obtained. The sixth space was then tried in the same position as before, but the result was negative. At the autopsy, which occurred less than two weeks later, the left pleura, from which fluid had been withdrawn, was completely obliterated, and so was the pericardial sac with the exception of a few small pockets.

CASE VI. T. M., male, thirty-eight years old. Markedly alcoholic. Admitted November 20, 1899, with a history of rheumatism of three weeks' duration. He was slightly delirious, and little reliance could be placed on his statements. The area of cardiac dulness was somewhat increased. The apex was in the fifth space, $\frac{1}{2}$ inch outside the nipple line. A soft systolic murmur was heard both at the apex and over the aortic area. The second pulmonic sound was accentuated. On the 24th his delirium increased, and on the 28th he grew very hoarse. On December 2d a little consolidation was noted at the base of the right lung. The heart sounds had become distant and feeble and the area of cardiac dulness extended to within an inch of the nipple line on the right, and on the left to just outside that line. A friction rub had been present for one day over the fourth left cartilage. Two days later the cardiac area extended on the right almost to the nipple, and on the left $1\frac{1}{2}$ inches outside it. His respirations and pulse were rising and he was evidently losing ground. A needle introduced in the fifth right space obtained 3 drachms of flocculent fluid. Further attempts at aspiration were made on succeeding days by introducing the needle in the fifth left space, $1\frac{1}{2}$ inches outside the nipple and twice again in the

fourth space. Although the tip of the needle in each instance moved freely as though in a cavity, the results were negative. He gradually failed, and death occurred on the 15th, to which his alcoholic excesses largely contributed.

To summarize these attempts: The fourth right space was used four times with one successful result; the fourth left space once, without result; the fifth left space, outside the apex, was no more successful on the one occasion it was used, but from the fifth right space 3 drachms of fluid were obtained. From the sixth left space just outside the nipple line, the largest amount, 38 ounces, was withdrawn, but owing to the equivocal nature of the physical signs it cannot be said with absolute certainty that it did not come from the pleura. The autopsy failed to throw light on this point. The fact that the fluid was twice obtained in one case below the margin of the ribs is a medical curiosity, and instructive as showing the amount of displacement which occurs with large effusions.

CASES OF ACUTE ORAL INFLAMMATION.

BY JOHN C. MUNRO, M.D., BOSTON.

A SEARCH of the records of the Boston City Hospital of cases of stomatitis, glossitis and Ludwig's angina, severe enough to be treated in the surgical wards, has been made in the attempt to secure a clinical picture of these distressing and serious diseases. No account has been made of the lighter forms treated in the out-patient departments. Too few cases have appeared in recent years to give data as to the bacteriology of these affections. In the few cases examined the streptococci and staphylococci were the predominating agents.

Ulcerative stomatitis.—Of 29 cases, 6 were of the gangrenous type, but the distinction between the ulcerative and the gangrenous case is often difficult, the former so easily advances to the latter, and undoubtedly some of the ulcerative cases were rapidly becoming gangrenous until checked by good care and treatment. The lighter cases exhibited more or less superficial ulcerations of the gums, cheeks, tongue or pharynx, singly or collectively, and probably diphtheria was the true condition in some of the earlier cases. In many there appeared to be no recognizable cause, while others started presumably from carious teeth, a glossitis or from burns of liquids. One case of recovery showed ulceration of the entire oral cavity; another had a deep, foul, indurated slough of the cheek that was prevented from perforating by treatment with poultices, washes, etc.; still another had severe swelling of the palate that required incision, but without showing the presence of pus.

In the recovery cases, main reliance was placed upon washes containing myrrh, chlorate of potash, permanganate of potash or hydrogen peroxide, in addition to vigorous supporting and stimulating diet. One child four years old, where the noma perforated the cheek, recovered under this treatment. The process never advanced rapidly enough to warrant surgical interference.

One fatal case is interesting in that the process originated in a tubercular glossitis that could not be

Contributed to the Boston City Hospital Reports, Eleventh Series.

recognized until after death. Swelling of the tongue, cheek and neck started two weeks before entrance to the hospital; soon the tongue ulcerated and gave rise to occasional hemorrhages and at entrance the mouth was filled with the swollen tongue, sloughs and blood clots. The local condition improved under treatment, but the general condition grew steadily worse. Autopsy showed tuberculosis of the tongue and epididymis, and a severe stomatitis much like that seen in mercurial poisoning. One male, thirty years old, with a gangrenous ulcer of the inside of the cheek, but not perforating, died a few days after entrance, apparently from general sepsis.

Four cases designated as noma died, 2 being young children, and 2 men fifty years old. Pneumonia and measles preceded the noma in each child respectively. There was the typical gangrenous ulcer of the buccal surface advancing to perforation, autopsy showing also a necrosis of the upper jaw and an acute bronchopneumonia in the case that lived two weeks; sepsis and a pneumonia probably killed the other child at the end of four weeks before the cheek had become perforated. One of the adults entered in collapse with a gangrene of the cheek extending from the mouth to the ear. In the other case the disease started as an alveolar abscess followed by a series of abscesses, retraction of the gums and loosening of the teeth. Sloughing of the cheek and necrosis of the lower jaw followed, with death at the end of a week.

Acute glossitis.—These cases are interesting from the lack of ascribable cause in many instances, from the rapid onset of swelling and the equally rapid subsidence under treatment. Of 28 cases all but 5 were in males of about thirty years of age. A sore throat, a blister, a rough tooth or a bite was given as the exciting cause in some, but more frequently no cause could be found. In several the swelling attained its maximum within a day or even within an hour, but in the majority it took four or five days. In half the cases the swelling affected the entire tongue, while in the remainder it was confined to one side or to the base. The swelling was great enough in most instances to almost completely fill the oral cavity. Pus was rarely noted, and where the organ was incised relief followed as well from evacuation of blood as from pus. In 11 cases in which the tongue was opened, either spontaneously or with the knife, there was alarming dyspnea, while the cases treated with washes and poultices to the neck were for the most part not urgent and rapidly yielded to the milder form of treatment, a patient rarely being detained in the hospital longer than five days. Two patients died, one from uremia and cystic kidneys, and the other probably from acute sepsis. The latter, a woman of thirty, entered delirious, in high fever, and with a phlegmon of the tongue and floor of the mouth. Operation was done at once on account of dyspnea, but the patient died in a few hours. One markedly alcoholic patient had three attacks at intervals of a month, with two operations.

The history of the cases throughout impresses one with the fact that the phlegmonous type is much severer than the abscess type. In some it is difficult to distinguish between a true glossitis and a Ludwig's angina, and indeed the two conditions may coexist, or the disease may start as a cellulitis of the floor of the mouth and extend to the tongue.

Ludwig's angina.—Only 9 cases were indexed, 1

being fatal. Eight were in adult males, and 1 in a girl of fourteen. One case opened spontaneously into the mouth; all of the remainder were operated upon, some within the mouth, but the majority beneath the chin. The origin of these cases is obscure, carious teeth being the favorite cause ascribed by the patients. The clinical picture is very characteristic in all; a brawny fulness beneath the chin, an elevation of the floor of the mouth to the level of the edge of the teeth, with a pushing upwards and backwards of the tongue, and in some a cellulitis extending in various directions as far as the shoulder or the chest. The single fatal case obtained temporary relief from dyspnea by free incisions into the sublingual space, but within a few hours a tracheotomy was necessitated; dyspnea, however, returned, and the patient died two days later, probably from a septic pneumonia.

The impression that one obtains from studying these records is that the diseases are severe and that the treatment required must be vigorous. Where, as in glossitis and angina, the cases are not severe enough to demand immediate operation for the evacuation of pus or (of equal importance) of blood for relief of obstruction to respiration, the medical procedures must in their way be equally energetic. Catharsis, abundant food, rest, cleansing and antiseptic washes and large hot poultices to the neck and face will often abort a case that threatens to become serious within a few hours. When, however, there is doubt, or when delay seems dangerous, a free incision into the swollen tongue or the mouth floor is best, whether pus is present or not. The cases of stomatitis can probably be benefited if the gangrenous sloughs are removed with the curette or the cauterizer.

The incision in glossitis, unless there is a well-defined collection of pus—which is not to be expected—is best made into the dorsum on each side of the median line. In the angina cases the incision is best made, in most instances, in the median line below the chin, whence each lateral space can be easily explored with the finger or a blunt instrument until the small focus of pus, if present, is found.

The distress and suffering of these cases is frequently intense; the drooling, the inability to swallow or talk, often the dyspnea and cyanosis, in addition to the acute general infection, make the condition a grave one, but, fortunately, under good treatment, of brief duration and without sequelae for the most part.

THE RESULTS OF OPERATIONS ON VARICOSE VEINS.¹

BY J. B. BLAKE, M.D., BOSTON.

THE treatment of varicose veins has always been unsatisfactory. Non-operative treatment is palliative, but in recent years a cure has been attempted by operation. This consists either in (1) ligation of the veins in several places, with or without the removal of small sections; or (2) excision of a considerable portion of the vessel in continuity. Accurate statistics are necessary to determine the success of operative treatment. Cases must be traced and reported after the patients have returned to their customary occupations and habits of life; after the conditions which produced or

¹ Contributed to the Boston City Hospital Reports, Eleventh Series.

favored the original varices have again been established.

Statistics of this character are not numerous, and are not easily obtained. Hospital cases are proverbially difficult to trace, and this class of patients is no exception to the rule. Furthermore, it is essential before attempting to classify results, to determine what constitutes a "cure" or a completely successful operation. A simple standard, and one which seems reasonable, is, that if the patient can follow his customary occupation, and considers himself well, the surgeon may consider him cured. And the reverse of this (if the patient's statements can be believed) should equally be held true.

Finally, the element of time and the age of the patient present additional complications, and render a positive standard still more difficult to obtain. An interval of six months after operation is the minimum time limit, and it is probable that this should be extended to a year.

Statistics conforming to the above requirements have been obtained in 11 cases, all but 2 of which were operated at the Boston City Hospital. Of these, 7 were cured, 3 were relieved temporarily or partially, and 1 was worse than before. Some of these patients were examined personally, others replied in writing, and, in 1 or 2 cases, members of the immediate family furnished the information.

It is obvious that no sweeping deductions can be drawn from so small a number of cases, but an examination of them shows certain instructive and interesting facts. Briefly stated, these are as follows:

The single case in which the condition was described as "worse than before operation" seems to represent a type in which operation of excision will probably be followed by little or no improvement. It is therefore described in some detail.

The man was sixty-three years of age, born in Ireland, and was a street laborer. He had extensive varicose veins for forty years, and had been operated upon four times, once on the right, and three times on the left leg.

Seventeen years ago, the veins in the right leg were ligated subcutaneously with silver wire, at points 5 inches above, and 5 inches below the knee. He has had complete relief from painful or distressing symptoms since then. The veins are still visible, and are large and tortuous, from ankle to saphenous opening, and over the entire inside of the thigh, but the man stated definitely that they do not cause him any trouble.

The left leg was subjected to a similar operation, in London, twenty-five years ago; it was followed by relief of symptoms for about ten years. Pain and distress then began to return, and in 1893 a second operation was done in Boston. This consisted of a dissection and the removal of about 10 inches of the left internal saphenous vein. After leaving the hospital he was free from pain for six months, and then the symptoms recurred. In 1895 a third operation was performed—also in Boston. The man said that, owing to his previous experience, he requested that this last operation should be by "tying, and not cutting." The surgeon, however, made a dissection of about 5 inches, and the man insists that he has had pain ever since, and worse than before. Examination shows two wide scars, corresponding to the operations described above, but no veins above the knee. Below, the veins are distended, but not as much as on the

right side. The leg swells, however, and the pain makes him lame.

This case is an excellent illustration of the fact that size or extent of varicose veins, whether in the scrotum, at the anus, or on the extremities, bears no necessary relation to the discomfort or disability of the patient. A large mass of veins may be free from distressing symptoms, and a small varicosity may at times cause a patient to seek hospital treatment.

Three cases are classed as "partially or temporarily cured." In 1 of these the unpleasant symptoms have entirely disappeared, but an ulcer, which closed after the operation, has broken out again, though its area is smaller than formerly.

A second man has returned to work, though he writes that his "leg still pains him and some of his cords bother him."

The third case was relieved for one year. This patient is a cook and is on her feet all day before a fire. At the end of the year the veins above and below the incision began to swell. Pain commences soon after she begins to work, and increases during the day. She is, however, able to continue her occupation.

Seven cases are considered cured. In 1 of these the internal saphenous vein had previously been ligated, but without relief. It is to be noted, however, that some of these cases have been operated less than a year, and as it sometimes happens that relapse follows a year of relief, it is obvious that these cases have not yet passed the final stage. These cases represent various degrees of severity, with the exception of extreme varicosity, complicated by advanced age. The ages in this group vary from twenty-five to fifty years, and the occupation included engineers, stablemen, cooks, clerks, etc. In all cases the scars are firm, not tender and not painful. In 4 the operation was performed at least three years ago.

In conclusion, it may be said:

(1) Operation for radical cure of varicose veins by dissection is not successful in every case.

(2) To obtain successful results, cases must be selected and certain conditions avoided, and recommended to palliative treatment.

(3) The conditions which will probably militate fatally against satisfactory results are: (a) Old age, or an extremely debilitated condition; (b) excessive and very extensive varicosity; (c) occupations which to an extraordinary degree favor the development of varicose veins.

(4) Cases which may be cured by a thorough and careful operation are: (a) Local varix, even of marked prominence, particularly if thrombosis has occurred, either in thigh or lower leg; (b) extensive varix, limited to a single venous stem; (c) varicosities, which are a bar to passing civil service, military or naval examination; (d) cases in youth and middle life; (e) cases in which the development of the permanent varicosity was at least partially due to more or less removable conditions (flat foot, garters, etc.).

(5) Operation, even if not entirely successful, will usually relieve such complications as thrombosis, hemorrhage and ulceration.

(6) The usual conditions which follow unsuccessful operations are: (a) Pain in and around the scar; (b) general swelling and tenderness of the leg; (c) development of varicosities above or below the operation scar, but not at the site of the operation itself.

(7) In all operated cases, general systemic treatment as well as local treatment should be prescribed, together with exercise and the avoidance of a continued upright position whenever possible.

(8) Cure of symptoms does not necessarily mean the removal of all visible varicosities.

(9) Comparison of relative methods of multiple ligation and continuous dissection must be based upon a larger number of cases than are here recorded.

(10) Bennett's conclusions² and his extreme limitation of the indication for successful operation are too sweeping.

A CONTRIBUTION TO THE THERAPEUTIC ACTION OF HEROIN.

BY BERNARD LAZARUS, M.D., NEW YORK,
Assistant Surgeon, Bellevue Hospital; Physician to Demilt Dispensary, New York, N. Y.

In the treatment of patients suffering with diseases of the respiratory organs the indication frequently arises for a remedy which will allay the irritation of the affected mucous membranes and relieve the harassing cough. For this purpose opium and its alkaloids have been hitherto the chief reliance of the physician. This was from necessity and not from choice, for morphine presents many objectionable features in this class of cases. The relief of cough is often obtained at the expense of gastric disturbance, constipation, and a feeling of general lassitude, while the drug is apt to arrest the bronchial secretions and render expectoration more difficult. For these reasons, when my attention was drawn to heroin by the very extensive studies of Dr. Manges, of New York, I decided at once to give the preparation a trial, with the view of determining its relative advantages as compared with the opium alkaloids. My connection with the Bellevue Hospital Outdoor Department and the Demilt Dispensary afforded me an excellent opportunity for making such experiments.

Professor Dreser, who was the first to make careful investigations of heroin on animals, demonstrated that it produced a diminution in the number of respirations, with an augmentation of the volume of inspired air and an increase in the force of expiration. The same phenomena have been observed in human beings by a large number of observers. It has been found that while heroin acts as a sedative in conditions of irritation, its action upon the respiratory centres is that of a stimulant. Moreover, it is free from any depressing action upon the heart or circulation, a fact which I have always noticed in my own experience, thus permitting the use of heroin even in cases in which cardiac lesions exist. The observation that heroin has a regulating influence upon the breathing also caused it to be employed in conditions of dyspnea, to which attention has been directed by Professor Leo.

Its analgesic properties have also been utilized in the treatment of neuralgias by Professor Enlenburg; of painful uterine affections by Dr. Mirtl, of Vienna; and in diseases of the stomach attended with pain by Dr. Einhorn, of New York.¹ Recently a very thorough investigation of its analgesic and hypnotic qualities has been made in the Howard Hospital, of Philadelphia, by Drs. S. H. Brown and E. D. Tompkins,²

who upon the ground of their experiments pronounce it a very safe and reliable analgesic. Professor Enlenburg further suggested its use in the treatment of morphine habitués, a suggestion which has been adopted with excellent results.

As heroin is insoluble in water, it is of advantage to employ it in the form of the hydrochloride, which may be readily dissolved, and is therefore adapted for hypodermatic use. My experiments have been conducted exclusively with this preparation, which is identical in effect with heroin, both as regards physiological action and dosage. Below I have subjoined a few cases among the large number treated, with a view of illustrating the action of the drug in various diseases of the air passages, as well as in other conditions:

CASE I. J. B., age twenty-two, employed in a cigar factory, complained of a feeling of thoracic discomfort, resembling constriction within the chest. At times he became nervous, anxious and restless, and this was generally followed by a spasmodic attack. Examination revealed long drawn out inspiration and prolonged expiration, the patient stating that he felt as if the air were unable to enter the lung fast enough to prevent constriction. There was present extreme dyspnea and whistling breathing. On expiration the abdominal muscles contracted, assuming a board-like firmness and hardness. During these attacks the patient found it necessary to fix his shoulders by grasping the back of a chair in order to bring the supplementary muscles of respiration into action, although little relief would be obtained. During one of these attacks I discovered a subnormal temperature. On both inspiration and expiration distinct sibilant and sonorous râles could be heard all over the chest, being audible even at a distance.

The patient was instructed to change his employment, and I placed him on heroin hydrochloride, $\frac{1}{2}$ grain every four hours, and at bedtime, with cascara sagrada, $\frac{1}{2}$ drachm, as he complained of constipation. The attacks, which were quite frequent and usually lasted for a half hour, diminished both in severity and duration after the first week's treatment. Since three weeks the patient has never suffered a night attack (which was quite frequent), but as the disease is of hereditary origin, a permanent cure cannot be expected, although no attack has occurred in twenty-three days.

CASE II. W. K., age nineteen, employed in a hide and leather house, had been able to speak only in a husky whisper for seventeen days. He was troubled with hoarse and stridulous cough with abundant mucopurulent expectoration, frequently streaked with blood and of a very offensive odor. Respiration was accompanied by a whistling sound, and swallowing of solid food often excited spasms of the glottis; talking caused fatigue. Severe paroxysms of coughing and straining were experienced in the morning, due to the accumulation of secretion at night, which was thrown off with considerable difficulty. At first I put him on astringents and general expectorants, but with very little relief of the cough, straining and dyspnea, until I placed him on heroin hydrochloride, $\frac{1}{2}$ grain three times daily, and $\frac{1}{8}$ grain before going to bed. After two doses the cough and dyspnea were considerably relieved, but not until the following night did the patient enjoy a perfect and undisturbed rest, the want of sleep having been the cause of his

¹ Philadelphia Medical Journal.

² Therapeutic Gazette, August 15, 1900.

³ Lancet, October 15, 1898.

utter exhaustion. I continued the treatment in doses of $\frac{1}{2}$ grain, four times daily, for a period of nine days, which effected an entire disappearance of cough, pain, dyspnea and sleeplessness.

CASE III. Miss M. L., age twenty-four, shop girl, applied for treatment, suffering with severe pains behind the sternum, difficult breathing and severe cough, which had been present for some time. Examination revealed frequent and obstructive breathing, so that she was unable to lie down, but generally had to sit inclined forward; shallow respirations reaching 38 to 40 per minute; the inferior part of the chest and the epigastrium were drawn in with each inspiration, while the upper part of the chest was immovable. Her speech was short and jerky. The alae nasi were dilated; the face congested, cyanosed and swollen; and the jugular veins distended. The most prominent and troublesome symptom of all was the harassing cough, accompanied by severe pains, and as the patient was also quite anemic, the cough and dyspnea rendered her at times utterly exhausted. I therefore put her on an appropriate remedy to counteract the anemia; but to overcome the severe pain, cough and dyspnea, which was of paramount importance, nothing gave as much satisfaction and such prompt relief as heroin hydrochloride, $\frac{1}{2}$ grain hypodermatically, and followed by $\frac{1}{6}$ grain every four hours for the first twelve hours. The remedy was then continued in $\frac{1}{2}$ -grain doses every four hours, internally, for the next twenty-four hours; and as I was going out of town for a week I instructed her to continue it in $\frac{1}{4}$ -grain doses every four hours. On my return I found that the pain had entirely disappeared, the harassing cough had become much less troublesome and was gradually subsiding, and the cyanotic lividness of the lips and face had vanished. Under the hypodermic injection of $\frac{1}{2}$ grain daily for four days the inferior part of the chest and epigastrium became elevated instead of being drawn in during inspiration, while the upper part became normally movable. Speech was easy, and sleep was undisturbed. There was no increase nor decrease of weight the first five days, but at the end of the second week the weight had increased 7 pounds. I am now convinced that the treatment with heroin hydrochloride not only relieved the symptoms but entirely cured the patient, the anemia being combated by the usual tonics.

CASE IV. E. M., age thirty-one, applied for treatment of an intercostal neuralgia, which has caused her the most agonizing suffering. The pain was intermittent, of a tearing character, and was increased by coughing or sneezing. Her sufferings dated back three months. To overcome the pain I put her on heroin hydrochloride, $\frac{1}{4}$ grain, every two hours for ten hours until relieved, and then $\frac{1}{2}$ grain four times a day. She had no severe exacerbations. The administration of $\frac{1}{2}$ grain was continued for five days, and at the end of that time she was told to take a dose of $\frac{1}{6}$ grain only when she felt indications of a return of a paroxysm of pain. As no attack occurred, she was discharged cured in two weeks of an illness of fully three months' standing. One point which was greatly appreciated by the patient was that she did not suffer pains of any account from the time she first came to my office.

CASE V. J. C., age thirty-two, suffered with advanced pulmonary disease with laryngeal involvement.

The patient was quite emaciated and weak, suffering severely from coughing usually at night, with scarcely any relief from the usual applications and inhalations. He had not obtained a comfortable night's rest for months, until I tried heroin hydrochloride in $\frac{1}{2}$ -grain doses every three hours. The administration was begun at 10 A. M., and continued until 9 P. M., at which time the cough had been greatly relieved, and a refreshing sleep secured for the first time in quite a while. Being much interested in the patient, I noted on my second visit the following day the appearance of comfort and relief instead of the usual expression of suffering.

In 7 other cases of advanced phthisis which have come under my observation, heroin hydrochloride administered in $\frac{1}{4}$ -grain dose at 8, 10 and 12 A. M., and $\frac{1}{2}$ grain at 3, 6 and 9 P. M., controlled the cough sufficiently to permit of rest and comfort at night. Under its administration in pulmonary tuberculosis great relief is obtained so far as cough, dyspnea and sleep is concerned, although it acts only as a palliative in such cases.

CASE VI. F. A., age ten; acute coryza and nasal catarrh, attended with severe sneezing and lachrymation. In this case I prescribed the following, from which the patient obtained wonderful relief, namely:

Heroin hydrochloride	$\frac{1}{4}$ gr.
Caffeine citrate	3 gr.
M. ft. pulv. No. 6.	

The patient took one powder, followed within an hour by another and experienced considerable amelioration, but not until he had taken four was complete relief afforded.

CASE VII. B. G., age twenty-nine. Physical examination showed a cavity in the middle lobe of the right lung and the upper lobe of the left lung. The patient was put on heroin hydrochloride, $\frac{1}{4}$ grain every two hours during the forenoon, and $\frac{1}{2}$ grain every three hours during the afternoon. Within three days the cough diminished to a considerable extent, and the pain disappeared. I continued the remedy in doses of $\frac{1}{2}$ grain every four hours, and $\frac{1}{6}$ grain at bedtime.

CASE VIII. G. S., age forty, complained of hard, dry, persistent and troublesome cough, especially at evenings. There was very little expectoration, the removal of which caused considerable pain and dyspnea. Heroin hydrochloride, $\frac{1}{2}$ grain, every three hours for two days eased the cough; the pain and dyspnea vanished, and the expectoration became easy and free.

CASE IX. D. S., age twenty-two, complained of severe cough and pain, usually coming on at night and lasting until morning. Heroin hydrochloride, $\frac{1}{2}$ grain every four hours in afternoon, and $\frac{1}{6}$ grain at bedtime relieved the patient, and after a week's treatment the entire symptoms disappeared.

My clinical material, from which the above cases have been selected, consists of 38 cases treated in the hospital and 14 in private practice, and comprises pulmonary tuberculosis, bronchitis, asthma, pneumonia, laryngitis, coryza, rhinitis and intercostal neuralgia. Under the administration of heroin hydrochloride the relief of pain, cough and dyspnea was obtained in from one to five days. Among the 52 cases heroin hydrochloride caused nausea and giddiness in only 2 after the administration of $\frac{1}{6}$ grain; but this disappeared promptly after the dose was reduced to $\frac{1}{2}$

grain. In 1 case it produced gastric disturbance similar to morphine when given on an empty stomach, but this was not observed when it was administered after meals. In 3 cases it caused constipation, which was relieved by the addition of $\frac{1}{2}$ grain of calomel to each dose. It will be noted in the above cases that the after-effects observed in a few instances appear only after large doses of $\frac{1}{2}$ grain, and promptly vanished after the dose was reduced to $\frac{1}{12}$ grain.

The very thorough investigations which I have made with heroin hydrochloride in my practice enable me impartially to state that I consider this drug a most valuable aid to the medical profession. Its range of application, while originally confined to the treatment of respiratory affections, has been much extended by later observations. In pulmonary affections accompanied with coughs, I would rank it as a specific, while its analgesic qualities in neuralgia and its antispasmodic effect in asthma and whooping cough have been so well established as to entitle it to a prominent place in the treatment of these affections.

Medical Progress.

REPORT ON PROGRESS IN MENTAL DISEASES.

BY HENRY R. STEDMAN, M.D., BOSTON.

(Concluded from No. 23, p. 582.)

THE INFLUENCE OF MATERNAL INEBRIETY ON THE OFFSPRING.

SULLIVAN¹ states that maternal inebriety is a condition peculiarly unfavorable to the vitality and to the normal development of the offspring. Its gravity in this respect is considerably greater than that of paternal alcoholism. While its influence, particularly as measured by the test of infant mortality, appears to be exercised in a considerable degree indirectly through deterioration of the *milieu*, a large part also depends on the primary action of the poison. The reality of this latter mode of influence is evidenced by the tendency to stillbirths and abortions, by the high rate of epilepsy in the surviving children, by the prevalent mode of death, by the effects of modifications of the intoxication. This primary influence of alcohol is due in part to the permanent effects of the poison on the maternal organism, inducing a transmissible degenerate condition; in part to a direct toxic action on the embryo, owing to continued excesses during pregnancy and lactation. The first of these modes of primary influence is, by its nature, permanent, with a tendency to increase. The second mode, while tending also to a constant and constantly increasing operation, is susceptible of temporary augmentation or diminution.

Under these combined modes of influence the normal tendency of the family with alcoholic maternity is towards a type the inverse of the syphilitic family; that is to say, the firstborn children are normal, then come more or less defective children who live beyond infancy, then children dying in infancy, then stillbirths, and, finally, abortions.

Deviations from this type are probably due in many cases to oscillations in the intensity of the second

mode of influence. Deviations originating in this fashion may be seen, for instance, in the death in infancy of the earliest born children of the family as a result of conception in drunkenness, and in the survival of late born children when the mother has been imprisoned during part of the pregnancy.

It is hardly necessary to point out in conclusion the evidence which these observations furnish as to the social gravity of female inebriety, and the social profit in its removal. In suppressing the female drunkard the community not only eliminates an element always individually useless and constantly liable to become individually noxious; it also prevents the procreation of children under the conditions most apt to render them subsequently, if they survive, a burden or a danger to society.

THE INSANE JEW.

Beadles² has studied something over 1,000 cases of insanity in the Jewish race, and notes, first of all, the abnormally great predominance of general paralysis among the men, 21% of all male Jewish admissions being cases of this disease, in contrast to 13% of the general yearly average. The mental strain resulting from excessive zeal in acquiring riches, with the consequent worry and annoyance, he considers plays no small part in the mental breakdown of these people. It is difficult to determine the exact amount of insanity among the Jews, but apparently it is not very much greater than the average. The average age at which Jews become insane is distinctly earlier than the age of non-Jews. At Colney Hatch the relapsed cases form 14% of the admissions, which is twice the amount formed by the entire admissions to the London County asylums. This high figure is due in part to the greater frequency of relapses and the greater number of Jewish patients discharged as only relieved; the recovery rate appears better than among non-Jewish patients, and the death rate is lower. This is due mostly to the small number of deaths among women, owing to the large proportion of puerperal insanity, over 15% of all the Jewish women admitted being puerperal cases. In non-Jewish admissions the percentage of puerperal cases is a trifle over 6. The explanation of this large proportion of puerperal cases he attributes to the neurotic temperament of Jewish women, the early age at which marriage takes place, and impaired nutrition from unhealthy occupations and surroundings. Notwithstanding the seemingly good recovery rate, he does not look upon the prospects of complete mental recovery as particularly hopeful, very many Jewish patients being discharged to their friends when they are only relieved.

SUICIDE IN GENERAL PARALYSIS.

Monestier³ comes to the following conclusions: Suicide is quite common in general paralysis, both in the course of the disease and in its initial period. There are, however, a number of cases where the suicide is only apparent, and where the patient does not really wish to put an end to himself. He becomes the victim of his illusions, and loses consciousness of the danger he may run on account of the marked disturbance of a clear perception of the reality of things. In most of the cases of delib-

¹ Journal of Mental Science, July, 1899.

² Journal of Mental Science, October, 1900.

³ Ann. med. psych., March, 1900.

erate suicide the suicidal ideas have the characteristics not only of dementia, but also of the delusion which the patient may have, a delusion which is almost always irregular and transitory. This irregularity and transitory character are more or less marked; most frequently the ideas of suicide are sudden and of short duration. It is easy to divert the patient from them and he takes no care to hide them. There are, however, other cases where the means employed to commit suicide differ in no degree from those which other insane employ. The patients seem to have a definite idea of committing suicide as shown by the precautions which they take, by the premeditation of the act, and by the length of their preparations for it. In these cases there is less dementia.

PROGNOSIS OF THE PSYCHOSES OF PUBERTY.

Cullere⁴ has studied 120 attacks of the psychoses of puberty in subjects from fifteen to eighteen years of age—53 males and 57 females. Of these 3 died in the first attack. There were 33 cases of dementia precox which came on in 18 during the first attack, in 9 during the second, and in 2 in the third. In 4 cases the attack degenerated into secondary systematized insanity with mental enfeeblement. There were 20 cases of periodic insanity, all forms being represented. There were 25 cases of recurrence with varying issue. These recurrences were most frequently benign and were at considerable intervals apart. This group was the most favorable in point of view of ultimate prognosis. There were 9 cases of insanity with a consciousness of the condition, obsessions, or impulsive states. These cases were generally permanent. In 30 cases the patient disappeared from observation after the first attack. The clinical aspect of the first attack, however, would permit us to classify them with the subjects of the preceding groups. The prognosis of the attack in the insanity of puberty is favorable in the enormous proportion of 79%, but the ultimate prognosis of the disease is more serious. The individual who is cured of this form of mental disease runs the risk in the future of recurrences, of dementia precox, of periodic insanity, or of returns of the insanity of obsessions. The least sad feature is that the inevitable recurrences are reduced to a small number at long intervals apart, with long periods of more or less normal health between them.

THE TREATMENT OF INSANITY BY REST IN BED.

Korsakow,⁵ in a communication presented to the Thirteenth National Congress at Paris, comes to the following conclusions: In the question of treatment of mental disease by rest in bed, we must distinguish between the system of bed treatment as a mode of the internal organizations of asylums and the employment of bed treatment as a therapeutic measure. The foundations of the system of bed treatment are as follows: The use of the bed is considered as an essential element in the treatment. The stay in bed is obtained not by violence but by means of the moral influence and the suggestive effect of the environment. It requires a particular organization of attendants, which is only one manner of caring for the patients and for following and carefully observing the physical and

mental symptoms of the disease. The refusal to make use of separate rooms as a principle is not a fundamental condition of the system in question, but it is a powerful aid in the development of the bed treatment, and, on the other hand, the diminution in the use of separate rooms is one of the first benefits of the régime. The exact determination of the time which the patients must remain in bed, of their walks and occupations out of bed, constitute the essential part of this system. The rest in bed must be regulated in all its details from absolute confinement to the bed up to the most limited use of it. The use of common wards is a powerful means in the regular organization of the system of bed treatment, although we may be obliged to apply the bed treatment equally well in separate rooms; this has a secondary importance in the system in question. The forced detention in bed is not an element of the régime of bed treatment as a system.

The principal advantages of the system are as follows: Greater order in the asylum, especially if it is crowded; greater security for the patients; greater facility in caring for them and in clinical observation; a limited use of isolated rooms, the system of rest in bed being capable of abolishing completely the imprisonment in cells. Finally, the diseases characterized by a state of agitation have a more moderate course. In the asylums where the system of bed treatment is applied the mortality of some grave acute psychoses is notably diminished. With the system of bed treatment we must not include other systems which have a favorable action, such as that of moral influence, of non-restraint, of work, and of open doors. It is possible to successfully combine all these systems. The indications for absolute rest in bed are only very imperfectly established. To have these indications upon a scientific basis, we must not only multiply researches, but also their sphere. Investigations are desirable as to the effect of rest in bed and lack of exercise upon the composition of the blood, the elimination of toxins from the organism, and the mental functions, and above all upon the energy of the directing force of the mind. The principal indication for rest in bed is a state of excitement. Prolonged rest in bed carried out in a rigorous manner is contraindicated in patients with a sluggish intelligence, predisposed to apathy, anemia, and masturbation. It will be very important to study the effect of this treatment upon mental diseases in young subjects, in case they become incurable. Rest in bed must be applied in different ways, according to individual indications in almost all acute psychoses, especially at the initial period of the disease. It has an especially favorable action in the majority of maniacal cases, in cases of alcoholic delirium, and in many forms of mental confusion and of melancholia. There are vital indications for its application in patients whose mental trouble is connected with infection and high temperature, and in patients who are greatly exhausted.

ARTIFICIAL SERUM IN MENTAL DISEASE.

Jacquin⁶ believes that injections of artificial serum may be of advantage in psychiatry. These injections have the advantage of ease of administration, of simple technique and freedom from accidents. They are indicated in all cases where the mental troubles seem

⁴ Arch. de neurol., September, 1900.

⁵ Loc. cit., October, 1900.

⁶ Ann. med. psych., May, 1900.

associated with infection or auto-intoxication, that is, in cases of poisoning of the organism of the brain, either by microbes, by products of secretion or by toxic substances resulting from the increased formation or insufficient elimination of normal poisons. They fulfil these indications by eliminating the toxins, diluting them, re-establishing the secretions, and acting quickly. He calls especial attention to their action upon the urinary functions and the importance of proper functioning of the kidneys in the insane.

THE TREATMENT OF ACUTE MANIA WITHOUT SEDATIVES.

Hitchcock⁷ gives the results in 206 consecutive cases of acute mania observed during sixteen years at York. One hundred and seventy-one recovered, 8 died during the attack from the disease, 3 died during the attack from intercurrent disease, 12 were discharged relieved, 7 were transferred, and 5 remained under care. The average period under treatment was for males three and a half months, and for females five months. Seven cases recovered after one year, 2 after three and five years respectively. The ratio of recoveries to the number of cases under treatment was 83%; the ratio of deaths, 3.8%.

Although excitement and sleeplessness were prominent symptoms in all these cases, he did not use sedatives in the treatment of any one of them, and he firmly believes that he thereby secured a larger proportion of recoveries, a calmer after existence for the cases which have not recovered, and perhaps a diminished death rate.

THE STATE IN THE CARE OF THE INSANE.

Kraepelin⁸ says that the helplessness of the insane and their need of protection make it necessary that the State should pay some attention to their condition, even when they are not dangerous and do not demand institutional care. In general it would be practical to leave such patients to the care of their families and not to interfere unnecessarily with them. Only when the patients are not able to withstand the struggle for existence and all other aid has failed does it become a public duty to give aid to the feeble in order that an aggravation of their mental disorder and an increase of suffering may not result from their poverty. The task of solving these questions belongs to individuals rather than to the magistrates. They can only be dealt with properly by the various philanthropic associations, since a thorough knowledge of the conditions under which the patient lives and a choice of the means to be used are necessary. The participation of the charity organizations and their representatives in this kind of work is to be emphatically commended. Experience has shown that these bodies have done excellent work in the care of the insane outside of institutions, their efforts having been especially useful in caring for discharged patients. The State has every reason, as in many instances it

has already done, to aid the unpretentious but sterling work of these societies.

RECEIVING HOUSES FOR THE INSANE.

The Tenth Annual Report⁹ of the Asylums Committee of the London County Council states that receiving houses seem to be in a fair way to become accomplished facts, as their establishment has been recommended by a special subcommittee and by a conference of guardians representing the metropolitan unions and parishes. The Commissioners of Lunacy seem to favor their establishment.

New Instrument.

A MODIFICATION OF THE OLD SIMS NEEDLE FORCEPS.

BY W. L. BURRAGE, M.D., BOSTON.

THE needle forceps here figured embodies no new principle of construction, but is rather a revival of an old form with several additions and improvements as suggested by the good points of other popular forceps. It is in effect a large hemostatic forceps, having needle holding jaws and shears handles.

The length of the forceps is a trifle over seven inches. The handles are like those of shears, and are bevelled to protect the thumb and fingers of the operator from chafing and to give a better hold, also, one loop being larger than the other ensures the instrument always being handled right side up.

The jaws are made narrow so that they will not break full curved needles. One jaw is faced with a copper plate held in place by two rivets passing through the steel of the jaw, thus ensuring a firmer fastening than by the old method of soldering. The face of the other jaw is roughened by rather coarse

checks in the steel. One groove is cut in each jaw, one opposite the other, for the reception of a Hagedorn needle, the upper groove being bevelled for a full curved Hagedorn.

The forceps will hold any sort of a needle firmly in any useful position without breaking the needle. It is perfectly simple in construction, easy to keep clean, and cannot well get out of order.

A needle forceps should not only hold a needle in a variety of positions, but it must be so constructed as to easily seize the needle after it has been forced through the tissues and extract it without injury to

⁷ Journal of Mental Science, January, 1900.

its point or without breaking it. To hold the needle firmly this forceps has the malleable copper opposed to the checked steel, a combination long known as one of the best for this purpose, and to seize the needle readily after it has been pushed through, it has jaws opening widely and closing like the jaws of a hemostatic forceps, simulating the action of the human fingers in picking up a small object.

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

H. F. HEWES, M.D., SECRETARY.

REGULAR meeting, Wednesday, November 21, 1900, DR. V. Y. BOWDITCH in the chair.

DR. H. L. MORSE read a paper entitled

LEUCOCYTE COUNT IN SEROUS PLEURISY.

He said in part: The leucocytes were counted daily in 20 cases of primary serous pleurisy from entrance to discharge or recovery. Their number exceeded 10,000, the normal limit, in only 13 of 224 counts. Nine of these occurred in 1 case with a secondary pneumococcus infection. Nine of the cases were certainly tubercular, the others probably so. In the cases certainly tubercular the count never exceeded 10,000. There was no evident relation between the duration of the disease or the temperature and the number of white cells. Blood and microscopic amounts of pus in the fluid did not affect their number. There was no apparent relation between the amount or progress of the fluid and the leucocyte count.

Serous pleurisy is only exceptionally accompanied by an increase in the number of white corpuscles, and then intermittently. The white count is of value in two ways in the diagnosis of serous pleurisy. If the physical signs are doubtful, and there is no leucocytosis, the condition is almost certainly not pneumonia or empyema, but serous pleurisy. If there is a serous pleurisy and a continuous leucocytosis, some complication is present.

DR. SEARS: I can remember no other observations so carefully made as those reported by Dr. Morse. He has covered the ground so thoroughly that it is scarcely possible to add to his conclusions. The leucocyte count has been made in all the cases which I have seen at the City Hospital at some time during the course of the disease, but often not more than once or twice. They have been entirely in accord with what Dr. Morse has said. In a large proportion of the cases they have numbered less than 10,000. It therefore seems probable that in those in which the number was greater some complication existed, but it has rarely been possible to detect what this was. In a few, the number has run up to 14,000 or 15,000. Almost every case which I have had has reacted to the tuberculin test where this has been tried.

DR. HEWES: I should like to ask Dr. Morse if any of his patients were children.

DR. MORSE: No; all of these patients were adults.

DR. HEWES: Has your experience with children been different in any respect?

DR. MORSE: I have not made any careful observations of the blood in serous pleurisy in children. I have made single examinations in various cases, but my results are not extensive enough to warrant any conclusions.

DR. HEWES: I have seen several cases of serous pleurisy in children with a continuous leucocytosis. It is well known that leucocytosis occurs much more easily in children with any inflammatory condition that can produce it than in adults, and it is probable from my experience that a continuous leucocytosis of several days' duration has not in these cases the significance which Dr. Morse's results would indicate that it has in adults.

DR. V. Y. BOWDITCH: I should like to express my pleasure at the paper by Dr. Morse. It seems to me that anything we can get to enlighten us in these cases that he speaks of where the physical signs are doubtful is of the greatest value to us. I have not made any similar experiments, but I certainly shall do so in the future.

DR. GEORGE G. SEARS read a paper entitled

PERICARDITIS WITH EFFUSION.¹

DR. G. C. SMITH: I have been very much interested in this paper on account of its conciseness and on account of the clearness of detail with which Dr. Sears has gone into the subject. I would like to ask one or two questions connected with it. First, how much value he attaches to the rational history in these cases from a diagnostic standpoint; whether in all of these cases or in any part of them it was not possible to rule out hypertrophy of the heart by the history; whether a distinction could be made between eccentric and concentric hypertrophy; whether or not, in the cases that were considered from the point of view of hypertrophy, the dilatation of the right side could always be ruled out? If it could, would not the hypertrophy always displace the apex to the left and downward and you fail to get your increased cardiac dulness on the right side, provided you have no pleural effusion, and providing you could rule out any consolidated or lung tissue or old retracted pleuritic conditions? It seems to me that perhaps in many of these cases at least, not particularly of his, but in many of the cases which come to us, if we can rule out all heart murmurs, can rule out old chronic bronchitis, emphysema and nephritis, and other causes for hypertrophy (the idiopathic so-called hypertrophy of the heart can be practically ignored), and if hypertrophy, uncomplicated by old pleuritic or fresh pleuritic trouble, can be ruled out, as it can of course in many cases, why, we would expect the hypertrophy to show an increase of dulness to the left largely, and would not expect it to carry it to the right very much, nor to give the form of bag shape which Dr. Sears speaks of. In the few cases I have seen, it seems to me, *this form* he describes could be pretty clearly made out, but owing to the fact that so many of our cases are complicated by pleurisy and emphysema it often becomes exceedingly difficult to define clearly the outlines of dulness or flatness. But I would like to ask how much significance he attaches to the rational history in these cases of pericarditis. It seems to me that perhaps more can be attached to the rational history than to physical signs oftentimes.

DR. MORSE: My experience with pericarditis with

¹ See page 595 of the Journal.

effusion has led me to realize very thoroughly the great difficulty there sometimes is in the diagnosis between pericarditis with effusion and hypertrophied and dilated heart, especially hypertrophied and dilated right heart. My experience has also led me to the same conclusion that Dr. Sears's led him, that the one most important sign is the angle between the right side of the heart and the liver. The next most important sign is the position of the apex with relation to the outer limit of dulness to the left. The other signs are, I think, of subordinate importance. I have also been struck with the comparatively slight importance of the area of dulness in the left back. It seems to me that this is present in many conditions besides pericarditis with effusion. My experience in tapping in pericarditis with effusion has been very slight and rather unsuccessful.

DR. HEWES: Have you ever tried paracentesis from below the arch of the diaphragm, a method recommended by some foreign observer whose name I have forgotten?

DR. SEARS: No, I never have. I have preferred the other method, but, as my results show, not with the success I had hoped. There is one thing to be said about the epigastric route—that if flocculi in the fluid are the reason why one gets so few successes they would more naturally tend to collect in the lower portion of the sac than in the upper. But it is doubtful whether this is worth considering, since the fluid must be kept in pretty constant motion from the churning of the heart, and would be therefore less liable to follow the laws of gravity.

DR. HEWES: I remember one case in the service of Dr. F. C. Shattuck at the Massachusetts Hospital while I was house officer which was aspirated after death from below the arch of the diaphragm. The case had been tapped three times during life without result except that once a few drops of bloody fluid were obtained. Immediately after death we tried the method of tapping up through the diaphragm and obtained over a pint of fluid which flowed very freely. Of course the conditions of the organs after death may have been so different as to make it easier to get the fluid out then, but it certainly came very freely in a case in which after tapping in three other places we failed to get any fluid at all with the patient in the same position as when we tapped after death. If we had succeeded in aspirating successfully at first it would doubtless have prolonged the patient's life for a short period at least.

DR. SEARS: That position has been recommended by first-rate observers who have obtained fluid there. I confess that I have never aspirated the pericardial sac without some misgivings, and I think I may have had more at the thought of going in there and have therefore not done it.

DR. V. Y. BOWDITCH: Dr. Sears does not touch upon the more strictly surgical procedures in these cases. I should like to know his views as to whether there is any objection to making a surgical incision to the left of the sternum, even in serous effusions, simply because of the comparative ease of making this and the lessened danger of wounding the heart by the puncturing needle.

DR. SEARS: I have had no practical experience and can express no opinion.

In reply to Dr. Smith, I hardly know how to answer so complicated a question. Certainly in a very large

proportion of the cases pericardial effusion is found first on physical examination and its presence is not suggested by subjective symptoms. Pain, pericardial distress and dyspnea might point to pericarditis, but none of them are constant and might result from other causes. In all cases of marked cardiac enlargement, whether the right or left ventricle is most involved, a certain amount of lateral increase in the area of cardiac dulness is present which is most marked in the former. But in practically every case, normal or abnormal, except where there is marked emphysema, one can detect by gentle percussion an area of dulness on the right of the sternum, so that the mere presence of the dulness on the right has little significance unless it is increased beyond what one would normally expect,—a finger's breadth or a finger's breadth and a half.

DR. SMITH: I had particularly in mind not the symptoms that go with the rational history of pericarditis, but of hypertrophy. You generally have a pretty straight history of a case with hypertrophy of the heart which frequently may help you to decide whether you have got hypertrophy or not. Of course if you can rule out all the causes of hypertrophy it aids somewhat in making a diagnosis of pericarditis if you have that broad area of dulness.

DR. SEARS: It would not help you in cases of pericardial effusion occurring with a large heart, by no means a very rare combination in chronic nephritis.

DR. SMITH: In the uncomplicated cases when you can rule out nephritis, and the histories of other things like emphysema and chronic bronchitis, and anything in the way of disease that may lead to hypertrophy; if you have no cause for hypertrophy that you can find in the rational history would you not be quite justified in ruling out hypertrophy in favor of pericarditis with effusion?

DR. SEARS: I think you might, but it is difficult to rule out all causes for hypertrophy from the history. Practically the diagnosis must be made on physical signs rather than on statements of the patient.

DR. MORSE: It seems to me there can be no question that the diagnosis of pericarditis with effusion rests on the physical signs and not on the history. Most of the cases I have seen have been discovered on routine physical examination. As to the question of diagnosis between a hypertrophied heart and a pericarditis with effusion it does not seem to me that it is at all difficult. The diagnosis between pericarditis with effusion and a dilated hypertrophied heart in one thing; that between a pericarditis with effusion and a hypertrophied heart is another. The physical signs are practically opposite. The area of dulness is different, the cardiac action different—in the hypertrophied heart, strong, active; in pericarditis with effusion, comparatively feeble. In the hypertrophied heart the impulse is at the outer limit of dulness; in pericarditis with effusion, inside the limit. The sounds are strong in hypertrophy; comparatively weak in pericarditis with effusion. One second sound is accentuated in hypertrophy; both very likely to be weakened in pericarditis with effusion. Hence the diagnosis between hypertrophy and pericarditis with effusion does not seem to me to be difficult, but between an hypertrophied heart which is dilated a great deal and a pericarditis with effusion it is often very difficult.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

TWENTY-SIXTH ANNUAL MEETING, HELD AT ASHEVILLE, N. C., OCTOBER 9, 10 AND 11, 1900.

DR. M. H. FLETCHER, Asheville, chairman of the Committee of Arrangements, called the meeting to order, and prayer having been said by the REV. R. F. CAMPBELL, addresses of welcome were delivered by MR. THEO. F. DAVIDSON on behalf of the city and State, and DR. JOHN HEY WILLIAMS on behalf of the profession of Asheville. Prominent reference was made in these speeches to the beautiful climate of the popular health resort, which occupies a commanding position on the Blue Mountain Ridge of the Alleghanies. Though the place is full of doctors, one of the speakers said they would die of starvation were it not for the patients sent to them from less highly favored parts of the country.

THE PRESIDENT'S ADDRESS.

The president, DR. H. N. MOYER, in the course of his address, said an apology for the medical profession had lately been delivered at Paris by one of its own nestors. The American medical profession needed no apology, and as proof thereof, they had only to read the tribute paid to it by the *London Lancet*, which pointed out that, allowance being made for the difficulties that had to be overcome in a new country, and particularly one where democratic principles prevailed, and there was a consequent dislike of interference with individual liberty, it was remarkable what American physicians and surgeons had achieved, and what had been and was being done to raise the standard of education among students of medicine. In the light of this quotation it was evident that they did not require to apologize for their profession, but only for their representative who had been appointed to speak for it in Paris. He (Dr. Moyer) had no desire to wash any professional dirty linen. If there was anything of that kind to be done it could best be attended to in the local professional laundry. But some of the matters touched on in the address referred to were of the utmost importance alike to the profession and the public. Among other things the essayist had gone into a question of ethics which was at least twenty years old, and which most of them no doubt thought was dead and buried long ago. Unfortunately, it had not been embalmed, and now it had been resurrected with all its old malodorousness.

Passing this by as a matter which was of little interest now, save to a few practitioners on the Atlantic seaboard, he came to the statement of the essayist that there were too many medical societies. The essayist said there were only two in the old colonial days, and he seemed to regret that they were not living in these days still. He (Dr. Moyer) did not think there were too many medical societies. On the contrary, he believed that even the most insignificant societies were helping to advance medical science, and that it was principally due to their united efforts that so much progress had been made, and that the profession occupied the position which had evoked the tribute of the *London Lancet*. In this country, it was to be remembered, they had almost no endowment of medical education or research. They had no government subsidy, and no paid hospital staffs. But in spite of all this the physicians and surgeons of Amer-

ica were acknowledged to take high rank by reason of their achievements. The medical societies had enabled the profession to do for itself what abroad was done for it by legislation and subsidy. As to the Mississippi Valley Medical Association, some people thought there was no particular need for it, inasmuch as it did not represent any definite geographical area, and the State and national associations might be supposed to meet all legitimate wants. The prosperity of the Mississippi Valley Association, however, was sufficient to show that it served a useful purpose, and it was noteworthy that its members for the most part were also active members of the national association, of which the Mississippi Valley Association was a valuable auxiliary instead of being in any sense a rival.

Another matter of importance was the relation of law to the medical profession. A good deal of misapprehension existed as to the attitude occupied by physicians and surgeons to the movement for the passing of statutes for the regulation of medical practice. Legislation was required, not so much for the protection of the profession as for that of the public; and with the view of making the law operative against unqualified practitioners he suggested that, instead of attempting to define what was meant by "practising medicine," they should leave it to the courts to say what came within the scope of these words. The law required that pilots and others should possess certain qualifications as a guarantee that they could be entrusted with the lives of the public; and that was all that medical men asked should be required in regard to their own profession. Personally they might prefer that there was no such thing as a Medical Practice Act; but the fact remained that laws of the kind were necessary for the protection of the public.

Reverting to the essayist who had drawn up the apology for the American medical profession, Dr. Moyer said that another of his allegations was that there were too many medical journals in this country, and that they did not all preserve the same high standard that was desirable. The medical journals could no doubt be left to look after themselves, but those acquainted with the facts knew that the medical journals of America could stand favorable comparison with those of Europe. Only the best of the latter were known here. On the other side of the Atlantic, as on this, there were plenty of weak-kneed, advertising, nostrum-fostering periodicals which no member of the profession could regard with anything but contempt.

In the concluding part of his address, Dr. Moyer dealt with the subject of specialism, laying stress on the fact that there was too great a tendency on the part of beginners to aim at this branch of practice in total ignorance and disregard of the fact that the only genuine descriptions of specialism were those that were founded on a thorough experience in the field of the general practitioner. Specialism was like matrimony — not to be forced, but only to be adopted when it came naturally.

DR. H. O. WALKER, Detroit, Mich., read a paper on VAGINAL VERSUS ABDOMINAL HYSTERECTOMY.

The question, he said, was largely one of working in a light or a dark passage. The conclusion at which he had arrived was that the abdominal route was the better of the two, and that for this reason, not only

could they see more clearly what they were doing, but they obtained a better control of hemorrhages, and ran less risk of complications through the slipping of ligatures. In other words, the danger to the uterus was limited, and if any injury was done it could easily be repaired.

The paper was favorably commented on by DR. LEE, of St. Louis, and others.

CANCER OF THE UTERUS.

A paper on this disease and its treatment was read by DR. R. S. SUTTON, Pittsburg, Pa.

Cancer operations, he believed, should be recommended, not as curative, but as palliative, and in that respect useful. Total vaginal extirpation of the uterus at or after time of climacteric, he said, should find a place as prophylactic treatment against cancerous disease. After reviewing the anatomy, pathology, diagnosis and present method of treatment, the author expressed the opinion that treatment for existing cancer of the uterus had probably reached its complete evolution; but in view of the ultimate results of this treatment, which he heartily endorsed because there was no other known treatment to take its place, he asked, *Cui bono?*

Proceeding to discuss the question of prophylaxis, he stated that the average age of the patients he had operated on was forty-three years and a fraction, and claimed that if these patients had all been subjected to total vaginal extirpation at the average age of forty, all of them would have escaped cancer of the uterus. According to statistics he had prepared, only 4% of them would have died, whereas nearly 100% did die within a period of two or three years after operations for cancer. He urged greater attention to the early repair of lacerations of the cervix, together with a more painstaking observation and consideration by physicians at large of the train of symptoms which preceded and led up to the development of cancer of the uterus. Radical surgical treatment should be resorted to in all such cases; but above all if they were to reduce the number of cases of uterine cancer, and consequent mortality, steps must be taken to forestall the disease.

TRACHELOPLASTY.

DR. H. P. NEWMAN, Chicago, read a paper on this subject, in which he called attention to the need of recognizing the normal and pathological significance of the cervix uteri, the importance of its function, and the improvement which had been introduced in the technique of the surgical reparation of this organ.

POST-OPERATIVE INTERNAL HEMORRHAGE.

DR. A. H. CORDIER, Kansas City, Mo., read this paper.

He showed that in diagnosing post-operative hemorrhage a review of the operative history should be gone over carefully. Symptoms of shock and hemorrhage were very similar, but in suspected cases a single stitch cut in a closed wound would tell the difference. In all cases where a hemorrhage was feared, a tube should be introduced. The surgery must be quick and decisive in post-operative procedures, and large quantities of normal saline solution would save many cases.

DR. GEORGE W. CALE, Springfield, Mo., described

A CASE OF INTERMITTENT HYDROPS OF THE KNEE.

The patient was a lady of forty years of age who had recurrences of the disease at intervals from one to six months during the last five years.

VENTRAL HERNIA FOLLOWING LAPAROTOMY.

In this paper DR. B. BRINDLEY EADS, Chicago, emphasized the importance of this sequel of abdominal operations, discussing the principles involved in the choice of incision, the making and closing of the incision, and the way to cure ventral hernia.

DR. E. H. RICHARDSON, Atlanta, Ga., reported a case showing

PERFECT RECOVERY FOLLOWING GANGRENE OF THE SCROTUM AND PENIS.

The initial lesion was an abrasion of the skin near the os pubis with probable infection from the *erysipelas cocci* at this point, and later a mixed infection from the *streptococcus* of gangrene, terminating in the destruction of the gangrenous portion of the entire integument of the penis and of three-fourths of the scrotum. Plastic operation was adopted with the effect of preserving the integrity of the penis and testes.

MIDDLE EAR DISEASE IN ITS RELATIONSHIP TO THE CRANIAL CAVITY.

DR. OTTO J. STEIN, Chicago, contributed this paper. Stereopticon demonstrations were given by an assistant. The object of the author was to show the necessity of recognizing the importance of possible intercranial complications in every case of middle ear disease.

SECOND DAY.

The proceedings commenced with the

ADDRESS IN MEDICINE,

by DR. I. N. LOVE, formerly of St. Louis, now of New York, who chose as his subject "Nutrition and Stimulation."

The physician, he observed, should be the family counsellor, and in particular should be consulted in regard to all matrimonial plans. When a new being was brought into existence its proper nutrition should be looked after from the very beginning—even prior to birth. After birth the security of the infant depended upon the proper appreciation of its proper feeding. One danger which had to be guarded against was that of overfeeding, which was apt to lead to infantile obesity and gigantism. On the other hand it was necessary to give sufficient nutrition to provide for growth as well as life. After maturity was reached less food was required, for it was only necessary to furnish nutrition that was needed for the maintenance of life. Food, like alcohol, was used too much for pleasure rather than the maintenance of life. Stimulants, the speaker went on to say, were of value if used in the right way and at the right time, but in the healthful condition they were not needed. They were essentially a luxury, and all luxuries should be used with the greatest care, only the thoroughly healthy being able to indulge in them at all freely. The use of tobacco, particularly when the smoke was inhaled, as it usually was by cigarette smokers, he maintained, did even more harm than the abuse of alcohol.

PROCTOLOGICAL DISEASES.

A symposium of papers on proctological subjects followed, the first being one by DR. JOHN L. JELKS, Memphis, Tenn., on the treatment of

PERIRECTAL ABSCESSSES.

The author maintained that these abscesses when properly treated were not so serious as when poulticing was in practice and that they need not necessarily result in fistula. The walls, he pointed out, were not gotten rid of when simply incised and drained; thorough curetting was also essential. The next paper was by DR. J. PAWSON PENNINGTON, Chicago, who described a

SIMPLE OPERATION FOR THE ENUCLEATION OF HEMORRHOIDS.

Each quadrant was grasped with a pair of T-forceps, the hemorrhage being controlled by torsion and rubber covered tampon. He contended that there was less pain and that earlier recovery could be relied on by this method than by any other.

DR. STERLING B. TAYLOR, Columbus, O., who read the third paper of the series, dealt with the subject of

OBSTIPATION.

Having obstipation, constipation and costiveness, he proceeded to classify the causes of the first-mentioned complaint, principal among them being hypertrophy of the rectal valve. He defended Martin's views and methods.

The discussion on the papers was opened by DR. JOSEPH M. MATHEWS, Louisville, Ky., who said he had been very much interested and entertained by the papers, and that of Dr. Jelks he wished to commend very highly. When fistulas were at all complicated, no man could say that he could cure them by a first operation, therefore, if they could prevent them they should certainly do so. Dr. Pennington had also given them a number of useful suggestions, but he did not agree with his method of treatment. He used to excise tumors, but he had ceased to do so because of the severe hemorrhages which ensued, and had gone back to the old method of the ligature. He admitted that excision was the ideal method, or at least would be so were it not for the danger of hemorrhage, and if Dr. Pennington had discovered a means of effecting it without that danger he had done a great thing. He suggested, however, that to make the operation safe it would be well to bring the parts of the mucous membrane together and suture them. As to the last papers, he remarked that if they substituted the word "constipation" for "obstipation" it would convey a better idea of the complaint, and many old country doctors would tell them how to cure it. The authorities made no mention of these rectal valves about which they had recently been hearing so much, and for his part he did not believe in their existence. Folds no doubt there were, but they could not have the effect attributed to them. He would certainly await further developments before adopting the new procedure, which was known as "valveotomy."

Several other speakers said they had been very anxious to see those rectal valves, but had never succeeded in doing so.

DR. PENNINGTON, in replying to criticisms, said

if he could not control a hemorrhage by torsion he would use a ligature, but he had never found it necessary to do so.

DR. TAYLOR maintained that the question of obstipation had been dodged by those who did not admit the existence of rectal valves while acknowledging that every one had what they preferred to call folds.

THIRD DAY.

ADDRESS IN SURGERY.

This was delivered by DR. C. A. WHEATON, St. Paul, Minn. He devoted himself principally to the subject of "Appendicitis," which he claimed was essentially a disease for the surgeon to deal with.

TUBERCULOSIS OF THE SPINE.

A paper on the treatment of this disease was contributed by DR. ALEX. C. WIENER, Chicago. He entered a plea for early diagnosis before deformity was visible, extension and hygienic treatment being essential, if complications such as paresis and gravitation were to be avoided. He exhibited a specimen showing the possibilities of Cobat's forcible correction of the spine, and described cases of psoas abscess which had been cured by injections of carbolic acid, accompanied by other treatment.

DR. H. HORACE GRANT, Louisville, Ky., followed with a communication on the

MEDICAL AND SURGICAL TREATMENT OF ACUTE AND CHRONIC LYMPH NODES.

Having referred to the useful purposes served by the lymphatics, he said they should not be removed except for good and sufficient cause. When they became diseased and useless there should be no hesitation about taking them out.

In the course of the discussion which followed, DR. WHEATON protested against the indiscriminate use of the knife in the case of affected glands, his belief being that the majority of cases would get better with proper hygienic surroundings and internal medicine.

COCAINE ANESTHESIA OF THE SPINAL CORD.

DR. CARL H. ANDERSON, Chicago, reported a number of cases in which this operation had been performed, and discussed the physiological and clinical results of the procedure. While advocating the operation, he warned the profession against the dangers it involved, chiefly because of the difficulty of obtaining a sterile solution. He had tried in vain to get a sterile solution by Tuffier's method, though he had succeeded in doing it by a process of his own.

DR. MOYER gave a demonstration of the technique of the operation as performed by Dr. Anderson. If he were asked his advice as to this method of administering an anesthetic he would say with their present knowledge, and having regard to the delicacy of the operation and other circumstances, "Don't do it." At the same time the subject was a fascinating one and incalculable benefits would result from the procedure if it could be freed from some of the dangers now attending it. Therefore further experimentation was desirable, but it should only be carried on in well equipped clinics.

DR. A. M. PHELPS, New York, read a paper on the TREATMENT OF TUBERCULAR AND PURULENT HIP-JOINT DISEASES WITH LARGE SPECULUM DRAINAGE AND PURE CARBOLIC ACID.

All abscesses, he said, should be opened as soon as diagnosis was made, for the purpose, primarily, of exploration, and secondarily, for drainage, and any surgical operation which might be deemed advisable. The action of the carbolic acid on the skin and tissues was neutralized by the use of pure alcohol. Incidentally it was brought out that carbolic acid thus was a specific for erysipelas. The profession was much indebted to Dr. Seneca Powell, New York, for discovering the antidotal properties of alcohol as regarded carbolic acid, thus making the latter available for use in the ways indicated as well as in others.

PULMONARY TUBERCULOSIS IN INFANCY AND CHILDHOOD

was discussed in a paper by DR. FRANK P. NORBURY, Jacksonville, Ill. Heredity was a factor, but not so important a one as was sometimes thought. Infection was the most common source of the disease. The principal avenues of infection were the respiratory and the intestinal tracts. Other diseases, as was well known, paved the way for the infection. House pets frequently introduced it into a household; therefore care should be taken. Cats, dogs and other domestic animals feed upon tuberculous meat. The author then proceeded to discuss the parts that hygiene, climate and symptomatic treatment played in the cure of the disease.

DR. STEIN, Chicago, in discussing the paper, advocated intratracheal injections of oil to relieve patients whose stomachs were liable to be upset by taking it by the mouth.

THE PHYSICIAN AS A SANITARIAN

was the subject of a paper by DR. HUGH A. COWING, Muncie, Ind. While many physicians rendered invaluable services to the community by the attention they devoted to the cultivation of sanitation, there were others whom he considered criminally negligent and careless, and were often the means of spreading infection.

THE GIRL AT TWELVE.

This was the title of a paper by DR. J. H. TAYLOR, Indianapolis, Ind. Discussing the management of girls at the age of puberty, he laid stress on the bad effects of manual labor and overwork in school, contending that physical and mental overexertion were alike to be deplored. Emmenagogues should be avoided in the case of girls at this period, and more attention paid to the general health. He appealed to mothers and physicians to unite in giving more care to girls entering on the stage of womanhood, as by so doing they would prevent many diseases which now so frequently resulted from lack of care and excess of work or study.

ASTHMA.

DR. R. A. BATE, Louisville, Ky., in discussing this subject, quoted the saying of Loomis that the primary cause of asthma is undoubtedly some constitutional idiosyncrasy and also the remark of Haig that asthma represents one of the effects of uric acid on the circulation. The curative treatment consisted of diet, hygiene and antilithic measures.

DR. THOMAS H. STUCKY, Louisville, Ky., said the primary causes of asthma were imperfect salivation or mastication. Personally he knew when he was going

to have an attack of asthma, not by how he felt, but by what he ate. Asthmatics were fond of sweet, starchy food, they were people of full habit and they were lazy. He confessed that he filled the bill all through.

DR. C. L. MINOR, Asheville, referred to the relation between asthma and tuberculosis. He believed every asthmatic had uric acid and pulmonary patients who had uric acid were fortunate. In this respect asthma was like gout. They probably knew of the physician who told a patient he had the choice of dying of gout or tuberculosis. The patient chose gout, and showed his wisdom by so doing, because he lived much longer. Gout and asthma were alike favorable symptoms in pulmonary patients.

CURABILITY OF INEBRIETY BY MEDICAL TREATMENT.

DR. T. D. CROTHERS, Hartford, Conn., read this paper, in which it was maintained that inebriety was a neurosis, usually self-limited, and very largely curable. The craze for drink was symptomatic. The real causes were central nerve irritation, exhaustion, poisoning and starvation. The success of medical treatment depended upon accurate knowledge of the causes and conditions present in each case, and the accurate application of general means and measures for their removal. Each case required special means and measures particularly adapted to meet the conditions present. The family physician as well as the specialist should treat these cases successfully. The stopping of the use of spirits should always be followed by medical treatment, but it was necessary to guard against the substitution of drugs which would produce even worse effects than alcohol. When properly treated as a disease a degree of cure far beyond expectations would be obtained, and when it was so recognized the family physician and not the clergyman or the quack would be called on to advise in such cases.

THE SUPRARENAL CAPSULE.

DR. W. H. BATES, New York, contributed the results of some further observations he had made on the clinical application of this drug, the aqueous extract of which he said was the most powerful astringent, hemostatic and heart tonic known. It lessened the congestion of the eye and other organs. The extract was not irritating or poisonous, and, unlike other powerful drugs, it was never contraindicated. There was no remedy which was so useful in all forms of inflammation.

DR. J. A. STUCKY, Lexington, Ky., said he had obtained excellent results from the use of the suprarenal liquid combined with chloretone, particularly in middle-ear complaints and hay fever.

THE PHILOSOPHY OF THE SCIENCE AND ART OF MEDICINE.

In this paper DR. WM. F. BARCLAY, Pittsburg, Pa., showed the value of approaching the study of medicine from a purely philosophical point of view. The philosophy of medicine was the comprehension of the truth in the investigation of the science enabling one to arrive at rational conclusions in the study of the physical laws which governed organized matter in their normal and pathological condition.

DR. EDWIN ROSENTHAL, Philadelphia, read a paper on the

CLINICAL VALUE OF PURGATIVE MINERAL WATERS, of which he took Apenta as a type.

WHAT THE LAW REQUIRES OF A SURGEON

was the subject of a paper by DR. DUDLEY S. REYNOLDS, Louisville, Ky.

DIFFERENTIAL LEUCOCYTOSIS

was discussed in a paper by DR. L. H. WARNER, Brooklyn, N. Y.

NEW OFFICE BEARERS AND NEXT PLACE OF MEETING.

The following were elected the office bearers of the association for the ensuing year: President, Dr. A. H. Cordier, Kansas City, Mo.; First Vice President, Dr. Charles F. McCahan, Aiken, S. C.; Second Vice President, Dr. C. L. Minor, Asheville, N. C.; Secretary, Dr. Henry E. Tuley, Louisville, Ky.; Treasurer, Dr. Dudley S. Reynolds, Louisville, Ky., the last two being re-elected.

It was arranged to hold the next meeting at Put-in-Bay, Ohio, on September 10, 11 and 12, 1901. Dr. J. C. Culbertson, Cincinnati, was appointed chairman of the Committee on Arrangements.

Drs. Wheaton, Lamphear and Moyer were appointed delegates to the Pan-American Medical Congress to be held at Havana in December.

The proceedings were brought to a close by a banquet in the Battery Park Hotel.

Recent Literature.

Handatlas der Anatomie des Menschen. Mit Unterstützung von WILHELM HIS, bearbeitet von WERNER SPALTEHOLZ. Dritter Band, I Abtheilung. Leipzig: S. Hirzel. 1900.

Hand Atlas of Human Anatomy. By DR. WERNER SPALTEHOLZ, Extraordinary Professor of Anatomy, etc., with the advice of WILHELM HIS, Professor of Anatomy in the University of Leipzig. Translated from the third German edition by LEWELLYS F. BARKER, Professor of Anatomy in the University of Chicago, with a preface by FRANKLIN P. MALL, Professor of Anatomy in the Johns Hopkins University. Vol. I, Bones, Joints, Ligaments. Leipzig: S. Hirzel. 1900.

We have had occasion in the past to praise the first two volumes of this work, parts of which have reached us at different times. We have now the first division of the third volume before us. This treats of the viscera, among which the teeth are properly included. We are happy to find a continuation of the same rare combination of high art and anatomical accuracy.

That the book is a success is evident from the fact that, while it is still incomplete, the first volume has reached a third edition. More than this, an English translation of this third edition has appeared, making the first volume accessible to our students. In fact, however, this is hardly an accurate statement, for the book is meant to be essentially an atlas. The author states that he wrote the text unwillingly. He had the fear of seeming to write a compendium before his eyes. It is intended to help in the use of the plates, not to pose as a textbook.

In his preface to the English edition Dr. Mall brings up the sore subject of anatomical nomenclature, endorsing that of the German anatomists. Such Latin terms as *facies* for surface and *crista* for border, to say nothing of more complicated ones like *articulatio-talo-cruralis* for ankle joint, strike us as very pedantic. The law of the survival of the fittest will probably help us out of this snarl in spite of anatomists. As for the rest, we are delighted to have the book in an English form.

The Medical News Visiting List for 1901. Weekly (dated, for 30 patients); Monthly (undated, for 120 patients per month); Perpetual (undated, for 30 patients weekly per year); and Perpetual (undated, for 60 patients weekly per year). The first three styles contain 32 pages of data and 160 pages of blanks. The 60-patient Perpetual consists of 256 pages of blanks. Each style in one wallet-shaped book, with pocket, pencil and rubber. Philadelphia and New York: Lea Brothers & Co.

One of the best and most convenient of the many medical visiting lists is the *Medical News Visiting List*. Its blank pages are arranged to classify and record memoranda and engagements of every description occurring in the practice of the physician, surgeon or obstetrician. The work opens with 32 pages of printed data of the most useful sort, including an alphabetical table of diseases with approved remedies, a table of doses, sections on examination of urine, artificial respiration, incompatibles, poisons and antidotes, a diagnostic table of eruptive fevers, and a full-page plate showing at a glance the incisions for ligation of the various arteries, an invaluable guide in such emergencies. The *Medical News Visiting List* is issued in four styles, adapted to any system of records and any method of keeping professional accounts.

Anleitung zur Diagnose und Therapie der Kehlkopf-, Nasen- und Ohrenkrankheiten. Vorlesungen gehalten in Fortbildungscursen für praktische Aerzte. Von DR. RICHARD KAYSER, in Breslau. With 121 illustrations. Berlin: S. Karger. 1901.

The object of the author is to supply to students in a post-graduate clinical course a systematic summary or set of lecture notes covering the same ground that such a course might be expected to cover. As may be presumed from the fact that the book contains only 160 pages, no attempt is made to discuss doubtful points, nor to describe rare and unimportant conditions. The author in the preface points out that this is the first time in Germany in which the diseases of the larynx, the nose and the ear have been united in one book. To his readers it would seem more remarkable that one book should unite these three and leave out the oropharynx. If it is possible to treat a subject like laryngeal tuberculosis satisfactorily to anybody in three pages, the author has done it well. The troublesome subject of vasomotor rhinitis is practically given by title only. The classification of nasal polypi under hypertrophic rhinitis has much to recommend it, but their connection with disease of the accessory sinuses should not be omitted. The simple inflammatory diseases and the inflation of the middle ear are concisely and clearly described. So are the sections on methods of examination. The same may be said of most of the conditions often met in a clinic. The illustrations are well chosen and as a whole the book is good for what it aims at, brief lecture notes.

Modern Medicine. By JULIUS L. SALINGER, M.D. Demonstrator of Clinical Medicine, Jefferson Medical College; Chief of Medical Clinic, Jefferson Medical College Hospital, etc., and FREDERICK J. KALTEYER, M.D., Assistant Demonstrator of Clinical Medicine, Jefferson Medical College; Hematologist to the Jefferson Medical College Hospital, etc. Illustrated. Philadelphia and London: W. B. Saunders & Co. 1900.

This is an octavo volume of 800 pages. The first section of 170 pages is devoted to a consideration of symptomatology and semiology, physical diagnosis, clinical bacteriology, laboratory methods. This is followed by the main body of the work on clinical medicine, and this again is subdivided into eleven parts treating consecutively of infectious diseases; diseases of the circulation; diseases of the respiratory system; diseases of the digestive tract; diseases of the kidneys; constitutional diseases; diseases of the blood and ductless glands; diseases of the nervous system; diseases of the muscles; intoxications and sunstroke; diseases due to animal parasites.

The authors and the publishers have produced a good and useful book of its kind. Truth will not permit us to say that it is the only book on the subject, or that it either covers new ground or old ground in an absolutely new way. But it is up to date, accurate, well turned out, and would prove a good guide and companion to the student of clinical medicine.

Pathology and Morbid Anatomy. By T. HENRY GREEN, M.D., F.R.C.P., Physician and Special Lecturer on Clinical Medicine at Charing Cross Hospital, etc. New (ninth) American from ninth English edition. Revised and enlarged by H. MONTAGUE MURRAY, M.D., F.R.C.P., Lecturer on Pathology and Morbid Anatomy at Charing Cross Hospital; Revised for America by WALTON MARTIN, Ph.B., M.D., of the College of Physicians and Surgeons, New York City. Philadelphia and New York: Lea Brothers & Co. 1900.

This octavo volume of 578 pages needs no introduction to English-speaking medical students. In the present edition, the ninth, nearly half of the subject matter has been rewritten, several new sections have been added and 180 new illustrations have been inserted. Dr. Walton Martin has supplied chapters on malaria and on the pathology of the blood, as well as a chapter on microscopical technique.

It is needless to say that the book appears in a greatly improved form. While not as pretentious a volume as some other recent books for medical students, it seems to the reviewer that it should continue to be of great usefulness to beginners in medicine. There are 4 colored plates and 339 engravings.

A Manual of Hygiene and Sanitation. By SENECA EGBERT, A.M., M.D. Second edition, enlarged and revised. Philadelphia and New York: Lea Brothers & Co. 1900.

In this new edition Dr. Egbert has added about 65 pages of new matter, including several new illustrations. Each page has been carefully revised, and much of the material has been entirely rewritten, so as to bring the matter up to date. A chapter upon Military Hygiene has also been added, with references to the most recent improvements in this department of sanitation.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 13, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.50 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE PROPOSED GARBAGE PLANT ON LONG ISLAND, BOSTON HARBOR.

THE difficulty of finding a location for the establishment of a municipal garbage plant has led certain members of the city government to consider Long Island as a suitable place for such a plant. It is, no doubt, generally known that the city almshouse and hospital is located on this island, but this knowledge apparently does not bring with it a realization of the fact that the residents of this island, some six or seven hundred in number, there by necessity and not by choice, are deserving of consideration at the hands of those who are responsible for their care. The island is not a large one, and it must be perfectly evident to any one who considers the matter seriously that a garbage plant, with all that it entails, in the immediate neighborhood of the institution buildings would be a nuisance of the most flagrant character. A daily contemporary well expresses the situation when it says: "That the plant is a nuisance in its present location is quite probable, and as such the citizens of Dorchester are justified in their clamor against it. But that fact does not furnish a warrant for placing this unwholesome and offensive institution where it will constantly distress a class of people who cannot help themselves; who cannot get away or command any influence to get their troubles abated. The theory of the new spirit of our city charities is that the paupers, who may be very worthy though unfortunate people, are entitled in food, lodging and nursing to the best treatment possible, and certainly to the freest of God's blessings, fresh and untainted air. To make them breathe the sickening garbage odors would certainly be a cruelty, and a mean string tied to our humanity."

It has been the aim of an increasing number of public-spirited persons in Boston to raise the standard of the institution at Long Island to a level of efficiency and usefulness in accordance with its importance to the city. To this end hospital methods have been introduced, far greater attention has been paid to the

needs of the sick than ever before, and a creditable hospital for chronic disease has by degrees been established. It is now proposed to interfere with this good work by the erection of buildings which will more and more, as the city grows, stamp the island as an undesirable place of residence for the variously afflicted who are forced to take refuge there, and so indirectly but none the less surely hamper the development of the institution as a whole. This inevitable consequence we believe the city government does not desire, and we can hardly think that it will on mature consideration consent to so short-sighted a policy as the proposed plan implies. There is certainly not room on Long Island for a city garbage plant and a city almshouse and hospital. If the garbage plant is established there it cannot be many years before the almshouse and hospital will have to seek another location. If, on the other hand, the present institution is allowed to remain in possession, there is offered a possibility of growth and usefulness, which only those who have closely followed its development during the past few years can fully appreciate. We are, therefore, in entire accord with the vigorous protest against this location of the garbage plant recently urged upon the mayor by the Board of Pauper Institutions Trustees, which we publish in full in another column. Were no other location possible we should withhold judgment, but under the existing circumstances, we can see no possible excuse for the deliberate establishment of a public nuisance on an island already being developed for other purposes and in close proximity to various other institutions which would suffer hardly less than the residents of Long Island itself.

THE PROPOSED CHANGE IN THE CONTROL AND MANAGEMENT OF BELLEVUE HOSPITAL.

IN our last issue we referred briefly to the proposed revision of the charter of the city of New York as affecting Bellevue and its allied hospitals, the management of which it is proposed should be taken from the Department of Public Charities, in which it is at present vested, and given to a board of trustees, seven in number, with a term of office of seven years, to be appointed by the mayor. The charter further provides that the terms of these trustees shall be so arranged that one member of the board shall go off each year; that each year the mayor shall appoint a new member of the board; that no member of the board of trustees shall receive any pecuniary compensation for his services, or be interested directly or indirectly in any contract relating to the hospital, or hold any office or other position of emolument under the county, State or national government except the office of notary public or commissioner of deeds, or that of an officer in the National Guards, and that the commissioner of public charities is to be *ex officio* a member of the board.

It is said that those who were interested and instru-

mental in these proposed changes were much influenced by a study of the conditions which obtain at the city hospitals of Boston and Cincinnati, these hospitals being regarded by them as models of their kind and bearing well comparison with private hospitals in any of our cities, being run as business institutions on business principles.

In other large cities where the city hospitals are a part of a city department—generally the department of public charities—they are too apt to be considered as belonging to the party in power and to form an important share of the party patronage. An interested observer calls attention in the *New York Sun* to the fact that in both Boston and Cincinnati Democrats have been appointed trustees by Republican mayors, and Republicans have been appointed trustees by Democratic mayors; and furthermore emphasizes the statement that in Boston the Board of Trustees of the City Hospital went at one time for fourteen years without change; that one member of the board has held office for twenty-four years, and another for sixteen years, and that the superintendent has held office for twenty-one years.

The experience of Boston certainly justifies the expectation that Bellevue would have much, very much, to gain by the adoption of these provisions of the proposed charter; at the same time it should not be forgotten that even with the full responsibility for appointments resting on the mayor, and without the temptation of spoils or direct emolument, a constant vigilance on the part of those interested in good hospital administration cannot be dispensed with. The force of this seems to have been realized by those who revised the New York charter in their suggestion of certain advisory organizations which shall be consulted by the mayor before making his appointments to the board of trustees.

THE THIRD PAN-AMERICAN MEDICAL CONGRESS.

Too late to withdraw our editorial note last week concerning the Pan-American Medical Congress, a notice was received from the secretary, announcing a change of date for the meeting.

At a meeting of the International Executive Committee, held on December 4th, in Washington, at the office of Surgeon-General Wyman, of the Marine Hospital Service, notice was received from Dr. Santos Fernandez, president of the Third Pan-American Medical Congress, saying that it had been postponed until February 4th. The reason for this was on account of the yellow fever which has been existing in Havana during the last two months, and of which, although it has nearly subsided, there are still a few cases.

This, together with the fact that the meeting was about to take place during the Christmas holidays, had led a number of delegates who had desired to attend to write asking if it could not be postponed.

It may be said that although there will doubtless be a larger attendance in February, the success of the meeting was assured, even if it had taken place during Christmas week, as over a hundred papers have already been prepared, and between two hundred and three hundred delegates had signified their intention of being present from this country. The exact date for the congress will be communicated as soon as decided upon.

PERIPHERAL NEURITIS DUE TO ARSENIC IN BEER.

THE appearance of an epidemic of peripheral neuritis in Manchester, Eng., has led to certain interesting and important facts regarding etiology, which have a general application. It appears, as reported in the *British Medical Journal*, that the affected persons were found on investigation to be habitual beer drinkers, and it was furthermore noted that the type of symptoms corresponded more closely to effects produced by arsenic than by alcohol. Chemical analysis of various samples of beer showed that they contained arsenic. It furthermore appeared that the cheaper beer used by the persons afflicted with neuritis was manufactured by the use of so-called commercial sulphuric acid, which has been demonstrated to be highly contaminated with arsenic. The fact, therefore, seems very probable, though not absolutely proved, that the arsenic contained in this rather inferior beer was sufficient to produce a very decided general outbreak of neuritis. The cases showed a somewhat unusual symptomatology, which is explained on the ground that the alcohol menstruum, in which the arsenic was ingested, may have played a part in the production of the final result. The *British Medical Journal* raises the further question of the possible contamination of many other articles of food with arsenic. It is at any rate certain that small amounts of arsenic taken over a considerable period of time may produce very marked disturbances, against which it is well to be forewarned and forearmed.

MEDICAL NOTES.

SAMUEL D. GROSS PRIZE. — As announced in detail in another column, this large prize, \$1,000, has not been awarded this year, because no sufficiently worthy essay was presented. No doubt the standard set is high, but it remains a noteworthy fact that so tempting a money offer should not call forth earnest competition of distinguished merit. That this has not been the case forces the conclusion, which we have before several times expressed, that the offer of a prize is not the best means of stimulating scientific research.

BRITISH CONGRESS OF TUBERCULOSIS. — The British Congress of Tuberculosis will be opened in

London, July 22, 1901, by the Prince of Wales. In May, 1899, a German Congress on Tuberculosis was held in Berlin, under the patronage of the Empress of Germany and the presidency of the Duke of Ratibon and Professor von Leyden. This congress was so great a success that it was thought an English congress of similar aims would serve a useful purpose.

GINSENG. — The inhabitants of China, generally estimated at 400,000,000 people, are said to value ginseng root as a panacea for nearly all human ailments, and there seem to be some North Americans who consider this form of commerce likely to be more profitable than that in cotton cloth, and who propose to devote themselves to supplying this precious medicine in desired quantities.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, December 12, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 165, scarlatina 36, measles 12, typhoid fever 20.

BOSTON MORTALITY REPORT. — The number of deaths reported to the Board of Health for the week ending December 8th was 202, as against 207 the corresponding week last year, showing a decrease of 5 deaths, and making the death rate for the week 18.79. The deaths from consumption were 28, pneumonia 20, heart disease 28. The number of children who died under five years was 48; deaths in public institutions 73.

THE PROPOSED GARBAGE PLANT ON LONG ISLAND, BOSTON HARBOR; A PROTEST. — We quote the following protest, sent by the Board of Pauper Institutions Trustees, to the mayor relative to the proposed garbage plant on Long Island: "We, the undersigned, members of the Board of Pauper Institutions Trustees, having in charge the pauper institutions of the city of Boston, would respectfully call your attention to the fact that a proposition has been made to the effect that a garbage plant for the city should be established at Long Island Head, on the westerly portion of Long Island. Believing that it is our duty to set forth the evils which we are confident would result from the establishment of such a plant, we would also call your attention to the fact that there is at Long Island a hospital population of between 200 and 300 persons, to whom the presence of such a plant might be distinctly detrimental. It is to be remembered also that there are at Long Island a number of feeble and infirm persons, not hospital inmates, but who, by reason of their age and infirmity, are confined to the infirmary wards of the institution, and who are, to all intents and purposes, sick people. For all such persons, the necessity of pure and uncontaminated air is great, and on their behalf, and especially on behalf of the hospital patients, it is most strongly urged

that no such use as that contemplated shall be made of Long Island Head, or any portion of the island. The plan as proposed would bring a garbage plant within three-quarters of a mile of the pauper institutions, on an island where there are at present between 600 and 700 persons, of whom a large proportion are hospital patients, and it is believed that the injury to this department of the city would be irreparable. We trust that this remonstrance may meet with your favorable consideration, and may aid in determining the City Council to reject any such proposition as the one now before it."

DIPHTHERIA IN WAKEFIELD, MASS. — It has been voted to close the Warren School and the High School in Wakefield until further notice, on account of several cases of diphtheria which have broken out among the pupils. Fifteen or 18 cases have been reported during the past few weeks. Precautions are being taken to prevent the spread of the disease.

REPORT ON STATE HYGIENE, NEW HAMPSHIRE. — Dr. Granville P. Conn, president of the New Hampshire State Board of Health, draws attention in his report to various matters relative to public hygiene, the more important of which are the sanitary conditions of railway stations, the question of good roads, public lands and tuberculosis.

DR. S. H. DURGIN ADDRESSES NEW JERSEY SANITARIANS. — Dr. Samuel H. Durgin, the chairman of the Boston Board of Health, addressed the New Jersey Sanitary Association last week at Lakewood, on the subject, "Shall Regulations Relating to the Construction of Buildings be Extended to Include Piping for Gas and Water Supplies?"

ENLARGEMENT OF WALTHAM, MASS., HOSPITAL. — The Waltham Board of Aldermen has voted to give to the trustees of the Waltham Hospital 15,000 square feet of land from Mt. Feake Cemetery, which adjoins the hospital land. The hospital authorities have under consideration plans for enlarging the institution.

A HOSPITAL FOR PLYMOUTH, MASS. — It is reported that Eben D. Jordan, of Boston, has offered to build a hospital and present it to the town of Plymouth. Such an institution is needed, and it is expected that the offer will be accepted by the authorities.

CAUSE OF TYPHOID FEVER IN WALTHAM, MASS. — An investigation in Waltham by the State Board of Health is said to indicate that the outbreak of typhoid fever in that city was due to infected milk. The investigation is not yet complete.

NEW YORK.

AN IMPORTANT DECISION REGARDING DAMAGES AGAINST THE STATE. — Justice Gaynor, in the Supreme Court, Brooklyn, on December 3d, gave an important opinion in regard to suits for damages against the State and its subdivisions. This was rendered in

denying a motion for a new trial in the suit for \$20,000 damages brought by the widow of a lineman in the employ of the New York Fire Department who was killed by the breaking of a pole upon which he was at work. The justice, in his decision, said: "The negligence charged is that the defendant failed to have the pole inspected. Even so, the plaintiff cannot recover. It may not be easy in the conflict and variation of decisions in this State to state the principles of this, but it is settled by authority that the State cannot be sued, without its consent, for any negligence or omission of its officials, or liability created by them. And the rule that sovereignty cannot be sued in its own court prevents counties and towns in the State from being sued, for they are only subdivisions of the State government. They can be sued only in such cases when it is expressly permitted by statute. This is the common law, as we get it from England."

A MEMORIAL TO DR. HENRY D. NOYES. — The medical staff of the New York Eye and Ear Infirmary has issued a memorial in recognition of the services rendered to that institution by the late Dr. Henry D. Noyes, who, as assistant surgeon, surgeon and executive surgeon, was on the staff of the infirmary from 1859 to 1898, a period of thirty-six years. During these years the growth of the institution was marked. In 1859 there were 4,178 new dispensary patients and 144 in the wards, while the corresponding figures last year were 47,684 and 2,257. In 1859 it was simply an eye infirmary; now there are three departments, one each for the eye, ear and throat. To Dr. Noyes's efforts is due in no small degree the well-ordered hospital of today, with its isolated cataract wards, pavilion for contagious ophthalmia, training school for nurses, school for the instruction of graduates in medicine, medical library and annual issues of volumes of scientific transactions.

GRADUATION OF COLORED NURSES. — At the Academy of Medicine on December 7th the graduating exercises of the Colored Home and Hospital Training School for Nurses were held, and six young colored women received diplomas. The address to the graduates was made by Dr. Stephen Smith, who mentioned the fact that the course of training through which they had passed was exceptionally thorough. This was an event of unusual interest, as it was the first time that there has been regularly graduated a class of colored nurses in the Northern States. In the South there are two schools for the training of negro nurses, but even they are of comparatively recent foundation. The Colored Home and Hospital, which has existed under various names for sixty years, was removed to new and commodious quarters in the Borough of the Bronx two years ago, and it was at this time that its training school was organized.

SMALLPOX. — Cases of smallpox continue to be reported, but are growing less numerous. On December 4th there were 10 patients suffering from the disease in the Health Department's Hospital on North

Brother Island, 2 deaths had occurred, and 2 new cases were discovered in the infected district on the West Side. Among the precautions taken to prevent its spread has been the closing of the public schools and various other schools in the neighborhood of the locality of the outbreak. It is likely to be some time before the disease is entirely stamped out, as cases have recently been reported in widely separated sections of the city, and also in the neighboring towns of Hoboken, Perth Amboy and Montclair. One additional death has occurred within the past week. Naturally, the outbreak has given a great impetus to the matter of vaccination, and this will be of invaluable service in the way of protection in the future.

PREVENTION OF SMALLPOX AT SING SING; PREVALENCE OF TYPHOID. — With a view to the prevention of the possible introduction of smallpox into Sing Sing Prison the warden has issued an order prohibiting visitors to the convicts and also the reception of packages by the latter, while all incoming mail matter is to be fumigated. While these precautions have been taken against a possible invasion of smallpox, another serious disease has actually broken out in the prison. Up to December 9th there were 19 cases of typhoid fever, all of which had developed within the preceding week. The newspapers report that the outbreak is supposed to be due to Croton water, which is supplied to the institution from the old New York City aqueduct; but it seems highly probable that a careful investigation will show some other origin for the disease.

BATHS FOR THE POOR. — In the fifty-seventh annual report of the New York Association for Improving the Condition of the Poor, just issued, special attention is called to the work of the society in providing baths for the indigent. Commissioner Kearney, it is stated, asked for an appropriation of \$52,000 to maintain the new city bath, in Rivington Street, during the year 1901, and has been allowed \$35,000 for that purpose. At the People's Baths, provided by the association, 131,000 baths were taken during the year. The operating expenses were \$5,775, and the receipts \$6,203; leaving a credit balance of \$428. The charge is five cents, including towel and individual piece of soap.

GOLF AND GOATS. — The Richmond branch of the Health Department, at the instance of members of the Harbor Golf Club, on Staten Island, has caused summonses to be issued for a number of goat owners to appear in court and explain why they are violating the sanitary code by keeping goats without a license. It is claimed by the golfers that the goats from a settlement of Italians near the club, familiarly known as Goatville, frequent the links and frighten the women players, while in several instances the animals have been seen to chase the balls and swallow them. The Health Department is involved, it is said, on the ground that gutta-percha is not good for the goats.

PRIVATE BUILDING AT THE NEW YORK HOSPITAL. — A new private patients' building in connection with the New York Hospital was thrown open on December 5th, when a reception was held in it by the Board of Governors. It occupies the site of the old Thorne mansion on 16th Street, which was formerly used for the library of the hospital, and is ten stories in height, with two separately equipped operating rooms on the upper floor. At the rear of the building, and detached from it, is an isolating department, which has its own independent heating and ventilating system.

A CENTENARIAN. — Mrs. Hannah Rosenthal died in New York on December 6th, in her one hundred and fourth year. Her age is recorded at the Health Department as one hundred and three years, eleven months and six days. Mrs. Rosenthal was born in Berlin, and came of a family noted for its longevity, both her father and his brother having been centenarians.

A DEATH FROM HYDROPHOBIA. — On December 6th there was a death from hydrophobia at St. Vincent's Hospital. The patient was ill only two days, and came from Hastings-upon-Hudson, where he was bitten about three months ago by his own St. Bernard dog, which was afterwards shot by a policeman. He had not taken the Pasteur treatment.

FREE TUITION FOR FILIPINOS. — At a meeting of the Trustees of Columbia University, held December 3d, it was decided to offer, through the United States Government, to five Filipinos free tuition in any department of the university except the Medical School.

Miscellanea.

THE STRANGE ADVENTURES OF AN ANATOMIST'S HEAD.

XAVIER BICHAT passed a considerable part of his short life in the dead house, but his own mortal remains appear to have had a more singular fate than usually befalls the fragments of humanity in which he sought so eagerly to discover the secret of life. Writing recently in the *Temps*, M. G. Clarétie says it is well known that when Cuvier was put into his coffin an iron cage was placed over his head so that it might not be stolen as Bichat's had been. A writer in the *Chronique Médicale*, commenting on this statement, says that in 1808 there came in a curious fashion of doing honor to "masters of medicine" by keeping their heads in the condition of anatomical preparations for forty years. Bichat was buried in the St. Catharine Cemetery, in a small corner bought by one of his colleagues at the Hôtel Dieu, and might never have been found if the pious care of friends had not from time to time renewed the marks by which the grave was identified. The cemetery having been closed, Bichat's remains were removed to Père Lachaise. On November 16, 1845, the body was

examined under the direction of Dr. Denonvilliers, and in the presence of four members of Bichat's family, one of whom was Dr. Adet de Roseville, assistant physician of Saint Lazare, husband of Bichat's niece. The report of the exhumation states that, under a gravestone bearing the inscription, "À Xavier Bichat, par les Membres de la Société d'Instruction Médicale," there was discovered, at a depth of 1 metre and 70 centimetres, in a soil of remarkable dryness, an excellently preserved skeleton. The cervical vertebra were perfect, but the head was missing. Further digging failed to bring the head to light. Professor Roux, who was present, came forward and stated that the head of Bichat had "come into his hands" three years after the death of the great anatomist. He described the head, calling attention to the following points: (1) The existence of a fracture of the occipital bone, which he himself had made at the post-mortem examination; (2) the obliteration of the alveoli of the first upper molar of the left side and of the corresponding one on the right, which Bichat had had extracted towards the end of his life, after having suffered much from those teeth, as he says himself in his article on the teeth in his "Anatomie Générale"; (3) the perfect correspondence of the articular surfaces of the atlas found in the grave with those on the skull. M. Malgaigne had previously arranged in an oak coffin all the bones as they were taken up, and M. Roux completed them by restoring with his own hands the skull which had been so long separated from the skeleton. It may be mentioned that the ceremony of the translation of the relics to Père Lachaise was attended by some 4,000 members of the medical profession. — *British Medical Journal*.

THE OPERATIVE TREATMENT OF TUBERCULOUS PERITONITIS.

In a paper contributed to the Eleventh Series of the Boston City Hospital Reports, Dr. John T. Bottomley reports and analyzes 28 cases of tuberculous peritonitis treated by operation. After careful discussion of the literature of the subject, and of these cases from the hospital services, Dr. Bottomley reaches the following conclusions:

It seems only prudent to wait at least a year before reporting cases as cured. The fact that this has not been done may account in part for the great variation in the percentage of reported recoveries.

Of this series of 28 cases, 11 recovered and an equal number died—a percentage of 39.3. Two cases (7.1%) improved, and 4 (14.3%) could not be traced. Of the 19 cases of the ascitic type, 8 (42%) recovered, 7 died, 1 improved and 3 were not traced. Three (42.8%) of the 7 fibrous cases recovered, 3 died and 1 improved. Of the 2 ulcerated cases, 1 died and 1 could not be traced. By most writers the ascitic form is said to give the highest percentage of recoveries following operation; but in this series operation was equally successful in both the ascitic and fibrous type. The prognosis in the ulcerative variety is always bad.

Of the many other treatments for tuberculous peritonitis, of the many theories as to why laparotomy often cures the trouble, nothing will be said. It may be noted in passing that tapping was tried in 6 of

these cases; in each case the fluid reaccumulated in a very few days.

The importance of early operation, as far as prognosis is concerned, is probably not great. The average time from the onset of the symptoms to the time of the operation in this series is practically the same in the fatal cases as in those that recovered. The comfort of the patient is, of course, to be considered.

To summarize briefly: (1) We may reasonably expect cures (one year or more after operation) in from 30 to 40% of all cases. Fatal cases usually die within a few months after operation. (2) Family history does not appear to be important etiologically. Previous inflammatory affections of the abdominal viscera may have etiologic significance. (3) Operation usually affords at least temporary improvement either locally or generally, even in cases that later prove fatal. The use of drainage should be avoided, when possible. (4) Inferences as to the remote results of operation should be drawn very guardedly, if at all, from the immediate results; though in cases which do not immediately receive from an operation either local or general benefit, the prognosis is very unfavorable.

INFLUENCES OF DIGESTION ON ANIMAL HEAT PROCESSES.

In a contribution from the Physiological Laboratory of the University of Pennsylvania, in the *American Journal of Physiology*, December 1, 1900, Dr. Edward T. Reichert reaches the following conclusions in regard to "digestion fever": (1) That the rise of temperature observed during the period of digestion is due to an increase of heat production; (2) that the temperature gradually rises and reaches a maximum during the fourth hour, or possibly later; (3) that the greatest increase of heat production occurs during the first hour after feeding; (4) that the changes in temperature and heat production are not proportional; (5) that the most marked effects, as a whole, are observed when the diet consists of proteid and fat, next with proteid, and least with fat; (6) that the increase of heat production is not nearly so great as is indicated by the results of the oxygen experiments of Fredericq.

METEOROLOGICAL RECORD

For the week ending December 1st, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

BILLINGS, W. C. assistant surgeon. To proceed to Clarksburg, W. Va., for special temporary duty. November 24, 1900.

THORNBURY, F. J., assistant surgeon. Granted leave of absence for four days. November 23, 1900.

MOORE, DUNLOP, assistant surgeon. To proceed to Port Townsend Quarantine and report to medical officer in command for duty. November 28, 1900.

EARLE, B. H., assistant surgeon. To proceed to Columbia River Quarantine and report to medical officer in command for duty. November 28, 1900.

LONG, J. D., assistant surgeon. To proceed to Baltimore, Md., for temporary duty during absence of Assistant Surgeon BILLINGS. November 24, 1900.

LLOYD, B. J., assistant surgeon. To proceed to San Francisco Quarantine and report to medical officer in command for duty and assignment to quarters. November 28, 1900.

PIERCE, C. C., assistant surgeon. Relieved from duty at the Tortugas Quarantine Station and directed to proceed to Key West, Fla., and report to medical officer in command for temporary duty. November 27, 1900.

BAILEY, W. C., acting assistant surgeon. Granted leave of absence for three weeks from November 14th. November 23, 1900.

BROWN, F. L., hospital steward. Relieved from duty at Cape Charles Quarantine and directed to proceed to Boston, Mass., and report to the medical officer in command for duty and assignment to quarters. November 27, 1900.

PROMOTION.

L. E. COFER, assistant surgeon, commissioned as passed assistant surgeon. November 23, 1900.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold its meeting at 19 Boylston Place, Wednesday, December 19, 1900, at 8 P. M. At 8 o'clock: Dr. J. L. Goodale, "Retropharyngeal Abscess in Adults." At 8.15 o'clock: Dr. Fredk. C. Cobb, "Peritonissilar Abscess." Discussion by Drs. Farlow, Knight, Langmaid, Coolidge and Clark.

HENRY F. HEWES, M.D., Secretary.

MEDICAL SOCIETY OF THE STATE OF NEW YORK. — The ninety-fifth annual session of the society will be held in Albany, January 29, 30, 31, 1901.

Those who desire to read papers will communicate at once with the chairman of the Business Committee, Dr. Frank Van Fleet, 63 East 79th Street, New York City, or with the president, Dr. A. M. Phelps, 62 East 34th Street, giving the title of the paper and such other information as the author desires.

THE SAMUEL D. GROSS PRIZE.

ONE THOUSAND DOLLARS.

No essay which the trustees deemed worthy of the prize having been received on January 1, 1900, they hereby announce that the prize will be awarded on October 1, 1901.

The conditions annexed by the testator are that the prize "Shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the competitor who receives the prize shall publish his essay in book form and that he shall deposit one copy of the work in the Samuel D. Gross Library of the Philadelphia Academy of Surgery, and that on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery.

The essays, which must be written by a single author in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 S. 13th St., Philadelphia," on or before October 1, 1901.

Each essay must be distinguished by a motto and accompanied by a sealed envelope bearing the same motto, and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

The committee will return the unsuccessful essays if reclaimed by their respective writers, or their agents, within one year.

The committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

W. W. KEN, M.D.,
J. EWING DEARS, M.D.,
J. CHALMERS DA COSTA, M.D., } Trustees.

BOOKS AND PAMPHLETS RECEIVED.

Proceedings of the Eighth Annual Meeting of the Association of Military Surgeons of the United States, held at Kansas City, Mo., September 27, 28 and 29, 1899. Columbus, O.: The Berlin Printing Co. 1900.

Deaths reported 1,894; under five years of age 580; principal infectious diseases (smallpox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 453, acute lung diseases 273, consumption 225, diphtheria and croup 107, typhoid fever 42, diarrheal diseases 33, whooping cough 15, cerebrospinal meningitis 15, scarlet fever 8, measles 5.

From whooping cough New York 8, Baltimore, Providence, Boston, Pittsburg, Cambridge, Somerville and Clinton 1 each. From cerebrospinal meningitis New York 9, Providence, Boston, Worcester, Lowell, Gloucester and Brookline 1 each. From scarlet fever New York, Pittsburg and Boston 2 each, Worcester and Malden 1 each. From measles New York and Pittsburg 2 each, North Adams 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending November 17th, the death rate was 17.6. Deaths reported 3,917: acute diseases of the respiratory organs (London) 352, diarrhea 72, fever 71, diphtheria 70, whooping cough 62, measles 47, scarlet fever 31.

The death rates ranged from 9.5 in Norwich to 24.8 in Salford: Birmingham 18.9, Bradford 14.0, Cardiff 12.1, Derby 16.4, Hull 18.3, Leeds 19.1, Liverpool 20.5, London 17.1, Manchester 21.9, Newcastle-on-Tyne 21.6, Nottingham 18.7, Portsmouth 19.3, Sheffield 18.8, Sunderland 18.4, West Ham 13.4.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING NOVEMBER 29, 1900.

STONER, J. B., passed assistant surgeon. Bureau letter of November 20th, directing Passed Assistant Surgeon Stoner to assume temporary command of the service at Norfolk, Va., amended and directed to assume command of the service at Norfolk, relieving Passed Assistant Surgeon J. M. EAGER. November 24, 1900.

EAGER, J. M., passed assistant surgeon. Relieved from duty at the port of Norfolk, Va., to take effect November 30, 1900.

HOBDY, W. C., assistant surgeon. Granted leave of absence for seven days from November 25th. November 27, 1900.

Original Articles.

REMARKS UPON QUESTIONS ARISING DURING THE REMOVAL OF FIBROIDS, WITH ESPECIAL REFERENCE TO THE TECHNIQUE OF THE OPERATION.¹

BY MAURICE H. RICHARDSON, M.D., BOSTON.

My subject may seem one about which so much has already been written that there is nothing further to be said. There is one reason, however, for the present communication which seems to me sufficient, namely, that the dangers inseparable from the operation for fibroids are grave or slight according to the methods used in performing it.

Before advising so serious an operation as hysterectomy careful examinations should be made as to the urine and the amount passed in twenty-four hours.

In tumors which threaten life one must often proceed to operate even when the amount of urine is dangerously insufficient, or when there is definite evidence that the kidneys are not perfectly normal. In hopeless and advanced renal diseases, however, it is unjustifiable to perform so severe an operation as extirpation of the uterus. In fibroids which do not threaten life—which justify hysterectomy, though they do not demand it—trivial changes in the quantity and amount of urine should receive careful consideration. Such changes should always suggest at least a postponement of operation until they have disappeared, or until it is apparent that they are secondary to the tumor, and that its removal is essential for their disappearance. In most fibroids it is possible to wait for this favorable period of intervention. In some it is not; the patient must run the risks of operation at an unfavorable time.

One cannot see a large number of abdominal cases without being impressed by the difficulties of palpation upon the conscious patient. Tumors which apparently were easily perceptible and well defined often present, when the abdominal walls are relaxed by thorough anesthesia, characteristics entirely different—so different, indeed, that one's previous estimate of the case, as to diagnosis, prognosis and indications, is entirely upset. An acute diffused tumor, for example, filling the right iliac fossa in suspected appendicitis often is resolved into the small and definitely outlined mass of an enlarged appendix. Smooth tumors, apparently fibroids, evidently connected with the uterus, may under anesthesia assume characteristics which suggest even more strongly an enlarged and inflamed tube, a tense solid ovarian tumor, or even an extra-uterine pregnancy. Neglect to examine under ether as a preliminary procedure has led me into several unnecessary operations, and into at least one costly error.

The importance of preliminary examination under complete anesthesia seems to me therefore great. Not that it is always essential, for in some cases as complete an examination of the pelvic viscera is possible without ether as with it. But even in such cases it is important to make a pelvic examination at the time of operation, for the reason that renewed examination may present new features; it may present old ones in a new light, or even the entire absence of features previously found. The importance of such

preliminary examination cannot be too strongly emphasized. The "ether examination," so called, may be made some days or weeks before the operation; even then a second should be made at the time of intervention. Too often one will find that changes which he can hardly believe possible will have taken place between the two examinations. The chief objection to the early preliminary anesthesia is in the occasional demoralization of the patient, and in the not infrequent disagreeable effects of the ether itself.

I could mention several examples of the errors into which I have fallen by neglect of the rule to examine vaginally just before opening the abdomen, and that, too, in apparently simple cases. Fortunately all the cases in themselves required operation.

The surgeon should never take the responsibility of operating upon the advice of another; he should himself concur or not concur in the diagnosis, for he himself has to bear the whole responsibility. The previous examiner, though experienced and skilful, may have made a hasty examination; he may have been drawn by preconceived ideas into a false opinion; he may not have used an anesthetic; he may have been entirely wrong. I have learned to take no man's opinion without a careful, unbiased history and examination of my own. On the other hand, I do not wish another to take my diagnosis without making his own investigation. A boy was once operated upon for appendicitis on the strength of my diagnosis, which was acute appendicitis. He had a pneumonia and later a pleurisy, with marked abdominal symptoms. I have several times operated for extra-uterine pregnancy on the advice of skilled examiners. Once I found a normal pregnancy, and once a tumor on the opposite side from that in which the tumor had been detected. At another time I operated for a fibroid and found a normal pregnancy. In all these cases, however, I had examined carefully under ether and concurred in the diagnosis.

The chief objection to vaginal examination just before opening the abdomen lies in the danger of carrying sepsis upon the examining fingers. This danger, considerable though it may be in careless and hasty sterilization of the hands, is completely obviated by thorough methods; it is absolutely prevented when—the vaginal examination having been made with gloved hands—fresh sterilized gloves are substituted after fresh sterilization of the hands.

From many observations in cases of my own, and from many in the hands of my colleagues, I have become convinced that the risks of the operation are minimized by the careful following of a certain technique. These dangers are, chiefly, owing to sepsis and to faulty dissection. The dangers of sepsis inseparable from every operation, no matter how rigid the precautions, may be greatly increased by faulty dissection. Faulty dissection adds the danger of wounded bowel, bladder and ureter to those of hemorrhage. An ideal hysterectomy is one in which all these dangers are reduced to a minimum.

Time as an element in hysterectomy is important in so far as it is reduced to a minimum consistent with careful and intelligent dissection. Time bears a similar relation to the dissection of pelvic viscera that it does to the removal of a tumor from the subclavian triangle, for instance, except that prolonged exposure of the peritoneal cavity is a more serious matter

¹ Read before the Obstetrical Society of Boston, October 16, 1900.

than prolonged exposure of the tissues of the deep neck. He would be a rash operator—not to say a careless one—who should dissect the subclavian triangle with the speed that made a clear recognition of structures impossible. Yet he would be an incompetent one, perhaps, who would waste time in a tardy recognition of the phrenic nerve, or even of the subclavian vein.

It is too often true that the operator uses caution in beginning his dissection when rapidity is safe, and ends it with rapidity when caution is essential. The truth is that he gets tired by the time that he should work carefully. Beginning with short and painstaking strokes of the knife, he ends with long and careless ones. In abdominal surgery the time for rapid work is in exposing the field; the time for caution is in dissecting the depths of it.

In hysterectomy, whether abdominal or vaginal, speed is permissible everywhere except in the dissection about the cervix, for in uncomplicated cases no harm can be done by the most rapid methods. As soon as the broad ligaments below the ovaries are secured, no step should be taken without exact knowledge of what is being done. In this way, and in this way only, can the uterus be removed without the mistake of wounding bladder, bowel or ureters.

To remove the uterus in absolute safety as regards these structures requires, by the method herein described, from fifteen to thirty minutes; to close the peritoneum over the stump of the uterus, and to finish the operation, from fifteen to thirty minutes more. This makes the operation from half an hour to an hour in duration. In some instances the time is, by unusually facile dissection, somewhat reduced; in others somewhat prolonged. When the operation is in progress, and when it is completed, I am absolutely sure that no harm has been done other than that inseparable from the operation itself.

In complicated cases, when, for example, the uterus is adherent to everything about it, when the tubes are inflamed and adherent, additional care must be used; free and rapid steps are impossible at any stage of the operation. Incision through the abdominal wall itself must be slow and painstaking to avoid wounding an intestine or a misplaced bladder, or rupturing too early an abscess cavity. In these cases the anatomy of the parts is frequently so obscured that it is only with extreme care and difficulty that no harm is done, and the time of operation is thus unavoidably prolonged.

In uterine tumors, especially those of large extent situated near the cervix, the normal anatomy is sometimes excessively distorted. A tumor in the cervical region may grow beneath the ureter and push it high into the lateral and upper aspects of the mass. A tumor starting in front of the uterus and becoming adherent to the bladder may, in years of growth, project slowly backward and to one side, and drag with it the bladder into an unexpected and apparently impossible position. In very rare cases a ureter may become obstructed and even obliterated among the changed tissues about the cervix. Fortunately the enlargement of uterine tumors generally pushes both bladder and ureters away from operative dangers rather than toward them. The occasional occurrence of the converse, however, should always put the operator on his guard.

The displacement and non-recognition of the bowel is much less frequent and therefore less important.

The intestine should always be easy of recognition and of avoidance; yet occasionally, in complicated cases, failure to recognize and to avoid the bowel leads to costly errors.

In the exposure of the uterus the median incision through the linea alba or the lateral one through the fibres of the rectus may be used. I prefer and use the linea alba, for it is a space without blood vessels, and incision through it is therefore bloodless. The prevention of hernia is in no way ensured, in my opinion, by the lateral cut. In cutting through the peritoneum the greatest care must be taken, even in the simplest cases, for the tumor may prove to be not what it seems; it may have caused perplexing changes in both parietal and visceral peritoneum; it may have distorted bladder and intestine, and too bold and rapid cutting may open one or both.

In large uterine fibroids of slow growth, attacks of peritonitis may cause early adhesions to intestinal coils, which have thereby been displaced by the enlarging mass into positions of easy wounding.

The tumor itself may not be uterine: it may be an old abscess with thick and firm walls, or one whose anterior wall is the abdominal wall, and the first sign of which may be its unexpected and untimely rupture. The mass may prove to be one of the many varieties of ovarian tumor; it may be a salpingitis or an extra-uterine pregnancy—lesions which should be approached and unmasked with caution.

Whether uterine or not, the tumor may be covered by intestine flattened out over it. The bladder may be much higher over the tumor than one would think possible, even from extensive previous experience. Obscure pelvic tumors simulating uterine may prove to be tubercular masses to which the peritoneum is so closely adherent that free incision opens at once the intestine. It is a good rule to proceed with extreme caution whenever anything in the gross appearance of the peritoneum suggests the abnormal. A bladder wall will then be avoided as well as an adherent bowel. In certain rare instances excessively thin peritoneum will lie over distended intestine and be indistinguishable from it. So transparent is the peritoneum that it will have been cut through before the surgeon is aware of the fact. The intestine projecting into the wound may have precisely the appearance of parietal peritoneum. Such an intestine may be incised even when extreme care is used—it is almost sure to be when the cut is hastily made. The combination of transparent peritoneum and pale intestine is fortunately rare. Error will always be avoided by pushing the finger or a blunt instrument into the doubtful area. If the peritoneum has been incised, the finger or instrument will push by the intestine into the peritoneal cavity, and demonstrate at once the situation of things. This precaution seems worth mentioning because I, for one, have been very nearly deceived into opening the gut, and at a time when, perfectly sure that I was cutting parietal peritoneum, I was really cutting intestine. Such an error, especially liable to occur in changed conditions of the peritoneum, must be guarded against in the simplest cases. Not that incision into the bowel adds much to the danger—though the unavoidable escape of gas and fecal matter cannot but add something to it—but it delays further proceedings until the cut is repaired, and it is humiliating to the last degree. I have known an operator to go through the abdominal wall, intestine, and into

the tumor in one cut, and I have known several instances in which the peritoneal cavity has been opened by the first stroke of the knife. In such cases it is a matter of luck and not of skill that serious injury is not done and that the success of further procedure is not compromised.

It is a good plan to make in the first place a cut just large enough to admit one finger, for things may be found that will contraindicate further measures, and obviate the disadvantages of a larger incision. This cut should next be enlarged enough to admit the hand, by means of which the whole abdominal cavity may be thoroughly explored. In most cases this exploration will be negative, but in some it will prevent a worse than useless operation. Such conditions are, for example, hopeless malignancy of the tumor itself, metastases, contiguous infiltrations, and remote tumors too extensively and intimately adherent to permit removal. Independent and hopeless diseases of other viscera are extremely unusual, for the previous study of the case should have been too thorough to overlook the effective contraindication to operation which slight disturbances in other organs justify. In obscure tumors of the pelvis, and especially in malignant disease, the contraindications must be very strong to justify the giving up of further steps.

No contraindication having been found by exploration with the whole hand, the incision should be enlarged until there is abundant room for a clear view of the field. Such a cut must extend from the pubes to the umbilicus, and in very large tumors even higher. No greater mistake can be made than the dissection of a uterus through an incision too small for a clear view. I have found Doyen's pubic self-retaining retractor of great assistance. With this and a retractor on each side the whole lower abdomen may be inspected and examined with the greatest ease and satisfaction.

The tumor itself should be first examined, especially as to its nature and the difficulties of its removal. If malignant, with infiltrations into viscera that cannot be themselves excised, further procedure must depend upon questions of relief rather than of cure. In fibroids it is rather a question of extent and operability, for in some instances the tumors will present difficulties of such magnitude that removal will be too dangerous to be justifiable. Under such circumstances the lesser evil should be chosen, and the patient should be allowed to live with her tumor, uncomfortable and dangerous though it may be, rather than subjected to an operation so severe as to give but slight chance of recovery.

I recall several tumors of this class, in some of which I have proceeded to extirpation, in others to abandonment of the operation. I have been influenced in my decision by the wishes of the patient as expressed before operation. In one case I was begged to proceed at any cost; in another to undertake nothing desperate. It seems clear to me that the patient should be advised to make the choice under all circumstances, and especially in the case of tumors which — no matter what they may ultimately become — are at the time of operation discomforts rather than dangers.

The duty of the surgeon seems quite different when, in addition to the discomforts of the tumor, there is found evidence of pressure upon the ureters and beginning changes in the kidneys, both easily perceptible to the examining hand. In such cases the operation

should be continued, even at great risk, for with increased pressure the changes in the kidneys, perhaps just beginning, cannot but progress to a fatal termination. It is well, therefore, as a preliminary step, to palpate both kidneys, and to examine the ureters at the most accessible point.

In a recent case I found both ureters distended — the right to a considerable, the left to an extreme degree. The renal pelvis were themselves dilated correspondingly. The obstruction was found near the cervix. That involving the right ureter was a calcification of a semi-solid ovarian cyst which complicated a uterine fibroid; that of the left a deviated and thickened cervix uteri. The right ureter ended apparently in the calcareous mass, from which it was dissected free enough to permit its insertion into the bladder. The left ureter was relieved by amputation of the uterus low down upon the cervix. In this case the tumor was sessile and everywhere adherent below the plane of the true pelvis. The question of possible removal arose, and it was decided to go on, in spite of the formidable difficulties of separation. The tumor involved the sigmoid flexure, and removal left a gap in it. It was impossible in this case to ascertain the true condition of things until the dissection had been carried too far for retreat. It was fortunate that the difficulties were not known, for they would have been prohibitory. They were successfully overcome, however, and the patient has made a brilliant convalescence. Early recognition of the hydronephrotic kidneys would perhaps have justified abandonment of the operation on the ground of hopelessness, for it would have seemed too much to impose upon a patient with double hydronephrosis the dangers of a formidable dissection.

In uterine fibroids it is important to ascertain the situation of the fundus and the cervix, in order that the possibility of saving the uterus may be considered. Careful examination of the tumor after hysterectomy has shown in several cases that it would have been feasible to remove the tumor without sacrificing the uterus — a most desirable procedure, especially in the young.

The rules for guidance in deciding between hysterectomy and myomectomy depend upon many things, chief among which are age, likelihood of marriage and childbearing — conditions which make conservation of uterus and ovaries desirable. The general condition of the patient must be considered, as well as conditions of heart, lungs and kidneys — conditions perhaps requiring that procedure which is quickest and least bloodless; or conditions, on the other hand, permitting leisurely and painstaking dissections. The one characteristic of the fibroid itself which indicates myomectomy is facility of removal. A fibroid with small pedicle should always be removed from the uterus; so should small subperitoneal fibroids, especially those which are hard and bloodless. Large, hard fibroids which bulge from the uterus, even if they are not pediculated, are often easy of separation. They present pale masses, smooth and rounded, over which numerous flattened veins ramify. Such fibroids do not bleed when incised; moreover, the veins over them bleed but little, the hemorrhage soon subsiding after enucleation of the tumor. Many fibroids which lie deep in the uterine wall, even subserous ones, present features of hardness and mobility which strongly indicate easy enucleation. When the indications favor

enucleation, the possibility can be settled almost with the first stroke of the knife, for an easily separated tumor projects into the incision as soon as its capsule is cut. Brief attempts at separation with finger or blunt instrument will show at once the feasibility of extirpation. The operator will proceed to extirpation or to hysterectomy in accordance with the information thus gained. If, with incision, hemorrhage is excessive, and from numerous points and difficult of control, not ceasing or diminishing as the tumor is uncovered,—if this difficulty increases rather than diminishes as the depths of the tumor are reached,—it may become necessary to abandon enucleation, and to remove the uterus and all. Exploration of the tumor in this way takes little time; it adds little to the risk, for it is undertaken only in those cases in which the patient is in good general condition.

A contraindication to myomectomy lies in the presence of many small fibroids, some of which are difficult if not impossible of removal. It is obviously unwise to remove one or two large tumors and to leave several small ones. Even if all that can be felt are removed, it by no means follows that some too small for detection do not remain. This argument against myomectomy is not sufficient to contraindicate the operation when the desirability of saving the uterus is great—for it does not follow that the fibroid, if any is left, will ever grow, or that growing, it will ever cause symptoms; moreover, if it does grow and cause symptoms, years will probably elapse before a second operation becomes necessary, if indeed it ever does.

In examining the uterus to determine the feasibility of myomectomy, the region of the cervix must not be overlooked, for not infrequently a fibroid will be found there which may be the chief cause of the symptoms.

From the experience thus far gained, I should say that when in doubt it is better to perform a hysterectomy than to attempt a myomectomy. Yet with renewed experience it may prove that the uterus has been sacrificed more often than was really necessary.

Deep pelvic examinations, besides demonstrating the presence of tumors at or near the cervix uteri, will show whether there are adhesions, inflammatory masses, cervical or incarcerated portions of the tumor. One of the dangers in the forcible delivery of abdominal tumors is tearing the rectum or other pelvic structures—an accident which may happen when the pelvic portions of the tumor are firmly adherent to surrounding parts. One should examine carefully the ovaries and tubes. I have in several instances been surprised to find that the masses which I supposed to be fibroids were tense ovarian cysts or solid tumors, dilated and tense tubes, or even extra-uterine pregnancies.

In myomectomies the incision should be carried well down upon the fibroid; otherwise the separation will be carried through uterine tissues so difficult of separation that a false impression will be given as to feasibility of enucleation. The actual substance of the fibroid must be reached, and this will be easy of recognition. I grasp the presenting mass with double hooks, and often am able to deliver and separate it by traction alone. At times tumors of great size can be torn out of their beds with the greatest ease; if not torn out, dissected with a few strokes of the knife. The hemorrhage comes usually from the edges of the incision, where it may be easily controlled. Occa-

sionally it comes from the loose tissues of its matrix, where it can be easily checked by ligation. When there are several fibroids I usually pack with gauze the spaces left after removal. When all have been enucleated, the wounds in the uterus are closed by inverting their edges and suturing in the interrupted Lembert fashion. If blood fills the spaces, it is confined there until it has been absorbed. I have never seen any unpleasant results from this method. Even when the tumors have been large, or have been taken from the submucous spaces of the depths of a large uterus, no evil has followed.

In hysterectomies, as well as in myomectomies, it is desirable that the field be bloodless. First, because loss of blood adds greatly to the shock of operation; secondly, because blood is a very inviting medium for infection; and, finally, because a bloody field encourages slovenly methods.

It is impossible to make myomectomies bloodless, for the blood vessels cannot be secured before the incision is closed. The enucleation of some tumors will be practically bloodless. The incision exposing others—particularly the soft, vascular and rapidly growing ones—will often cause formidable bleeding, and, in fact, demand immediate ligation of the uterine arteries and removal of the uterus.

Removal of the uterus with the fibroids may be, in the majority of cases, absolutely bloodless if the following technique is carefully followed. Occasionally, in spite of the greatest care, the operation will be marked by a bloody, slovenly field. The cause of unavoidable hemorrhage lies in the situation of those numerous large veins which surround the tumor and inosculate freely with the venous plexuses of the broad ligament. These veins are flattened out over the tumor, where they cannot be grasped by pressure forceps, and where attempts at ligation only cause fresh bleeding. In such cases oozing continues until the uterine arteries are tied.

When it has been determined that no deep adhesions or other complications prevent the forcible delivery of uterus and tumor, the fundus may be grasped between the hands or by some especially adapted instrument. The corkscrew has one disadvantage in that it may penetrate the uterine cavity, the contents from which, with the oozing blood, may contaminate the peritoneum. Another disadvantage is in the impossibility of rotating the tumor about its longitudinal axis—a very desirable manipulation while working upon the structures about the cervix. Instead of the corkscrew, therefore, I use a pair of very large specially constructed double-hooked forceps, with broad grasping areas. These forceps are carefully applied, including between their teeth, perhaps, two or three inches of the presenting summit, whether tumor or uterus. When the fundus uteri presents, it is usually possible to tell whether the hooks will be likely to penetrate and tear the uterine cavity. If the uterine wall is thin, the hooks should be superficially inserted. I usually apply them so that they grasp the fundus or the tumor anteroposteriorly. When applied to friable tumors they often tear the tissues and cause oozing. It is best to seize such tumors as a whole rather than their summits. The hooks should be applied in vascular tumors in such a way that the venous plexuses will not be torn open. The handles are firmly closed and held by a ratchet or tied together by means of a strip of gauze. Very considerable control may thus

be exerted over the tumor: it may be forcibly drawn from the pelvis in any direction; it may at the same time be rotated so as to bring to the operator, standing, say, on the patient's left, the anterior cervical region, the posterior, and, in very long pedicles, even the opposite side.

The minute details of dissecting and removing uterus and tumor are of great importance in carrying out a bloodless and safe operation — one which gives no post-operative anxiety as to bladder, intestines, and especially ureters. The method which I have used for many years, and the one which I think all practical anatomists would naturally adopt, is one of clean dissection, beginning at the summit of the broad ligament and ending with the amputation of the cervix, or with its separation from its vaginal attachments. Every step that is taken, every cut that is made, is in regions and through tissues that are seen and recognized. Not a single blind step is taken from beginning to end. The first step is the passage of a ligature, by means of the Cleveland needle, between the left ovary and the uterus, through an area of the broad ligament translucent and free from veins. This ligature tied checks hemorrhage from the uterine side. If the ovary is to be removed, the next ligature is passed outside the ovary and fimbriated extremity of the tube through a translucent space in the broad ligament. The third ligature passes through the openings made by the second and first, and is tied below the ovary. Ligation of the ovary in one ligature is dangerous because the ligature, after the ovary and tube have been cut away, is near the apex of a truncated cone, and often allows the slippery peritoneum to escape before the operation is completed.

The next ligatures are placed about the round ligament far enough apart to cut safely between them. The left ovary and tube are now hanging from the left side of the summit of the tumor, which can now be lifted considerably above its former position, until the deeper regions of the left broad ligament are accessible. The knife is now used to make an anterior flap, the incision being carried through peritoneum as far as the reflexion of the right broad ligament. A similar flap is made posteriorly. The anterior flap will be dissected with ease, being loosely connected with the uterus; the posterior with difficulty, being intimately adherent to the back of the cervix. The cut may be freely made through peritoneum without injuring the veins lying upon the tumor, if one is skilled in making such cuts. If not, careful dissecting is essential, for the subjacent veins lie flattened upon the hard surface of uterus or tumor, and can be controlled only by the slow process of passing a ligature under them — a manœuvre which is quite as likely to increase the hemorrhage as to check it.

In making the flaps and in dissecting the deeper regions of the broad ligament the assistant intelligently rotates the tumor with his double-hooked forceps, at the same time drawing it upward and toward the right. The uterus with its tumors is now rapidly dissected through the loose tissues of the left broad ligament until the cervix is reached. The exact position of the vaginal attachment should be ascertained, for we may be in close proximity to the ureter, and it is therefore important to know the level upon which we are working.

With the uterus pulled upward and to the right, there will appear the blood vessels running verti-

cally, the uterine artery being surrounded and buried up in plexuses of veins. Its position can be found by its pulsation. It may be necessary, however, to relax the traction to feel them. I uncover the uterine artery by dissecting the veins away from it. The artery is so intimately connected with its surrounding veins, and both artery and vein are so firmly bound together by unusually dense and strong connective tissue, that isolation by blunt instruments almost always tears open the venous plexuses and causes abundant hemorrhage. When the artery has been satisfactorily isolated from the vein, a fine silk ligature is passed under it and tied. No other ligature is applied. The ureter, being the most important structure in this region, is sought for and exposed, that it may not be injured; but only in case the dissection is being carried into evident proximity with it. In most cases the isolation of the uterine artery is the lowest point reached, and the amputation of the cervix is so much above the point of ligation that no anxiety need be felt for the ureter. The left half of the dissection is now complete. A large piece of gauze is now placed in the region just dissected, and the uterus and tumor are drawn toward the left. Any oozing or renewed bleeding is controlled by pressure of the uterus upon this gauze. The operator and assistant now change places, and the right side is dissected precisely like the left. The uterus now remains attached only by its cervix. Returning to the left, the pelvic gauzes are removed and large fresh ones substituted all about the cervix. A single gauze is placed just behind and below the cervix, where it is proposed to make the amputation.

The Paquelin cautery is used to cut through the cervix. The cut is made low enough to go through healthy uterine tissue. It begins on the left side, well above the ligation of the uterine artery, and is carried across the cervical canal to the right side. The canal itself is carefully seared above and below. Frequently fluids will run down from the uterine cavity; these must be met and destroyed before leaving the canal. The remaining portion of the cervix is then divided, and finally the veins and ligated artery of the right broad ligament. Just before the uterus is separated, an assistant grasps the anterior half of the stump of the uterus with small vulsellum hooks, and draws it up into view. Any bleeding points are grasped with pressure forceps. The single pad placed behind the cervix to catch the discharges from the uterus is now removed and a fresh one substituted. The stump is carefully inspected and all its bleeding points tied. The cervix is sewed up anteroposteriorly by means of interrupted silk ligatures. Over the stump the peritoneum is drawn, inverted, and closed by continuous silk sutures of the Lembert style.

Before the cervix is sewed over, it is wiped with gauze wrung out of corrosive sublimate solution 1-1,000. The completed peritoneal suture is wiped with gauze wrung out of corrosive sublimate 1-5,000. When the operation is completed, nothing remains but a short transverse line of peritoneum marked by a running silk thread.

Since seeing Doyen use the angiotribe I have tried to save time by it, applying the instrument where I have used temporary ligatures to prevent bleeding. I found that the great veins of the tumor, though crushed together, began to bleed when disturbed by subsequent manipulations. Its use to make a sulcus

of crushed tissue for the more efficient application of the ligature I have tried and abandoned.

When it is decided to remove the cervix greater care is essential for the preservation of the ureters. After ligation of the uterine artery, the cervix is dissected toward the vagina, the dissection being carried close to the uterine tissues when the cervix is benign, and as far from it as possible when the cervix is malignant. The ureters need not be exposed when the dissection hugs the cervix unless the operator is in doubt. When in doubt, or when dissecting far from the cervix, the ureter should be sought by careful dissection with blunt instruments between the cervix and the sacro-iliac synchondrosis. If it cannot be found elsewhere, it can be found as it passes over the iliac vessels and followed down to the desired point. At the cervix the ureter lies in loose tissues and its isolation is easy. Indeed, its easy displacement is the very characteristic which makes blind grasping and cutting so dangerous in hysterectomies.

When the posterior flap has been carried well down behind the cervix, the posterior lip is grasped with forceps and drawn upward and backward, making tense the retro-uterine fold. The vagina, previously sterilized, is now opened. The vaginal attachments are divided with scissors close to the cervix on all sides. As soon as the separation between the cervix and the vagina is complete, the uterus is easily torn from the remaining loose connective tissue, and the operation is completed by inverting the peritoneal flaps over the gaping vagina.

The operation of hysterectomy seems to me one of the most gratifying and satisfactory in surgery. When it is performed anatomically — when every step is taken in full recognition of the anatomical structures involved — no harm can be done. When carried out in darkness, with blind grasping and cutting, no operation is so likely to lead to costly and irreparable blunders. It is perhaps natural for me to emphasize the anatomical features of this operation. Indeed, anatomists are said to be timid — but when the dissector is timid it is time to be timid. The time to be cautious is when caution is needed. A hysterectomy performed in the full light of day, with sigmoid flexure, bladder, rectum, ureters, arteries and veins conspicuously shown in their relations to the uterus, is an operation followed by no harassing fears that the ureters may have been tied or cut, that feces may be escaping into the abdominal cavity, that the bladder may have been included in a ligature or a suture. On the contrary, the surgeon feels that no avoidable harm has been done, that the patient will run only the risks incident to the removal of the uterus itself, and that her chances of recovery are at least 95 per cent.

maintaining in the blood, on account of imperfect functional activity of the eliminative organs.

Renal insufficiency is doubtless chiefly responsible for the gradual accumulation of toxic products in the blood. But every obstetrician has seen serious cases of eclampsia, in which renal activity was but slightly impaired, and, indeed, fatal cases in which autopsy revealed little or no pathological change in the kidney. Indeed, it must not be overlooked, that the lungs, liver, skin, and bowels have important eliminative functions, and that imperfect action of one or more of these organs must often play an effective contributory part in the development of eclampsia. It is also to be remembered that the condition of the nervous system must be taken into account in all considerations of the etiology of eclampsia. To be sure, nervous systems of equal strength and stability react differently to similar irritations; but it is rational to believe that a nervous system depressed by malnutrition and anemia, by overwork, by the frequently observed dependency in those illegitimately pregnant, and in those who have an abnormal dread and fear of labor — or a nervous system rendered unstable by insufficient or disturbed sleep, undue excitement or inadequate mental repose, is more liable to the eclamptic seizure under a given toxemia, than a nervous system well nourished, well rested, well balanced, and not unduly subjected to the worriments, annoyances, and excitements of daily life.

It is perhaps superfluous to repeat the generally accepted dictum that prevention of disease is the greatest function of medical science. But when it is remembered that eclampsia is probably the most serious, and in these days, under whatever treatment, the most fatal, complication of pregnancy and parturition, it behooves the student and practiser of medicine to realize that the symptom-complex known as puerperal eclampsia is to a large degree a preventable disease.

Intelligent and successful prophylaxis of eclampsia presupposes an opportunity for the observation of pregnancy from the early months. It presupposes that the observer will exercise an intelligent supervision over the daily life and general health of the gravida: that he will not content himself with an occasional test for albuminuria, but will assure himself that the skin, bowels, and liver are performing their functions, that the lungs, unhampered by undue compression by tight clothing, are supplied with pure air, and that the nutrition is adjusted to the increased demands of fetal development, with a view to preventing undue impairment of the maternal well being. He will satisfy himself that the kidney is eliminating a proper percentage of urea, and, when necessary, will so regulate the use of highly nitrogenous food that this important organ will not be unduly taxed. He will bestow especial attention upon the condition of the gravida's nervous system, enjoining freedom from needless excitement, worriment, and mental perturbation, quieting groundless fears, and ensuring undisturbed and adequate sleep and mental repose. It is unfortunately true that adequate supervision of pregnancy is not always possible; but it is also true that except in the lowest social strata it generally would be possible, were its importance fully appreciated. Nor is it to be supposed that proper supervision of the pregnant entails, as a rule, either a large expenditure of time on the part of the physician or burdensome pecuniary expense to the patient: under

THE VALUE OF THE HOT-WATER IMMERSION BATH IN THE TREATMENT OF THREATENING PUERPERAL ECLAMPSIA.¹

BY CHARLES M. GREEN, M.D., BOSTON.

ALTHOUGH the etiology of puerperal eclampsia is not, as yet, fully known, it is undoubtedly true that the group of symptoms leading up to the eclamptic seizure must be attributed to the ultimate, toxic effect on the nervous system of excrementitious products re-

¹ Read before the Obstetrical Society of Boston, October 16, 1900.

ordinary circumstances, an occasional visit enables the physician to teach his patient how to live under the new conditions in which she finds herself, and to correct by appropriate advice and treatment any departure from normal, physiological function.

But it is not my purpose, in this brief paper, to discuss the etiology or the prophylaxis of puerperal eclampsia; but rather to call attention to the value of a therapeutic expedient in the presence of threatening symptoms, which seems not to have been fully appreciated.

The general principles on which, in the writer's opinion, threatening eclampsia should be treated have already been indicated in his remarks on prophylaxis. When symptoms indicative of toxemia appear, the patient should be put to bed, and mental and physical rest secured. If necessary, sodic bromide, chloral hydrate, or other nerve sedatives should be employed to ensure a stable equilibrium to the nervous system. Meanwhile vigorous measures must be adopted to relieve the blood of accumulated toxins. If, as is generally the case, the kidney is chiefly at fault, whether from simple hyperemia or actual parenchymatous nephritis, the diet must be such as to throw a minimum of work on the disabled organ: experience has shown that an exclusive milk diet is the best, until a decided amelioration of symptoms makes a cautiously enlarged dietary advisable. Then, increased functional activity of the other eliminative organs must be invoked, to relieve the overburdened kidney: it is seldom wise to give other than the mildest diuretics, such as water and bitartrate, or acetate, of potassium. In some cases the old Basham's mixture has been found very serviceable, and in some, small doses of digitalis may be advantageously employed. The lungs to perform their full function must be supplied with pure air. To stimulate the action of the liver and bowels, croton oil, elaterium, calomel, or simple salines are most commonly used, according to the urgency of symptoms. Increased function of the skin may be induced by diaphoretic drugs, or by the external stimulation of dry or moist heat. Pilocarpine has been largely used to meet this indication; but experience has shown this drug to be at times not only inefficient in its action on the skin, but disastrous in its effects on the lung. Nitroglycerin has been used with admirable results: by its action on the capillaries more blood is brought to the surface and the sweat glands thereby stimulated to increased activity; and incidentally blood tension is lowered and the heart's action relieved.

Cutaneous stimulation by heat may be effected by the hot-air bath, by the hot wet pack, or by hot-water immersion. In the writer's judgment the hot-air bath is most appropriately used in the treatment of actual eclampsia, and then chiefly because the patient is often comatose and unable to help herself: under most circumstances, certainly in most private practice, it is impracticable to use hot-water immersion baths, when the patient is comatose, for want of adequate assistance. The hot wet pack is often successful in its results; but when circumstances permit its use the hot-water immersion bath, in my opinion, more satisfactorily meets the indications. Not only does it produce profuse diaphoresis and reduce blood tension, but it acts, as is well known, as a marked sedative to the nervous system. This bath is easily administered to a conscious patient, the aid of a single assistant being

sufficient: few houses today, even among those in humble circumstances, are without a bath tub. The water should be as hot as can be borne, and the patient should remain therein until profuse perspiration of the face shows that the sweat glands are in full activity. If the heart's action is at all weak, it is wise to administer brandy before immersion. When, as often seen in hospital practice, the skin is obviously dirty, its activity, and cleanliness as well, may be promoted by the friction of a flesh brush. When free perspiration has been induced, the patient should be rolled in a blanket, placed in a warm bed and covered with several blankets and perhaps a rubber sheet. In this use of the hot-water bath it should be remembered, however, that it is a powerful agent in the induction of labor, and should not be employed unless the termination of pregnancy seems indicated, or at least warrantable. To be sure, the free use of chloral may prevent this common effect of the hot bath; but the inhibitory action of chloral cannot be depended upon, and the use of the hot-water bath is therefore inadvisable prior to fetal viability or shortly thereafter, except in the presence of urgent symptoms not otherwise relieved. It should also be remembered that when free diaphoresis is employed, there should be an ample ingestion of liquids. In the comatose patient in actual eclampsia normal salt solution, by hypodermic or rectal injection, or intravenous infusion, meets the indication. But in threatening eclampsia the patient is able to drink freely and thus supply the needed volume of fluids.

As an illustration of the writer's experience with the hot-water bath, in the treatment of threatening eclampsia, the following cases are quoted from the records of the Boston Lying-in Hospital. I am indebted to Dr. J. S. Stone, a former house officer, for the notes:

CASE I. A primigravida, seven months advanced, aged twenty-four, entered with the following history: For several months she had suffered with headaches, and for two months there had been edema of the feet. Five weeks previously she had vomited considerably, had several "fainting spells," and had been slightly incoherent, although never losing consciousness. There had been marked muscular twitching, particularly when startled. After a few days she had got better, and so remained until two days before entrance. At that time she had severe headaches, chills, "fainting spells," and the same muscular twitchings as before. There was no loss of consciousness. For several days there had been increased edema of the extremities. The day before entrance only about a half pint of almost black urine was passed. Her diet had been limited to beef tea, milk, and brandy. Morphine had been given subcutaneously. Throughout the day of entrance there had been severe headache, nausea, and vomiting.

On entrance the patient was conscious, the skin was hot and dry, the face and hands puffy, with marked edema of feet and ankles, — the pulse 84, of high tension. The uterus extended two-fifths of the distance from the umbilicus to the ensiform. The fetal heart was 156. Labor had not begun. The urine was slightly smoky, containing $\frac{1}{4}\%$ of albumin. The sediment contained many granular, epithelial, and fatty casts, with considerable uric acid and many leucocytes.

The patient was immediately placed in a hot tub-bath, and when sweating freely was put to bed surrounded by heaters and blankets. She was given elaterium, $\frac{1}{8}$ grain, chloral, 20 grains, and sodic bromide, 30 grains, together with potassic acetate, 20 grains, every four hours. The diet was restricted to milk and lime water. She soon sweated well, and remained comfortable until labor began at the end of twelve hours. Then the headache increased, and the skin became hot and dry. As labor progressed the patient became very noisy and restless, in spite of further doses of chloral. After eleven hours of labor, she was delivered naturally of a 3½ pound baby, which lived for sixteen hours. After delivery she remained restless, at times becoming drowsy, and roused only with difficulty. Pilocarpine, $\frac{1}{4}$ grain, was given subcutaneously with good effect. Next day the urine still contained $\frac{1}{2}\%$ of albumin, and was slightly smoky, though the amount was increasing, and the patient was now sweating well. On the second day she was much brighter, sweating freely. The amount of urine had increased to over 24 ounces, and contained but $\frac{1}{8}\%$ of albumin.

The convalescence was rapid and normal. On the fourth day she was allowed soup, bread, and gruel. Two weeks after delivery she was discharged well, except that there was still $\frac{1}{10}\%$ of albumin in the urine, which now varied in quantity between 50 and 75 ounces.

CASE II. A primigravida, aged eighteen, a little over eight months advanced, entered with this history: Throughout the day she had suffered severe epigastric pain, which extended up into the shoulders, and down the arms, being marked about the elbows. There was some headache. Nothing suggested digestive disturbance. Similar pain had occurred a week previously, lasting a day. For a fortnight micturition had been frequent, and the amount of urine small.

The patient on entrance was writhing with almost constant epigastric pain; she was pale, the skin hot and dry, the pulse of rather a high tension. Labor had not begun, although the head was low. The urine was found to be smoky, containing over $\frac{1}{2}\%$ of albumin. She was put to bed, surrounded with heaters and blankets, and an ice cap was applied to the head. She was given potassic acetate, 15 grains every two hours (later to be reduced to half that amount), potassic bromide and chloral, which were vomited, and two $\frac{1}{8}$ -grain doses of elaterium. For several hours the condition was threatening: she was restless, tossing from side to side, with head and eyes aching, epigastric pain severe, pulse of high tension, skin hot and dry. Finally, however, she dropped off to sleep for three hours, sweating freely, and waking much better. During the night there were passed 8 ounces of very dark, smoky urine containing much blood and many hyaline and fine granular casts. The amount of urine passed during the first twenty-four hours was 30 ounces, containing about 180 grains of urea.

For eight days the diet was limited strictly to milk. The acetate was continued, and cream of tartar water, cracked ice, and water were given *ad libitum*. Bromide and chloral were given occasionally, although during labor chloral was used freely. Pilocarpine was given subcutaneously once at the end of twenty-four hours. The bowels were kept open with ela-

terium. Drugs were not pushed, however, after the least nausea appeared.

For several days the patient slept but lightly, frequently waking with a quick start, and twitching the muscles during sleep. Improvement was rapid, however; at the end of a week the daily amount of urine was about 80 ounces, containing about 400 grains of urea and only $\frac{1}{8}\%$ of albumin. With this improvement the diet was increased cautiously. On the ninth day gruel was allowed, on the tenth soup, on the twelfth toast and crackers. With these slight additions, however, the amount of albumin in the urine increased to from $\frac{1}{8}\%$ to $\frac{1}{4}\%$, while the daily amount of urine decreased to about 40 ounces, and the amount of urea to about 250 grains. Together with these unfavorable changes in the urine, there was slightly increasing headache. There had been, after a fortnight, occasional labor pains which had just begun to dilate the os.

On the seventeenth day it was deemed unwise to temporize longer, and the patient, after taking $\frac{1}{2}$ ounce of brandy, was put into as hot a bath as she could stand, until perspiration started freely, in the hope that labor might be hastened. From the bath she was immediately put back into the hot bed. In a few hours the occasional, spasmodic pains became more regular and more severe, although later they gradually diminished in spite of repeated hot vaginal douches. Next day the bath was repeated, the pains thereafter again starting up, and the os dilating to the size of a half dollar. On the twentieth day the pains were coming regularly, but lacked strength: the os was easily stretched without ether to the size of a dollar, and later to half the full dilatation, the membranes meantime having ruptured. When the os was three-fourths dilated the patient began to show signs of exhaustion, together with increasing headache: she was therefore etherized and delivered with forceps without incident. After delivery the amount of urine began to increase and the albumin to diminish. In two days the patient was given gruel, broths, and bread: at that time the albumin was but $\frac{1}{10}\%$, and the amount of urine was 120 ounces.

Despite the starvation she had undergone, the patient made a rapid convalescence, and was discharged well two weeks after delivery. The baby at birth was thin and scrawny, but gradually began to gain.

CASE III. A primipara, aged twenty-four, entered the hospital with this history: About a month before, she had caught cold, and had had a cough ever since. During the same time there had also been headaches, worse in the morning, and accompanied by nausea on rising. For a week past the headaches had been worse and there had been dizziness on rising: there had been no vomiting since the early months. There had been edema of the hands, face, and feet, first appearing in the feet a month before. The edema had subsided slightly within a few days before entrance, and the urine had increased in amount. There had been no epigastric pain. For several days she had walked a good deal, and on reaching home the afternoon before entrance she became very dizzy and her eyes were blurred. Headache had markedly increased during the afternoon, and she had had several dizzy spells.

On entrance there was marked edema of feet and ankles, slight of the hands. The skin was hot and

dry. The pulse was 69, of not particularly high tension. The patient was so dizzy that she had to be supported by a nurse. Labor had just begun, the cervix being partly taken up, and the os admitted one finger. The urine was smoky, and contained over $\frac{1}{2}\%$ of albumin. The sediment, which was considerable, contained many hyaline, fine granular, and epithelial casts, together with some blood, pus, and large round cells: there were only $2\frac{1}{2}$ grains of urea to the ounce of urine.

After taking $\frac{1}{2}$ ounce of brandy, the patient was given a hot-water bath, and when free perspiration had started was put to bed, and surrounded with heaters and blankets: an ice cap was applied to the head. She was given 45 grains of chloral in three doses. Labor progressed rapidly, and was finished in six hours. Throughout labor the patient sweated profusely, and great care was taken to avoid exposure. She was given 20 grains of potassic acetate every four hours, and a tumblerful of cream-of-tartar water every six hours.

After delivery the headache subsided, the edema rapidly disappeared, the amount of albumin diminished, and the urine increased greatly in amount, reaching 100 ounces on the third day, and containing but a trace of albumin. Drugs were then omitted. The diet, which had been limited to milk, was increased by adding soup, bread, and gruel. The next day the edema was gone, and house diet was allowed; but two days later meats were prohibited, since the amount of albumin had increased to $\frac{1}{8}\%$. Two weeks after delivery mother and baby were discharged well, there being no albuminuria.

A PLEA FOR LARGER DOSES OF ANTITOXIN IN THE TREATMENT OF DIPHTHERIA.¹

BY JOHN H. MCCOLLOM, M.D., BOSTON.

SINCE 1878, when a report of each case of diphtheria was required by the Board of Health, Boston has suffered more than any other of the large American cities from the inroads of this disease. During this time, particularly from 1878 to 1894, a comparison made with some of the foreign cities is not favorable to Boston. The actual number of deaths each year from diphtheria has varied from 817 in 1894 to 170 in 1898. The percentage of mortality to the number of cases in the city at large has ranged from 35.7 in 1881 to 9.76 in 1899. Some of this diminution in the mortality percentage may be explained by the fact that by means of a bacteriological examination, many cases are recognized that otherwise would escape detection, but this does not explain the continuous and marked diminution in the death rate of diphtheria in the past five years in Boston. A study of the ratio of mortality from any given cause per 10,000 of the living is a much more satisfactory manner of arriving at a definite conclusion regarding the benefits to be derived from any particular line of treatment. The ratio of mortality of diphtheria in Boston per 10,000 of the living from 1893 to 1899 has been compared with that of five European and five American cities. Chart A shows the ratio of deaths from diphtheria per 10,000 of the living in Boston, London, Liverpool, Glasgow, Paris and Berlin from 1893 to 1899, inclusive. It will be seen from

this chart that in 1893 and 1894 Boston had the highest death rate of any of these cities. Chart B shows the ratio of mortality from diphtheria in five American cities taken for comparison with Boston, namely, New York, Philadelphia, Brooklyn, Chicago and St. Louis. It will be seen from this chart that in none of the other American cities has there been the marked and continuous diminution that has occurred in Boston. This reduction commenced in 1895, in the latter half of which year the South Department was opened and antitoxin was given to each and every patient at the hospital ill with diphtheria. A diminution from 48 per 10,000 to 4.99 in five years cannot be attributed to good fortune, nor to the mild types of the disease. This diminution can only be explained by the use of antitoxin and treatment in hospital. It must be borne in mind that previous to 1895 only about 10% of the reported cases were treated in hospital, while in 1896, 1897, 1898 and 1899, about 50% had hospital treat-

CHART A. Ratio of deaths from diphtheria, per 10,000 of the living, in Boston, London, Liverpool, Glasgow, Paris and Berlin, from 1893 to 1899, inclusive.

ment. In none of the five American cities taken for comparison has the percentage of reported cases treated in hospital been so large as in Boston. In London the percentage of cases of diphtheria treated in hospital was, in 1898, 56.88; while in Boston for the same year it was 50. In Glasgow, in 1898, 60% of the reported cases of diphtheria were treated in hospital.

The fact is evident to the intelligent observer that diphtheria in Boston has been extremely prevalent, and that it has been a very important factor in increasing the death rate. If the number of cases of the disease occurring in Glasgow during 1898, for example, is compared with that in Boston for 1899, it will be seen that in Glasgow, with a population of 724,349, there were 433 cases reported, giving a ratio of morbidity per 10,000 of 5.9, while in Boston, with a population of 550,057, there were 2,836 cases reported, the ratio of morbidity being 51. The ratio

¹ Contributed to the Boston City Hospital Reports, Eleventh Series.

of morbidity per 10,000 for London for 1898 was 25.62. In New York City (Boroughs of Manhattan and Bronx) for 1898 and 1899, it was 37.06 and 38.77 respectively. The morbidity ratio per 10,000 in Boston has fallen from 81 in 1895 to 51 in 1899. A comparison of the morbidity ratios previous to 1894 with those of the succeeding years cannot be made, as there were no general bacteriological examinations previous to 1894. Chart C shows the ratio of morbidity in Boston per 10,000 of the living for five years, 1895 to 1899, inclusive. It will be seen from this chart that there has been a reduction in the morbidity ratio of diphtheria since the opening of a special hospital for the treatment of this disease. For instance, compare 1895, an epidemic year, with a ratio of morbidity of 81, a ratio of mortality per 10,000 of 11.73, and a percentage of mortality to the number of cases of 14.48, with 1899, also an epidemic year, with a ratio of morbidity of 51, a ratio of mortality per

time 7,657 patients were treated, the percentage of mortality was 12.9. It must be borne in mind that these were all cases of diphtheria, both from a clinical and from a bacteriological point of view. The death rate of diphtheria in young children has always been very high, as high as 76%. Elderly people generally succumb to the disease. A comparison of mortality rates in the Asylums' Board Hospitals in the years 1888 to 1894, during which time 11,598 patients were treated without antitoxin, and the same hospitals from 1895 to 1898, when 20,382 patients were treated with antitoxin, with that of the South Department from August 31, 1895, to August 31, 1900, when 7,657 patients were treated with antitoxin in large doses, may be of interest. The death rate in the London hospitals before antitoxin was used was 30.3; in the same hospitals with antitoxin, 18.4; while that of the South Department was 12.9. Chart D shows the per cent. of mortality, by age, of diphtheria in the Asylums' Board Hospitals, London, before antitoxin was generally used; the percentage of mortality in the same hospitals from 1895 to 1898, when antitoxin was generally used, and the mortality percentage from diphtheria in the South Department for five years, when antitoxin was given to each patient ill with diphtheria. A study of this chart shows that in the London hospitals, before antitoxin was used, the mortality percentage in children under one year of age was 61.8; that in the London hospitals, when antitoxin was used, the rate was 38%; that in the South Department the rate was 34.6%. In children from one to five years the percentage in the London hospitals before antitoxin was 49.33; that in the London hospitals, when antitoxin was used, it was 26.83; at the South Department the rate was 17.8%. From five to ten years the percentage was 28.1 before antitoxin, 16.3 with antitoxin; 8.1 at the South Department. It is of interest to note that the rate in patients from five to ten years of age at the South Department is lower by one-half than in the London hospitals. In the other ages the difference is not so marked, but in each instance the rate of the South Department is lower than that of the London hospitals. Lest it should be said that a large number of cases is compared with a smaller number of cases to the manifest advantage of the latter, Chart E has been prepared, which gives the percentage of mortality by age for one year in the following hospitals, namely, South Department, Boston City Hospital; Municipal Hospital, Philadelphia; Belvidere Hospital, Glasgow, and Asylums' Board Hospitals, London. By following the full black line, it will be seen that the rate at the South Department is generally lower than that of the other hospitals taken for comparison. For instance, compare the hospital in Philadelphia with a percentage of mortality of 63 in children under one year of age with that of the South Department with a percentage of 26. There is also a marked diminution in children from one to five years of age in favor of the South Department. In the epoch of life from fifteen to twenty-five years the difference between the percentage of mortality in the Glasgow hospital as compared with the Boston hospitals is very marked. It is a very significant fact that in 1899 the cases of diphtheria were of an extremely virulent type, and, therefore, that much larger doses of antitoxin were required than in some of the previous years, and yet

CHART B. Ratio of deaths from diphtheria, per 10,000 of the living, in Boston, New York, Philadelphia, Brooklyn, Chicago and St. Louis, from 1893 to 1899, inclusive.

10,000 of the living of 4.99, and a case percentage of mortality of 9.76.

Before the advent of antitoxin the death rate of diphtheria varied from 30% to 50%. In the table prepared by Lennox Browne in his work on diphtheria the per cent. in 11,598 cases treated in the Asylums' Board Hospitals, London, from 1888 to 1894, inclusive, was 30.3. In the Boston City Hospital the rate previous to 1895 was 46%. Other hospitals give mortality rates of 40% and 50%. In Bayeux's comprehensive work on diphtheria the death rate is given as 55% before antitoxin and 16% since the advent of this agent. The rate of 16% is based upon an analysis of more than 200,000 cases. Bayeux in his work also makes the statement that not a single death has been scientifically demonstrated to be due to the use of the serum. In the five years that the South Department has been in operation, August 31, 1895, to August 31, 1900, during which

the death rate was lower generally than in any of the hospitals taken for comparison.

It is generally conceded that laryngeal diphtheria is a very serious disease, and that in operative cases, intubation and tracheotomy, the death rate is very high, being in pre-antitoxin days from 75% to 87%. Since antitoxin has been in use, the death rate has fallen very materially. In 313 cases of tracheotomy in the Asylums' Board Hospitals of London, the percentage was 38. In the Belvidere Fever Hospital, Glasgow, the operative cases for the year ending May 31, 1899, had a percentage of 41.9. In the Willard Parker Hospital, New York City, according to Dr. W. H. Park, there were 737 cases of intubation treated from 1895 to February, 1900, with a per cent. of mortality of 63. In the last two years the rate was 52%. In the Municipal Hospital of Philadelphia, the rate in 165 cases was 58.78%. At the South Department during 1899, there were 192 intubation cases treated, the percentage of mortality being 34, as compared with a percentage of mortality of 46 in 1898. This reduction must be attributed to the large doses of serum given in the severer cases when there was an indication that the membrane was extending into the bronchi.

It has been shown by the foregoing figures that the ratio of mortality of diphtheria per 10,000 of the living has been diminished in a marked degree in Boston since the introduction of antitoxin; that there has also been a marked reduction in the mortality per cent. in the operative cases since larger doses of the healing serum have been given. No hard and firm rule can be made regarding the use of the serum; the agent must be given until the characteristic effect is produced on the diphtheritic membrane; in some cases 4,000 units will accomplish this, in other instances 60,000 or 70,000 units may be required. When a guinea pig is inoculated at the laboratory with a certain definite amount of the toxin of diphtheria it is a very easy matter to antagonize this with a certain amount of antitoxin. In the case of a patient ill with diphtheria there is no way of estimating the quantity of toxin generated by the membrane, and therefore one must administer the agent until the characteristic effect is produced, namely, the shrivelling of the membrane; the diminution of the nasal discharge; the correction of the fetid odor, and a general improvement in the condition of the patient. In the operative cases the beneficial effect of large doses of antitoxin has been marked, preventing, in many instances, the extension of membrane to the smaller ramifications of the bronchi; a most important factor in raising the death rate in this class of cases. In the operative cases it is safe to say that nearly 20% of the deaths was caused by blocking of the bronchi with diphtheritic membrane. At the South Department the autopsies proved this fact. It was observed in pre-antitoxin days that patients in operative cases would do well for from twenty-four to forty-eight hours after the operation, and then would commence to have a limited amount of dyspnea; the temperature would rise; the tube would become clogged with a thick, tough, tenacious mucus; the physical signs in the lungs would be those of a bronchopneumonia, and the patient would succumb in a short time. This clogging of the tube with hard mucopurulent discharge is an indication of extension of membrane; a symptom of very serious import, and demands the heroic administration of antitoxin. No case of diphtheria in

the acute stage should be considered hopeless. Antitoxin should be administered in each and every instance. It has been my experience during the past few years to see so many patients apparently hopelessly ill recover that my convictions are very firm on this subject. When one sees a patient with membrane covering the tonsils and uvula; profuse sanguinous discharge from the nose; spots of ecchymosis on the body and extremities; cold, clammy hands and feet; a feeble pulse, and the nauseous odor of diphtheria, and finds that after the administration of 10,000 units of antitoxin in two doses the condition of the patient improves slightly; that after 10,000 units more have been given there is a marked abatement in the severity of the symptoms; that when an additional 10,000 units have been given the patient is apparently out of danger, and eventually recovers, one must believe in the curative power of antitoxin. When one sees a patient in whom the intubation tube has been repeatedly clogged; when the hopeless condition of the patient changes for the better after the administration

CHART C. Ratio of morbidity of diphtheria in Boston, per 10,000 of the living, for five years, 1895 to 1899, inclusive.

of 50,000 units, one cannot help but be convinced of the importance of giving large doses of antitoxin in the very severe and apparently hopeless cases. In the majority of instances these large doses are not required, particularly if the patients are seen early in the attack, 4,000 to 6,000 units being enough to produce the characteristic effect on the membrane. As illustrating the advantage of the early administration of antitoxin, an allusion to the cases of diphtheria occurring in the staff of the South Department may be of interest. There have been since September, 1895, 104 instances of diphtheria contracted in the line of duty, and not a single death. Each patient received a full dose of antitoxin, 4,000 units, at the outset, or as soon as there were any symptoms of the disease. In some instances it was not necessary to repeat the dose; in others the doses were repeated two or three times. It is of interest to note that in this series of cases there were no marked symptoms of paralysis; that heart complications did not occur, and that the duration of the illness was comparatively

short. It must be borne in mind that these were genuine cases of diphtheria, contracted under unfavorable conditions. The results obtained with cases of diphtheria injected with antitoxin by the Health Department of New York City also prove the advantage of the early administration of the serum. Dr. Park gives the following figures: Of 319 patients injected on the first day of the illness, 13 died, a mortality of 4%; 850 were injected on the second day, 57 died, a mortality of 6.7%; 573 were injected on the third day, with a mortality of 12%.

In the study of any particular line of treatment for a special disease, the clinical picture presented by patients ill with that disease is always of interest and is frequently more conclusive than a simple array of figures. A short history of a few of the extremely severe cases of diphtheria in which antitoxin was administered in large doses will be given.

CASE I. A boy, six years of age. When admitted he had been ill three days; there was a large patch of mem-

Smith, D. M. 1875-1879 — May Board 1885-1894 — May Board 1894-1898

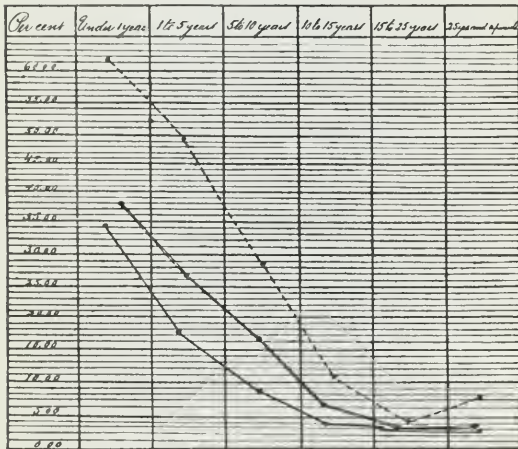

CHART D. Percentage of mortality, by age, of diphtheria in the Asylums' Board Hospitals, London, 1875-1894, antitoxin not used; in the Asylums' Board Hospitals, 1885 to 1893, antitoxin used; in the South Department, Boston City Hospital, 1895 to 1899, antitoxin used.

brane on each tonsil; the uvula was edematous; there was a profuse nasal discharge. Dyspnea was very great and there was marked cyanosis. The cultures were positive. Pulse feeble and rapid. Temperature 99.5°. There was a slight trace of albumin in the urine. He was intubated at once and given 4,000 units of antitoxin. The intubation tube not giving relief, it was removed in ten minutes, when the patient expectorated a quantity of thick, tough, tenacious mucus, and the breathing immediately became easier. On the second day after the admission the dyspnea was urgent and the boy was re-intubated with marked relief. In four days this patient had 56,000 units of antitoxin without any injurious effect and with positive relief. He was discharged well. He had none of the usual sequelæ of diphtheria. He did have a troublesome urticaria. The heart did not at any time have an irregular action; there was no indication of paralysis.

CASE II. A girl, six years old. She had been ill three days when admitted. The tonsils and uvula were covered with a thick membrane. Pulse rapid and weak. The membrane commenced to disappear in three days, but on the fourth it commenced to re-form and therefore large doses of antitoxin were given. In all, this patient received

80,000 units of antitoxin. The cervical glands suppurated. At one time during the course of the attack the action of the heart was irregular. There was a slight palatal paralysis. At one time there was a slight trace of albumin in the urine. She made a good recovery.

CASE III. A man, eighteen years old. He had been ill one week at the time of admission. There was great prostration; a profuse nasal discharge with a foul odor; there was a very extensive membrane covering the tonsils, uvula and palate. The action of the heart was feeble; the sounds indistinct. Pulse feeble. The general condition indicated speedy death. He had on entrance an initial dose of 6,000 units of antitoxin, repeated in five hours. The next day he had four doses of 6,000 units each, and on the third and fourth days, a like quantity. On the fifth day after entrance the throat was clear and the mucous membrane normal in appearance. For the first four days delirium was a marked symptom. The patient was unable to swallow any food and stimulants were given by the rectum. At one time there was a slightly nasal voice, but there was no marked paralysis. The action of the heart was regular at the time of discharge. A slight trace of albumin was found in the urine. Urticaria was an annoying complication, but not a grave one. There was no arthralgia. Brandy and strychnia were given in large doses. It is cases of this class that swell the mortality ratio of hospitals. The patient was moribund when admitted; he left the hospital well and has been well up to the present time. It is possible that the man might have recovered with a slightly diminished dose; it is certain that the usual doses of antitoxin would not have saved his life, and it is also certain that no injurious effect followed the large dose.

CASE IV. A colored boy, seven years old. On admission this patient had a very weak pulse; the heart sounds were feeble; the tonsils, uvula and hard palate were covered with a dirty necrotic membrane; there was a profuse nasal discharge; the cervical glands on the right side had sloughed; there was an intolerable odor. His condition was as unfavorable as it could well be. The boy had 84,000 units of antitoxin in five days. He was discharged well in sixty-six days. At the end of the sixth day after entrance, the condition of the patient had improved so much that no one who had not seen him on entrance would have believed that he had been so critically ill. He made a good recovery, which was somewhat delayed by post-diphtheritic paralysis. He was nourished during part of the time by the rectum. At one time during convalescence he had one-eighth of 1% of albumin in the urine. This albuminuria could not, however, be attributed to the antitoxin, as it is one of the most frequent symptoms in severe attacks of diphtheria and was recognized and described long before the days of antitoxin.

CASE V. A boy, age eight years. On entrance there was profound prostration; very extensive membrane in the throat; a marked dyspnea; feeble and irregular action of the heart. This certainly could not be called a mild attack of the disease. This patient had 56,000 units of antitoxin. He made a good recovery. He did not have paralysis. There was an eruption of urticaria of moderate severity. A slight trace of albumin was found in the urine.

CASE VI. A woman, age twenty-four years. When seen, the patient had been ill five days. There was a profuse fetid nasal discharge; extensive diphtheritic membrane in the fauces; marked prostration; a weak and irregular pulse; a dilated heart, feeble in action; the sallow hue of the skin seen in toxemia. This patient had 76,000 units of antitoxin in four days. On the fifth day after entrance the membrane had disappeared from the throat, and her general condition had very much improved. In the case of this patient, the irregular action of the heart continued for some little time. She, however, was discharged well at the end of fifty-four days. The somewhat prolonged stay in the hospital was due to the condition of the heart and a slight paralysis of the muscles of deglutition. Urticaria was not a distressing symptom in this case. Arthralgia was not present. A slight trace of albumin was

found in the urine for three or four days during the period of convalescence.

CASE VII. A girl, eleven years of age. This patient had been ill two days when admitted. Her condition was as follows: Marked prostration; profuse nasal discharge; extensive membrane on the tonsils and uvula; a strong fetid odor; the action of the heart was irregular and the sounds indistinct. In four days she received 52,000 units of antitoxin. Urticaria and arthralgia caused some considerable discomfort. No paralysis developed. The patient was discharged well in thirty-nine days. From the rapid spread of the membrane in the two days before admission to the hospital it is evident that this was an extremely virulent attack of diphtheria. The conclusion that the girl would have died if antitoxin had not been given in large doses is justifiable.

CASE VIII. A man, eighteen years of age. He had been ill three days before admission, with sore throat, headache and vomiting. When seen, there was considerable prostration; a profuse nasal discharge; marked enlargement of the cervical glands; hypertrophied tonsils covered with a thick membrane; an extremely fetid odor to the breath. The action of the heart was regular, but somewhat weak. This patient had 50,000 units of antitoxin in four days. The throat cleared in three days, but as the nasal discharge continued, two additional doses of antitoxin were given. The man made a good recovery and was discharged in thirty-five days. Urticaria and arthralgia did not cause much discomfort in this case. The patient did not have paralysis. Albuminuria was a transient symptom. In this case, if the toxin of diphtheria had not been antagonized by large doses of antitoxin, judging by experience, paralysis would have been a very prominent symptom. Six months after leaving the hospital this man was well.

CASE IX. A man, nineteen years of age. He had been ill three days when admitted. On examination, the following condition was found: Enlarged cervical glands with great tenderness; a profuse nasal discharge; tonsils greatly enlarged, meeting in the median line, and covered with thick diphtheritic membrane; uvula covered with membrane; profound prostration. Prognosis unfavorable. This patient had 90,000 units of antitoxin in five days. The throat cleared in three days; the nasal discharge diminished; the offensive odor of the breath was not so marked. The patient was discharged well in thirty days. Albuminuria was not pronounced. There were no complications of serious import due to the use of antitoxin. Urticaria and arthralgia, although present, did not cause a great amount of discomfort.

CASE X. A man, age thirty-four years. He had been ill four days when admitted. There was very extensive diphtheritic membrane on each tonsil; the uvula was covered; there was a profuse nasal discharge; the cervical glands were much enlarged; there was marked prostration; the pulse was feeble and irregular; there was some dyspnea; the voice was husky. The clinical picture he presented was that of a patient moribund from an attack of diphtheria. The condition of the man seemed absolutely hopeless, but acting on the principle that no person ill with diphtheria should be considered beyond help, 8,000 units of antitoxin were given; a second dose of 4,000 units was given in three hours and repeated every four or six hours until 92,000 units had been administered. In four days there was a marked improvement in the condition of the man. In five days the throat was clear of membrane. He made a good recovery, was discharged well in twenty-six days. He, however, had post-diphtheritic paralysis about three weeks after his discharge. Recovery from this, however, has been complete, and at the present time, one hundred and thirty days after the commencement of the attack of diphtheria, this patient is well; therefore, the statement cannot be made with truth that he has suffered any ill effects from the large dose of antitoxin.

CASE XI. A woman, whose age was forty-eight years. She had been ill five days. On entrance, the tonsils, posterior pharyngeal wall, uvula and soft palate were covered

with a thick diphtheritic membrane. There was also a patch of membrane on the lower lip. The cervical glands were enlarged. The patient was aphonic; there were frequent attacks of dyspnea, so that at one time operative interference was imminent. She was unable to swallow, and was therefore nourished by the rectum. The prostration was profound. In five days 48,000 units of antitoxin were given, 12,000 units being administered the first day. At the end of the fifth day the throat was practically clear, the general condition of the patient much improved. The cervical glands suppurated. For two or three days the slightest possible trace of albumin was found in the urine. Urticaria and arthralgia caused a certain amount of annoyance. There was no special heart complication, although at one time the action of the organ was irregular, as is always the case in severe attacks of diphtheria. Post-diphtheritic paralysis ensued, but was not sufficient at any time to cause great anxiety. This certainly cannot be considered a mild attack of the disease. If a less amount of antitoxin had been given, the patient would have died, without doubt. It is of interest to note that four other members of this family had diphtheria, but as antitoxin was given early in the course of the disease, only small

South Dept. - Municipal Hosp. - Belvidere Hosp. - Asylums Board

CHART E. Percentage of mortality, by age, of diphtheria at the South Department, Boston City Hospital, 1899; Municipal Hospital, Philadelphia, 1899; Belvidere Hospital, Glasgow, 1898, and Asylums' Board Hospitals, London, 1898.

doses were required. This woman had a tedious convalescence, but was discharged well. Seven months from the date of the attack she was in good health.

Many more cases might be cited in which large doses of antitoxin were given with satisfactory results, but enough has been said to prove that small doses of antitoxin are of little avail in the treatment of grave types of the disease; that in order to obtain the best results the serum must be heroically administered. It is true that all of the patients to whom large doses of antitoxin have been given have not recovered, but so many of them have that one must be convinced that large doses are imperatively demanded in very severe cases. When death has occurred, it has been from nerve degeneration or from sepsis. In no instance was there any injurious effect produced by either the large or small doses of antitoxin. Albuminuria, although present in many cases, cannot be attributed to the serum, as albuminuria is one of the most frequent symptoms in diphtheria. Heart com-

plications of a serious nature have not been so frequent in the 7,657 patients treated at the South Department as would have been the case in a like number treated without antitoxin. Paralysis, although occurring in the severer cases, has not been so prominent as it would have been in an equal number of cases treated without antitoxin. Urticaria and arthralgia are certainly very annoying complications, but they do not imperil the life of the patient, and are, therefore, not worthy of being considered an argument against the use of the serum. It has been observed that the serum from certain horses caused a larger percentage of urticaria than that from others. There is no explanation of this fact. It is to be hoped that in the future there may be some way of eliminating this troublesome symptom. The time in which an urticaria may appear varies from ten minutes after the injection of antitoxin to three weeks. Abscesses after the injection should be of rare occurrence, and when they do appear are an indication of some error of technique in the sterilization of the syringe or in the quality of the serum. In the last 1,500 injections given at the South Department, an abscess occurred twice.

It must be conceded that diphtheria at the outset is a local disease caused by the bacillus of diphtheria. The constitutional symptoms are the result of the extension of membrane and the formation of toxin. If the local process can be stopped, if the membrane can be prevented from extending, the life of the patient will be saved. Although different remedies were used to prevent the extension of membrane before the advent of antitoxin, the death rate from diphtheria remained about the same until the introduction of antitoxin. Before the days of antitoxin there was no method of limiting the extension of the membrane. It is true that the membrane could be torn off, leaving a raw surface, but the organism of diphtheria would not be destroyed, and therefore the membrane would re-form. The number of different applications to the diphtheritic membrane was so great as to prove that no one of them was satisfactory. No germicide can be of sufficient strength to effectually destroy the bacilli of diphtheria without causing destruction of the mucous membrane, and thus opening a fresh field for the growth of the organism. In the light of our present knowledge regarding the etiology of diphtheria, there can be no more unscientific method of treating the disease than by the application of caustics to the membrane, with the hope of destroying it. The experiments of Roux and Yersin proved conclusively that the bacilli of diphtheria would not grow on intact mucous membrane, and, therefore, the less the throat of a patient ill with diphtheria is abraded the better.

Of the 7,657 cases of diphtheria treated in the five years that the South Department has been open, 772, or 10.08%, required operative interference. In about 100 instances there were marked laryngeal symptoms, but operative interference was not required, the stenosis being relieved by antitoxin. The use of steam for the relief of the stenosis has been discarded except in cases of tracheotomy, because it was found that the relief was not sufficient to offset the debilitating effects of the steam on the patients. The sublimation of calomel was tried in many cases, but without satisfactory results, as the patients almost invariably required operation. To discuss the rela-

tive advantages of intubation as compared with tracheotomy would prolong this paper to an unseemly length, but a death rate of 34% in intubation cases as compared with the death rate reported in tracheotomy cases shows conclusively the advantage of intubation over tracheotomy.

From a comparison of the health reports of Boston before and after the introduction of the antidiphtheritic serum; from a comparison of the health reports of other cities; from a study of hospital reports; from a clinical observation of nearly 8,000 cases of diphtheria, the following conclusions are justifiable:

(1) That the ratio of mortality of diphtheria per 10,000 of the living was very high in Boston previous to 1895.

(2) That the ratio of mortality per 10,000 has been very materially reduced since the introduction of antitoxin.

(3) That the percentage of mortality in the South Department is lower than that of any of the hospitals taken for comparison.

(4) That since larger doses of antitoxin have been given the death rate has been materially reduced, this reduction having occurred in the apparently moribund cases.

(5) That no injurious effect has followed the use of the serum.

(6) That to arrive at the most satisfactory results in the treatment of diphtheria, antitoxin should be given at the earliest possible moment in the course of the disease.

Clinical Department.

NOTES FROM THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

IV. CASE OF MYASTHENIA GRAVIS PSEUDOPARALYTICA.

BY W. E. PAUL, M.D., BOSTON.

A. P., an American woman, twenty-three years of age and three years married, came to the clinic in Dr. Walton's service.

Family history.—One maternal uncle is insane. Nothing further appears in the ancestry on either side, beyond neurotic tendency in the father's family.

Personal history.—In early childhood she suffered from scarlatina, but made an uncomplicated recovery. Occasionally there was some stomach trouble, but if ill she recovered promptly. The catamenia appeared at fifteen years, were somewhat irregular, and accompanied with moderate pain. She gave up going to school on account of "fainting spells" in the morning. The first of these attacks occurred at sixteen years of age; she felt as though she would like to lie down and sleep, but did not lose consciousness. The last attack occurred at about the time of her marriage. Six months after marriage she took ether and had the left breast removed by Dr. Harrington for a cystic tumor. A year after this operation she gave birth to a healthy boy after a retarded but natural labor. No septic symptoms developed and a good convalescence followed. There were perineal and cervical lacerations; these were repaired two and one-half years later, under ether, by Dr. Campbell. She did not nurse the child, but cared for him besides attending to

the household duties. Her environment was of a character to disturb somewhat her peace of mind, and on one or two occasions she lost self control.

Clinical history.—Eight months before presenting herself at the hospital, and eighteen months after her confinement, while taking the part of a Japanese girl in private theatricals, she stooped low, in a line with a number of other performers; at a given cue all the line were to resume the standing attitude; but the patient could not rise, and asked for help. She was ridiculed a bit and then assisted to stand. In the final performance she received assistance from her comrades on either side and suffered no further disability. Ascending stairs became difficult; in boarding a car she could not lift her feet without assistance. If merely helped in the usual way by taking her hand or arm she would be pulled forward and fall on her face. This loss of muscular power was of brief duration. Crossing the knees at times required assistance. She could usually walk on a level, but stepping up was frequently difficult. In spite of her myasthenic symptoms she attended to her housekeeping and cared for her baby.

Transient weakness in the arms next appeared; at times they would drop like lead without sensory disturbance; her husband had to support them when she arranged her hair; to insert a hat pin she rested the elbows on the mantel. In playing the piano both hands tired easily. She would sometimes have to drag the baby to her lap rather than lift him clear. Once when attempting to take him from his crib it was impossible to straighten up until assisted. She refrained from handling fragile objects. There was difficulty at times in buttoning, and ability to do millinery and embroidery was lessened. The attacks of weakness became more frequent. These symptoms were of short duration and came on usually after severe use of those muscles in which weakness or complete loss of power developed. She not infrequently fell backwards on the stairs, and on one occasion when near the top the legs gave way and she fell with the baby in her arms, sliding down several steps without injury. Transient diplopia occurred in the course of the disease and it was noticed at times that when she looked up the head was thrown back, indicating ptosis. The muscles of mastication escaped. There was lack of expression in the face, and the laugh seemed incomplete. The voice at times was nasal and somewhat indistinct, though not lowered. Words were correctly chosen and speech was never really lost. One day the words ran together and the lips seemed powerless, but holding the upper lip with the fingers obviated her difficulty. Swallowing was sometimes awkward, and in the later stages this difficulty became serious. The neck muscles sometimes suddenly gave way so that the head required support.

The symptoms became more frequent, and involved on several occasions very nearly all of the voluntary muscular system. One evening six months before death, after climbing the stairs safely, she fell to the floor unable to move or speak, but finally succeeded in attracting attention by tapping the floor with her heel. Later, in attempting one day to step up on the piazza, she fell in a heap and had to be carried bodily into the house. In a third instance, five weeks before death, she fell helpless at the top of the stairs. After a few moments she regained control of her muscles in

each instance; some drowsiness followed the last attack, but no unconsciousness.

The most serious symptom to develop was choking, the first attack occurring about six months before death. At the commencement of a meal, the first attempt to swallow water caused strangulation; she became cyanosed and unconscious, but revived at the end of about thirty minutes. A month later after taking two swallows of water without trouble, the third choked her. Cyanosis and unconsciousness followed, and Dr. Campbell, who was present, seriously considered tracheotomy. Such attacks and the accompanying apprehension impaired nutrition materially, but there was no local atrophy. Her mind remained clear. Palpitation and dyspnea occurred, but were not prominent symptoms.

There was no numbness or prickling. Appetite and digestion were good. The disposition was unaltered; the catamenia reappeared after confinement and did not modify the symptoms. The sphincters were unaffected; there was no spasmodic movement, stiffness, or tenderness. Emotional excitement aggravated the disturbance.

During the last few months of life the attacks of weakness became more frequent and profound, yet, when seen in the intervals, she gave no impression of serious illness. The bulbar symptoms became more pronounced and at one time rectal feeding was practised; but the ability to swallow food and liquids returned while at the Boston City Hospital, some months before death. Toward the end she was sometimes unable to roll over or to sit up in bed, showing involvement of trunk muscles.

The ocular symptoms also increased, but there were remissions with apparent normal muscular balance. Exposure to cold did not aggravate the condition, as a rule; but once, on leaving the cars after a journey, she became helpless on encountering the chill of a March air. Three days before death she was able to try on a dress, and two days before death she sat in a chair and swallowed without trouble. At this time she complained of palpitation, and of a sharp pain in the right iliac region. The lungs filled up but became clear again after several hours; there was temporary inability to spit out or swallow the secretions. Death occurred eighteen months after the first symptoms.

Autopsy, by Dr. G. B. Magrath, revealed macroscopically nothing pathological in the nervous system or the musculature. The microscopical examination of the cord and brain will be reported later.

Examination (eight months after the first symptoms).—Of medium size and well nourished, the patient was rather indifferent and calm in manner. Her color was good, but the blood was not investigated. No marked weakness of voluntary muscles appeared at the time of examination. The gait was normal; she could raise either foot to a chair seat, but required some slight assistance to mount the chair. The grasp and various movements of the fingers and arms were made easily, with apparent normal strength. She talked, swallowed water, and used her ocular and facial muscles with no sign of paresis. Objectively no change in sensation to touch or pain could be discovered. No tenderness existed over the muscles or nerves. Vision and hearing were undisturbed and the fundus was normal. The visual field was not limited, and there was no diplopia. Romberg's symp-

tom was absent. The knee jerks were both normal; no attempt was made to tire this reflex; the pupils were equal and reacted to light and accommodation. The urine was 1.014 and showed a trace of albumin. Unfortunately, an electrical examination was omitted, so that no data exist as regards a "myasthenic reaction." This reaction obtains when a faradic current tetanizing the muscle tires it in a brief time so that no further contraction is elicited by this current; a rest of one or two minutes restores the normal reaction.

This case presents a profound motor disturbance with the symptoms varying in duration, severity and anatomical location. It developed eighteen months after confinement and, apparently, no other factor can be discovered that would bear a possible etiological relation to the symptoms. The patient grew worse steadily and death ensued in eighteen months. Sensory disturbance was absent excepting slight pains in the arms and knees, and the feeling of something grasping the throat. No atrophies developed. The sphincters did not fail. The mind was clear. The autopsy revealed nothing of a pathological nature in the cord or brain.

Diagnosis.—The diagnosis of this case requires the consideration of hysteria, bulbar paralysis, polioencephalitis, general asthenia, as well as myasthenia. A general asthenia resulting in death would progress steadily. Polioencephalitis as the sole condition or as a complication is thrown out by the transient character of the symptoms, by lack of atrophies, and a negative autopsy. Bulbar paralysis existed at times as a part of the clinical picture, and such cases have been called "asthenic bulbar paralysis." The variation in symptoms, the lack of local atrophies, and the distribution of the myasthenia to muscles other than the bulbar group, render it impossible to classify this case as one of pure bulbar paralysis.

Such cases have undoubtedly been many times mistaken for hysteria or other psychoses; possibly some of the deaths attributed to hysteria might have had a clinical history not unlike this. There was nothing of a decided hysterical character about this patient, and no stigmata were present. Possibly the drowsy attacks of her school life, apparently not epileptiform, represented precursors or equivalents of the myasthenia, but this question is purely speculative.

The symptom complex entitled "myasthenia gravis pseudoparalytica" by Jolly, or "myasthenia gravis" for short, is strikingly exemplified by this history. Other names for the diseases are "asthenic bulbar paralysis," "Erb's Disease," "Erb-Goldflam," and "Hoppe-Goldflam, symptom complex." Only 60 or 70 cases, with a mortality of over 33%, have been described in the literature; and the subject of these notes is the first case in which the diagnosis has been made in this clinic.

Pathology.—This case offers no new help toward determining the location of the lesion, nor does it throw light on the agent or agencies that cause the symptoms. Two recent writers¹ have studied the disease exhaustively, and sum up their views as follows: "What we suggest, then, is that a toxin, probably of microbic origin, circulates in the blood, and acts selectively upon the lower motor neuron, so as to modify its functional activity. This change in functional ac-

tivity is such that the lower neuron soon becomes exhausted by transmission downwards of stimuli, whether originating in an act of the will or started by the faradic current. As to which part of the (lower) neuron the poison acts on primarily one can only vaguely surmise; but we lean to the view that it is upon the axon." For the evidence adduced to support these views, the reader is referred to the original article, to which a comprehensive bibliography is appended.

Medical Progress.

REPORT ON PROGRESS IN OBSTETRICS.

BY FRANK A. HIGGINS, M.D., BOSTON.

ANTENATAL DIAGNOSIS.

BALLENTYNE¹ contributes two lectures to the subject of antenatal diagnosis, which he says should include the discovery of normal and of plural pregnancies, of fetal death, of diseases and monstrosities of the fetus, of hydramnios, and of morbid conditions of the placenta, all of which should be kept in mind in examining the pregnant patient, and there is an increasing probability that the diagnosis may be well established under favorable circumstances with care and skill. He says that the diagnosis of the antenatal morbid state is best accomplished by taking up the following lines of investigation in order: (1) The previous medical history of the mother, both general and sexual, must be inquired into, as there are certain circumstances which may be regarded as commonly preceding the development of the morbid states in pregnancy; (2) the past history and present state of the father and the family history of both sides ought to be taken into account, for there are fetal diseases and embryonic deformities which appear to be hereditarily transmitted; (3) the maternal symptomatology during the pregnancy which is in progress must be carefully investigated; (4) a very complete physical examination ought to be made of the maternal organs and especially of the abdominal viscera; (5) the fetus should be fully examined by the hands, ear, cephalometer and the Röntgen rays, and, finally, the maternal blood and urine should be subjected to chemical and microscopical investigation. He has been impressed by the frequency with which women with disastrous obstetrical histories have also previously suffered from neuroses of various kinds, from tubercle, alcoholism, syphilis, kidney trouble, rheumatism and gout. It does not necessarily follow that these medical conditions of the mother have so altered the ova as to prevent healthy development or that her system is so altered as to be unable to react in a healthy fashion to the contents of her uterus. Rather that the morbidity and the bad medical history are results of the common cause, heredity. This is supported by the fact that the same laws of transmission apparently govern the medical conditions which preside over malformations, morbiparities, etc. The maternal reproductive history is of importance as regards the menstrual habit and type, the conditions of the mother as to marriage, and with regard to the histories of previous pregnancies. The paternal medical and reproductive history is important, espe-

¹ Campbell and Bramwell: Brain, Summer Number, 1900.

¹ British Medical Journal, 1900, vol. 1, pp. 1458 and 1525.

cially with regard to the age, the use of alcohol, and the presence of many diseases, for it seems certain that paternal morbid states are potent in inducing antenatal pathological conditions. The influence of paternal alcoholism has not yet been fully worked out, but attention is called to Sullivan's contribution that total abstinence on the part of the father does little, if anything, to improve the prospects of the unborn infant so long as there is maternal alcoholism. Family medical history is necessary, as morbid states are not infrequently hereditary, but not always of the same kind. There is a striking tendency in some families toward multiple pregnancies, to monstrosities, and to the reproduction of certain malformations. With respect to maternal symptomatology the closest scrutiny must be given to all the symptoms of the mother during pregnancy. The very fact that the diagnosis of pregnancy is not easily made is presumptive evidence that there is an abnormal pregnancy, and further, the very ease with which we recognize that there is the normal symptomatology of gestation is indirect evidence that intra-uterine affairs are progressing in a natural way. The patient may complain of deviations from the normal in all the symptoms and conditions of pregnancy, but the symptomatology must be normal to prove positively that the fetus is developing normally. We must also inquire into symptoms not connected with the pregnancy but which may have been present during the pregnancy, such as erysipelas in the mother which has been followed by a streptococcus endocarditis in the fetus, or traumatic injuries to the mother may be transmitted to the fetus. After the history and symptomatology of the pregnancy have been obtained it is necessary to proceed to an exhaustive physical examination of the maternal and fetal organisms, and in the case of the mother it will be important to examine not only the reproductive organs but also the other bodily systems, as the circulatory and respiratory. During labor it is important to determine abnormalities in the fetus in order to decide questions of operative procedure.

HYDATID MOLE IN A VIRGIN.

Bock² relates the case of a child, age twelve years, living well cared for and under conditions which rendered her virginity above suspicion. Two months after her twelfth birthday the first period occurred; clots were passed without pain. At the second period there was pain and a clot was passed which was covered with a white membrane forming a perfect cast of the uterus. On microscopical examination the cast proved to be endometrium with uterine glands and ciliated epithelium. Thus already the child suffered from membranous dysmenorrhœa, which was repeated at the third period. The fourth was extremely painful, being only a slight show for three days, then a typical hydatid mole was expelled. Its base measured over three-quarters of an inch. It was made up of vesicles arranged like rows of beads; each vesicle was full of a transparent serosity; the wall was made up of loose fibrocellular tissue with many veins. The vesicles varied in size; the smallest were of the dimensions of a pinhead, the largest as big as a pea. The succeeding periods have all been normal, since the expulsion of the mole four years

ago. Bock suspects some relation between the membranous dysmenorrhœa and the mole. A piece of the diseased endometrium or menstrual decidua may have remained behind and undergone a pseudoplacental change. Jacobs has already asserted that the hydatiform mole may develop independently of gestation, and Bock's case, in his opinion, proves that theory. Keiffer suspects that there may be more than one variety of hydatiform mole.

PROTRACTED GESTATION.

Phillips³ reports a case of protracted gestation in a primipara, who ceased menstruating on August 24th, who indulged in sexual intercourse only on one occasion, on September 6th, and in whom labor did not begin until July 13th, or three hundred and twenty-three days after the cessation of her last period and three hundred and ten days after the date of coitus. He says there is not the slightest doubt that no menstrual period occurred subsequent to that in August. The case is exceptional and interesting, and is equalled by only a limited number of cases scattered through obstetric literature.

(To be continued.)

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

MEETING of October 16, 1900, the president, DR. ALFRED WORCESTER, in the chair.

DR. C. M. GREEN read a paper entitled

THE VALUE OF THE HOT-WATER IMMERSION BATH IN THE TREATMENT OF THREATENING PUERPERAL ECLAMPSIA.¹

DR. W. E. BOARDMAN: The suggestion, while not new, is an attempt to emphasize the advisability of a practice that time has shown valuable in the treatment of convulsions in children. In the cases read we do not know for certain that convulsions would have occurred in the absence of the baths. As it was they did not, and no ill effects followed from the baths. I fancy in cases where the symptoms occur early in pregnancy the liability to miscarriage as an effect of the baths would not be so great as in the later months. The remedy is simple and almost always applicable, and I can see no possible bad effects except that of possibly inducing labor. My experience with eclampsia has happened to be very limited. In the few cases I have seen in private practice no preventive measures were used. Though now much more common than formerly the observation of pregnant women is not yet as universal as it should be.

DR. H. E. MARION: I am thoroughly in sympathy with the hot baths. I have used them perhaps indiscreetly before the viability of the child, but in such circumstances have kept the patient in the baths only a very short time. No ill effects have followed.

DR. G. W. W. BREWSTER: As to the question of the advisability of the use of pilocarpine in suppres-

² British Medical Journal, 1899, vol. ii, p. 18. Epitome of Medical Literature.

¹ See page 624 of the Journal.

³ The Lancet, January 13, 1900.

sion of urine, while I have had no experience with it in puerperal eclampsia, I do remember a case in which Dr. Richardson had performed nephrectomy, in which I gave pilocarpine to relieve the tension on the other kidney, with the result that the patient was nearly lost through edema of the lungs.

DR. F. A. HIGGINS: I am glad to hear this paper, as we do not generally hear enough of prophylaxis. I have once or twice been induced to operate against my will in cases in which had prophylaxis been more carefully carried out the result might have been otherwise. Jardine has recently published a series of 23 severe cases with a mortality of only 4, in which he used injections of saline solution with the addition of one drachm to each pint of acetate of potassium, a suggestion which is certainly worth bearing in mind.

DR. M. H. RICHARDSON: While I no longer see cases of puerperal eclampsia, I do see many cases in which it is desirable to increase the flow of urine by other channels than the bladder. I remember a case of nephrectomy in which the patient was kept alive for many days by the elimination of fluid through the skin. I have often been impressed by the success of diaphoresis in treating anuria following such cases as division of strictures, etc.

DR. F. W. TAYLOR: Until last year I had begun to think that a patient need not die of eclampsia, having had a number of successful cases. Since then I have lost 2. The hot water treatment accomplishes two results that in certain circumstances are most desirable—it helps elimination of fluid and favors emptying the uterus. As to pilocarpine, I have seen good results and bad results. In 1 case the woman probably would have lived had the dose been smaller, as forty-eight hours after the administration of $\frac{1}{2}$ of a grain she died with consolidation of the lungs. In another case, however, it worked most favorably with good diaphoresis lasting two or three days after its use.

DR. J. L. HILDRETH: Prophylaxis seems to me even more important than actual treatment, and one would expect that the best results would follow the use of the hot water baths.

DR. G. H. WASHBURN: I agree with the last speaker as to the importance of preliminary treatment. Absolute milk diet and rest have carried several threatening cases on for weeks for me and even through labor. There is danger in relying too much on the amount of urine passed—the amount of urea should be kept sight of. Dry heat has usually worked very satisfactorily in my hands. I have always avoided pilocarpine since, when house officer at the City Hospital, I saw 2 cases, 1 of which died of edema.

DR. H. D. ARNOLD: In some cases I have seen pilocarpine in small doses act very well as an adjuvant to the hot air treatment.

DR. C. M. GREEN: As to the use of hot air compared with that of hot water, I have seen many cases that did not respond well to hot air and which did seem unpleasantly affected by it. Hot baths are of course applicable only, under ordinary circumstances, to ambulant patients rather than the comatose. I would emphasize that I regard the hot water treatment as especially suited to cases with profound symptoms, yet I do not wish to give the impression that I would put every such case into hot water; it

would be only when they do not respond to other treatment. Its greatest use will be in hospital cases where there has been no chance to keep the patient for several weeks on appropriate treatment and diet, and where energetic treatment is demanded at once.

DR. M. H. RICHARDSON read a paper entitled

REMARKS UPON QUESTIONS ARISING DURING THE REMOVAL OF FIBROIDS, WITH ESPECIAL REFERENCE TO THE TECHNIQUE OF THE OPERATION.²

THE MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

STATED meeting, December 10, 1900, the president, DR. ROBERT F. WEIR, in the chair.

SPINAL ANESTHESIA.

The discussion on this subject was opened by DR. J. LEONARD CORNING, who read a paper on

THE NEUROPHYSIOLOGICAL ASPECT OF THE SUBJECT.

He gave a brief résumé of the manner in which, by induction and experiment, he found that cocainization of the spinal cord was possible and practicable. Having discovered that cocaine had a chemical affinity for the sensory nerves, he reasoned that it also had this affinity for the sensory conduction portions of the cord and demonstrated the correctness of his supposition upon animals. By injecting a cocaine solution within the membranes of the spinal cord of a young dog he produced inco-ordination of the posterior extremities which lasted for two hours, while the forelegs remained unaffected. It was conceivable, however, that if the quantity of the drug had been larger the inco-ordination might have extended to them also. He continued his experiments until he arrived at a stage where, in the human subject, he produced anesthesia of the cord by deliberately puncturing the membranes in the lumbar region and depositing a cocaine solution directly upon the cauda equina.

The fear had been expressed by some that poisonous effects, more or less permanent, might perhaps be produced by this use of cocaine. He did not think there need be any apprehension of this, and recalled the fact that there was the same talk when cocaine was first used as a local anesthetic. It was entirely possible that when cocaine was employed upon the peripheral nerves a considerable quantity of the agent might reach the central system. Incidentally Dr. Corning referred to some of the objectionable features attending intraspinal cocainization. The frequent defecation and urination that had been noted could be avoided, he thought, by first thoroughly emptying the lower bowel and the bladder. As to vomiting, this was not peculiar to this form of anesthetization, and the same precaution as to previous abstinence from food should be taken as when other anesthetics were used. He urged the necessity of rigid asepsis, and said, in conclusion, that modifications of technique would no doubt be made from time to time.

DR. GEORGE R. FOWLER read a paper on

SPINAL ANALGESIA IN GENERAL SURGERY.

His experience now embraced 81 cases, which he had divided into the following classes: Class 1: op-

² See page 619 of the Journal.

erations involving the peritoneum, 26; Class 2: operations on the trunk and genitals not involving the peritoneum, 34; Class 3: amputations, 5; Class 4: operations on the lower extremities not included in the above, 13; Class 5: unclassified operations, 3. Among the operations in the first class were abdominal sections for acute and chronic appendicitis, vaginal hysterectomy, abdominal hysterectomy, double oöphorectomy, incarcerated hernia and ectopic gestation. In 5 of the cases the analgesia was incomplete. In all of the cases of abdominal section there was some sort of a mishap, and in 1 instance such violent peristaltic action occurred that there was imminent danger of intussusception. Among the conditions operated for in the second class were varicocele, hydrocele and fistula in ano. In 1 or 2 cases general anesthesia had to be resorted to. Of the amputations 1 was at the hip joint, 1 of the thigh, at the middle third, for elephantiasis, and 2 of the toe for gangrene. Among the operations in Class 4 were arthrotomy at the knee joint, wire suturing for fractured patella, and ligation of the internal saphenous vein. The 3 unclassified operations were costal resection, nephrectomy, and incision of the abdominal wall for dermoid cyst.

The point usually selected for the puncture was the space between the third and fourth spinous processes, but occasionally the space above or below was chosen. A double needle was generally used, in order to avoid occlusion of the instrument. One minute was taken for the injection. The cocaine solution should always be freshly made. In the disagreeable symptoms occasioned it seemed to make no difference whether a large or small quantity of the drug was used. One-quarter or $\frac{1}{2}$ grain of cocaine was employed, according to whether short or more prolonged analgesia was desired. The position of the patient seemed to make very little difference, but, as a rule, he thought the Sims position the most satisfactory to the patient. In all the cases, with 2 exceptions, there was analgesia of the parts below the level of the umbilicus for at least forty minutes. Failure to induce analgesia, he believed, was due to failure to inject the cocaine solution into the spinal canal. From his very first case, on September 8th last, he had employed a preliminary injection of cocaine at the seat of injection. He also was in the habit of making a slight incision, with a view to prevent possible infection from the skin.

Among the unpleasant consequences of the procedure were vertigo, nausea, vomiting, increase of temperature, pallor, cold, and involuntary defecation and urination. That all these were due to the drug he was not willing to admit. In all cases there was a rise of temperature, the degree of elevation varying in different instances. In 1 patient it went up to 106.8° in less than four hours. Pronounced chills occurred in only 4 cases. Increased pulse rate alone seemed to be due to the nervousness of the patient. There was apparently some relation between nausea and vomiting and the circulation, and where the heart was at all weak it was advisable to give $\frac{1}{10}$ grain of strychnia hypodermically. In all but 1 case the defecation occurred during vomiting. It was his practice to order a purge the night before. In 1 case of hemorrhoids, however, in which no preliminary precautions were taken, there was no defecation, vomiting or urination. He had found that all the dis-

agreeable symptoms had materially decreased since he had adopted the plan of using a preliminary hypodermic injection of $\frac{1}{10}$ of a grain of strychnia.

Beyond mere hearsay he had no information in regard to deaths being caused by this procedure. While in Paris last summer he had heard rumors of fatal cases. Tuffier was repeatedly quoted in this connection; but in 1 of his cases the autopsy showed cardiac and pulmonary lesions, and he had distinctly stated that death was not due to cocaineization. His own cases were not selected cases, and cardiac, pulmonary and renal lesions were disregarded. In 1 instance gangrene of the lung was actually present. In many of his cases a general anesthetic could not have been employed. It had been proposed to associate other drugs with cocaine, in order to diminish the effect of the latter, and the plan had been tried; but he could not see that any less injurious effects resulted than from cocaine alone. In spite of his favorable experience with cocaineization he was by no means entirely satisfied with the method. He held with Dr. Keen that the ideal one, in addition to perfect safety, will include unconsciousness as well as anesthesia. The vomiting and defecation, the shock itself and the patient's own feelings are serious objections to the intraspinal injection of cocaine, and he thought it more probable that the ideal anesthetic would be a general rather than a local one.

DR. S. MARX read a paper on the

OBSTETRICAL AND GYNECOLOGICAL ASPECT OF THE SUBJECT.

In opening, he said that Dr. Fowler had exactly voiced his sentiments. His original experiments were commenced last April, but they failed because he did not get cerebrospinal fluid. At last there was 1 case in which he did get fluid. The injection was followed by vomiting and symptoms resembling locomotor ataxia. He was badly frightened at first, but was relieved afterwards when the woman gave birth to a child without knowing that the child had been born. She could not be convinced till she heard the baby cry. Intraspinal cocaineization was then employed in the case of every woman confined at the hospital, for experimental purposes only. It was far from his thought, however, to recommend this procedure in every obstetrical and gynecological operation. It was a serious matter. The injection once inside the cerebrospinal tract, its effects were beyond the operator's control. He had used it, he thought, in about 125 cases. Two of the cases were absolute failures, and in 1 other the anesthesia was incomplete. As to the matter of failure, this might be absolute or relative. Thus, the failure might be only apparent, and psychic sensitiveness (fear) was a prominent element. In a case of strangulated hernia in an old lady suffering from chronic bronchitis and emphysema, the patient complained at some times of pain, and at others, not. This was undoubtedly a psychic or apparent, not a real, pain.

In all these cases Dr. Marx said he had obtained cerebrospinal fluid, and unless he did get fluid he would not inject cocaine. In 1 instance that he had heard of the needle went in further and further until it had penetrated the peritoneal cavity. This was a danger that he had not thought of. As to the symptoms, which had been so admirably described by

¹ British Medical Journal, Aug. 25, 1900.

Dr. Fowler, they were so absolutely regular that he could not regard them as due to the cocaine itself. It had been found that they occurred in cases where cocaine was not used, as well as in those where it was. Thus, in control cases where a saline injection was employed the vomiting, etc., resulted, but not anesthesia. He was convinced that it was the loss of cerebrospinal fluid which caused the symptoms. In a case of coceyodynia (before cocainization) there were chilliness, headache, rise of temperature, vertigo, and nausea and vomiting, and they disappeared when the fluid ceased to escape. From his experience he believed that these symptoms could be anticipated and prevented by the use of drugs, such as bromides. It was his conviction that they were simply nervous phenomena, or, in other words, due to shock. He would recommend one large dose of bromides at the beginning, and if this was not sufficient, caffeine, etc., later, as the symptoms arose. The vomiting was the same as in general anesthesia.

As to the dose, he believed that too large a quantity of cocaine was generally employed. In his opinion, $\frac{1}{8}$ grain was ample, and in many cases $\frac{1}{2}$ of a grain would be quite sufficient. The anesthetic effect was not apparently increased by using a large amount. As a rule, the analgesia extended from the umbilicus down; occasionally it started from the level of the nipple. Eucaine, in his experience, was utterly valueless as an anesthetic. Experiments seemed to show that it was of great advantage to have the solution injected as nearly as possible of the same specific gravity as the cerebrospinal fluid. The effect upon the labor was absolutely *nil*. If the anesthesia was complete there was no necessity of bearing down. If he were asked if he had observed no bad effects, he would reply that he had seen some very unpleasant symptoms, but they were evanescent, and he did not fear them. He believed that we were too prone to attribute every untoward circumstance to the cocaine. As to the indications for its use in labor, it was of the greatest service in very prolonged first stage. Under its influence dilatation of the os proceeded with great regularity.

In gynecology this procedure had but a small field. It would never supplant general anesthetics, but in cases where the latter could not be employed it was of great value. He had known personally of no deaths from it, and did not believe that the reports of fatal cases were well substantiated. Its use was absolutely contraindicated in two classes of individuals: (1) Those on whom cocaine has no effect, and (2) the highly neurotic.

DR. S. ORMOND GOLDAN read a paper on

INTRASPINAL COCAINIZATION FROM THE ANESTHETIST'S STANDPOINT.

Since reporting his first series of 20 cases, he said he had had 11 others, making 31 in all. These later cases were not materially different from the others. In general, his experience included more successes than failures. He recognized the desirability of finding out and anticipating the causes of failure, such as the solution not being good, using too large a needle, withdrawing the needle too soon, etc. After eliminating all these, he had still had some failures. In obstetrics he thought cocainization had no advantage over chloroform, which in this field was acknowledged to be safe. In surgery it was too dangerous, and

convenience could never be preferred to safety. Ether, preceded by nitrous oxide gas, was our safest anesthetic. Cocainization was the least safe, and it should be resorted to only in cases where from renal or cardiac disease a general anesthetic was inadmissible.

Sometimes cocaine was so perfect in its results that the bad effects were *nil*. If in all cases it acted thus happily, it would leave nothing to be desired. But, he asked, is not this true of other anesthetics also? Sometimes anesthesia by cocaine was not extensive enough. In such cases a second injection, smaller in quantity, might be given without bad result. He did not think it safe, however, to resort to a third injection. Instead of this a general anesthetic should be given, and under these circumstances a less quantity than usual was required. A quick return to consciousness depended, as a rule, upon the quantity of the anesthetic administered. Recently it had been proposed to employ cocainization in the cervical portion of the cord. This meant introduction of the needle not only into the subarachnoid space, but into the cord itself. No matter how fine the needle, it would be attended with great risk. Remote complications were to be feared which were not liable to be met with in the lower cord. To inject into the cervical cord would involve the risk of affecting the medulla oblongata and causing instant death. In his cases he never failed to get fluid before proceeding with the injection.

Dr. Goldan then briefly described his last 11 cases. In Case 27, where cocainization was employed for the removal of a tuberculous testicle, the anesthesia extended up to the lower ribs. In Case 28 two injections were necessary. They were given between the fourth and fifth vertebrae, on account of an ankylosed condition of the spine, which had resulted from a fall from a window. In Case 29, where a celiotomy was to be performed, absolutely no anesthesia was produced. In Case 30 the patient was highly neurotic. Perfect anesthesia was obtained, but just as the needle was about to be withdrawn the patient gave a sudden movement which bent the instrument double. Fortunately, it was of gold, and did not break. In Case 31, the last case, the patient was also highly neurotic. Here, again, there was perfect anesthesia, but, in spite of it, it was found necessary to administer a general anesthetic, on account of increasing hysteria.

DR. V. P. GIBNEY said the range of orthopedic operations was small. Cocainization had been regarded not as favorable in children as in adults, and he had therefore as the subjects for its use patients fifteen or sixteen years old. He had experienced no difficulty in finding fluid. In 1 case a second injection was required. In another no analgesia resulted in an hour, but in this same patient successful analgesia was secured a week later. Two or 3 osteotomies were performed under the influence of the cocaine injections, and the analgesia was so complete that the patients laughed at the idea of any pain. It seemed to him that in this procedure we now had at our command a very useful means of anesthesia. He had met with 1 or 2 instances of nausea and headache, but he saw no reason to attribute these to the cocaine. Dr. Marx had stated that the method was contraindicated in those individuals who do not respond to cocaine in any form; but how were we to

determine this fact? He had been under the impression that every one could be cocaineized.

Dr. E. H. GRANDIN said that his experience was limited to 3 cases, the details of which he had given on another occasion. The first 2 were in his own practice and the patients were both neurotic Italian women. The injections were made by an expert, and there was no analgesia after periods respectively of twenty-nine and nineteen minutes. The third case was that of an apathetic Irishwoman in the service of a colleague at St. Mark's Hospital, who was operated on for strangulated hernia. The cocaineization was done by an expert, but the patient complained of more or less pain during the whole operation, which lasted thirty minutes. From his experience, therefore, he was rather skeptical in regard to this measure. In the first place, it was an uncertain method. In the twenty to twenty-five years that he had been cognizant of anesthesia he had never known ether or chloroform to fail to anesthetize, and what we wanted was certainty. He had been told that this method was preferable to ether because ether may affect the kidneys. But who knew but what cocaine might affect the cord? Chloroform was objected to on account of its effect upon the heart; but might not cocaine also affect this organ?

He did not think its use justifiable in obstetrics. Parturition was a physiological act, and he did not feel that we had a right to subject a woman in labor to a possible injury to the cord. In tedious first stage large doses of chloral could be used if necessary, and later on chloroform was our most efficient resource. In gynecology, nitrous oxide gas was very useful for minor operations, if any anesthetic at all was called for. As to major operations, he did not like the idea of the patient's retaining consciousness, and he believed it would be impossible to maintain the Trendelenburg position, for instance, for a sufficient length of time. In conclusion, he said that he had been misquoted in his remarks before another society. He had not made the positive statement that cocaineization was already damned, but that if the statistics of 5 deaths in 100 cases are correct, the method was damned.

Dr. RAMON GUTERAS said that he had in an off-hand way mentioned to Dr. Grandin that in 125 cases of Tuffier 5 of the patients had died. He had since looked the matter up in the *Medical Bulletin*, the organ of the International Medical Congress. Tuffier did report that in 125 cases 5 patients died. Of these 5, 1 died from asphyxia, and it was thought that the other 4 could be attributed to other causes than the anesthetic. From this report he judged that Tuffier thought the 1 death was due to cocaineization. At the autopsy congestion of the lungs was found. He had seen some of Tuffier's cases himself while in Paris. It seemed to him that there was a good deal of shock, and that the consequences were more serious than with other anesthetics. When any new method was brought forward, however, there were always a number of doubting Thomases, and he did not think any positive conclusions should be arrived at until the whole matter had been very carefully investigated and sifted. When Morton first attempted to produce anesthesia with sulphuric ether it was a failure, and the measure was received with much opposition in Boston. But now ether was everywhere acknowledged to be the greatest anes-

thetic that we have. If cocaineization was to be compared with the latter he thought it should be with ether administered by the rectum, which was attended with more or less danger, because we cannot control its action. So cocaine, once within the spinal canal, was beyond our control. Its field, he believed, would be found to be comparatively limited. In conclusion he gave the statistics of cocaineization presented by various operators at the recent congress.

Dr. W. S. BAINBRIDGE said that he had made a considerable trial of the method in children with a view to testing its efficacy in this class of subjects. He knew of no instance in which it had previously been used with a child as young as eleven years. The patients in whom he employed it ranged from two and one-half to nineteen and one-half years. His first 7 cases were all successes. Analgesia was perfect, and there were no dangerous symptoms. It was a novel sight to see little girls playing with dolls while their legs were being broken or an umbilical hernia was being operated on. He also made experiments for the purpose of comparing the efforts of eucaïne with cocaine, and in some instances tried different methods on the same child. In a patient two years and eight months old, suffering from incarcerated hernia, two injections of cocaine were given. Partial analgesia was obtained, but not sufficient for the operation. In the same patient, two weeks later, eucaïne was tried, and proved entirely successful, though there was some vomiting at first. His experiments had led him to conclude, however, that, as a rule, the analgesia is not so complete from eucaïne as from cocaine. There was no difficulty in introducing the needle in children. He agreed with Dr. Fowler that the unpleasant consequences noted from this method were not due to the cocaine, since other solutions injected within the spinal canal produced the same disagreeable symptoms, but no analgesia.

Dr. F. KAMMERER said that he had 40 cases in the field of general surgery. From the outset he had employed as small a dose of cocaine as possible, usually $\frac{1}{10}$ grain, and rarely over $\frac{1}{2}$ grain. It might perhaps be on this account that he had had a certain proportion of failures—in 4 out of the 40 cases. He had found the method well adapted for genito-urinary surgery, but not so serviceable in intra-abdominal work. He had seen some symptoms which were alarming, such as violent changes of pulse, but had had no deaths. Perhaps for the reason that he used such small doses, the after symptoms had been very slight. He could not agree that the disagreeable symptoms referred to were due to pressure. If this were the case, why should we not have them after lumbar puncture? Neither did he believe that the operation caused shock. In 1 case this occurred an hour after the operation. This was certainly a very interesting method from a physiological point of view, and one also of great practical importance. He believed that in general a great many deaths following an operation are really due to the anesthetic. To ether only 1 death in 17,000 cases was attributed. He thought this was a great mistake, and that a considerable number of deaths after operations were caused by the ether employed. While accidents are liable to happen, he was convinced that cocaineization had a distinct field, and that it should be given a careful trial.

The president, Dr. WEIR, said it was a well recognized fact that there were fads and fashions in sur-

gery as well as in medicine. Many could recall the enthusiasm which had been aroused by Dieulafoy's aspirator and Esmarch's bandage, which had since died out; and this method might perhaps share the same fate. The interest in Tuffier's demonstrations during the recent congress in Paris was most intense, and the subject seemed to have taken hold of the Americans to a greater extent than any other nationality. Tuffier himself said that he had had 5 deaths, and that 1 of them was due to the method. The questions that presented themselves were, "Is it as safe as ether?" "Is it applicable to cases where, on account of cardiac or renal conditions, etc., we cannot give ether?" The foreigners contended that it was not yet proved as safe as ether. He had tried it in 10 cases at the Roosevelt Hospital. In 3 eucaine was employed, and it failed miserably. In 1 or 2 of the others he was for a time on the "anxious bench," and he had to confess that he had not felt so disturbed by anything of the kind for many years. So far, this procedure had not presented itself to him in a very encouraging way. At the New York Hospital since ether was first introduced, in 1847, there had been 1 death from the anesthetic in 3,000 cases. He had collected the figures of cord anesthesia, and found that in 400 recorded cases there were, including Tuffier's 5, 8 deaths altogether. All admitted that it was apt to be attended with serious and dangerous symptoms, and this should deter us, he thought, from rushing in and using it in such small operations as circumcision or the amputation of a toe. He did not see why we should speak of cocaine as being so very safe in this connection, since its use in other ways was acknowledged to be attended with considerable risk. He did not wish to pose as being distinctly opposed to the method, but he believed that a word of caution might be useful at the present time, and, at all events, a sufficient period must be allowed to elapse before any definite judgment could be passed upon it.

Recent Literature.

Physical Diagnosis of Diseases of the Chest. By RICHARD C. CABOT, M.D., Physician to Out Patients, Massachusetts General Hospital; Assistant in Clinical Medicine, Harvard Medical School. With 142 Illustrations. New York: William Wood and Co. 1900.

The number of books on auscultation and percussion which have recently appeared inclines one to be particularly critical toward each new volume, so few have seemed adapted to the purpose for which they were written, the use of students. The endeavor to smooth their way by condensing facts about the physical examination of the thorax into the smallest possible space has resulted in leaving the impression that all are of equal value and importance in arriving at a diagnosis. The method admits of no shading. This error has been avoided by Dr. Cabot, and consequently the student gets an idea of perspective in which the various signs take their proper place. This entails a larger volume, but the additional pages could not well be spared. In the preface, he says he has written it because he has not been able to find any small work on the subject which does not contain glaring errors, while the correct books are too large. He has just-

ified himself by his success, and has avoided the "well-worn myths" of which he speaks, but such a statement challenges criticism of his own work. While he writes with enthusiasm and directness, he also appears at times to have written with haste, and to have allowed some statements to appear which, for the sake of clearness, would bear modification. We doubt, for instance, if all physicians are yet ready to advise the resort to the aspirating needle in differentiating between cardiac enlargement and pericardial effusion in obscure cases, which he seems to do by implication in saying that "the diagnosis can be made only by puncture."

Each subject is fully discussed, and the recent additions to the physical signs of disease incorporated, but the chapters on the muscle sounds, adherent pericardium and atelectasis, deserve special mention, since they usually receive inadequate treatment.

It is altogether the best book in English with which we are acquainted, and while primarily intended for students, older practitioners will read its pages with profit. It is well printed on excellent paper and is profusely illustrated. Occasionally some of the illustrations seem unnecessary, in that they add nothing to the clearness of the description in the text, of which the two cuts on "Accidents to be Avoided in the Use of the Stethoscope" are examples. In a second edition, which it is quite safe to prophesy, it will be possible to correct a number of typographical errors, one or two of which are sufficiently serious to alter the sense.

Ulceration of the Bladder. Simple, Tuberculous and Malignant. By E. HURRY FENWICK, F.R.C.S., Surgeon to the London Hospital; Surgeon and Pathologist to St. Peter's Hospital for Urinary Diseases; Consulting Surgeon to the West Herts Infirmary. London: J. & A. Churchill; Philadelphia: P. Blakiston's Son & Co. 1900.

Mr. Fenwick gives what is justly the keynote of the spirit of this interesting brochure in its short preface in saying that "each fact has been fairly criticised, and probably will stand the test of time and experience. . . . The treatment which he suggests is not only open to criticism, but will undoubtedly be greatly modified as our knowledge of antitoxins increases and serotherapy improves," and certainly one could not ask of an author a fairer or fuller critical comment than that with which he examines the results of the very valuable observations which are embodied in this little volume. It is probably not too much to say that Mr. Fenwick is one of the most, if not the most, expert of endoscopists in the profession. He has devoted much time to this work, and has had an unusual experience in it; whatever he puts forward, therefore, has a special claim to attention, and in this instance, as on former occasions, the attention is well repaid.

The observations recorded rest for the most part on endoscopic examinations of bladders in which there were lesions associated with ulcerative processes. He is a believer in the existence of solitary ulcer of the bladder having a like character to that of perforating gastric ulcer. It occurs on the posterior wall of the viscus near the ureteral orifices, results in cicatricial formation and consequent deformity of the part affected, is slow to heal, and of rare occurrence.

The routes of invasion of tuberculous disease are

discussed with much intelligence, and some rather original suggestions are offered.

Amongst the most instructive parts of the work are the sources of error that occur in connection with cystoscopic examinations. Amongst these may be noted the difficulties in gauging the size and progress of an ulcerated surface at different examinations. The author points out that the withdrawal or approach of the prism of the cystoscope to an object diminishes or magnifies its size correspondingly, and that it is almost impossible to place the prism at the same spot at different examinations, and so to be sure that it is at the same distance from the ulcer on both occasions, and the same is true of the variations in appearance of objects according to variations in the angle produced by different positions of the tube; furthermore, the size and depth of an ulcerated surface will vary according to the degree of tension of the bladder surface upon which they have their seat, and this is changed according to the amount of the bladder contents, and the degree of elevation of the pelvis. If these factors are not identical at each examination, the degree of variation in the size of the ulcer is surprisingly great. If an ulcer be examined in a fully distended bladder it will appear as a flat erosion; if the fluid be now withdrawn it will gradually assume the look of a projecting, rolled Hunterian, chancre-like sore.

Some of the author's statements in connection with inflammation (tuberculous or otherwise) of the kidney toward the end of the volume are of much interest, and require, perhaps, more faith than the practitioner not skilled in the use of the cystoscope will be possessed of, in order to credit. Thus, "If the cystoscopist finds an irregular-shaped, caked, and patulous ureteral orifice, he may diagnosticate destructive changes in the kidney of that side. If no renal tumor can be felt on that side, and he notices that the ureteral orifice is as described above, and that it is also *displaced*, he may diagnosticate without hesitation a retracted, inflamed and adherent kidney, with probably one or more small cortical abscesses in the upper end of the organ." Yet when the author's reasons are detailed upon which these assertions are based, it is difficult not to share his views.

The monograph is one suited more particularly to the specialist than to the general practitioner, though it must be found interesting to all classes of the profession.

Eye, Ear, Nose and Throat. A Manual for Students and Practitioners. By WILLIAM LINCOLN BALLENGER, M.D., Assistant Professor of Otolaryngology, Rhinology and Laryngology in the College of Physicians and Surgeons, etc., Chicago; and A. G. WIPPERN, M.D., Professor of Ophthalmology and Otolaryngology, Chicago Ear, Nose and Throat College. Illustrated. Philadelphia and New York: Lea Brothers and Co. 1900.

This belongs to a series of so-called pocket textbooks. It is too large for a pocket and too small for a textbook. For the student or practitioner who needs a short résumé of the numerous subjects of the title this manual has certain attractions. Many of the morbid conditions are treated with a conciseness suggestive of a medical dictionary, others are given in more detail. The section on the eye is conservative, that on the ear, practical, that on the nose

and throat, strenuous. As an example of the latter, we find under such common affection as spurs of the septum, adenoids, peritonsillar abscess, a series of the most distressing symptoms, of which one or more may undoubtedly occur in some cases, but their form of presentation is such as to give an erroneous impression of the average case. Treatment in most cases is active and hopeful, but is it not contrary to our present views of pathology to cauterize the stump of a polypus after removal?

The book has about 500 pages, of which a discussion of the eye is contained in 170 and of the ear in 100. There is much in it that is good, concise and clear. It is not supposed to contain much that is original; what little there is is out of place. Such brief summarizing suggests superficial study; but the book, if properly used, will be of value.

The American Illustrated Medical Dictionary. A New and Complete Dictionary of the Terms used in Medicine, Surgery, Dentistry, Pharmacy, Chemistry and the Kindred Branches, with Their Pronunciation, Derivation and Definition. By W. A. NEWMAN DORLAND, A.M., M.D., Assistant Obstetrician to the University of Pennsylvania Hospital, etc. Philadelphia and London: W. B. Saunders & Co. 1900.

There is already no lack of medical dictionaries of varying size and completeness, but we confess that this latest one attracts us anew, both by its form and matter. It is of medium size, containing 770 pages, and its definitions are brief. Certain words are treated at greater length and short descriptions given of the prominent symptoms of diseases, and of the functions of organs. Tables and diagrams are used extensively and with excellent effect. The binding of the book is sumptuous and no pains have been spared to make the pages as attractive in appearance as the covers. Although we do not quite agree with the author that "physicians and students have long felt the need of such a work," we are quite ready to admit that the book will find a useful place in the hands of physicians and others.

Stringtown on the Pike. A Tale of Northernmost Kentucky. By JOHN URI LLOYD, author of "Etidorhpa," etc. Illustrated. New York: Dodd, Mead & Co. 1900.

The author of "Stringtown on the Pike" has written a book which will do much to keep alive the traditions of one of the most deeply interesting States of the South. He clearly knows whereof he writes and has a fund of information regarding the details of negro life and superstition, which lend to his pages a decided charm. The book deals largely with certain primitive types of the negro, types which we fear are growing less with the advance of civilization, and one gets a glimpse into the inner working of the negro mind which is of very considerable psychological interest. As is to be expected from the character of the story, the text abounds in dialect, which it requires some attention to render easily intelligible to the average reader. The book is attractively illustrated, chiefly with photographic reproductions, and both the binding and the presswork are a credit to the publishers. We would cordially recommend Mr. Lloyd's book to all those who are likely to find an interest in a characteristic and little described type of primitive American life.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 20, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
 283 WASHINGTON STREET, BOSTON, MASS

TWENTIETH CENTURY CEREBRAL PHYSIOLOGY.

SOME months ago there appeared in a New York medical contemporary two remarkable papers on certain brain functions and anatomical structures. One of these papers, which was profusely illustrated, was entitled "Rampancy, the Fervor of the Forehead." We read it with interest and no small degree of expectancy as to the possible light it might throw on subjects of vast interest to the human race. Our quest for knowledge resulted in disappointment, or at least in a painful sense of our inability to grasp the conceptions of the author. For example, however much we were edified by the following statements, we were impressed with an increasing consciousness of our own ignorance of recent work on the nervous system. "Life is rampancy. Take the body: the whole body is a series of ramping tissues, while the highest, the supreme or pro-ramp, the acme, is that of the neck and head; the ramp heavenward or skyward—for example, the neck of swan, fowl, or stallion. The ramp of the head is a secondary characteristic." And again: "When the master pats his dog on the head this lobule" (the metopic lobule of the author) "is touched—the creature ramps. The cavalry soldier and his horse are tied by this lobule as by an invisible navel cord. The generous steed is rampant to serve, to die if need be. By patient study of the brain, accepting what we find, we must acknowledge that the heart of the non-immortals—that is, those who have not the *logos*; for instance, "man's best friend," the cow; that master philanthropist, the dog, and that leader of man through the ages, the lamb—have also the heart in the right place." And finally we are told that "The subject of this brief essay is the localization of the greatest thing in the world, the greatest thing—indeed, in final analysis, the only thing, for it is the alpha and omega, the oldest and youngest of the gods, Eros, Agape, Philia, Spes, Caritas, Humanitas. It is the alpha and omega, the all in all."

All this may be true and based on a profound knowledge, but what does it mean? We confess that the "rampancy," as a recognized scientific fact, has not yet penetrated New England. We were inclined at the time of the appearance of this and its companion paper to enter a plea of ignorance and ask for light. We refrained, thinking that our contemporary knew whereof it wrote, and that in due time the mystery would be solved through the attention such a paper would attract among recognized experts. Our hope was disappointed, and the matter, important as it is, had passed from our mind. It has been unexpectedly revived by the appearance in a no less esteemed Philadelphia contemporary of another article by the same author, which bears the title, "The Struggle for Like Lobule." This would seem to indicate that New York is no longer to be the sole possessor of these secrets of brain structure, and that the new knowledge is slowly spreading westward. Unfortunately for us, this new paper in no way elucidates the preceding.

The following is clearly enough expressed, but so far as our intelligence goes carries with it no meaning: "I confess that my study of the brain of ruminants has led me to a different conclusion" (it is unnecessary to the sense to quote the previous conclusion), "which is, that these lobes are vital, belong not to the three higher senses, but are rather of the animus of the physique; that in the bull, *Bos taurus*, for instance, these lobes hold the animus of the bull tongue, and bull throat, and of the bovine corporosity, and the power of reproducing and propagating the bovine race. They can be nothing else. The rational inference is that in *homo*, a being that in many respects resembles this far from ignoble animal, these lobes have the same significance; that in them we are to seek the spirit of substantial living and lusty thriving, and sound propagating; in short, the root, stalk, and flower of the vegetative life. The dissection, preparation, casting, and photographing of the brains of something over a hundred ruminants have convinced me that the posterior spheres in *bos* and *homo* are homologous."

This is also illuminating to dull minds: "The sphenoidal pole is gustatory, of this the evidence is conclusive. This stoma-looking lobule with its cross incision is the image of the glossopharyngeum, can be nothing else than the cerebral head of the glossopharyngeal nerve, together with associate centres. It is the chef and criterion, the lobule of the banquet. In its labyrinths are the spiritual representatives of the bountiful table of nature or of art. The opposing pole, the occipital, the united gyri fusiformis and lingualis, with terminal bulbs or ramps or lobules, from the superior or middle temporal, or the third occipital or from two or all three of them, is the lobus genitalis. Its shape in primates is more or less palliform, and this form made up of stemons, ramps, or stamen-like or serpens-like double curves. This, then, is the "burning bush," the ever budding "rod of Jesse,"

the fleur de lis "fairy tree," etc., the soul and maintenance of the life of the race, as its polar opposite, the sphenoidal pole, a veritable lobus succulentius, is the spiritual supporter or nourisher of the life of the individual."

It is perhaps not necessary to quote more, although it is furthest from our intention to do any injustice to the writer of these somewhat revolutionary ideas by partial quotation. To show our spirit of fairness, however, we add the following bit of information: "I do not see how it is possible, in the light of comparative anatomy, for the under surface of the brain to represent anything very lofty or spiritual. It seems to me rather as the soul of the vegetative life. . . . Succulence and corpulence are the main characteristics in the physique *et morale* of the domestic swine, as of the stall-fed ox, and these spirits swell and fill the lowest parts of the brain, just as salience and insolence are the two striking features in the physique *et morale* of the wildcat, which two spirits rise to the highest point of the brain."

In fact, these papers are so filled with ideas which are new to us that we are compelled to admit that the progress of the study of cerebral function in New York and Philadelphia has gone far beyond our boldest conjecture. We regard the future with some trepidation, however, if such startling acquisitions of knowledge have already been made as these narrated in two of our most trustworthy contemporaries. It occurs to us also that it would have been kinder to suppress these ideas at least until the world at large is better prepared to receive them. What is written is naturally beyond editorial control, but publication carries with it a responsibility. It is, on the whole, a wise policy to refuse absolute nonsense.

THE ARMY BILL AND THE MEDICAL DEPARTMENT.

THE bill for the reorganization of the army as sent to the Senate at Washington shows a surprising discrimination against the medical corps. It is generally recognized that the best administrative ability, the most thorough knowledge of hygienic and sanitary principles and details, the best medical and surgical technical skill are of the first consequence for the safety and well being of troops on active service and for the successful issue of a campaign. Our soldiers should be able to feel that they have these on their side whenever the emergency arises. It is also very well known that no profession, not even that of arms, requires from its foremost representatives a higher order of intelligence, a longer or more expensive training, than does that of medicine.

Now, either our national representatives expect to get something for very much less than its recognized value, or else they really think that what is not good enough for anything else is good enough for the U. S. Army. For the former attitude they should

be too shrewd, for the latter too patriotic. The object lessons of the Spanish War, the campaigning in the Philippines, the South African War, are too immediately present as examples of the importance of a first-rate medical department to permit of even so poor an excuse as ignorance.

Now what does the proposed army bill, if not amended — and we are glad to learn there is a good prospect that it may be amended — what does it offer the Medical Department?

The Medical Department is graded for rank, promotion, and, in consequence, for pay, below every other department and special corps of the army, and, second lieutenants excluded, is graded below the line. Compared with staff departments having captains but no lieutenants (Quartermaster's, Subsistence and Pay Department), each officer in these departments in order to reach a colonelcy has to pass through thirteen and one-half files, while an officer of the Medical Department has to pass through thirty-nine files. Compared with those special corps and departments having lieutenants, while a medical officer has to pass through thirty-nine files, an officer of ordnance has to pass through but sixteen and one-half, an officer of engineers above the grade of second lieutenant has to pass through but seventeen files, and including the grade of second lieutenant has to pass through but twenty-two files.

A medical officer to obtain a colonelcy has to pass through three times as many files as an officer of the Quartermaster's, Subsistence or Pay Department, through more than twice as many files as an officer of the Engineers or Ordnance, and more than one and one-half times as many files as even an officer of the Signal Corps.

But aside from the total ratio of files to pass to a colonelcy, and consequent promotion and rank, the Medical Department is strongly discriminated against in the higher grades, those gained only after long service, and consequently most deserving of reward. An officer of the Medical Department having gained the grade of major after having to pass through approximately two or three times as many files as an officer of the other staff corps, to gain a colonelcy has to pass through nine files, while officers of the other staff corps, having officers below the rank of major, have to pass through but four and one-half files in all corps, except the Engineers, where but six files have to be passed. Thus to gain a colonelcy, after reaching a majority, officers of the medical corps have to pass through twice as many files as do officers of other staff corps, the Engineers excepted, and through one-half times more files than do officers of this latter corps. The discrimination against medical officers, compared with ranking officers of the line, is equally striking. Officers of the line having gained a majority have to pass through but four files to a colonelcy against a medical officer's nine. Even compared with the line of the army, while strongly discriminated against in the higher grades (nine to four files above captain), if the second lieutenants are excepted, medical officers have less rapid promotion than do officers of the line; the line having but thirty-three to thirty-four files to a colonelcy, against the Medical Department's thirty-nine files.

But not only is the proposed grading of the Medical Department unjust, as compared with other staff and special departments, but it will seriously impair the future of the corps, in that, by materially reducing the emoluments, it will, in the future, offer too small inducements to that bet-

ter class of professional men whose entry to the corps maintains its efficiency.

Under the present grading of the corps, with twenty-one files to gain for each majority, the average length of time required to reach that grade is eighteen years. With the proposed grading of thirty files to each majority, it will take an average of twenty-five years' service to obtain even this grade. The consequence will be that officers will serve in the junior grades much beyond a length of time consistent with the attainments of members of a trained profession, and few men of attainments in the medical profession will enter upon a life career offering so few opportunities for advancement. This especially, when after having attained a majority by this long service, they are still discriminated against in the higher grades, and have to pass through many more files to obtain a colonelcy than do officers of any other special corps or officers of the line.

To, in part, equalize the Medical Department with the other staff corps, it would seem no more than just and wise certainly to at least equalize them with the Engineer and the Signal Corps, especially as these corps resemble the Medical Department, in that they are, in part, made up of enlisted men.

NEWSPAPER EXAGGERATION.

In certain daily papers during the past few days has appeared in conspicuous type a much exaggerated statement regarding the presence of influenza in Boston. It was stated, for example, that the hospitals were overcrowded with sufferers from the disease, and that even the private rooms were taken by the more well-to-do sufferers. As a matter of fact the wards of the Boston City Hospital are at present far from full, and there is no indication whatever of the overcrowding suggested by our somewhat too ardent contemporary. That there is a certain amount of influenza prevalent is both probable and natural; that it has reached epidemic form is untrue. Protests, no doubt, in such matters are quite unavailing, but it is at least a satisfaction to express one's feeling of utter disapprobation at such means of making copy. Unfortunately such reports, reduced to print, have a far-reaching effect upon the minds of the ignorant and unreasoning classes in the community, and so unquestionably do harm by exciting a quite unnecessary fear. It is to be hoped that editors and reporters may finally be awakened to a true sense of their privileges and duties in dealing with a too readily receptive public.

MEDICAL NOTES.

ANNOUNCEMENT OF COMMITTEE ON SCIENTIFIC RESEARCH, AMERICAN MEDICAL ASSOCIATION.—The Committee on Scientific Research of the American Medical Association desires to announce that it has available the sum of \$500 for the assistance of researches to be undertaken in the next six months, and that the money will be appropriated if applications be received within the month of January, 1901. Applicants should state clearly the character of the research

to be undertaken, and the facilities at their command, addressing Dr. H. C. Wood, chairman, 1925 Chestnut Street, Philadelphia, Pa.

SIR WILLIAM HUGGINS, PRESIDENT OF THE ROYAL SOCIETY.—Sir William Huggins, who succeeds Lord Lister as president of the Royal Society, shares with Sir Joseph Hooker, a past president, the record of having received three of the society's gold medals. Sir William was elected a fellow in 1865, and has served five times upon the council. He is a K.C.B., D.C.L. of Oxford, LL.D. of Cambridge, Edinburgh, Dublin and St. Andrews, Hon. F.R.S.E., F.R.A.S., etc. The remaining letters of honor occupy seven lines in the Royal Society's calendar.

VITAL STATISTICS OF MASSACHUSETTS.—We have lately received and shall publish next week an important paper, read at a recent meeting of the New Jersey Sanitary Association, on "The Practical Use of Vital Statistics," in which to our regret and mortification, but not altogether to our surprise, we find the present vital statistics issued by Massachusetts held up as a warning and an example of what to avoid, rather than cited as a notable standard of the best, as would formerly have been the case.

VITAL STATISTICS OF HAVANA.—Major W. C. Gorgas, chief sanitary officer of Havana, gives a most favorable report of the death rate in that city for the month of November. There were 444 deaths, less than during any month during the preceding ten years. The number of cases of yellow fever has, however, been large for this time of the year, due chiefly to recently arrived immigrants. The fever is, however, decreasing, and it is thought will disappear by the middle of December.

WOODBIDGE TREATMENT OF TYPHOID FEVER.—It is said that the Woodbridge method in the treatment of typhoid has not stood the test of experience. The opportunity of testing his method, accorded Dr. Woodbridge at the Fort Meyer Hospital, gave a mortality of about 10%, as contrasted with a mortality of about 7% by usual methods.

RESIGNATION OF DR. ANITA NEWCOMB MAGEE.—Dr. Anita Newcomb Magee, Acting Assistant Surgeon, U. S. Army, in charge of the Army Nurse Corps, has tendered her resignation to the War Department. The resignation has been accepted, to take effect December 31st. The position will hereafter be abolished.

PASTEUR DEPARTMENT AT THE BALTIMORE CITY HOSPITAL.—The College of Physicians and Surgeons of Baltimore has established a Pasteur Department at the Baltimore City Hospital, for the preventive treatment of hydrophobia.

"A DEATH FROM HYDROPHOBIA."—We are informed that the death from hydrophobia reported in our issue of December 13th occurred after an illness of four days and not of two days, as there stated.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON.—For the week ending at noon, December 19, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 155, scarlatina 26, measles 26, typhoid fever 24.

TWO CENTENARIANS.—Mrs. Angelique Galipeau recently died in Northampton, Mass., in the one hundred and fourth year of her age. Mrs. Galipeau was born in Montreal, January 25, 1797. Her father is said to have died at the age of one hundred and one, and her mother at one hundred. Mrs. Galipeau was married four times. She was remarkably vigorous until recently, and at her birthday celebration in 1898 she sang and took part in the dancing. Captain Jonathan A. Norton, aged more than one hundred and four years, died last week in East Lee, Mass. He was born August 1, 1796, and had been a tradesman, a farmer, a soldier, a poet and an inventor. He was probably the first man to make matches in Berkshire County. He was commissioned a captain of infantry by Governor Brooks. When sixteen years of age he was drafted for the War of 1812, but was not allowed to serve. Two of his sons served in the War of the Rebellion.

CHANGES IN THE FACULTY OF THE YALE MEDICAL SCHOOL.—The recently published Yale University catalogue announces the following changes in the medical faculty: Dr. Otto G. Ramsay, of Baltimore, has succeeded the late Prof. James Campbell as professor of obstetrics; Russell H. Chittenden, director of the Sheffield Scientific School, has succeeded Prof. Benjamin Moore as professor of physiology; F. S. Hollis has succeeded W. H. Parker as instructor in chemistry, and Dr. Percy D. Littlejohn has taken the place of Dr. W. H. Crowe in the medical clinic. The only changes in the courses of instruction are the additions of recitations and hospital work in Dr. Robert E. Peck's clinical dispensary work in neurology and a series of six lectures by Dr. Shepherd on "Life Insurance Examinations."

CHILDREN'S DEFORMITIES DISCUSSED AT A MEETING OF THE BOSTON PHYSICAL EDUCATION SOCIETY.—Physical deformities in school children was the subject discussed at the last meeting of the Physical Education Society. Statistics have shown that only 13% of school children assume correct positions habitually while studying. The papers were discussed by Drs. Sargent, of Cambridge, and Stone and Fitz. of Boston. Many of the malformations in school children were attributed to defective furniture. It was pointed out that very little was known as yet of the physical endurance of children, a great deal of their restlessness being due probably to inability to stay in one position long, from mere lack of strength.

PROPOSED HOSPITAL FOR TUBERCULOSIS AT PROVIDENCE, R. I.—Providence is said to be engaged in an agitation regarding the establishment of a hospital for tuberculosis. The State Board of Health

has lent its support to the movement. Being a State board, this body proposes to induce the General Assembly to vote it the sum of \$200,000 to establish the hospital and thereafter to provide the means for its continued support. The Providence Medical Society and the Rhode Island Medical Society have both appointed committees to further the plans of the State Board of Health.

POSSIBLE NEGLIGENCE OF WALTHAM, MASS. DOCTORS.—A notice from the Waltham Board of Health has been sent to all the physicians in the city informing them that they must report all cases of typhoid fever as soon as they find them. Negligence has been claimed in failing to report a certain case of typhoid occurring near the Cambridge water supply.

A CASE OF SUSPECTED SMALLPOX AT WATERTOWN, MASS.—A woman recently from Nova Scotia is supposed to have contracted smallpox there. Examination by several physicians justified her removal to the contagious hospital.

Correspondence.

UNUSUAL PREVALENCE OF IMPETIGO CONTAGIOSA.

BOSTON, December 17, 1900.

MR. EDITOR: Permit me to call the attention of your readers to the unusual prevalence of impetigo contagiosa in adults at the present time.

This affection has been very common among children in schools and crowded tenements for several years, often associated with pediculosis capitis, and has been occasionally seen upon the faces of adults in the form called staphylococchia by French dermatologists. Within the last two or three months these cases have increased greatly in number, especially in private practice. It affects chiefly the shaven parts of the face of young men, spreading from this region to cheeks and forehead, and downwards upon the neck.

It rarely shows itself upon the hands and lower limbs, common seats of the disease in young children. In three instances I have observed it upon the scalp in men, chiefly on parts free from hair. The lesions in adults differ, as is well known, from those in children, being larger, varying in size from a dime to a quarter of a dollar. The crusts are not so heavy, and they are often much more numerous.

The history of contagiousness is frequently a striking feature in these cases. A young man says his roommate is affected in a similar manner, or the young lady with whom he is intimate. He knows several persons having it who shave at the same barber shop, or who work in the same factory. I have in a few instances treated several adults in one family. It is especially prevalent now among students in a university in this vicinity.

It is without doubt easily communicated from person to person by direct contact, and indirectly by using the same towel, soap, shaving apparatus and garments; possibly also by the infection of towels and clothing at the laundry.

Fortunately it is a disease easily controlled. The staphylococci and streptococci which produce it are destroyed by such simple applications as sulphur, salicylic acid, and boric acid in ointment form, or by a mild wash of corrosive sublimate. Of chief importance is the careful disinfection of every article which has come in contact with the affected skin. The mere dipping of such articles, towels, brushes, razors, etc., in hot water is not sufficient for this purpose, for this reduces the temperature of the

water to an ineffective degree. They must be thoroughly boiled.

It is to call attention to the importance of such precautionary measures in households, schools, gymnasiums and barber-shops that I send this communication.

Very truly yours,
JAMES C. WHITE, M.D.

METEOROLOGICAL RECORD

For the week ending December 8th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps:—

Deaths reported 2,363; under five years of age 677; principal infectious diseases (smallpox, measles, diphtheria and croup,

cerebrospinal meningitis, diarrheal diseases, whooping cough, erysipelas, fevers and consumption) 532, acute lung diseases 376, consumption 281, diphtheria and croup 115, typhoid fever 40, diarrheal diseases 35, cerebrospinal meningitis 15, whooping cough 12, scarlet fever 10, measles 7.

From whooping cough New York 6, Philadelphia 3, Boston, Cambridge and Salem 1 each. From cerebrospinal meningitis New York 4, Everett 2, Baltimore, Boston, Lawrence, Somerville, Salem, North Adams, Quincy and Medford 1 each. From typhoid fever New York 21, Philadelphia 7, Pittsburg 3, Baltimore and Boston 2 each, Worcester, Lowell, Lawrence, New Bedford and Springfield 1 each. From scarlet fever Pittsburg 4, New York 3, Philadelphia, Baltimore and Boston 1 each. From measles New York 4, Pittsburg, Worcester and Holyoke 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending November 24th, the death rate was 17.6. Deaths reported 3,924: acute diseases of the respiratory organs (London) 322, diphtheria 76, whooping cough 68, fever 65, measles 58, diarrhea 46, scarlet fever 38.

The death rates ranged from 10.0 in Norwich to 24.3 in Salford: Birmingham 17.0, Bolton 23.2, Cardiff 10.5, Derby 20.3, Gateshead 20.0, Halifax 16.1, Leicester 14.5, Liverpool 21.9, London 17.2, Manchester 21.0, Newcastle-on-Tyne 15.8, Nottingham 20.4, Portsmouth 15.2, Sheffield 20.4, Swansea 20.3, West Ham 14.1.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING DECEMBER 13, 1900.

AUSTIN, H. W., surgeon. Detailed as medical officer in command of the national quarantine service on the Delaware Bay and River. December 5, 1900.

MEAD, F. W., surgeon. Granted leave of absence for one day. December 7, 1900.

CRAIG, R. C., acting assistant surgeon. Granted leave of absence for seven days from December 19th. December 13, 1900.

WALERIUS, M., senior hospital steward. Granted leave of absence for seven days from December 4th. December 4, 1900.

CASUALTY.

JAMES CRAGG, senior hospital steward, died at Key West, Fla., December 2, 1900.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, Wednesday, December 26, 1900, at 8 P. M.

Papers: Dr. E. S. Boland, "Report of Three Cases of Hernia in Children Cured by Use of the Yarn Truss."

Dr. C. H. Hare: "Report of a Cesarean Section for Placenta Previa."

Drs. Frederick Coggeshall and John W. Lewis will each report "A Case of Placenta Previa."

Business: Election of a chairman for the ensuing two years. W. H. GRANT, M.D., Secretary, 419 Boylston St.

RECENT DEATH.

PETER F. CURLEY, M.D., one of the best known physicians in Newport, R. I., died last week after an illness of some two months. He was born in Newport in 1861, received his degree from the Albany Medical College in 1883, practised two years in Albany, two in Providence and since 1887 had been in Newport.

OPERATIVE TREATMENT OF GOITRE.¹

BY J. COLLINS WARREN, M.D., BOSTON.

THE operative treatment of tumors of the thyroid gland appears to be indicated in rapidly growing tumors in young persons in whom the medical treatment has been ineffective. As soon as the tumor has reached a size sufficient to cause pressure symptoms the operation becomes urgent.

It is in young married women under these conditions that I have performed the majority of my operations.

The operation consists either in the removal of a limited portion of the gland, such as an isolated lobe or a more or less independently growing adenomatous mass of solid gland tissue, or in the enucleation of a cyst.

The incision which I have adopted is U-shaped, one or both of the arms being used according to circumstances—usually it is not necessary to complete the entire sweep of the letter, as the lobe on one side is smaller than on the other; a portion or the whole of the more normal lobe should be allowed to remain according to circumstances. The incision through the skin usually divides one or more large veins. They should be secured with forceps before division if possible, as they are liable to retract beneath the skin and to be overlooked in the final treatment of the wound.

In order to reach the surface of the tumor the edge of the sternomastoid muscle should be sought for and that muscle, which is thin and flattened, must be drawn aside. Occasionally it is necessary to divide the sternohyoid and sternothyroid and also the omohyoid muscles, and there is no harm in so doing, as they can readily be sutured after the extirpation if desired. These muscles can, however, be drawn aside and the different layers of connective tissue covering the capsule are then divided. This releases pressure over the tumor and it begins to rise up from the depths of the wound and become more superficial. When the capsule has been reached care should be taken not to injure it with the knife, as the resulting hemorrhage is hard to control.

In order to lift the tumor from its bed the tissue holding down the upper and outer margin of the lobe should be clamped and divided, the edge of the lobe drawn gently forward, and an effort made to secure the superior thyroid artery. The tumor can now be lifted easily forward and towards the median line in order to disclose the inferior thyroid artery. The recurrent laryngeal nerve lies in close contact with this vessel and is directly behind it. It is not readily found, and in securing the artery care should be taken not to clamp the surrounding tissues too generously, as the nerve may thus be included in the ligature. By keeping close to the surface of the tumor and avoiding wandering between outlying layers of connective tissue, this complication may be avoided. The entire mass of the tumor is now reflected over to the opposite side of the neck and the attachments of the gland to the anterior wall of the trachea are brought into view. In order to free these the knife

must be used. The dissection may be continued to the opposite side of the neck and the smaller lobe removed in much the same way as the larger one. Care should, however, be taken to leave a portion of the gland behind to avoid the production of an operative myxedema. The amount necessary for this purpose need not be large, and when I have occasion to include both lobes of the gland in the operation I have found that a mass about the size of an English walnut is amply sufficient for the purpose.

It is not, however, necessary to remove such a large proportion of the gland in the majority of cases, as a division of the lobe operated upon at the point of its junction with the isthmus is usually sufficient. In this case the opposite lobe either does not increase in size after the operation or grows gradually smaller.

There are many cases reported in which total extirpation of the thyroid gland has not been followed by myxedema, but this is accounted for by the presence of accessory glands near the arch of the aorta, at the side of the trachea, or between it and the esophagus, or near the hyoid bone. It is not justifiable, however, to count upon the existence of any such glands, and a portion of the thyroid gland itself should therefore always be allowed to remain.

All vessels should be tied with scrupulous care. The material I prefer for the purpose is fine silk, as it is much less likely to slip than any of the forms of animal ligature. The neck is so supple and movable a region that the chances of such a mishap are greater than elsewhere, especially when there is much vomiting during the recovery from the anesthetic. It is well, therefore, to take the precaution to give a subcutaneous dose of morphine either before or directly after the administration of the anesthetic to prevent vomiting and to keep the patient quiet. A tight dressing cannot be applied in this region, and the nurse should therefore be instructed to watch for vomiting and to exert gentle manual pressure upon the wound during the act. On one occasion, owing to a neglect of this precaution, I was summoned hastily an hour or two after the operation to arrest a serious hemorrhage which, on opening the wound, appeared to have originated from a comparatively unimportant vessel.

The edges of the wound had better be brought together with silkworm gut and one provisional stitch taken at the most dependent point to allow a small gauze wick to be inserted as far as the deeper portions of the wound. The object of this precaution is not to avoid sepsis, but to prevent a distention of the walls of the wound by serum or blood clots and thus avoid the danger of sudden pressure on the trachea. This danger will be greatly increased by tight bandaging. The dressing should therefore be so applied and should consist of such materials as will give support without causing pressure. For this purpose the horse-collar dressing may be applied; rigidity being given to the collar by paper or pasteboard, pressure and counter pressure being thus exerted on the jaw and clavicles. Fixation of the neck and head may be secured by the application of the ordinary tin internal angular elbow splint to the neck, the head being secured firmly to the upright arm of the splint, while the horizontal arm is bandaged to the shoulder. (Figs. 1 and 2.) The gauze wick should be removed at the end of twenty-four hours and the stitches can ordi

¹ Read before the Surgical Section of the Suffolk District Medical Society, November 7, 1900.

narily be removed a few days later, and the wound edges can then be covered with cotton and collodion, all further bandaging being abandoned.

Enucleation is an operation which should be reserved for small solid adenomata or cysts which are easily separated from the surrounding gland tissue. I have not found hemorrhage troublesome in any of these operations. It is better, if possible, to avoid opening the cyst wall during its removal, for in large

FIG. 1.

FIG. 2.

cysts if a vein be injured it is difficult to secure. The time has gone by when the surgeon should be content to open such a cyst and pack it with gauze. The cyst should be attacked externally and not internally.

Resection of a large wedge-shaped piece of the gland on one or both sides has been recommended by Mikulicz. The remaining portions of the gland tissue are brought together by subcutaneous sutures. Reinbach reports 80 cases of resection by this method, with a mortality of 3.75%.

EXOPHTHALMIC GOITRE.

I have operated upon but 2 cases of this disease and my experience has not been encouraging. In the first case there was an exceedingly stormy convalescence, due apparently to the absorption of thyroid juice from the stump of the portion of the gland left behind. The temperature rose the first evening to 106° F. and the pulse to 202, but the wound healed by first intention. This patient has been from time to time since under Dr. Putnam's observation. Her health was only partially restored by the operation. In the second case the patient passed through several days of convalescence without bad symptoms of any kind. On the fourth day, however, during a sudden attack of tachycardia she died.

I have never tried division of the isthmus; it is possible that relief may be obtained from pressure upon the trachea in an otherwise inoperable case in this way. It is said to be followed by some atrophy of the lateral lobes. Unless the isthmus were well defined it would seem best not to adopt this method, as extensive incisions without extirpation might lead to various undesirable complications.

In regard to the mortality of the operation, in my own experience with benign goitre other than Graves's disease, I have had but one death and that was due to heart failure at the close of an operation for the removal of an enormous goitre of twenty years' standing. As a rule, goitres in this region of the world do not attain an exceedingly large size and the operation for their removal appears to be one attended with little danger if the ordinary precautions above referred to are observed. Reverdin collected 6,103 cases with a mortality of only 2.88%.

I have never observed a recurrence of the tumor after operation, although Brunner reports cases collected from literature in which there were 31% of recurrences, 18% recurring on the operated side and 23% on the opposite side.

I have never performed division of the cervical sympathetic. The operation is intended chiefly for the vascular form of goitre. Jonnesco reports 10 cases operated upon by this method for Basedow's disease; 6 were cured and 4 improved.

Operations upon cases of aberrant goitre are reported from time to time. Hofmeister reports such a tumor under the skin of the breast. I have operated upon a thyroid growth between the base of the tongue and the epiglottis—the point of origin of the thyroglossal tract of His.

In regard to the anesthetic, I have always been able to use ether. Many surgeons prefer local anesthesia and this is strongly recommended by Kocher when the pressure symptoms are strongly marked. Many formidable operations have been performed with cocaine anesthesia without causing suffering to the patient. A 1% solution is sufficient for the purpose.

In advising the operative treatment of this disease it should be remembered that many cases yield to medical treatment. Kocher makes the somewhat surprising statement that 90% of the cases which come into the hospital at Berne are so improved by medical treatment that operation is not necessary. He does not consider that thyroid extract gives any better results than preparations of iodine.

Since the thyroid treatment of goitre has been em-

ployed I have had comparatively few cases sent to me for operation, but I have seen quite a number of cases in which the treatment has produced no effect. Thus far I have failed to see any beneficial effects myself in the use of the drug and I am not personally cognizant of a single case in which it has effected a permanent cure.

STATISTICS OF OPERATIVE TREATMENT OF THYROID TUMORS.*

BY LINCOLN DAVIS, M.D., BOSTON.

SIMPLE GOITRE.

THERE has been a rapid decline in the mortality of operations for simple goitre during the last fifty years. In 70 operative cases reported before 1850 Kocher¹ placed the mortality at 40%; in about 400 operations between 1850 and 1883 it fell to less than 15%; and finally in the period since 1883, in 6,000 operative cases, the mortality is under 3%.

These latter figures are quoted from J. Reverdin,² of Geneva, who reported before the French Congress of Surgery in October, 1898, the largest and most complete collection of operative cases of goitre, excluding malignant and exophthalmic goitre, which exists in the literature. His exact total is 6,103 cases, of which 2,120 were derived from the literature; the remainder were obtained through personal communications. There were 176 deaths, a mortality of 2.88%. The number of operations reported since the publication of Reverdin's great collection is altogether too insignificant to affect his figures. These figures, however, dating back to 1882, and including all kinds of cases, with the two exceptions before mentioned, treated by a large number of surgeons, employing a variety of methods, are very naturally surpassed by the latest statistics of certain notable individual operators in this line of work.

Kocher³ in 1895 reported 1,000 cases of goitre before the German Congress of Surgery. Of these 870 were benign, with 11 deaths, a mortality of 1.37%. Some were *in extremis* when operated upon; 5 died as the immediate result of the operation, 3 died of Basedow's disease, 2 of infection, and 1 death was due to chloroform. In 1898⁴ he reported 600 additional cases, prefacing his statistics with the statement that 90% of the cases coming to his clinic were so benefited by medical treatment as to require no operation. Of 556 cases of benign goitre which were operated on in this last series, there was but a single fatality, and that due to chloroform; mortality, 1.8%, about one-thirtieth of the mortality of his first 100 cases reported in 1883. Since the latter date, his total number of operations for simple goitre is 1,426, with 12 deaths, a mortality of .84%. Partial extirpation of the gland was performed in the great majority of cases.

At the German Congress in 1896, Bruns⁵ reported 400 operations for goitre dating back to 1883, with a mortality of 1½%. He had no deaths in his last 150 cases. Girard,² of Berne, reported in 1898 545 cases, with 6 deaths, a mortality of 1.1%.

Socin,² of Bâle, stated in 1898 that in his last 200 cases he had 1 death from pneumonia, a mortality of .5%. He is an advocate of the method of enuclea-

tion. Kronlein⁶ in 1892 reported 200 cases without a single death.

In this country and in England the disease is comparatively rare, and operations consequently few. Martin⁷ collected 182 cases of goitre from the reports of five hospitals in Philadelphia for ten years down to 1897; only 5 of these cases were operated on, with 1 death. The records of the Massachusetts General Hospital show 37 operations for simple goitre, with 2 deaths.

In considering the mortality of the various operative measures and the causes of death, the statistics of Reverdin are again quoted. In 3,408 operations of which he has details there were 118 deaths, distributed as follows:

137 total extirpations	26 deaths,	18.98%
1212 partial extirpations	42 "	3.46 "
1276 enucleations	10 "	.78 "
343 resections	23 "	6.66 "
438 other methods	17 "	3.88 "

The mortality of the 1,276 enucleations is practically that of Kocher in his 1,426 cases, in the majority of which he performed partial extirpation. In 96 of the 118 fatal cases the causes of death were known. Forty-five were of respiratory origin divided as follows: Pneumonia, bronchopneumonia and bronchitis, 32; asphyxia, 10; fatal lesions of recurrent laryngeal nerves, 3. Twelve cases were due to collapse and shock. There were 19 cases of fatal hemorrhage; none of these followed enucleation. Thirteen deaths were due to sepsis, 3 deaths from tetany, 1 from myxedema.

In the whole literature Reverdin knows of 9 published cases of death due to entrance of air into the veins.

Deaths due to anesthetics are not infrequent. Kocher reports 2 from chloroform. He uses local cocaine anesthesia in the majority of cases.

Post-operative complications.—Marked elevation of temperature following operation has been noted by a large number of observers. Bergeat⁸ states that only 3 histories out of 249 cases showed absence of fever in convalescence, although the usual course of wound healing was nearly perfect. This phenomenon, called thyroid fever by Berard, is ascribed by him to absorption of thyroid secretion set free at the time of operation.

Symptoms of what is now called cachexia strumipriva, following total thyroidectomy, were first noted by Reverdin⁹ in 1882. The condition was further described and named by Kocher the following year. The committee of the Clinical Society of London, in preparing its report on myxedema¹⁰ in 1887, collected 277 cases of intentionally complete thyroidectomy for simple goitre, in which the patients recovered and were kept under observation. In 69 cases, or 25%, cachexia strumipriva of a more or less severe type developed. Out of more than 550 cases of partial thyroidectomy, in which the patients recovered and were followed up, 6 only showed distinct symptoms of myxedema, a little more than 1%. Since the appearance of this report the operation of total thyroidectomy has been practically abandoned, except for malignant disease. Reverdin's statistics give a like percentage of cachexia strumipriva in total thyroidectomy, and a percentage of less than .5 in partial extirpation. Kocher reports 4 cases of myxedema in 1,600 operations for goitres of all kinds, including malignant disease, .25%.

* Read before the Surgical Section of the Suffolk District Medical Society, November 7, 1900.

Tetany is more common; it occurred 5 times in 137 total thyroidectomies, in Reverdin's series, 3.64%. Fourteen cases followed all other operations, less than .5%. Koehler reports a case of tetany following ligation of the four thyroid arteries.

Disturbance of phonation as the result of injury to the recurrent laryngeal nerves occurred 57 times in 1,212 partial extirpations, 4.7%, and 11 times in 1,276 enucleations, .86% in Reverdin's collection. Koehler's percentage is 7 in 900 cases. It proved temporary, however, in all the cases of benign goitres.

Recurrence.—All operations in use at the present day are liable to recurrence since total thyroidectomy is proscribed. Of 146 cases of simple goitre operated in Czerny's clinic, which were followed from one to eleven years after operation, 30, or 20%, had recurrence.¹¹ Kopp¹² re-examined 103 cases operated on by Roux, of Lausanne, after an interval of from one and one-half to six years. He found 36 cases where the remaining portion of the gland had increased in size, in 19 to a slight extent only. Of these 36 cases, 13 were operated on by Socin's method and 20 by Koehler's. The statistics of Bruns are more favorable; he reports 800 cases of Socin, Krönlein, Kappeler and his own, out of which less than one dozen required secondary operation for recurrence.

MALIGNANT GOITRE.

The surgical treatment of malignant disease of the thyroid gland has not taken part in the great advance made in the treatment of simple goitres. Koehler's mortality in 1883 was 25%, and it is 33% in his last report in 1898. Thirty-three cases operated in Czerny's clinic gave a mortality of 15%. Five cases were free from recurrence up to four and one-half years.

Sarcoma is rarer and more fatal than carcinoma. Tiffany,¹³ in 1897, collected 16 cases of sarcoma which were operated on, all with fatal results. Without making special search I have found 3 more reported cases in the literature,^{14 15 16} and 3 in the records of the Massachusetts General Hospital; all fatal.

EXOPHTHALMIC GOITRE.

Tillaux was the pioneer in the surgical treatment of this condition, performing thyroidectomy as early as 1860.¹⁷ He has had many followers.

Schulz¹⁸ published in May, 1900, the largest collection of operative cases of exophthalmic goitre to be found in the literature to date. He gives the results of 319 operations as follows: Cured, 175, 51%; improved, 89, 28%; unimproved, 13, 4%; died, 41, 13%. There are three principal operations in use at the present time: (1) Removal of a portion of the thyroid gland; (2) ligation of thyroid arteries; (3) resection of cervical sympathetic nerves.

In Schulz's collection there are 177 cases in which a portion of the gland was removed with cure in 102, 57%; improvement in 47, 26%; no improvement in 4, 2%; death in 24, 13%. One hundred and forty-nine of the cases were followed up. The causes of death are not tabulated in this collection. The operation, in addition to the dangers attaching to any thyroidectomy, seems to present a special gravity in this disease. A considerable number of sudden deaths, either during or after the operation, have been reported.^{19 20} These deaths are ascribed by many to acute poisoning

from absorption of the secretion of the incised gland.

The principal exponent of ligation of thyroid arteries is Koehler, who has tied three arteries in 49 cases of exophthalmic goitre, with 5 deaths. In 34 cases, reported in 1895, there was cure or improvement in 31. Rydygier has tied all four arteries in 22 cases. Cure or improvement resulted in 20; no improvement in 2; no cases of myxedema or tetany followed the operation.²¹ Kopp, however, reports a case in which only three arteries were tied, followed by tetany and death. In 81 cases²² treated by this method the mortality is 8½%.

Section of the cervical sympathetic nerves was first performed for exophthalmic goitre in man by Jaboulay,²³ of Lyons, in the spring of 1896. Jonnesco,²⁴ of Bucharest, is perhaps the principal exponent of this method; at the Thirteenth International Congress this year he reported 126 resections of the cervical sympathetic nerves; 15 of these cases were of exophthalmic goitre. His operation is total bilateral resection of the nerve with its three ganglia. In his last case he even removed the first thoracic ganglia. He reported 6 cases as completely and definitely cured of all symptoms after the lapse of from two to four years. There were 4 lasting improvements. In the 5 later cases the immediate results were excellent, but sufficient time had not elapsed to speak of the final result. He has had no fatal cases. In 35 cases reported by other surgeons²⁵ there are 5 reported cures, 20 cases of notable amelioration of all symptoms, 4 cases not improved, and 6 deaths: 2 from pneumonia; 1 from delirium tremens, 1 sudden unexplained death on the table, 1 after secondary operation five weeks later, 1 from cachexia. Total number of cases treated by this method 50, with a cure in 11, 22%; improvement in 29, 58%; no improvement in 4, 8%; death in 6, 12%.

INFLUENZA IN ST. PETERSBURG.—Influenza has appeared in epidemic form in St. Petersburg.

NEOPLASMS OF THE THYROID GLAND.¹

BY CHARLES G. LUMSTON, M.D., BOSTON.

IN looking over my notes I find that I have had under my care 42 cases of neoplasm of the thyroid gland, divided up as follows: One case each of sarcoma and carcinoma of the thyroid gland, 12 cases of parenchymatous goitre, 14 cases of colloid goitre, 4 cases of cystic goitre, 7 cases of adenoma of the thyroid gland, and 3 cases of strumitis. Of these cases 31 were operated on Professor Kummer, the remainder by myself.

With the exception of the malignant cases, the principal symptom complained of by the patients which required relief was dyspnea, while hoarseness and dysphagia were less frequently prominent; palpitation of the heart was noted frequently. In many of our patients a careful treatment with iodide compounds had been carried out before the operation, which had only produced a slight improvement in the condition, or none at all.

The dyspnea complained of by the patients, the degree of which appeared to be very often in decided disproportion to the size of the goitre, has often been explained at the time of operation, when it was found that the goitre had become retrosternal in its development, and produced a very marked compression of the trachea. This compression was shown by a flattening of the trachea, either laterally or anterior posteriorly, and in the majority of cases the organ was displaced and formed more or less of a curve which also diminished its calibre. We have never met with the so-called softening of the trachea as far as we can recollect.

In operating, we occasionally employ the angular incision of Professor Kocher, and more frequently his transversal incision. The latter incision has the great advantage of leaving linear cicatrices which are easily hidden by the clothes. It certainly must be admitted that it gives less working space than the angular incision, and on several occasions we have been obliged to make a second oblique incision, but much space can be made if, after the transversal incision, the superficial muscle and aponeurosis are peeled back with the skin as far as the sternum and upwards as far as the cricoid cartilage. By thus proceeding, the transversal incision will often allow the surgeon to deliver a very large goitre.

In most cases we have not divided the sternomastoid muscle, but have simply split up the tissues in the median line from the sternum to the larynx in cases of very large goitre, and if the delivery of the neoplasm through this opening was not possible, one or several lateral nicks in the sternomastoid muscle were necessary and in some instances we have penetrated between the sternothyroid and the sternohyoid muscle.

In cases of very large goitre, where it was impossible to draw it out on account of vascular or fibrous adhesions, we were obliged to divide both sternomastoid muscles in order to bring the neoplasm into view and to ligate the vessels *in situ*. To extirpate the goitre, we performed enucleation in those cases where the growth was composed of cystic or colloid masses, but in the much more numerous class of cases of involvement of the entire lobe, with the formation

of multiple foci of colloid or cystic formation, extirpation of the entire lobe was resorted to, and if necessary enucleation of one or several nodules situated in the isthmus or in the other lobe was performed.

We operated on one patient who several years previously had had enucleation performed by another surgeon, and she came to the hospital on account of a recurrence which had produced the same respiratory trouble that was present before the former operation. In this case we performed a total extirpation of one lobe, and the patient remained in excellent condition, but a few years after the operation a nucleus of disease had appeared in the remaining lobe, which had increased considerably in size, and it is a very interesting point to notice that for all that respiration had remained perfectly unimpaired.

I have notes of another similar case which is quite as instructive. A young girl underwent a total extirpation of the right lobe of the thyroid gland on account of very difficult respiration; the respiratory symptoms completely disappeared in spite of a recurrence of the goitre in the left lobe which was very pronounced. Thus it is demonstrated, and Kocher has already insisted on this fact, that when once the trachea has been completely freed on one side by the total extirpation of one lobe of the thyroid, a recurrence may occur in the other lobe, and the trachea remaining free on one side will never be compressed by the newly formed goitre so as to produce difficulty in respiration. This in no way applies to enucleation, because after this operation the trachea remains surrounded on both sides by thyroid tissue, and consequently a recurrence of the neoplasm would probably produce symptoms which would necessitate total extirpation.

An anatomical study of our preparations distinctly demonstrated how little enucleation was indicated in those cases where we performed total extirpation of one lobe, because they consisted in diffuse colloid degeneration, with formation of small and large cysts, each one of which could never have been enucleated alone, and which if allowed to remain in place would very easily have given rise to a recurrence of the affection. We consequently believe that enucleation is an excellent operation for those rather rare cases of cystic formation and simple colloid foci, and also that it is applicable in cases of recurrence after total extirpation of one lobe has been performed. But all things considered, total extirpation, in our way of thinking, is by far the better operation in the large majority of cases of goitre. Total extirpation has, nevertheless, one great drawback, and this is the possibility of wounding the recurrent nerve. It is usually considered that the most dangerous point for wounding this nerve is at that point where it crosses the inferior thyroid artery, and near which this vessel is ligated.

I think that I can be affirmative in stating that in every case where this nerve was injured it was at another point than that which we have mentioned, because I find that in all of our cases it is expressly noted that the inferior thyroid artery was carefully isolated, and that it alone was included in the ligature. Several times the recurrent nerve was quite visible, and we were able to note that it remained perfectly intact while tying off the inferior thyroid artery, but for all that, after the operation the patient presented symptoms of paralysis of this nerve. Another point at which the recurrent nerve is very

¹ Read before the Surgical Section of the Suffolk District Medical Society, November 7, 1900.

much exposed to wounding during the total extirpation of a lobe, and which, according to our way of thinking, is the point where we wounded it, is the posterior lateral aspect of the trachea where the recurrent nerve passes before it enters into the larynx, and in detaching the gland from the trachea it is easily wounded, and in our future operations we shall follow the advice of Kocher, which is to leave a bit of thyroid tissue at this place in order to avoid the nerve at this point.

After having made a careful hemostasis with fine silk, we immediately close the incision, and union by first intention has usually been the result. In 1 case a small abscess formed six days after the operation, but was well in a few days. In 2 instances, once in a case of strumitis typhosa, and in another which we will relate, the ligatures were eliminated *en masse*.

I unfortunately have not been able to find the complete notes of the case of typhoid strumitis, but the history of the case was briefly this. A young girl of eighteen or nineteen years, during her convalescence of typhoid fever, noticed that her throat began to swell. The swelling slowly increased and she began to run a temperature, and on account of the respiratory symptoms to which the tumor gave rise, operation was performed a few weeks later. Convalescence was uninterrupted. An examination of the thyroid gland showed that it was an ordinary vascular strumitis, and cultures taken from the substance of this gland revealed a growth of Eberth's bacillus.

The other case to which I referred was one where we removed by extirpation the right lobe and the isthmus of the thyroid gland, and at the time of operation it was noticed that the left lobe was extremely small and there was present a small pyramidal process which was left intact. The silk ligature which had been placed on the isthmus set up a suppurative process which lasted five months. The fistula which resulted was opened up and a silk ligature was removed, after which the wound healed definitely in a few days. After the operation this patient presented a change in the general condition, which, in all probability, could be classed as one of strumipriva cachexia. The patient was very nervous, slept badly, cried easily and would get very angry at the slightest cause, and with all this her memory diminished; she often did not know what she was doing, but she never had what could be termed a true nervous attack. She was weak, pale, the eyes had a languid expression, the skin of the face appeared puffed, but a careful examination of all the viscera and the urine revealed nothing abnormal. In the cicatrix of the incision in the median line, a fistula was present, while to the left of the trachea a small mass could be made out by palpation which corresponded to the left lobe of the thyroid gland. This was very small, as I have stated, at the time of operation, but it had evidently atrophied since under the influence of the suppurative process. Since the extraction of the ligature and the cessation of the suppuration, this little mass slowly increased in size, and a year and a half after the operation it was found to be about the size of an almond. The nervous symptoms disappeared, as well as the anemia, and the patient was feeling in excellent health.

This case appears to us most instructive, inasmuch as it points out the necessity of great prudence in ex-

cising the thyroid substance. The left lobe had particularly attracted our attention, on account of its small size, at the time of the operation; the pyramidal process which was present in this case, and which we did not touch, was also very thin, and by the aid of suppuration the remains of the thyroid gland became momentarily insufficient for the thyroid function, which is so necessary for general good health.

Consequently, should we ever meet with a similar case we should not employ ligatures *en masse*, or any other which might favor suppuration, and we should also preserve as large an amount of normal thyroid tissue as might be possible. Enucleation, if it is sufficient to remove the totality of the diseased tissues, would be the most economical operation, but in those frequent cases where this operation would be insufficient we would recommend a resection of the diseased portion of the lobe, preserving the healthy part. At any rate, the experience of the case just mentioned should warn us to examine the condition of the other lobe before performing a complete excision of the diseased side, and only perform this operation when the other lobe is sufficiently large to prove itself sufficient for its necessary functions. The influence of the removal of the thyroid functions on the general health was demonstrated in another of our cases where a nearly complete excision of the thyroid tissue was performed for carcinoma of the gland, and which was followed by tetany. Curiously enough, this unfortunate post-operative complication got better after a metastasis of the neoplasm in the neighboring lymphatic glands took place.

The following case is interesting on account of its rarity. I refer to sarcoma of the thyroid gland, but as this case has already been published in the *Philadelphia Monthly Medical Journal* for May, 1899, I will be very brief. The patient, a German, age forty-seven, had had a small movable goitre about the size of a lemon present about six months. She was treated for three months with thyroid extract without any apparent benefit, and was then lost sight of. She returned, however, about a year and a half later, stating that for about ten weeks the tumor had begun to increase in size. Examination showed that the left lobe of the gland had attained the size of an apple; its surface was still quite smooth and it was movable. The skin covering it was normal, and there were no dilated subcutaneous veins. On account of its rapid growth a diagnosis of malignant transformation was made and the growth was removed. The patient made a perfect recovery and was discharged ten days after the operation. The microscopical examination showed a typical follicular goitre the upper part of which had become invaded by a spindle-cell sarcoma in the septa dividing the vesicles of the gland. A focus of sarcomatous tissue was found in the lower part of the gland. The operation was performed on November 8, 1898, and the patient died of generalized sarcomatosis in April, 1900.

The last case that I should like to report is interesting, inasmuch as it shows how a goitre may become infected during the progress of an acute infectious disease, as occasionally occurs in ovarian cystoma. The patient was a woman forty-seven years of age. During her first pregnancy, which occurred about twenty-three years ago, the patient noticed that a tumor developed low down on the left-hand side of her neck, and which gave rise to quite sharp pains.

This tumor gradually increased in size, more especially after her second pregnancy, and finally attained nearly the volume of a grape-fruit. The growth did not produce any difficulty in respiration or in swallowing, and the patient did not notice any change in the nature of her menstruation, which was still quite regular.

In February, 1890, while recovering from a severe attack of influenza, she noticed that without any appreciable cause the tumor began to rapidly increase in size, especially in its upper portion, from which it had slowly sent out a prolongation which reached the angle of the lower jaw. Since the month of March the tumor remained stationary, but was the seat of very severe pain. The pain continued, and became more and more acute. During the last three weeks the skin covering the most projecting point of the upper prolongation had become red. The pain, which in the beginning only was present in the evening, was now practically constant. The patient has no recollection of having had chills or fever, she does not perspire, and there was no diarrhoea. Other than she suffered somewhat from indigestion and was not of a robust constitution, there was nothing of special note.

The left side of the neck was occupied by a tumor nearly the size of the patient's head. In shape it was irregular; inferiorly it formed a large projection which extended over to the right side, covering the trachea and the lower part of the larynx, and rested upon the sternum and the left clavicle; it extended to the entire left side of the neck, which it completely filled up, and extended upwards under the chin and jaw to its left angle. The skin presented a few dilated subcutaneous veins, and on the lateral external surface above the middle of the tumor a large projection was noticed, the skin covering it being of a bright scarlet, and it appeared that the tumor was just about to ulcerate through the integuments at this point. The skin was hot, especially where it was reddened, and all about it was quite an extensive inflammatory edema. The left sternomastoid muscle was pushed backwards. The tumor was elastic, somewhat soft, and fluctuation could be detected everywhere within it. In the lower aspect two nodules could be palpated which seemed to belong to the tumor. The larynx was pushed somewhat aside and the carotid artery was pushed backwards and pulsated exactly over the external margin of the tumor. The neoplasm was movable over the deeper structures.

All various treatments having been essayed without effect, and as the tumor continued to increase progressively in size, and as alarming symptoms supervened, an operation was undertaken on February 13, 1891. An incision was carried over the inflammatory area, and a small quantity of thick pus was evacuated. The tumor did not collapse, and when the finger was introduced into the cavity made by the incision, it came upon a friable tissue but not into the large cavity of the growth. The incision was then extended down to the sternum obliquely, and as the pretracheal muscles were stretched out over the growth, they were incised and the neoplasm was exposed. A trocar was introduced into the growth, which gave issue to a certain amount of pus which was different from that first evacuated.

The capsule of the neoplasm was incised, and the growth was enucleated with the finger, a task difficult to accomplish on account of very dense adhesions. Above, the wall of the cyst ruptured all of a sudden

and gave issue to a certain amount of pus. It may possibly have been by this route that the inflammation had extended upwards towards the skin. The loss of blood was insignificant. Above, at the point of the projection, a grayish mass was found about the size of an egg, and which had infiltrated the cellular and muscular tissues. With the scissors and curette, it was removed piecemeal without, however, being completely taken away. This mass extended towards the upper part of the cavity of the cyst, although no positive communication between the two could be found. The tissue composing it did not bleed. The middle part of the cyst was sutured to the skin and above and below it was packed with iodoform gauze. The patient made an excellent recovery.

I have purposely made no mention of Dr. Jaboulay's treatment by desiccation of goitres after having exposed them to the air through an incision, as I have personally no experience, but the reports that come from Lyons since this treatment has been in vogue would lead me to adopt it in those cases where there was some contraindication to extirpation or enucleation.

THE PRACTICAL USE OF VITAL STATISTICS.¹

BY FREDERICK L. HOFFMAN, ESQ., NEWARK, N. J.

VITAL statistics, in the words of Dr. Newsholme, "is the science of numbers applied to the life history of communities and nations," and this definition being accepted, we are on the outset confronted by a matter of general importance, since there are none of the people of this State so high or so low but that to them life has its value in direct proportion to its duration. Time was when mankind believed that those "whom the gods love die young," but this doctrine of fatalism no longer prevails in the light of modern medicine and sanitary science, for both of these efforts for social betterment and the amelioration of the conditions under which the people have to live could not exist but for the modern science of vital statistics, than which there is no field of research more promising of useful and practical results.

It has been necessary for me to confine myself in this discussion to mortality statistics, since even a superficial consideration of the other branches of the science, dealing with the statistics of marriages, divorces and births, would consume more time than I have at my command. But, manifestly, the mortality statistics must needs be looked upon as the most important branch of the science, since they affect more directly the interests and the welfare of the living people of this State. Although I readily recognize the great social value of the statistics of marriages, divorces and births, I personally have had but little opportunity to investigate these subjects.

My discussion as to the data of human mortality will be largely confined to the conditions as they exist in the State of New Jersey, and as they are made plain to us by the facts already in our possession through the efforts of the State Board of Health since 1878. Data of some historic value have been collected for previous years, but as regards the State as a whole, we have no information of scientific value for years previous to 1878. For some of the counties, especially for Essex, we have information of value for

¹ Read before the New Jersey Sanitary Association.

years as far back as 1859, in a report on the "Health and Mortality of Newark, N. J.," by Dr. Edgar Holden, for the period 1859-1878. Another valuable paper on the "Climatology and Diseases of Essex County," is to be found in the *Transactions of the Medical Society of New Jersey* for the year 1887, in which also the vital statistics for years previous to 1878 are incorporated in considerable detail. Since 1878 and to June 30, 1899, there have been recorded in this State 550,955 deaths, and of these records and their practical value it is my intention to speak to you this evening.

The essential facts known to us as to this large number of deaths are: (1) The year of occurrence; (2) the ages of those dying, by certain specified groups of years; (3) the sex; (4) the causes, arranged according to reasonably well defined groups of diseases; (5) the locality, with a reasonable degree of precision. More details would, of course, be desirable, more accuracy would be of great value, but on the whole, as the information has been made public, it is of practical value to the State, to the medical profession and to the public at large. The information available is sufficient to approximately indicate the rise or fall of the general death rate and the corresponding increase or decrease in the longevity of the people of this State. The information is not as useful as it could easily have been made had those in charge of the registration and publication of these statistics been more liberally supported by the State in their arduous efforts, but even in their present condition they are a valuable means of indicating to us the steady progress which has been made in this State during the past twenty years. It is but proper that mention should be made of one to whom we are largely indebted for the good work which has been done during a large part of this period, namely, Dr. Ezra Hunt, formerly the secretary of the State Board of Health.

Our information as to the mortality in this State is supplemented by the census reports made for the past fifty years on the mortality of the United States, but in particular by the life tables of New Jersey, which have been incorporated in the census reports of 1880 and of 1890.

A careful study of this available body of information, really the vital history of the people of this State, is indeed not only a most interesting subject, but one of great promise of practical results. The first fact which is impressed upon us by a study of the life tables of the two census years mentioned would indicate that the sanitary progress, of which we hear so much, has not affected as large a proportion of our population as is commonly supposed to have been the case. Unquestionably, immense progress has been made and almost wonderful results have been accomplished in the direction of diminishing the mortality of children under the age of fifteen years. As an illustration I may mention the fact that if we take the three years 1879-1881 and compare them with the last three years, 1897-1899, we have only 24,208 deaths under twenty years of age in the latter period against 28,880 deaths under twenty years during the earlier period of our history, although during the same years the population has almost doubled itself. But this gain in longevity at earlier ages has not been made at the ages past middle life, and we have a pertinent illustration in support of this theory in the two

life tables for New Jersey published in 1880 and 1890, showing that while in 1880 the expectancy of life at the age of twenty-five was thirty-nine and eight-tenths years, in 1890 it was only thirty-seven and four-tenths years; that while in 1880 at the age of fifty the expectancy was twenty-two and three-tenths years, in 1890 the expectancy was only twenty-one years. In other words, the mortality at older ages is today higher than it was twenty, or even ten, years ago. I cannot burden this paper with statistics on the subject, but I hope to add a series of tables in an appendix to this paper when the same is finally published in the *Transactions* of the association.

At present it is impossible to point out definitely and precisely the causes responsible for the unquestionable increase in the mortality at ages above twenty. We have not for this State the detailed information as to the causes of death which would be necessary for a thorough and complete study of the subject. I understand that these imperfections will be largely done away with in future reports under the new law, according to which the Bertillon system of classification will be adopted, and I sincerely trust that together with this improvement in disease classification there will come a corresponding improvement in the collection of more detailed information as to the ages at death. To make our vital statistics of more practical value, the ages at death, together with the corresponding causes, must be given for single years under the age of five and for five-year periods over the age of five. It is only in this manner that we can arrive at a definite conclusion as to the age incidence of disease and the causes which are responsible for the present excessive mortality at ages over twenty. But what is most needed in addition to a more complete registration of causes and ages is detailed information as to the occupations at death. At present we have absolutely no knowledge as to the relation of disease occurrence in different occupations, and it is in this direction that the greatest practical value of vital statistics finds its logical explanation.

As the result of frequent and comprehensive investigations, I am satisfied that there is no subject deserving of more thorough investigation and study on the part of our physicians and those in charge of the sanitary interests of our different towns and cities than the intimate relation which unquestionably exists between occupation and mortality. There are in this State trade centres where industries of a special order are carried on on a very large scale, and as such we may mention the pottery and rubber industries in Trenton, the glass industry in Southern New Jersey, the hat industry in Orange and Newark, and the silk industry in Paterson, yet, as far as our information goes, we know nothing of determining value as to whether these industries are responsible for the increased mortality at ages over twenty of which I have spoken. It is true, and we may speak of this with pride, that special investigations have been made by disinterested students of the subject, and that reports of great value have been published in the annuals of the State Board of Health and of the State Bureau of Labor Statistics. No reports of any other State boards of health contain such precise and satisfactory information as to the diseases of workmen employed in the principal industries of the Commonwealth. Commencing with 1878, we have in the reports of the State Board of Health a series of valuable

papers on the diseases of hatters, of potters, of glass-workers, of rubber workers, etc. Commencing with 1889 and terminating with 1895, we have in the annual reports of the State Bureau of Labor Statistics exceedingly valuable and suggestive inquiries into the trade life of workmen, not only in the principal manufacturing industries, but also in other dangerous and unhealthy occupations. Very little in this direction has, however, been done for the past ten years, and it is my plea to you at this meeting that our special efforts in this direction should not be relaxed, or that we should be satisfied with what has been done in the past, but that we should enlarge our scope of inquiry, supplement our limited body of observed facts with a large body of statistics collected by the State Board of Health as to the diseases of working men employed in the useful and productive trades and industries of this State.

Valuable as the investigations of the State Board of Health and of the State Bureau of Labor are to those who are most interested in the subject, they fall short in that they have not the support of a large series of observed facts to be found in the death certificates of those whose lives have terminated in this State during the past twenty years. I would urgently recommend that for practical use in our vital statistics, we should have in the future a detailed and comprehensive table, showing for all of the principal occupations or industries the causes of death according to age periods. That this task is not impossible, or even very difficult, is illustrated in the excellent reports of the health officers of Sheffield and Blackburn, England. These reports can well serve as a model for our own State Board, should it appear to be possible and feasible to undertake the construction of occupation mortality tables. I am fully aware of the inherent difficulties which accompany such inquiries; I fully realize the difficulty of obtaining exact information as to the occupation at death, but it is not for us to be discouraged by such difficulties, but for us who are really and vitally interested in the collection and publication of such statistics to solve the difficulty, and that this difficulty can be solved all of us know who are familiar with the excellent and useful reports published under the direction of the Registrar-General of England every ten years. In certain directions an improvement of our present statistics is easily possible. There should first be added to the death certificate a second question as to occupation, stating the industry or trade in which decedent was engaged at the time of his or her death. To explain to you the meaning of this point, I will say that at present a death certificate may contain a statement of the occupation of decedent at the time of his death as that of a moulder, but unless it is stated that he was a moulder in a pottery, he would be classified among iron moulders or stove moulders, as the case might be. Similar cases could be mentioned, as for instance, engineers, where we have no information as to whether decedent was a stationary engineer, employed on a railway, or possibly a civil engineer, but if the second line is added referring to our first illustration, it would have been stated that decedent was a moulder in a pottery, and his death in that case would have been accurately classified. I would, therefore, suggest that the State Board should adopt a new death certificate, in which the first line referring to the occupation would merely ask the question as to "oc-

cupation at death," the second line would ask the question, "industry or trade at death," and by an answer to these two questions we would obtain the accurate and necessary information demanded for the best interests of the working people of this State. A third question could be added which would materially increase the value of these statistics, which, however, is not of quite so much importance as the second question which I would like to have added to our present certificate. It would be desirable to have a definite statement as to whether decedent at the time of his death was an employer or an employé. Manifestly, it is a very different matter whether decedent was the owner of a pottery or a working potter at the bench. If we could obtain this information we would very materially enhance the practical value of the vital statistics of this State.

But a further decided and material improvement in this direction is possible through a co-operation between the Bureau of Labor Statistics and the Bureau of Factory Inspection. The reports of the latter are at present of practically no value for the study or solution of questions pertaining to the trade life and disease or accident liability of men employed in the unhealthy or dangerous industries of this State. I can conceive of no practical reason why so large an amount of routine information should be published which can serve no useful purpose except (and the reports are practically limited to this information), that of record, and why the energy and effort expended in this direction should not serve the more useful purpose of placing before the people of this State information of value as to the real sanitary condition of factories and the health factors affecting our working people in the same manner as this has been done for so many years in the reports of the Board of Factory Inspectors of Great Britain. Many of the reports of the factory inspectors of different States are in this respect of far greater value than the reports published by our own Board of Factory Inspectors, and I believe that if the subject were thoroughly investigated by a committee of the legislature or by disinterested citizens of this State, there would be inaugurated an improvement which would make it possible for those who are interested in the subject to realize fully the present state of factory life in this Commonwealth. It would be possible on the basis of the statistics and supplementary information collected by the co-operation of the State Board of Health, the State Bureau of Labor Statistics, and of the State Board of Factory Inspection, to produce a body of indisputable facts, on the basis of which it would be possible to frame more scientific rules and regulations by which our working people engaged in the most useful pursuits of life could be better protected than they are at the present time, and as they fully deserve to be.

These statistics of mortality by occupations, and the supplementary information as to the sanitary state of our factories, would have a secondary practical value to a large number of physicians, who in the light of published facts and on the ground of their own experience, verified and supplemented by such facts, would realize the almost boundless and at the present neglected opportunity for the study of diseases of working people employed in dangerous and unhealthy occupations for the purpose of developing special ability, which in time will give us a class of medical specialists of the diseases of workmen, as

we now have such specialists for diseases of the eye or ear, and for other parts of the body. Certainly no class of specialists is more urgently needed and none are likely to make more rapid progress in their own material welfare. The increase in general intelligence among our working people today, justly considered the most advanced industrial workers in the world, will soon create a distinct demand for more satisfactory and reliable advice on matters pertaining to illness and casualties directly the result of the industries in which our people are engaged. The advice of such specialists will be respected, and men will act thereon, and if necessary change their occupation, or change to another branch of their occupation less dangerous or injurious than the one in which they may be engaged, and in which they may have developed diseases in their incipient stages, not sufficiently advanced to be beyond improvement or complete recovery. Much has already been done in this direction by a few devoted and intelligent physicians, but most of all by such men as Dr. Arlidge, the English authority on diseases of men employed in the potteries. There will come a time when we will coin a new term in medicine and speak of industrial medicine, just as we today speak of industrial chemistry, and both sciences or arts will indeed be most closely allied to each other.

I have limited myself to this one illustration of the value and utility of vital statistics, for unless we have more accurate information and a larger body of collected data as to the diseases of our working people, supported by accurate and extensive statistics as to the deaths in different occupations and the ages at which the deaths occurred, the development of industrial medicine will not be possible. What is true of the necessity of such statistics for the purpose of industrial medicine, is equally true of all other branches of medical inquiry into the longevity of our people as affected by other determining factors, such as surface geology, proximity to forest areas, of sea-shore and mountain climates, and many other factors which unquestionably have a direct influence upon the health of the people of this State. To enhance the practical value of the collected vital statistics would require in every locality a sincere and genuine interest in the local phenomena and the factors making for a long or a short life.

We, unfortunately, have developed, first, but little of this local spirit of inquiry, and, second, but little public appreciation and demand for published data as to the local health conditions. In curious contrast to the excellent work which has been done by the State Board of Health for so many years in publishing practical and useful information for the State as a whole, the local boards of health in New Jersey have published practically nothing of value, with the notable and recent exceptions of the cities of Asbury Park and Montclair. Some advance has also been made in the city of Newark, but none in proportion to the immense interests which are involved. For our other large cities, especially for Trenton, Camden, Jersey City, Paterson and Orange, we have no health reports in such detail as they are required for the best interests of the people of these cities. There is absolutely no reason why the cities of this State should not follow the example of other large cities in this country and publish annually a separate health report con-

taining detailed information very much along the line as this has been done in so excellent a manner by the health officer of the city of Montclair, today perhaps the healthiest suburban city within fifty miles of the city of New York. In few States in this Union is it possible to supplement such local reports by all the necessary information as to geology, climate, water supplies and industrial statistics as this is possible in New Jersey. No other State in the Union has so thoroughly equipped a geological survey in the hands of men who have given primary consideration to matters of immediate and practical importance, while at the same time not neglecting matters of remote importance. Our State Weather Service has published reports of a very high degree of usefulness, and as regards the State Bureau of Statistics, it has also contributed its share of information of value to the health officer in supplementing his conclusions as to the local conditions making for a long or a short duration of life. It is much to be regretted that the reports of the State Bureau of Factory Inspection cannot be included in this praise of our State departments of supervision and investigation of subjects directly or indirectly affecting public welfare.

I cannot refrain on this occasion from calling your attention to a matter directly connected with the extension or development of the practical utility of vital statistics, and which but for urgent necessity I would gladly have left out of consideration, for in a measure it is to me a painful duty. You are all aware that in this State our vital statistics are in the first instance collected by the city clerks, and while there are certain reasons why this should be the case, in the light of the development of modern preventive medicine it is no longer desirable that this duty should fall to a class of men totally unfamiliar with the medical aspects of the data they are expected to register for the use of medical practitioners and sanitarians. This is not as it should be, and I urgently recommend that early steps be taken tending to a change in the law, and transferring this important duty from the city clerks to the local board of health or to a medical registrar of vital statistics, especially appointed for that purpose. In certain other States we have a still more antiquated system by which the Secretary of State is made the custodian of the vital statistics and under his supervision the statistics are compiled, published and analyzed. This is contrary to the purpose of collecting vital statistics, since one totally unfamiliar with the essential requirements and needs of the science cannot be expected to do justice to the task imposed upon him. In consequence of this anomaly, vital statistics are in many States collected without due skill and proper consideration of important details, while at the same time they are not in time placed before a trained medical observer for immediate consideration, verification and correction. Gross errors must needs result from so antiquated and unwarranted a practice, which owes its origin to a time when certificates of marriage, birth and death served merely the legal purpose of establishing proofs of identity, but at the present time the legal aspect of these certificates is but subordinate to the far more important one of the State supervision of the public health, and hence the urgent necessity that the duty of collecting vital statistics in the first instance be transferred from the city clerk to the medical officer

of health, or to a duly appointed medical registrar of vital statistics.

I cannot do better than illustrate the importance of this point by a reference to a slightly different matter, which at the same time will make clear to you the inexpediency of placing the collection, and, even worse, the analysis, of vital statistics in the hands of a State officer not directly connected with the sanitary administration or the preservation and improvement of the public health of the people of a State. Curiously enough, the illustration of which I shall make use is furnished by the State from which you would least expect so sorry an exhibition of ignorance and perversion, if not desecration, of a high public office, and at the same time of such utter indifference, if not contempt, of public requirements and public needs. In the State of Massachusetts vital statistics are also in the first instance collected under the authority of the Secretary of State, and it is by the authority of this same officer that the returns are annually published and analyzed by some one designated for this purpose. For forty-nine years, ending with 1890, this duty had been delegated to men trained in public health matters, to men thoroughly familiar with the science of vital statistics, to men deeply interested in the development of the highest degree of accuracy and skill, combined with a desire to make the vital records of the State attain to as high a degree of public utility as possible. During these forty-nine years the science of vital statistics had been more highly developed in Massachusetts than in any other State of the Union, and the registration reports edited by the foremost men and authorities in the science of vital statistics had reached a point of public approval such as has never yet been attained by any other State of this country. One would have expected where so high a degree of public utility had been reached and where this important duty of study and analysis of the vital records had been developed to the complete satisfaction of the public, as expressed in the medical journals and other competent channels of public opinion, that it would have been impossible to ruthlessly destroy or to tear down the work of earnest men for half a century. Yet without warning, without right, without justice, the Secretary of State in 1891 transferred this important duty away from the secretary of the State Board of Health to an unknown individual, who has since to the discredit of Massachusetts made the registration reports of that State not only a sorry evidence of his own ignorance, but an evidence of the indifference of the intelligent people of Massachusetts to an act of iniquity on the part of a high officer of State such as is, probably, without a parallel in the history of vital statistics in the civilized world. The registration reports of Massachusetts, as they have been issued since 1890, contain not hundreds but thousands of errors, the majority of which are inaccuracies and misstatements, which even a high-school graduate trained in simple arithmetic would not be expected to make. The reports are full of fallacies, full of discrepancies, and are today a discredit to the people of Massachusetts, and a discredit to the science of vital statistics, and a direct step backward in the development of the point to which I have called your attention, namely, the development and extension of the practical uses of the science of vital statistics.

I would not have spoken of this perversion of a high

public duty, and of the undoing of the good work of able and earnest men for half a century, were it not that I believe it to be our duty to recognize dangers which confront us in this State as much as they are present in every other community. I believe that it is only by the strictest vigilance exercised on the part of the public and of individuals who have the best interests of the people at heart that so difficult a task as the one in which you are engaged can be carried successfully onward from year to year. The results which follow the efforts of sanitarians are always remote, and more often benefit future generations than the people of the time who have to bear the immediate burden of expense. Hence this digression into a chapter of vital statistics, which to my mind records the most unfortunate and shameful betrayal of a public trust.

In conclusion, I may be permitted to touch once more, if ever so slightly, upon the value of vital statistics to the people of this State in other directions than the specific one of the inquiry into the diseases of the working people employed in the different industries recognized to be either unhealthy or dangerous, or both. We are in the last year of a century which marks a progress in sanitary science during fifty years such as has not been made during all the thousands of years of civilization which have preceded it. I believe it is not going too far to say that at no time in the world's history have the people been housed as well, have they been nourished as well, and have they in all respects lived as long and as well as the majority of our people do at the present time. But the problem which will confront us in the twentieth century more than in the nineteenth is the enormous growth of our large cities and the immense aggregation of millions of people upon a small area, such as we find to be the case in Greater New York, Greater Philadelphia and even Greater Newark. The census returns for 1900, as far as they have been published, disclose a tendency of which I believe the people of this State should take early advantage, namely, the tendency of recent times on the part of the more intelligent people to leave the large cities and settle in the more healthy and more advantageous portions of the surrounding territory, where under semi-rural conditions they can enjoy a degree of happiness and health such as under the best conditions is not possible in the crowded centres of population. I believe that this tendency will become more confirmed, will become a more definite phase, during the next quarter of a century and that it will prove of benefit to the people of this State, who from New York and Philadelphia will draw the best elements of the population as a new class of suburban residents in far greater numbers than has ever been the case before. But public intelligence has now reached a degree of development very considerably above that which prevailed a quarter of a century, or even a decade ago. Today, more than at any time in the past, do people inquire into the health factors of a community and the conditions making for a healthy and a long life, and only in proportion as our cities and country sections hold out inducements in this direction, and make clear beyond the shadow of a doubt that our State is healthy and advantageous from this point of view, will we attract in the very near future the overflow of the intelligent and desirable population of New York and Philadelphia, which will do much to aid us in the

more rapid development of this State. I believe I am not going too far when I say that on the basis of my own investigation and my own personal inspection of nearly every part of Northern and Southern New Jersey, I am warranted in the emphatic assertion that this State offers advantages for the health seeker and the home seeker such as cannot be found within a hundred miles of any other large city of this country. We have a State offering every variety of natural advantages, the seashore, the mountains, proximity to large forest areas, and even a lake country such as England itself has little more of beauty and attraction to boast of. You cannot extend the practical utility of vital statistics in a more beneficent direction than by giving strong encouragement to the local health officers of our cities and towns, and to all our physicians practising in the different sections of this State, in collecting and publishing the actual facts as they pertain to the longevity of the people of this State. Just in proportion as we thus demonstrate the practical value of vital statistics to the people at large, shall we gain for our State an increasing degree of public approval, which is so desirable and so fully deserved.

Clinical Department.

TWO CASES OF PERFORATING DUODENAL ULCER WITH SUBPHRENIC ABSCESS.

BY J. C. PEGRAM, JR., M.D., PROVIDENCE, R. I.

CASE I. Mr. C. O., age fifty-six, farmer. Had never had a day's illness till ten years ago, when he had an attack of stomach trouble, which was followed by a slow recovery lasting over a period of two years, since when he has been well. On the evening of December 8, 1899, Mr. O. ate heartily of pork and beans. During the night he was kept awake by a dull unlocalized pain in the abdomen. The following morning he was better, but still not feeling well; he drank a cup of coffee and went to his work. At ten in the forenoon he was seized with a violent pain in the right side of his abdomen; he was carried home, where he was seen soon after by Dr. Ford, but was in such pain that a good history was not obtained; however, the fact was elicited that the bowels had moved but once in three days, and only to a slight extent then; up to this time he had not vomited.

Physical examination by Dr. Ford showed a well developed and nourished man; face flushed and covered with perspiration; expression anxious, tongue coated and moist, arteries sclerotic, heart and lungs negative. Abdomen flat and rigid as a board; on palpation it was extremely tender throughout, particularly in the left groin and right hypochondrium.

Morphine for pain, hot fomentations to the abdomen, efforts to move the bowels by copious enemata, was the treatment begun. Following one of the enemata numerous small scybala of fecal matter were passed in a medium of thin, foul-smelling feces. The pain persisted, relieved only by morphia, the abdomen gradually changing from its rigid state to a condition of distention. On December 11th, at 5 p. m., I saw the case in consultation with Dr. Ford. At that time he presented for examination a pinched and anxious expression, coated and furred tongue, a fairly good pulse, temperature 99°, abdomen distended, tympani-

tic, tender and quite rigid. There had been no good movement of the bowels, and he had been vomiting all day, after a large dose of Epsom salts. There was no peristaltic movement of the bowels to be made out. The following morning his condition remaining about the same, I sent him into St. Joseph's Hospital, resolved to give him the one chance that relief of a possible strangulation might bring, due to whatever cause. Operation disclosed a perforated duodenal ulcer, with sharp, thickened edges, admitting the end of the forefinger, and lying on the anterior wall, near the pylorus, there was a subphrenic abscess holding at least two quarts of fluid containing small particles of food; this was evacuated. No attempt was made to close the ulcer, but instead to wall it off with gauze. The man died thirty-six hours later of his general peritonitis. On securing the duodenum and pylorus for examination through the incision post mortem, and laying the duodenum open, a scar of an old healed duodenal ulcer was found on its posterior surface on the same plane as the one which perforated.

CASE II. This case was seen at autopsy table, and I report it by permission of Dr. White, of the Rhode Island Hospital Medical Service.

Hospital records give the following history: A. J., age thirty-nine, painter, entered the hospital February 6, 1900.

Past history.—Has had asthma for two years. For the past year he has been losing flesh and strength steadily.

Present illness.—For two weeks he has had attacks of pain in his abdomen, and his bowels have not moved freely. No vomiting; kept at his work. A few hours before entrance to the hospital he was seized with severe pain in the epigastrium which radiated down into the right iliac fossa. Perspired freely; vomited and almost collapsed. He was brought to the hospital in the ambulance.

Physical examination.—Well-developed and fairly-nourished man. Expression anxious; tongue clean; pulse weak; knees drawn up and abdomen scaphoid; abdomen tender, especially in right iliac fossa; heart sounds inaudible; lungs negative; no blue line on the gums; urine negative. Temperature 95°, pulse 55, respiration 20.

He was stimulated; hot turpentine stupes to the abdomen; enemata. Following day he was decidedly worse; became delirious; pulse rapid and weak, and temperature rising to 102.5°. Bowels had not moved; abdomen had become distended; operation considered useless; patient gradually failed and died next day, February 8th, at 10.50 a. m. At death, temperature 105°, pulse 145, respiration 28.

Autopsy.—Reported by Dr. J. Perkins. Body well nourished; abdomen distended and very rigid. On making incision through abdominal wall a large amount of free gas escaped, and the walls collapsed. This gas would not ignite. There is much thin, brownish fluid in the abdominal cavity of fecal odor and appearance. Over the upper surface of the right lobe of the liver, and over the diaphragm, and that portion of the abdominal wall which comes adjacent to the liver, there is a thick, fibrinous and purulent exudate. Along the ascending colon the tissues are edematous, and to some extent hemorrhagic. There is a round opening in the upper anterior part of the duodenum, almost touching the pyloric orifice, about one centimetre in diameter, with thickened edges,

through which fluid, like that free in the abdominal cavity, is flowing. The kidneys, spleen, liver and stomach are normal; lungs are greatly distended and contain much air, otherwise normal. Heart normal; head not opened.

Diagnosis. — Perforating duodenal ulcer with sub-phrenic abscess. General peritonitis.

It is impossible to imagine two cases more alike one another in their pathological anatomy, and Dr. Perkins's description of Case II serves perfectly for Case I, with the single exception that Case II had no scar of previous healed ulcer.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

F. G. BALCH, M.D., SECRETARY.

REGULAR meeting, Wednesday, November 7, 1900,
DR. FRANCIS S. WATSON in the chair.

DR. J. C. WARREN read a paper entitled

OPERATIVE TREATMENT OF GOITRE.¹

DR. LINCOLN DAVIS read a paper entitled

STATISTICS OF OPERATIVE TREATMENT OF THYROID TUMORS.²

DR. J. J. PUTNAM: I have listened with great interest to both these papers, and this large array of statistics is certainly very imposing, and will be very valuable. There is no subject which is more fascinating than that of the diseases with which the thyroid is associated, and, indeed, the study of the functions of the thyroid altogether, and also none which is more obscure. It is certainly true in spite of all the immense research which has been devoted to it that today the physiologists are by no means agreed as to what the thyroid is for, and in many directions we have to be content to take clinical facts without adequate scientific explanations. So far as I know, the point with regard to the cause of the sudden death to which Dr. Warren and Dr. Davis have referred is not cleared up, and that is a need which is very greatly felt. If I am not mistaken, the chance that it is due in some of these operations to absorption of the thyroid juice suggested itself to us as a plausible theory through observation of the case Dr. Warren operated on before it had been noted elsewhere, and it certainly seemed plausible in that case because the gelatinous secretion was oozing from the wound on the neck; nevertheless, that theory does not seem to be generally accepted, and, indeed, if that was the common cause of death I do not know why the same result should not occur oftener after operations for simple goitre. Several observers still believe that edema involving cardiac nerves and the pressure of ligatures is the cause of death rather than the absorption of secretion. From that point of view, it is important to note that death occurs at different periods after the operation in different cases. In the case to which Dr. Warren first referred, where the temperature went up so high, and the patient seemed to hover between life and death with an ex-

ceedingly rapid pulse for one or two days before the symptoms began to ameliorate, these unfavorable effects showed themselves almost immediately, but in the other case I think it was four days, and then death occurred rapidly. It would seem strange that if the thyroid secretion affecting the fresh wound was going to be operative, it should not have exerted its effects earlier.

The part of the subject with which I am most familiar is that of Graves's disease, although the only operations I have seen are those which Dr. Warren has performed. I have, however, had one somewhat interesting experience with a case of simple goitre in a lady past middle life who had been bothered with great difficulty in breathing. I have given her thyroid preparations for about two years, and although the size of the goitre has certainly not materially diminished, — as Dr. Warren said, it has not been much in his cases, — the difficulty of breathing has been very much relieved, so that she has been practically not troubled with it at all since she first began to take the remedy. She feels ordinarily much more comfortable, but when the dose is increased beyond a certain point she is very nervous, restless and distressed.

As regards Graves's disease, I think the etiological study of that affection is very interesting, but satisfactory conclusions are still lacking. The theory of its thyroidal origin has certainly gained ground, but should not be accepted as absolute until we can explain the greater liability of persons with neurotic tendencies, or can show why medication with thyroid preparations on the one hand, or partial thyroidectomy on the other hand, sometimes turns out very well indeed, while at other times they seem to do no good.

The number of operations for Graves's disease, as Dr. Davis has shown, has risen to the hundreds, and with the result that every one would be in favor of operating were it not for the unfortunate mortality of 13%; and, as far as I know, there seems to be no way of foretelling what cases will be the ones to result unfavorably. For that reason I think everybody feels that it is not to be done lightly until other things have been tried. And the impulse thus given to the search for remedies has led to some interesting results. In the first place, although the thyroid preparations used so largely do not perhaps as a rule accomplish very much, still the point is interesting that they do not seem to do the patients the harm one would think they would if these diseases are due to hyperthyroidization, and only that, but in many cases they have been of positive benefit. Of course this is not so much against the theory of "altered thyroid secretion," as against that of hypersecretion, pure and simple. But, then, if we have to assume that we are dealing with an altered secretion, it is doubtful whether we ought to apply the arguments drawn from hyperthyroidization experiments. Another point is that occasionally the "sympathetic" operations result so well. Dr. Mixer did one on a very serious case which unfortunately ended unfavorably. A number of them have been said to give good results, and yet the thyroid itself is not touched. And then it seems to me, in looking over all the cases I have had to do with, and seeing how this kind of electricity works in one case and that kind of electricity in another, and this treatment and the other treatment give good results, that the essential thing is to strike a blow

¹ See page 647 of the Journal.

² See page 649 of the Journal.

at some part of the morbid chain of symptoms, — absolute rest, or working on the thyroid, or the cardiac nerves, or psychical influences of a quieting sort, operations in the nose, removal of pelvic tumors, each and all seem to be of service if only they can give a new "set" to the symptoms and processes concerned. It is my private opinion that thyroid operations do not do very much more than that. In looking over the literature this afternoon, I see that Eulenburg, one of the prominent Berlin physicians who has had to do with this disease very largely, thinks that operation should be resorted to only when serious local conditions resulting from the presence of the tumor exist, and that, in the great majority of cases, treatment of other sorts can be relied on to bring about more or less amelioration.

DR. MIXTER: There are a few practical points I wish to speak of in connection with removal of the thyroid and thyroid tumors. You see a great many cases, and upon very few of them is it necessary to operate. Because a person has an enlarged thyroid it is not always best to operate, and it seems to me that the question of decision as to operation or non-interference is of more importance and requires more judgment, and, if I may say so, more surgical knowledge than the mere removal of the tumor. I do not believe in the removal of large thyroids merely for cosmetic purposes. When we have a fairly rapidly growing tumor, however, it seems a good case for operation, although it is not interfering seriously with the health of the patient.

As regards the technique of the operation, mention has been made of injury to the inferior thyroid nerve and its effects. I have seen the thyroid nerve divided with serious results, and I have also, in a very considerable number of cases, seen the patient come out of ether where the surgeon feared that the inferior thyroid was injured on account of the loss of voice and trouble in breathing. This is not uncommon, I think, as all persons who have operated on thyroid tumors will testify, and it is due to pulling, and, perhaps, temporary pressure on the nerve. It disappears inside of a week. Another thing that should be remembered is that the relation of the inferior thyroid nerve and artery is not constant. Sometimes the order is reversed, therefore it is my rule never to tie a mass of tissue in this neighborhood, but to isolate all vessels before they are tied.

As regards operation for exophthalmic goitre, I think the statistics in this part of the country are not large. The only operation I have ever done — I have been asked to operate a great many times and have refused — was done on a patient Dr. Putnam has referred to where I resected the sympathetic ganglia. It is a most beautiful anatomical operation. You can find and remove the sympathetic much easier on the living than on the cadaver. The case I tried it on was a desperate one, and the operation was done at the urgent request of the boy's family. The operation was begun with the pulse about 180, and before I got through it was over 200. The patient died in the course of twenty-four hours. The other operations for exophthalmic goitre I have not done. I have certainly seen relief in a small number of cases from thyroid remedies. I have not followed these cases, because I do not consider that when they are to be treated in that way they are surgical cases. They are cases that should go to the neurologist.

DR. MUNRO: It seems absurd in the face of the thousands of cases of Kocher and others to report half a dozen. One young girl I have operated on twice for simple cyst. She had the growth first on the right side, and that was easily removed by enucleation. Three years later she appeared with a smaller growth on the left, and that came out in as easy a manner as the first one. She has had no recurrence since then. There is still another operated on, not for any exophthalmic symptoms, but more because of the mechanical discomfort. The tumor was a simple adenoma and shelled out as easily as in the first case.

Another case was that of an adenoma in a woman thirty-five years old, but much more difficult to dissect out. The capsule was adherent in all directions, so adherent to the thyroid cartilage that it could not be removed without taking off the cartilage itself. It was curetted and dissected out until practically all removed; it was hard, immovable, much more like a carcinomatous growth, but the pathological report was simple adenoma. Whether there has been any recurrence within the last year I do not know.

There is another case that Dr. Monks and I shared together. A woman came to me with a tumor of the thyroid of nine months' duration, considerable enlargement on both sides, no cardiac symptoms, but pressure symptoms. Soon after, Dr. Monks at the Carney Hospital removed a large part of the swollen left lobe, but a portion he had to leave. Three months later she came back with a marked recurrence and then entered the City Hospital in Dr. Monks's service and he operated again for recurrence, and operated still again three months later, the patient dying a few days after the last operation. There was no pathological examination, but it was evidently a malignant growth.

A carcinomatous case has been of interest to me. A woman came with a history of a small movable lump starting many years before in the region of the thyroid, but recently growing hard and troublesome. The tumor was hard, firmly fixed, $2\frac{1}{2}$ inches in diameter. At the operation nothing was attempted except to relieve her dyspnea. It was found impossible to remove the whole growth. It went below the sternum, involving the trachea and all the muscles. The muscles and as much of the growth as we could get at were removed. About the trachea was found a solid ring of growth that shut it up to about the size of a small quill. She was very much relieved by the operation, but came back two months later with recurrence and I did a tracheotomy. The growth had increased so much that we had to cut through a lot of hard, cork-like tissue to get room to put the tube in. After operation I sent her home to Cape Breton, and supposed after a month or two that she had died, but two years afterwards I had an express package in which was the original tracheotomy tube, with a request to send a duplicate, and saying that the patient had worn the tube all this time, but that it had rusted through and was causing irritation. While the tube was here the patient choked and died.

DR. MARCY: I hardly know any subject more interesting to surgeons today, and necessarily we must look to Europe for most of the instruction. In this country the occurrence of the disease is such that we are necessarily rather limited in our experience. I can add very little from my own experience, which is limited to 5 or 6 cases. I think we gain something in

this, as in any other operations, by closing the wound primarily without drainage and sealing with iodoform collodion. It takes off pressure and permits of an ease of condition to the patient which is marvellously in contrast with holding the neck by a fixed bandage. I think it is a decided step as to the comfort and as to the subsequent success of the operation. All the cases on which I have operated have made easy primary recoveries without suppuration. I have had 1 malignant case in which the tumor had reached considerable proportions, and I dissected very thoroughly the entire glandular processes on both sides. Primary union followed, but the disease recurred in a few months and the patient died. I must think that we are still in a tentative condition in reference to this subject, and that we are necessarily students of those surgeons abroad who must be our masters, and yet it occurs to me most forcibly that the history of surgery of the thyroid already points clearly, as in surgery of some of the abdominal organs, to the fact that the cases are doing so much better in the matter of primary recovery and subsequent cure because the surgeon does not wait until extreme conditions exist, as in the earlier days. Dr. Mixer propounds the most important question, I think, as to when we shall operate, and also the study of the case, as Dr. Putnam tells us, is of vast importance. It seems to me we are not quite prepared to lay down any rule except that we are not to wait too long, until we find we are handicapped in the matter of the conditions because the patient herself or himself is in such a sad condition that recovery is not very probable.

DR. TENNEY: It was my good fortune while in Switzerland a year ago to have a conversation with Theodore Kocher, of Berne, on this subject, though I did not see him operate on any thyroids. His results are remarkable, but due fully as much to his accurate personal knowledge of anatomy from the cadaver, and pathology from examinations of specimens, as to his careful technique. In the majority of cases he removes only one side of the gland, crushing the portion of the isthmus left to get it within a single ligature. Silk is the only ligature material which he buries, and in closing the wound he leaves drainage for twenty-four hours.

In almost all of his cases he has used cocaine—a 1% solution—in children as young as twelve years and in adults over seventy years, and he has never had an unpleasant symptom or a failure to get complete anesthesia under cocaine. As an anesthetic next to cocaine he prefers bromide of ethyl followed by ether.

Accessory thyroids have been mentioned. The most constant of these is the pyramidal process which extends upwards from the isthmus, covered by the depressors of the hyoid bone. This has been studied by different men, but the largest list of statistics published has been from one of the Paris laboratories. Soja investigated 143 cadavers, and found it present in 109. The gland is so vascular that it is much collapsed after death, and our dissecting-room cadavers show it badly. Where it was especially well preserved, I have investigated 38 and found the pyramidal process 4 times. Normally, it is a very small affair here, but it may be much larger in glands found in Paris, where many of the subjects are Swiss, or from Southeastern France. If it be present in 109 out of 143 cadavers, it is certainly not frequent enough to

rely on when one comes to consider the removal of the whole gland.

As to operation on the cervical sympathetic nerve, the three ganglia which appear in the neck seem to have fairly well defined "spheres of influence." The superior has much to do with the eye, and I believe there have been some brilliant operations recently in the removal of this ganglion for the relief of glaucoma. The middle ganglion is the one whose fibres seem to be distributed largely along the inferior thyroid artery to the thyroid gland, while the inferior sends its fibres to the heart. There are 36 cases collected by Dr. Alfred Gordon, of Philadelphia, and reported in the *Philadelphia Medical Journal* of June 23d, in which some portion of the cervical sympathetic was removed for exophthalmic goitre. There was no death. In all the cases, with 1 exception, there was either improvement or complete recovery, and the difference between complete recovery and improvement seemed to be very largely a question of the amount of the cervical sympathetic removed. Where the two upper ganglia were completely removed on both sides, or two on one and one on the other, the results were better than where less radical operation was carried out. Dr. Gordon's theory seems very reasonable, that the condition is largely central, in the floor of the medulla, and that the removal of these ganglia serves in some way to interrupt the currents from the medulla to the orbit, thyroid gland and heart.

DR. CHARLES G. CUMSTON read a paper on
NEOPLASMS OF THE THYROID GLAND.³

Recent Literature.

A Textbook of Histology. Including Microscopic Technique. By A. A. BÖHM and M. VON DAVIDOFF. Edited with extensive additions by G. CARL HUBER. Authorized translation from the second revised German edition by HERBERT H. CUSHING. Pp. 501, with 357 illustrations. Philadelphia: W. B. Saunders & Co. 1900.

We quote only a part of the cumbersome title page, which would be much improved if three-fourths of what it now contains were omitted. But the essential part, the text, is as excellent as the title page is awkward. The Böhm-Davidoff Textbook in the German edition is already widely and favorably known, for it gives clear and comprehensive descriptions of the histological structure of the organs, based in many cases upon human material; it gives also a good selection of illustrations, and a very admirable series of technical directions for preparing histological specimens. The translator's share in the American edition deserves cordial praise, for his rendering is both accurate and idiomatic, so that one has no sense of the German text behind the English. The American editor has introduced many changes, especially in the way of additions. Of the additions, a goodly proportion are taken from Dr. Huber's own special line of work, the study of the innervation of tissues and organs, a part of histology which, although important, is too often slighted in textbooks. Further ad-

³ See page 664 of the Journal.

ditions are noticeable, two of which may be specially signaled, namely, the results of two fine American investigations, that of Mall upon the spleen and of W. S. Miller upon the lung, thus rendering the descriptions of these organs at once more accurate and more comprehensible. Finally, the publishers have done their part creditably, and for the care bestowed upon the printing of the figures in the text all who use the work will be grateful. The book closes with an excellent index.

This new candidate for medical and scientific favor is unquestionably a textbook of the first rank, having been carefully written by thorough masters of the subject, and in certain directions it is much superior to any other histological manual. One welcomes the attention paid to the development of the tissues, especially as a prophecy of the time when the entire treatment will be based on the development, for histogenesis alone can offer the clue to the structure and pathology of the adult organs. One welcomes, too, the new account of the spleen to replace the traditional obscuration of the structure of this organ. Many other points of merit might be enumerated, but we must content ourselves with calling explicit attention to the long and admirable series of technical directions, the variety and thoroughness of which alone ought to suffice to render the book indispensable in every laboratory.

The book has some defects, which should be removed. The text throughout is somewhat lacking in conciseness, and does not always so present the subject matter as to render comprehension easy to a beginner.

Mallory's various stains, Weigert's resorcin-fuchsin stain for elastic tissue, and the useful applications of the Cox-Golgi method need to be added. None of the best microtomes, except the Thoma Jung, are described. Some of the figures are coarse, a few almost crude, as, for example, Figs. 136, 153, 196, 202, 316, 330, and should be replaced. The most defective section is probably that on the uterus, which omits altogether the menstruating and pregnant conditions of the organ from consideration. This omission is inexcusable. The needs of practical medicine make it further desirable to include in a new edition descriptions of the placenta, chorion, amnion and umbilical cord. These four parts are the only ones of the human body which frequently come into the practitioner's hands in a fresh and perfectly normal state.

To conclude, the work is to be warmly recommended, for it is thorough, scientific and trustworthy. We hope that it will be received with such general favor that a new edition will soon be necessary.

A Practical Treatise on Genito-Urinary and Venereal Diseases and Syphilis. By ROBERT W. TAYLOR, A.M., M.D., Clinical Professor of Venereal Diseases at the College of Physicians and Surgeons (Columbia University), New York; Surgeon to Bellevue Hospital and Consulting Surgeon to City (Charity) Hospital, New York. Second edition. One volume. Pp. 720, with 135 engravings and 27 full-page plates. New York and Philadelphia; Lea Brothers & Co. 1900.

When "Taylor on Venereal Diseases" was published in 1895 the medical public was provided with a most complete and exhaustive résumé of the subject in a book of 1,000 pages. Dr. Taylor's great ex-

perience and his ability as a medical writer made the book a standard for books of its kind and for the past five years it has been so recognized. The present volume is that book renamed, remade and thoroughly revised and brought up to date. That this has been successfully accomplished, and that the book has been at the same time reduced nearly one-third in size, is enough to show the amount and character of the labor expended upon the present edition. The author's aim has been "to present an up-to-date, practical and compact treatise." In order to accomplish this, many subjects are treated so briefly as, at first reading, to somewhat astonish the expert in genito-urinary diseases. For example, the endoscope, the cystoscope, the Bottini instrument, the various methods for collecting urine from the two kidneys separately, the various operations commonly performed on the kidneys, bladder and prostate are all, each in its proper place in the text, summed up in a few words of careful explanation, clearly indicating the writer's opinion that such special lines of work are not proper subjects for extended consideration in a book of this kind. In the same way the chapter on the seminal vesicle and its diseases consists of a single page, but the common inflammations of the vesicle as complications of gonorrhoea receive careful and adequate consideration in the pages devoted to that disease. In such ways as this the practitioner is given a perspective of the relative importance, to him, of various much-exploited conditions and procedures—a perspective which the author's long experience renders of the greatest value. The sections on treatment are refreshingly concise and practical, and one is glad to notice the absence of those many pages of prescriptions and general directions with which so many books are cumbered.

Paper, type and illustrations are all good and the publisher has earned his share of the book's success.

Rhinology, Laryngology and Otology, and their Significance in General Medicine. By E. P. FRIEDRICH, M.D., Privat Docent at the University of Leipzig. Authorized translation, edited by H. HOLBROOK CURTIS, M.D., New York. Pp. 335. Philadelphia and London: W. B. Saunders & Co. 1900.

The object of the author is to describe those lesions of the nose, the throat and the ear which are either caused by or are intimately associated with disease in some other part of the body, or with a general disease. This task he has performed admirably, and has given both to the general practitioner and to the specialist a book for collateral reference which is modern, clear and complete. He has carefully avoided all temptation to enter the field of therapeutics. The arrangement of the chapters is more from the side of general medicine than from the special regions. It is, for instance, easier to learn what to look for in the ear or nose in typhoid fever than it is to find what diseases might be present to account for epistaxis as a symptom.

The book is divided into twelve chapters and an appendix. Under the head of diseases of the respiratory organs is included the effect on the lungs of nasal obstruction and disease of the upper respiratory tract, and an excellent résumé of disturbances in the ear by way of the Eustachian tubes. Chapters on conditions in the upper air passages and the ear which may be looked for in cases of circulatory, digestive,

renal, infectious and chronic constitutional diseases are of equal interest to the general practitioner and the specialist. The description of tuberculosis and lupus, and of syphilis, as they appear in the nose, throat and ear, while not intended to cover the ground thoroughly, gives the essential features in a much more acceptable form than is found in many of the special textbooks. The relation of the sexual organs to the nose is briefly and seriously discussed, with an attempt to pick out the good from Fliess, but risking only a small paragraph from Mackenzie. The chapter on relation between diseases of the eye and the nose is a good summary of a subject which has been much discussed in the past few years. A most excellent chapter on nervous diseases reviews the whole subject of nerve supply of the larynx and the effect of different lesions of the nervous system upon the upper respiratory tract and the ear. Local manifestations in *tabes dorsalis* receive special attention. A section on "ictus laryngis," or laryngeal vertigo, appears to have strayed from this chapter into the chapter on chronic constitutional diseases.

Perhaps the most interesting part of the book is the appendix, where we find under "nasal reflex neuroses" all of the vexatious problems which such a title implies. In the appendix, also, the irritation of certain of the cranial nerves by inflammatory processes in their vicinity, a subject which is too often neglected, receives its due attention.

The editor of this English translation is to be complimented especially for having introduced the work to English readers, and also for the manner in which he has done it.

Chirurgie du Foie et des Voies Biliares. Par J. PANTALONI (de Marseilles). Pages 626, avec 348 figures dans le texte. Paris: Institut de Bibliographie Scientifique. 1899.

This book is devoted to the study of the operative work done in hepatic surgery. The aim is to write a complete review of what has actually been done surgically in the treatment of the liver, this organ being considered either as a special organ or as a biliary apparatus. Untried or theoretical procedures have been left unconsidered. The author does not attempt to deal with untested opinions.

The book is divided into four parts as follows: Part I. Operations on the liver as a whole, hepatic surgery proper; Part II. Operations on the hepatic ligament, portal and hepatic vessels; Parts III and IV. Operations on the biliary system, subdivided into (1) general biliary surgery, (2) special biliary surgery, according as the system is considered as a whole or in part.

The book is quite systematically arranged, each chapter presenting the same classification. The subject is defined, and synonyms, if any exist, are given. Then follows a brief historical résumé, then a description of the operation, the topographical anatomy involved, its technique, the instruments required, dressing, etc. Next is described the results and possible complications; finally, the indications for the procedure under discussion. This method, with its paragraph headings in heavy type, makes a book quite convenient for reference and comparison of subjects. It is also well indexed both as regards subjects, authors and illustrations.

A review of the text shows the volume to be an ex-

haustive treatise of the subject except as regards some minor details. For example, it would be interesting to know, in some cases, more details relating to "after treatment" and as to time required for recovery, especially during the immediate post-operative period, also as to immediate results and, again, in other instances as to end results. In other respects the work is fully done. Many operations are here described which do not usually appear. Of these one notes the operations on the hepatic arteries and veins; the hepatic ligaments; injection of the bile ducts; biliary anastomoses, atypical operations on the gall bladder; hepatic enterostomy and cholangiostomy.

The subjects are abundantly illustrated, notably the chapter on hepatic sutures and the operations on the biliary ducts. The discussion of the indication for the various operations described is a feature of the work. It is the part which is of interest to the physician as well as the surgeon, the book as a whole being devoted to the question of operative surgery. The author has tried to attract more attention to the efforts of modern surgery in this field, and to results that are too often lost sight of. He hopes that by reading these pages, where are stated and discussed the indications for each operation, a clear idea will be obtained of what has been accomplished; that convinced in their turn doctors will not allow their patients to reach the last stages of cachexia before considering the benefits derived from a skillfully performed operation.

The Physical Signs of Pulmonary Disease. The Sphygmograph in Clinical Medicine. By GRAHAM STEEL, M.D., Lecturer at the Owens College, Manchester. Philadelphia: P. Blakiston's Son & Co. 1900.

The publication of these tiny manuals is an illustration of the unwise separation of subjects from their natural accompaniment. Following such a plan, a complete consideration of the subject of physical examination would require at least half a dozen volumes, and judging from the present example there would be no great demand for such a library.

Diseases of the Tongue. By HENRY T. BUTLIN, F.R.C.S., D.C.L., Surgeon to St. Bartholomew's Hospital, etc., and WALTER G. SPENCER, M.S., M.B., F.R.C.S., Surgeon to the Westminster Hospital. Pp. 475, with 8 chromolithographs and 36 engravings. London and New York: Cassell & Co. 1900.

The medical profession will heartily welcome this, the second edition of Butlin's manual on "Diseases of the Tongue." The first appeared in 1885 and was reprinted without alteration in 1890. It is now enlarged, not only by the addition of new chapters and additions to the text, but also in the size of the book and the type. An excellent chapter on the anatomy of the tongue has been added. The chapters have been more or less rearranged, and the various morbid conditions brought under general headings, grouped as much as possible according to pathology rather than gross appearances. In the former edition, for instance, wandering rash and syphilitic plaques appear together. Now the former is under chronic superficial glossitis and the latter under syphilis, a much better arrangement. A few subdivisions have been added to include recent advances, such as the bacterial infections under glossitis. The author presents the results of his accumulated experience, as in

the treatment of leucoma, and especially in the surgery of malignant disease. The whole subject of malignant disease has been rearranged, enlarged, and the pathology illustrated.

The 8 excellent colored plates are reproduced in this edition and a few cuts in the text added.

As a whole the book is too well known to need any indorsement. In the most satisfactory way it fills a place which needs to be filled. Its present form is in better keeping with its character than the original edition. A critic must content himself by saying that the paper, though good for half-tone illustrations, is too highly polished for reading, and that the stiffness of the plates interferes with the turning of the leaves.

Clinical Studies in Vice and in Insanity. By GEORGE R. WILSON, M.D., Medical Superintendent, Mavisbank Asylum, Edinburgh. Pp. 225. New York: The Macmillan Company; Edinburgh: William F. Clay. 1899.

This book's chief claim to merit is the author's careful, and in the main successful, endeavor to explain the pathology of drunkenness according to the results of the most recent research in the histology and degeneration of the cortex. He regards true drunkenness as a disease which primarily affects the purposive functions. Its lesion is in the nature of a tonic degeneration which begins in the highest dendritic systems of the cortex and may be regarded as the immediate effect of alcohol on the minutest structures in them. From this as a starting point he deduces logically and in true pathological sequence its immediate and remote effects as a progressive disease. Several interesting cases of alcoholism reported in minute detail and in an entertaining vein serve to illustrate the writer's views of the relations of drunkenness to heredity, environment, natural qualities and vicious tendencies. This part of the volume decidedly enlarges one's conception of alcoholism as a degenerative disease and is an instructive and modern presentation of the subject. The rest of the book is devoted to a meagre and desultory consideration of certain aspects of insanity, with reports of a few cases. This portion is of little or no value as a contribution to our knowledge of the disease, but is the vehicle for the author's views on various mooted questions, which are full of originality, acumen and sound common sense.

The book itself might be improved by a less lurid cover and more accurate proof-reading.

The Care of the Consumptive. By CHARLES FOX GARDNER, M.D. New York and London: G. P. Putnam's Sons. 1900.

This is ostensibly a book for the laity and as such is quite worthy of commendation. In these days of inflammatory proclamation and scare-head lines on the danger of infection from the tuberculous individual it is a comfort to have a brief book dealing plainly with the elements of the pathology and the leading principles of prevention and treatment that can safely be put in the hands of those afflicted with the disease or those whose lot it is to be caretakers of such. The various aspects of diet, exercise, climate and outdoor treatment are intelligently presented, and there is a closing chapter on Colorado considered as a Mecca, and taking too encouraging a view, it seems to us, of the opportunities for patients finding ready means of livelihood as soon as their health is reasonably good.

THE BOSTON
Medical and Surgical Journal.

THURSDAY, DECEMBER 27, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: \$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; \$6.56 per year for all foreign countries belonging to the Postal Union.

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS

ANNUS MEDICUS MDCCC.

THE past year has been characterized rather by the prosecution of researches begun before than by any notable discoveries in matters pertaining to medical science. Investigations on the etiology of malaria have led to preliminary conclusions of moment, and the more difficult question involved in the investigation of the cause of cancer has been taken up with renewed interest both in America and Europe. Studies on infectious diseases, and notably on those prevalent in the tropics, have been productive of certain positive results. A peculiar opportunity has been offered to American physicians for the study of plague and yellow fever, owing to their occurrence in regions which are now more or less under the jurisdiction of the United States. The war in South Africa has again, as in the late Spanish-American War, afforded an ample, if unexpected, opportunity of studying the relation of typhoid fever to the conditions of camp life. An ample literature has also grown up within the year relating to the effects on the human body of various sorts of bullets, and of the treatment of bullet wounds. Much knowledge of permanent value has been gained by the study of these subjects, made, as it has been, by men of the first ability. The Chinese embroglio, with the peculiar difficulties for the troops engaged, incident to a trying climate, has been instructive from the medical point of view, as showing the possibilities of modern camp sanitation. The year has shown a general advance in every department of medicine, and particularly in those broad fields of research which look toward the discovery of the cause, and hence the prevention, of epidemic disease.

PLAGUE.

In British India during the month of December, 1899, the plague epidemic, which had been prevalent for some months, showed a marked decline, but in February, 1900, the number of deaths had again increased and by the middle of March had assumed alarming proportions. The epidemic reached its

climax in the second week of April in Bombay. This unfortunate city was the seat of a most extensive epidemic, even surpassing in severity and duration that of the winter of 1897-1898. For many weeks the deaths numbered 100 daily. There was also a simultaneous epidemic in Calcutta, the deaths numbering from 75 to 100 a day. In Kurrachee, India, the epidemic was of a much milder type, and by the middle of March, when the disease is usually at its height, only a few cases were reported. The disease spread far and wide into the Bengal Presidency, and for one week 4,725 deaths were recorded. Lord Curzon, Viceroy of India, did everything in his power to encourage the natives to submit to inoculation, with a considerable degree of success. It is significant to note that in one section the natives requested inoculation without external pressure. The increasing heat seemed to have very little effect in decreasing the epidemic, as is usually the case, and in its twenty-fourth week the disease showed no tendency toward abatement. The concealment of many cases, and especially the flight of certain natives from the towns to country districts, militated against the efforts of the government, and increased the spread of the disease. By the end of June the total number of cases for all India was 277,000. This epidemic in India was peculiar, in that it was accompanied by an increase rather than by a decrease of other contagious diseases. The prevalence of famine may stand in some relation to this fact. In the middle of February plague appeared in Aden, Arabia. At the end of fifty-two days, 290 cases had been reported, with 208 deaths. The infection was probably brought from India by cargo, or through the instrumentality of ship rats.

In Japan the epidemic began in the latter months of 1899, and the strictest quarantine was enforced against travellers. Early in January 2 new cases were reported in Osaka, but by the end of January the epidemic was fairly at an end. Osaka was the seat of the greatest number of deaths, because of its location and lack of sanitation.

During January there was an outbreak of plague in Oporto, Portugal, limited, however, to that city. Relatively few cases were reported. On April 4th a steamer from Oporto to Rio Janeiro, Brazil, landed a man with his wife and child, who took up their residence in the city, in a house already occupied by many persons. These new arrivals brought soiled linen and other clothing, which was removed from their trunk. On April 8th some of the tenants of the house were taken sick. The first death that occurred was classified as due to lymphangitis perniciosa. As more cases developed the real cause was suspected. The patients were isolated, and others who had been exposed placed under observation. Bacteriological examination demonstrated the existence of plague. No widespread epidemic followed these preliminary cases.

In Honolulu, Hawaii, plague made its appearance in December, 1899. January 1, 1900, 8 new cases

were reported and a little later the disease developed in fatal form with lymphatic involvement. The focus of the disease was supposed to be limited to Chinatown, and the attempt to eradicate it by burning infected buildings led to the accidental destruction of a much larger district. Fifteen thousand dollars was appropriated for the shelter of persons released from quarantine. These measures met with success, and after March 1st only 1 death was reported. The total number of cases had been 68; of the deaths following 30 were Chinese, 7 Japanese, 15 Hawaiians, and 3 whites.

On account of trade communications San Francisco and all other ports of the Pacific Coast were strictly quarantined. In spite of this, the existence of plague in Chinatown, San Francisco, was reported May 21st and a week later there had been 8 or 9 cases, all among the Chinese. House to house inspection and inoculation led to a checking of the disease. In December, 1900, it is reported that cases are still appearing in the city. Through its chargé in Washington, the Japanese Government joined the Chinese Government in a protest against the compulsory inoculation of Japanese and Chinese in San Francisco with antiplague serum, on the ground that if such inoculation were necessary to prevent the extension of the plague, it could not be contemplated that any discrimination should be practised against the Japanese and Chinese; the rule must be general, and include Caucasians as well as yellow men.

September 1st plague made its appearance in Glasgow, and at that time 80 cases were reported. An admirable quarantine and rigid medical supervision led to the gradual but complete eradication of the disease. It never attained alarming epidemic proportions.

In addition to the more important outbreaks narrated above, the disease appeared in sporadic form in various widely separated parts of the world. In Manila, Philippine Islands, an outbreak occurred, resulting in the death of 119 Chinamen and 66 Filipinos. In Persia there was an outbreak in the Javanrood district near the Turkish frontier, with upwards of 195 deaths. The feared epidemic of plague in Durban, South Africa, was causeless.

The general experience of the year from many reliable sources is that, as prophylactic, Haffkine's fluid for inoculation is the most potent and lasting. In the report of the Indian Plague Commission on Haffkine's Antiplague Inoculation, published in the *British Medical Journal*, February 24, 1900, it is stated, with regard to the feasibility of adopting a general policy of inoculation in India, that: (1) Experience gained hitherto has shown that it is very seldom possible to get a large proportion of the inhabitants of an uninfected place inoculated; (2) it has been possible, where the inducements of exemption from segregation and eviction have been offered, to get a large proportion of an infected place inoculated quickly. (3) it has been possible in one place — Mysore City

—even where no inducement that touched the great mass of the people could be offered, to get a considerable proportion of the inhabitants of an infected place inoculated quickly; (4) it has been possible also to induce a large proportion of particular communities, such as the Khojas of Bombay and Karachi, to be inoculated under the influence of their leaders.

The commissioners finally recommend that, under the safeguards and conditions of accurate standardization and complete sterilization of the vaccine and the thorough sterilization of the syringe in every case, inoculations should be encouraged wherever possible, and in particular among disinfecting staffs and the attendants of plague hospitals.

In the Bombay Presidency, in British India, the value of the Haffkine prophylactic is noted in a series of observations as follows:

	Number.	Cases.	Deaths.
Inoculated	147	2	0
Non-inoculated	172	12	6
Inoculated	147	3	0
Non-inoculated	127	10	6
Inoculated	71	8	3
Non-inoculated	64	27	26

These figures show that, in addition to affording a very large proportion of protection against the disease, the mortality was reduced by 80 or 80%. An instance of the average mortality is afforded by the statistics showing that in the city of Hubli the mortality among those not inoculated reached the appalling figure of 657 per 1,000 of those attacked. Further, in the cities of Bombay and Moffusil the following figures are given:

	Inoculated.	Cases.	Deaths.
Bombay	8,200	18	2
Moffusil	429	7	0
Non-inoculated	26	24

The duration of the immunity conferred was stated to be several months and this immunity was much increased by a second or even by a third inoculation.

Considerable investigation has been undertaken during the year regarding the possible relation of rats to the spread of the disease, with the general result of demonstrating that rats often serve as an intermediate host for the bacilli. Experiments have shown that rats easily become infected, and dying, are a prolific source of the spread of the disease. Its prevention, therefore, consists in destroying infected rats, and in carefully inspecting travellers by land and sea. In every country where plague has occurred a systematic destruction of rats has been attempted. In Aden a reward of 1 cent a rat was offered, and in Hawaii a bounty of 25 cents, with the appointment of a professional rat catcher by the Board of Health. The method of extermination by poison did not usually prove a success. In Japan 3,000 rats were killed in one week.

SMALLPOX.

Smallpox has not been a widespread disease during the year. In December, 1899, there was an outbreak in Mexico, which continued during the following three months. By the end of April there had been 298 cases with 166 deaths in the city of Mexico. In Vera Cruz it was also epidemic, but in less degree. From the Mexican border during the winter came constant reports of travellers detained for suspicious symptoms which often proved to be smallpox. Along the line of the Mexican International Railroad the disease was much in evidence. On the United States side, however, vaccination, done by the United States Sanitary Guards, was efficient and the disease gained little headway. A constant interchange of visits between the Mexican and Texan side proved a prolific source of infection. All Pullman trains were detained thirty-four hours in passing from Mexico into Texas, and thoroughly disinfected with formaldehyde, remaining tightly closed for eighteen hours. Throughout the Southern States during the winter there were a considerable number of sporadic cases. A severe epidemic occurred in Louisiana. By the end of February there had been 2,257 cases, while in one town, St. Landry Parish, there were 782 cases, with a large percentage of deaths.

In early January in Columbia, Ala., there were 32 well-marked cases in negro adults, and the slight epidemic which followed was confined to the negro population. Several cases were reported in Georgia, and the source of infection there was undoubtedly cotton shipped from infected ports. The Kansas City Board of Health ordered a quarantine against Kay County, Okla., January 19th, where there were said to be from 400 to 600 cases. In fact, a number of cities and towns in Kansas were infected from this source, and smallpox was epidemic in various parts of the State. In Illinois there were many cases, but no epidemic. The epidemic in Tacoma, Wash., began in the following manner: A young girl from Seattle, where there had been a few sporadic cases, visited in a physician's family in Tacoma. He noticed that she had a suspicious eruption and at once quarantined both the patient and his daughter. In spite of this precaution, within a few weeks 150 cases of the disease had developed. A few sporadic cases only occurred in San Francisco, Cal., owing to the rigid quarantine against Mexican travellers.

The steamer *Ohio* arrived at Nome, Alaska, on the 20th of June with 2 well-marked cases of smallpox on board and by July 10th 22 cases were reported. A house to house inspection was at once instituted and what promised to be an epidemic was averted. There were also a few cases reported at Dawson City.

In Canada an epidemic of smallpox began as early as August, 1899, at St. Phillippe de Neri, and gradually spread through different sections of the country, lasting until February. The origin of the disease was here traced to a tramp, who while suffering from a mild form of the disease went from place to place,

sleeping in stables and railway stations. In Ontario an epidemic appeared about the middle of January, the greatest number of cases being in Essex County.

Smallpox was more or less prevalent throughout Russia during the summer, but only in St. Petersburg attained epidemic form. In that city there were 460 cases during June, July and August.

In Marseilles, France, a slight epidemic occurred, limited to the month of March, also slight ones in one or two English towns, with 83 cases in London.

In Bombay, India, smallpox prevailed coincidentally with plague, though in much less degree.

The usual number of sporadic cases have occurred in various parts of the world. Boston and its vicinity have not been wholly exempt, though the disease has never reached epidemic form. The following experience of the steamship *New England*, sailing from Boston to the Orient, is of interest. The circumstances were briefly as follows: The steamer sailed February 1st, from Boston, with an excursion party of 425 persons, whose destination was the Orient. While at Rome smallpox appeared, which probably had broken out a considerable time before the vessel reached the port of Naples, where passengers were landed for the Italian sightseeing. The excursionists were on shore, sightseeing, and the captain of the steamer, seeing the desirability of prompt action, sailed for Liverpool without his passengers, after having disembarked their luggage. Several of the members of the party have since died of smallpox, and for a time something approaching a panic prevailed. The excursion naturally has come to an untimely end, to the discomfort and annoyance of all concerned.

The usual opposition on the part of certain fanatical persons against vaccination continues to prevail both in this country and abroad. The proper enforcement of vaccination has, in many instances, been rendered difficult, and this fact has, no doubt, often prevented the rapid extermination of the disease. In England the antivaccination element has been particularly in evidence, and a heated controversy has resulted, much of which has been aired in the English medical journals.

The increase in the number of vaccinations in all England, however, for the year 1899, as compared with that for 1898, was 33.8%.

YELLOW FEVER.

Of the three important epidemic diseases of the tropics, plague, cholera and yellow fever, the manifestations of the last during the past years have been least widespread. In January, 1900, the report regarding the yellow-fever situation for the month preceding gave the following statistics: New cases 70, deaths 22, recovered 30, under treatment 25. Of the patients, 23 were Americans and 50 Spaniards. Six of the former died and 10 of the latter. Experts hold that the difference in the ratio of deaths was due to the use of alcohol. Comparison of the whole year

with the ten preceding years is favorable, but the last three months of 1899 were unfavorable. The December record of deaths from 1890 to 1899 is 11, 17, 32, 10, 24, 19, 225, 17, 13, 22. The yearly totals for the same period are 327, 363, 362, 512, 418, 560, 1,540, 1,056, 162, 103. It is of interest that the records show that, in spite of favorable weather since September 1st, the situation has been worse than during the corresponding period of the Spanish occupation. The explanation offered is the great influx of Spanish immigrants who were not acclimated and who were huddled in the lower quarters of the city. They were badly nourished and were unable to resist the disease. One prominent fact is the failure of house disinfection to kill the germs of the disease. Every house in the city has been disinfected several times. Those familiar with the conditions are not surprised at these facts. The introduction of proper methods of sanitation will no doubt gradually overcome the disease.

During January, February and March there were but 39 new cases, while in April not a case was recorded. The general sanitary condition of the city was excellent. Pending a threatened outbreak at Cienfuegos, a careful inspection was instituted, but the fever at that port was limited to 7 cases on board the training ship *Lancaster*. Through the strenuous efforts of Col. Samuel M. Whiteside, commander of the Department of Santiago and Puerto Principe, up to September practically no yellow fever had occurred since December. The greatest possible precautions have been taken by cleanliness and disinfection to prevent the disease, which the result has amply justified. This fall, however, it was reported that yellow fever prevails in Havana to a greater extent than at any time since 1897. For the week ended September 15th there were 9 deaths. The week ended September 22d also showed 9 deaths, while there were 19 during the week ended September 29th. The Marine Hospital reports show a total of 49 deaths for August. The filthiness of Havana harbor is regarded as one of the essential causes of the continuance of the disease, in spite of active sanitary measures within the city.

The condition regarding yellow fever in the Philippines has, on the whole, been very favorable. A report from Major W. C. Gorgas, of the medical corps, chief sanitary officer at Manila, states that while the death rate for April was 482, there were no deaths from yellow fever, the first month so favored since May, 1899, and the only month when there were no deaths from this disease during the past ten years, with two exceptions, February and May, 1899. In general, yellow fever has not been a prominent factor in the diseases of the Philippines.

In Mexico yellow fever was epidemic, the cases numbering by May 1st 730, with 353 deaths. In Vera Cruz, however, by the last of April it was reported that the epidemic had been checked.

In South America, from Argentina there is no report of yellow fever after November 30, 1899, but in Colombia, at Barranquilla, there were 21 deaths in

June; at Rio de Janeiro, Brazil, yellow fever was epidemic in February, March and April, but by the end of May it was practically at an end.

During the summer a slight outbreak occurred at the Soldiers' Home in Hampton, Va. Apart from the few inevitable cases in the Southern States, the disease has not, however, appeared in the United States in threatening form. It appears, in fact, probable that our present knowledge of the disease will ensure us against epidemics in the future, which a few years ago were so great a source of anxiety.

Etiology.—The opinion is gaining ground, and is already accepted by many bacteriologists, that Sanarelli's bacillus is the cause of the disease. The general conclusions which have been reached are as follows:

That the bacillus icteroides, discovered by Sanarelli, is the specific agent of yellow fever. That micro-organism injected into certain animals, especially dogs, reproduces symptoms and lesions strikingly analogous to those observed in man. The toxin of this bacillus produces in animals the same effects as the microbe. The injection of this toxin into 5 individuals reproduced in man typical yellow fever, accompanied by its symptoms and anatomical lesions. The serum of individuals attacked with yellow fever agglutinates cultures of the bacillus icteroides. The bacillus has a prolonged vitality both in air and water (fresh and sea). It is certain that it is the same in the soil. Moulds favor its development. These facts confirm conditions that have been known a long time. They explain the reawakening of yellow fever a long time after the extinction of an epidemic, and the longevity of the disease aboard vessels in bad hygienic conditions. No new prophylactic measures have come out of this knowledge of the etiology of the disease. As formerly, the prevention of yellow fever consists in applying the measures of isolation and of disinfection, and of improving the hygienic conditions.

The rôle of the mosquito as a conveyer of the infection has also been studied, but with results much less conclusive than in the case of malaria.

CHOLERA.

In India while the plague and smallpox epidemics victimized Bombay, a cholera epidemic was causing one-sixth as many deaths in Calcutta as the plague itself. The disease seems to have limited itself to these cities, and although at Omam, in Turkey, sporadic cases are mentioned, there was no epidemic.

MALARIA.

During the past year much interest has centred in the study of the relation of mosquitoes and malaria, with results of a positive character. A large number of experiments have been made by competent observers in various malarious districts and a general unanimity of opinion prevails that mosquitoes of the genus *Anopheles* are chiefly concerned in the transmission of the disease. According to the researches of Bastianelli and Bignami, a single mosquito may infect an individual, and in fact, several individuals, for they have found numerous parasites in the salivary glands of mosquitoes by whose bites they have experimentally produced malaria in healthy subjects.

They have also made a study of the mosquitoes of very malarious districts in Italy, where almost the only genus is the *Anopheles*. In the months of June and July only 3% of the mosquitoes examined were found infected with the parasites, while those caught far from any habitation were found free from malarial infection. They concluded from this that the few malarial infected mosquitoes met with here acquired the parasite from persons who were suffering from relapses of malaria. They also reported the following interesting observations: A number of harvesters were housed in a big granary. In this on June 23d, only 1 mosquito was found. On the 24th, 8 mosquitoes were found, and on July 1st, 366. Of these 90 were examined and only 3 were found to be infected, but subsequently the number of the infected mosquitoes rapidly increased. At another place 42 laborers were housed in huts on an estate. On July 2d, out of 7 mosquitoes only 2 were found infected. On July 17th, 15 mosquitoes out of 32 were found infected, and on July 20th, 11 mosquitoes among 17 contained the malarial parasites. Mosquitoes captured during the same period in the stables of the estate or at a distance were found free from infection as a rule. At the end of July or early part of August, nearly all of the men who had lived in the huts during this period had become affected with malaria. They think that malaria should be regarded by the authorities as an epidemic or contagious disease and treated accordingly.

Professor Celli, director of the Institute of Hygiene at Rome, has traced the cycle of the infection, for the maintenance of which, in Italy at least, man is essential.

Beginning with the great multiplication of mosquitoes at the end of June or the early part of July, it is found that some of these are infected by the malarial parasite. They convey the infection to man, thus bringing about the great increase in the number of attacks of malaria observed in July and August, but sometimes continuing into the fourth quarter of the year. During the first and second quarters of the following year the malarious cases met with are generally recurrence of the infections contracted in the third or fourth quarters of the preceding year, and it is by these recurrent cases occurring even as late as June, when the mosquito once more becomes active, that the infection is again transmitted to the insect, and a new epidemic started.

Both Celli and Koch lay great stress on the part which the cultivation of rice plays in favoring the multiplication of mosquitoes. "The more rice fields," Koch reports, "there are in the neighborhood of a place, and the nearer they are, the greater the abundance of mosquitoes;" and Celli observes that it is well known that the "formation of rice fields causes the reappearance of malaria where it had become extinct, and where it already exists they are a very active focus of production." Rice is best cultivated on low lands subject to occasional inundation, but where inundation cannot be depended upon very copious artificial irrigation is resorted to.

An experiment which is also likely to prove conclusive was one undertaken by two English observers, Drs. Sambon and Low, under the direction of Dr.

Patrick Manson, who have lived in the malarious region of the Roman Campagna in a mosquito-proof hut. Retiring to their house at night when the mosquitoes bite, the observers have remained wholly free from infection, although the peasants in the neighborhood were all suffering from the disease. A visitor to this unique house writes in the *Journal of Tropical Medicine*:

I was in the Campagna when the rains set in and every one said, "Now is your time, you will all get fever." Two of us purposely went out in the rain and got soaked to the skin, but we disappointed our neighbors for we got no fever. On going into Ostia in two or three days' time, however, we found practically every one down with it. They crawled out of their houses looking the picture of woe and misery, and gave us their hot, feverish hands to feel. The explanation of this is of course evident, the inhabitants are all malariated, and chilling caused by the rain determined an explosion of fever.

Manson's experiments with infected mosquitoes and Koel's investigations were also important and demonstrative. Work undertaken in other parts of the world has been confirmatory of these results. Much remains, however, to be done in studying more thoroughly the habits of the mosquitoes and particularly in finding adequate means for their extermination. The following simple and somewhat self-evident conclusions have been reached: (1) The avoidance of the neighborhood of native houses—the perennial source of malaria parasites; (2) the destruction, so far as practicable, of *Anopheles'* breeding pools, (3) and principally, protection from mosquito bite.

TUBERCULOSIS.

The recognition of the fact that tuberculosis is highly preventable and in many cases a curable disease has led to an entire change of front in the attitude of the community toward it. As a consequence, institutions have come into existence for the rational treatment of tuberculosis, at first regarded with suspicion, but now rapidly being accepted as a necessary part of the hospital system. A new impetus has evidently been given to this tendency in New York State, through the report from a committee of the State Board of Charities. This committee strongly recommended the establishment of local sanitariums, as the most efficient means of combating the disease, rather than crowding tuberculosis patients into one or two large institutions, possibly at considerable distances from their homes. Such a plan appears possible, both from the point of view of expense and ease of management.

In New York there has been some discussion as to whether the new State Hospital for incipient tuberculosis, for which there is an appropriation of \$50,000, should be situated in Dannemora, in the Adirondacks. The completion of a new ward for the insane at Bellevue Hospital will render possible a much more adequate isolation of patients suffering from tuberculosis than has heretofore been possible in New York City. The *New York Medical Journal*

states that Dr. Louis Bazet, a member of the San Francisco Board of Health, has entered upon a vigorous campaign for the establishment of a separate hospital in San Francisco for the care of patients suffering from tuberculosis.

It is reported that arrangements are being made to establish a National Baptists' Home for Consumptives in Denver, Col.

The Iowa State Board of Health has placed tuberculosis on the list of infectious diseases, and recommended that persons afflicted with it and infected premises be dealt with accordingly. In a pamphlet issued this year are numerous suggestions and instructions for dealing with the disease. This somewhat recent attempt to institute a quarantine against tuberculous patients in some of the other Western States, as well as Iowa, met with the condemnation which it was the general opinion of the medical press it deserved, and the recent action of the Boston Board of Health that hereafter pulmonary and laryngeal tuberculosis shall be included in the list of diseases of which compulsory notification is required met with much criticism. In England the subject of sanatoria for tuberculosis has received much attention and several have been established recently; in general there is an increasing tendency everywhere to found sanatoria both at public and private expense.

There has recently been founded in France, according to the *British Medical Journal*, a society for the protection of the people against tuberculosis by popular education. It proposes to diffuse a knowledge of the means of preventing the disease by pamphlets, circulars, leaflets, placards, pictures, articles in the newspapers and popular lectures.

ETIOLOGY OF CANCER.

During the past year an active interest has been taken in the investigation of the parasitic origin of cancer, both in America and Europe. The early work of Ruffer, Pianese, Sanfelice, Plimmer and others has been subjected to critical analysis, with the following general conclusions as outlined by Nichols, working under the bequest of the late Caroline Brewer Croft to the Surgical Department of the Harvard Medical School. Certain bodies have been found in the cells of malignant tumors, of varying morphology and staining reaction, which certain observers have believed to be parasites and the cause of cancer. In two instances animals inoculated with blastomycetes have developed epithelial tumors, analogous to cancer in man, but the actual causal relation is not proved. The theory that cancer is due to a parasite is not yet proved. Nichols has studied a variety of tumors to determine if characteristic bodies are constantly present. His investigations are still in progress. The whole subject is one of great difficulty, but the preliminary work is encouraging for future results of more definite character than have yet been attained.

THE WAR IN SOUTH AFRICA.

"This war has been a war of surprises," writes Mr. Treves. "The casualties have been higher than

the gloomiest ever dreamed of and there was no reason to anticipate that the outbreak of enteric fever would assume the enormous proportions it has assumed." War was declared in October, 1899, and the stubborn resistance with which the Boers met the British in South Africa soon led to no little criticism of the British Government and the War Office for alleged lack of preparation. Whatever shortcomings, however, were brought to light, one branch of the service, the Royal Army Medical Corps, seems early in the war to have been more than equal to its arduous duties.

After the battle of Colenso, Sir William MacCormac writes: "In all the details of the necessary movements of the sick and the wounded, no army has ever been so well provided as ours now in the field. At this battle the wounded were taken directly to the hospital train and their wounds dressed extremely well under fire. At the field hospitals at Chieveley, about 400 yards outside the fire zone, some 800 patients were treated during the day, December 15th. The surgeons on duty began their work at 3 A. M., and were still at it in the evening without food or rest. As soon as the men were treated at the field hospitals, the hospital trains took them rapidly to the base." The heroic services of the medical force and of the 2,700 ambulance bearers is mentioned with the highest praise. The rapid healing of the bullet wounds was also a great source of satisfaction. Both the Mauser and Lee-Netford bullets made wounds that were small, clean and little disposed to suppurate, and wonderful recoveries from injuries were reported.

But as the war continued, disease and wounds made great havoc in the army. During the long siege at Ladysmith, dysentery and typhoid fever were the cause of many deaths.

In November the garrison consisted of 572 officers and 12,924 men. In March it had been reduced to 403 officers and 9,761 men. The admissions to hospital numbered 10,668, including 1,766 cases of enteric fever, and 1,857 of dysentery. The deaths were 600, including 393 from the former disease and 117 from the latter. The patients in hospital on March 1st numbered 1,996, 708 of whom were suffering from enteric fever, 341 from dysentery, and 189 from wounds. Other figures are as follows: Died of wounds, 59; killed in action, 18 officers, 193 men; killed in assaults and sorties, 17 officers and 160 men; killed by the bombardment, 2 officers, 33 men; wounded in assaults and sorties, 45 officers, 352 men. In November there were in Ladysmith 5,309 horses and 4,539 mules. At the end of the siege the horses numbered 2,900, of which only 500 were effective, and the mules 3,713. The rations which in November were issued for 40 days were, towards the end, made to extend over 120 days.

Both enteric fever and dysentery broke out also among the relieving forces. At Kimberley, where there were 20,000 men in garrison, both typhoid fever and scurvy appeared, the latter disease chiefly among the natives.

In Natal there was much sickness from the same causes.

The *Times* on June 27th published a letter, dated Capetown, May 29th, from Mr. W. Burdett-Coutts, in which he alleges that the medical arrangements in South Africa have failed to keep pace with the epidemic of typhoid fever, which has caused a very large number of cases of illness, especially among the troops in and about Bloemfontein. He gives a graphic and very distressing account of the overcrowded condition of a field hospital used as a stationary hospital in Bloemfontein.

The charges contained in this letter were so grave as to cause a protest from many sources. Among others Mr. Treves made a most vigorous protest against what he regarded as Mr. Burdett-Coutts's unwarranted and untrue strictures against the medical arm of the service. A parliamentary inquiry was ordered, which so far as we know is still pending. Inoculation against typhoid, which was extensively, though not universally, practised among the troops, has led to no definite conclusions as to its efficiency.

Shortly after the occupation of Pretoria, the following statistics were published:

Of the officers in South Africa 72.1 per thousand were killed or died from wounds; 30.6 per thousand of the officers died from disease, while of the men 19 per thousand were killed or died from wounds, and 31.3 died from disease. These statistics not only illustrate that while the officers and men have suffered approximately equally from disease, the risks of the officers in action have been greatly disproportionate, and also that the rate of mortality in South Africa is much greater than it was in the Franco-German War.

These statistics are also of interest:

Up to September 28th, 15,655 cases of typhoid fever had occurred and of these 3,642 had died and 9,128 had been sent home as invalids. A total of 267,311 men, exclusive of officers, were engaged in the war. On December 1st there were 210,293 in South Africa; up to November 30th there had been killed 3,018, wounded 13,886, died of disease or wounds or accidentally killed 7,786, and in hospitals in South Africa on October 2d, 11,927. No fewer than 7,541 not invalids had returned to England, while 35,548 had returned as sick and wounded, including those who had died on the passage.

NECROLOGY. — UNITED STATES, 1900.¹

John S. Cook, M.D., of Hackettstown, N. J., died January 1st, aged 73.

John Cargill Shaw, M.D., professor of diseases of the nervous system at the Long Island College Hospital, Brooklyn, N. Y., died January 23d.

Ernest G. Metcalfe, M.D., of Brooklyn, N. Y., died February 2d, aged 49.

A. P. Richardson, M.D., died at Walpole, N. H., February 3d.

A. J. Billings, M.D., of Freedom, Me., died February 7th, at Belfast.

Edward Lorenzo Holmes, M.D., former president of Rush Medical College, Chicago, died in Chicago, February 11th.

Edward F. Martin, M.D., twenty years connected with the New York City Board of Health, died February 24th.

Clarence Edwin Beebe, M.D., of New York, died March 1st.

¹ Deaths are recorded by months.

Harriet P. Bill, M.D., of New York City, died March 7th, in New Hampshire. Dr. Bill has been resident physician of the Sherborn Reformatory and of the Child Hospital on Staten Island.

Oliver Payson Hubbard, professor emeritus of chemistry and pharmacy at Dartmouth College, died in New York City, March 9th, aged 90.

Samuel H. Pennington, M.D., of Newark, N. J., the oldest living graduate of Princeton University, died March 14th, aged 94.

Arthur A. Beebe, M.D., died March 16th, in Boston, aged 28.

John Cooper, M.D., said to have been the oldest practising physician in Brooklyn, died March 29th.

George H. Conklin, M.D., the oldest practising physician in Suffolk County, N. Y., died April 12th, aged 89.

Fessenden Nott Otis, M.D., chiefly known for his work on venereal disease, died at New Orleans, May 24, aged 75.

Charles H. Mersereau, M.D., of New York, died May 2d, aged 37.

Matthew M. Bagg, M.D., of Utica, N. Y., died May 3d, aged 83.

Landon Carter Gray, M.D., of New York, died May 8th, aged 50.

Charles Herbert Voorhees, M.D., of New Brunswick, N. J., died May 13th.

Alfred H. Lindström, M.D., of Boston, died May 17th, at the Massachusetts General Hospital, aged 31.

E. O. Shakespeare, M.D., of Philadelphia, died suddenly June 1st, aged 54.

Paul Gibier, M.D., of New York, died June 9th, from injuries inflicted by an accident, aged 49.

William Pierson, M.D., one of the most prominent physicians of New Jersey, died in Orange, June 12th.

Benjamin Douglas Howard, M.D., of New York, died June 21st, aged 63.

Louis Arcularius, M.D., a prominent German physician in New York, died July 1st, aged 62.

Alexander J. C. Skene, M.D., of Brooklyn, N. Y., died July 4th, aged 62.

John Ashurst, M.D., of Philadelphia, died July 7th.

Franklin Booth, M.D., of Long Island City, died August 19th.

Alfred Stillé, M.D., LL.D., of Philadelphia, died September 24th, aged 86.

William S. Ward, of Newark, N. J., died September 1st.

J. M. Da Costa, M.D., LL.D., of Philadelphia, died September 12th, aged 68.

Hunter H. McGuire, M.D., LL.D., died in Richmond, Va., September 19th, aged 65.

Lewis A. Sayre, M.D., died in New York City, September 21st, aged 80.

James Hart Curry, M.D., a physician in Westchester and Putnam Counties, New York, died September 24th.

Samuel Smith Purple, M.D., a former president of the Academy of Medicine and one of the most venerated members of the profession in New York, died September 29th, aged 78.

Joseph L. Cutler, M.D., a leading surgeon of Alleghany County, N. Y., died October 14th, aged 71.

Wm. R. Larkin, M.D., a prominent Harlem, N. Y., physician, died October 15th, aged 42.

Laurence Turnbull, M.D., of Philadelphia, died October 24th. His reputation was made chiefly by his work on the ear.

Moses C. White, M.D., professor emeritus of pathology in the Yale Medical School, died October 24th, aged 81.

Edward R. Squibb, of Brooklyn, N. Y., the well-known manufacturing chemist, died October 26th, aged 81.

J. K. Phillips, M.D., of Bangor, Me., died November 5th, aged 42.

Henry Drury Noyes, M.D., an eminent ocellist of New York, died November 12th.

Horace Tracy Hanks, M.D., of New York, died November 18th, aged 64.

Rufus P. Lincoln, M.D., of New York, died November 27th, aged 59. He was eminent as a laryngologist.

Francis Charles Plunkett, M.D., of Lowell, Mass., died November 29, 1899.

J. H. Fruitnight, M.D., well known for his work on diseases of children, died December 18th, aged 49.

George H. Elliot, M.D., of New York, died in Manchester, N. H., December 17th, aged 55.

Charles F. Taft, M.D., died in Mount Vernon, N. Y., December 18th, aged 66. He was the first physician to reach the side of President Lincoln after he had been shot in Ford's Theatre, Washington.

NECROLOGY. — MASSACHUSETTS MEDICAL SOCIETY, 1900.

Milton Wilder Hall, M.D., M.M.S.S., died in Roxbury, January 9th, aged 51.

Austin Marsh, M.D., M.M.S.S., died February 2d, at Carlisle, Mass. He had been a member of the society since 1839.

William Henry Howe Hastings, M.D., M.M.S.S., died in Boston, February 16th.

Edward Augustus Perkins, M.D., M.M.S.S., died in Boston, February 20th, aged 72.

George Morrill French, M.D., M.M.S.S., of Malden, died at Suncook, N. H., February 23d, aged 45.

Frank Walker Graves, M.D., M.M.S.S., died in Woburn, March 13th, aged 58.

George Pinkham Bartlett, M.D., M.M.S.S., of Woburn, died March 27th, aged 49.

Paul Augustine Staekpole, M.D., M.M.S.S., died in Dover, N. H., March 28th, aged 86.

George Washington Warren, M.D., M.M.S.S., died in West Boylston, April 22d, aged 81.

Charles Carroll Street, M.D., M.M.S.S., died in Boston, May 7th, aged 64.

John Richardson Bronson, M.D., M.M.S.S., died in Attleboro, May 9th.

Philemon Eveleth, M.D., M.M.S.S., died at Marblehead, May 14th, aged 54.

Luther Blodgett Morse, M.D., M.M.S.S., died in Watertown, May 26th, aged 79.

Gardner Carpenter Pierce, M.D., M.M.S.S., of Ashland, died May 18th, aged 62.

Elisha Chenery, M.D., M.M.S.S., died in Boston, August 1, aged 70.

William Henry O'Hearn, M.D., M.M.S.S., died in Lawrence, June 4th, aged 30.

William Francis Howard, M.D., M.M.S.S., died in Lawrence, June 15th, aged 31.

Benjamin Webber Bartlett, M.D., M.M.S.S., died in Rowley, August 6th, aged 50.

Moses Warren Kidder, M.D., M.M.S.S., died in Waltham, August 15th, aged 72.

James Henry Robbins, M.D., M.M.S.S., died in Hingham, August 22d.

John Francis Ryan, M.D., M.M.S.S., died in Roxbury, September 1st, aged 29.

John Langdon Sullivan, M.D., M.M.S.S., of Malden, died September 5th, aged 73.

Robert Francis Forrest, M.D., M.M.S.S., of Cambridge, died in Watertown, September 18th.

Lawrence Mervin Gould, M.D., M.M.S.S., of Hyde Park, died in Portland, Me., October 7th.

As shown above there have been but 24 deaths in the Massachusetts Medical Society during the year. Seven of these had reached or passed their seventieth year and one had attained the age of eighty-six years. Three deaths occurred under thirty-two years of age.

NECROLOGY. — GREAT BRITAIN, 1900.²

William MacNeil Whistler, M.D., born in the United States, died in London, February 27th. He was senior physician, London Throat Hospital.

Major Walter Kiddle, M.D., R.A.M.C., born in 1864, was killed by the frontier tribes while serving with the Burmah-China Boundary Commission, February 9th.

Thomas Purcell, M.D., died suddenly February 9th.

Sir Thomas Grainger Stewart, M.D., F.R.C.P.E., F.R.S.E., LL.D., born in Edinburgh, 1837, died February 3d. He was one of the most brilliant lecturers in the University of Edinburgh.

William Mareet, M.D., F.R.S., F.R.C.P., died in Luxor, Egypt, March 4th.

George Vince Ellis, F.R.C.S., emeritus professor of anatomy, University College, London, died April 25th, at Gloucester.

Sir Robert Douglas Maclagan, M.D., F.R.C.P., F.R.C.S.E., LL.D., died in Edinburgh, April 5th.

Sir William Overend Priestley, M.D., LL.D., M.P., died April 11th, aged 70.

R. Glasgow Pattison, B.A., M.B., B.Ch., F.R.C.S.I., died April 11th.

Lieutenant-Colonel C. J. H. Warden, M.D., I.M.S., died July 28th.

Daniel John Leech, M.D., D.Sc., F.R.C.P., died July 2d, aged 60. He was a distinguished therapist.

Richard Hamilton Cowan, M.R.C.S., died October 6th, aged 42.

Sir Henry Aeland, Bart, K.C.B., M.D., F.R.S., died in October, aged 85.

Arthur Symons Eccles, M.B., C.M., M.R.C.S., died in London, October 22d, aged 45.

Richard Benjamin Anderson, F.R.C.S., died in London, November 8th.

Alexander George Davey, M.D., S.B., L.R.C.P., M.R.C.S., L.M.L.S.A., died November 5th, aged 63.

Francis John Boxwell Quinlan, M.D., F.R.C.P.I., died in Dublin, November 8th, aged 65.

Dennis Embleton, M.D., F.R.C.P., died November 12th, aged 90.

Richard Neale, M.D., died in November, aged 72. He was editor of the *Medical Digest*.

Deputy Surgeon-General George Mackay, M.D., died in Edinburgh, November 20th, aged 80.

G. Hutchinson Milnes, B.A., M.D., died in Plymouth, November 20th, aged 41.

DEATHS OF PHYSICIANS IN SOUTH AFRICA.

Captain William Fleming Hopkins, of enteric fever.

Captain Henry Esmonde Dowse, of the Royal Army Medical Corps, died at Bloemfontein, May 5th, of remittent fever, aged 32.

Hugh Arnold Bryant, M.R.C.S., Eng., L.R.C.P., at Bloemfontein, from enteric fever, on June 7th, aged 33.

Surgeon-Lieutenant-Colonel James Stevenson Forrester died on board the steamer *Dunera* on June 18th; he went out to South Africa on January 20th to take charge of the Princess Christian Hospital Train for Natal.

Lieutenant Edmund Leonard Munn, of the Royal Army Medical Corps, died at Boshof, May 23d, of enteric fever.

Major Charles Pope Walker, M.B., R.A.M.C., from dysentery at Ladysmith, January 5th.

William Chapman Grigg, M.D., M.R.C.P., died from enteric fever at Wynberg, South Africa, March 12th.

Richard Truman Fitz Hugh, M.B., London, died of enteric fever at Dulfontein in South Africa, in July.

Sir William Stokes, M.D., F.R.C.S.I., died of pleurisy at Pietermaritzburg, South Africa, August 18th, aged 61.

The following deaths of distinguished physicians, chiefly in Europe, have occurred during the year :

Julius Althaus, M.D. (Berlin), M.R.C.P. (Lond.), who was a voluminous writer, chiefly on electrical treatment and disorders of the nervous system; Dr. Heinrich Laudahn, director of the Lindenburg Asylum, Cologne; Dr. Korsakoff, professor of mental diseases in the University of Moscow; Dr. Apostoli, Paris; Dr. Birch-Hirschfeld, professor of pathology and pathological anatomy at the University of Leipsic; he was born in May, 1842, and after many years of comparative obscurity he was elected to the chair of pathology at Leipsic in 1885, in place of Cohnheim; Dr. Porfíxicio Valiente y Delmonte, who was chief of the Medical Department of the Cuban Army in the late revolution, and at the time of his death Alcalde of the city of Santiago de Cuba; Dr. Van Millingen, of Constantinople, a well-known ophthalmologist; Dr. Amenille, formerly a president of the Société Médico-Chirurgicale; Prof. Rudolf Ritter von Limbeck, physician to the Rudolfstiftung, Vienna, aged 39; Dr. G. Planchon, member of the Académie de Médecine and director of the Ecole Supérieure de Pharmacie, Lyons; Professor Bose, head of the Surgical Clinic of the University of Giessen, aged 60; Dr. Alphonse Milne Edwards, professor of zoology in the University of Paris, aged 62; Dr. Reinhold Long, of Berlin, one of the foremost medical jurists in Germany, aged 65; Dr. J. Chéron, former professor of zoology at Strassburg, and for the last thirty years physician to the St. Lazare Infirmary, Paris; Dr. Leopold Grossman, head of the Ophthalmological and Otological Department of the St. Johannes Hospital, Buda-Pesth; Dr. Mathias Hieronymus Saxtorph, professor of surgery in the University of Copenhagen; Alfred Fisher, L.R.C.P. (Edin.), M.R.C.S. (Eng.), at Liverpool; Prof. Josef Gruber, of Vienna, distinguished as an otologist; Dr. E. M. Shirtliff of Newlands, Ryde, the honorary secretary of the Isle of Wight District of the Southern Branch of the British Medical Association; Lieut.-Col. Archibald Adams, M.D., and F.R.C.S.I., Indian Medical Service, and administrative medical officer, Rajputana, died at Mount Abu, India, May 20th, aged 50; Prof. Lorenzo Bruno, senator of the Kingdom of Italy, and formerly physician to King Victor Emanuel; Dr. Adolfo Murillo, dean of the Medical Faculty of Santiago de Chile and president of the Scientific Society of Chile; Dr. Tito Ambroni, of Milan, described as "patriot, veteran and explorer," aged 90; Dr. Anton Tschurtschenthaler von Helmheim, professor of pathology and pharmacology in the University of Innsbrück, aged 83; Dr. Gombault, of Paris, for many years a collaborator of Charcot's, aged 59; Dr. Lanzet, chief surgeon to the hospital of Marseilles; Dr. Latrille, deputy professor in the Medical School of Poitiers; Dr. F. E. Aub, member of the Bavarian Chamber of Representatives,

² Arranged by months.

a prominent sanitarian and medical reformer, aged 63; Dr. L. Tomaszewski, medical director of the Nicolaus Hospital, St. Petersburg, and founder of the St. Petersburg Association of Specialists in Children's Diseases, aged 68; Dr. Hugo Bergcat, a well known laryngologist of Munich, aged 41; Professor Ollier, of Lyons, France, died in that city, early in December, aged 75; Dr. Gustave Peltier, of Sedan, who served as surgeon to the hospital of that town in the Franco-Prussian War, and was the author of numerous contributions to the *Progrès Médical*; Dr. Ant. Ferreira França, sometime professor of surgical pathology in the Medical Faculty of Rio de Janeiro; Dr. Apollinaris Podres, professor of surgery in the University of Charkow, aged 47; Dr. Bernhard Spinola, director of the Charité Hospital, Berlin, aged 64; Dr. Duplony, sometime director of the Medical Department of the French Navy; Prof. Eugene Boeckel died in Strassburg, in March; Dr. L. H. Petit, for twenty years assistant librarian of the Paris Faculty of Medicine, died in Mentone, in March; Dr. Cadet de Gassicourt died in France, in July; Dr. Max Schäfer, of Bremen, died in July while mountaineering in the Alps.

MEDICAL MEETINGS AND CONGRESSES. — UNITED STATES.

The ninety-fourth annual meeting of the Medical Society of the State of New York was held January 30th and 31st, and February 1st, in Albany, N. Y. The annual meeting of the Suffolk District Medical Society, commemorating the fiftieth anniversary of the society, was held in Boston, April 28th. The Association of American Physicians met at Washington, D. C., May 1st, 2d and 3d. The twenty-fourth annual meeting of the American Dermatological Association was held in Washington, D. C., May 1st, 2d and 3d. The meeting of the American Surgical Association was held in Washington, D. C., May 1st, 2d and 3d. The twenty-fifth annual meeting of the American Gynecological Society was held in Washington, D. C., May 1st, 2d and 3d. The American Neurological Association met at Washington, D. C., May 1st, 2d and 3d. The thirty-third annual meeting of the American Otolological Society was held May 1st in Washington, D. C. The ninth annual meeting of the Association of Military Surgeons of the United States was held May 31st, June 1st and 2d, in New York City. The forty-ninth annual meeting of the American Association for the Advancement of Science was held in New York City, June 25d to 30th. The twenty-fifth annual meeting of the American Academy of Medicine was held at Atlantic City, N. J., June 2d and 4th. The annual meeting of the Massachusetts Medico-Legal Society was held June 12th, in Boston. The tenth annual meeting of the American Electro-Therapeutic Association was held September 25th, 26th and 27th, in New York City. The forty-eighth annual meeting of the Maine Medical Association was held in Portland, June 13th, 14th and 15th. The annual meeting of the American Medical Association was held in Atlantic City, June 5th, 6th, 7th and 8th. The annual meeting of the Massachusetts Medical Society was held June 12th and 13th in Boston. The fiftieth anniversary of

the Middlesex East District Medical Society was observed the last week in October. The American Association of Obstetricians and Gynecologists held its thirteenth annual meeting in Louisville, Ky., September 18th, 19th and 20th. The Mississippi Valley Medical Association held its twenty-sixth annual meeting, October 9th, 10th and 11th, at Asheville, N. C. The eighty-seventh annual meeting of the Vermont State Medical Society was held at Rutland, October 11th and 12th. The twelfth annual meeting of the Tri-State Medical Society of Alabama, Georgia and Tennessee was held in Chattanooga, October 11th, 12th and 13th. The meeting of the Southern Surgical and Gynecological Association was held at Atlanta, Ga., November 13th, 14th and 15th.

MEDICAL MEETINGS AND CONGRESSES. — FOREIGN.

The German Congress of Medicine held its annual meeting at Wiesbaden in April. The British Medical Association held its sixty-eighth annual meeting in Ipswich, July 31st, August 1st to 3d. The Thirteenth International Congress of Medicine was held in Paris, August 2d to 9th. The Tenth International Congress of Hygiene and Demography was held in Paris, August 10th to 17th. The German Scientific and Medical Congress held its annual meeting in Aachen, beginning September 17th. The Fifteenth Congress of the Italian Surgical Society was held at Rome, October 27th to 30th. The second annual meeting of the Italian Society for the Study of Malaria was held at Rome. This society was founded in 1898.

MEDICAL NOTES.

THE SIZE OF LONDON. — An impression of the size of London is gained from the statement that in 1899 the killed and wounded in the London streets are said to have numbered 9,891, of whom 207 were killed outright. No battle in the South African War can show so large a total of losses as this list of casualties in the streets of London. The number of persons killed and wounded in the celebration of the return of the London volunteers equalled the losses of the British in any engagement those soldiers took part in.

A TRAGIC DEATH. — It has transpired that a mechanic was locked in one of the ballast compartments of the steamship *St. Paul* when she was launched five years ago. The skeleton has just been found in the hull of the vessel, which is undergoing repairs.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, December 26, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 135, scarlatina 31, measles 29, typhoid fever 18.

REQUEST TO CAMBRIDGE HOSPITAL. — By the will of the late Mrs. Harding, of Cambridge, \$20,000 is left to the Cambridge Hospital.

METEOROLOGICAL RECORD

For the week ending December 15th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

RECENT DEATHS.

J. H. FRUITNIGHT, M.D., consulting physician to St. John's Guild and a well-known pediatric specialist, died on December 18th. He was born in New York, November 9, 1851, and was graduated from Bellevue Hospital Medical College in 1875.

CHARLES S. TAFT, M.D., the first physician to reach the side of President Lincoln after he had been shot in Ford's Theatre, Washington, died at Mount Vernon, N. Y., on December 18th. He was born in New York in 1835, and shortly after the outbreak of the Civil War entered the army medical service, in which he continued until fifteen years ago when he was retired.

GEORGE H. ELLIOTT, M.D., of New York, died at the home of his father in Manchester, N. H., on December 17th, at the age of fifty-five. He was a graduate of the University of Denver and served in the Civil War with the 7th New Hampshire Regiment.

BOOKS AND PAMPHLETS RECEIVED.

Transactions of the New Hampshire Medical Society at the One Hundred and Ninth Anniversary, held at Concord, May 31 and June 1, 1900. Concord, N. H. 1900.
